|----------------------------------|----------------------|----------------------|
| First (latent and active phases) | Active labor | Complete dilation |
| Second | Complete dilation | Delivery of baby |
| Third | Delivery of baby | Delivery of placenta |
| Fourth* | Delivery of placenta | Contracted uterus |

*Not always considered a stage.

Instructions for coming to the hospital include vaginal bleeding like a period, rupture of membranes, painful contractions at least 3 to 4 minutes apart, and decreased fetal movement. A subset of women may have a prolonged latent phase that can be treated with morphine in a hospital setting. Often this treatment accelerates transition to the active phase.

Active Phase

The active phase of the first stage of labor is the segment of rapid dilation, the progress of which is not affected by sedation or conduction anesthesia. This phase usually occurs at about 4 to 5 cm of cervical dilation. In general, nulliparous women dilate at least 1.2 cm per hour and multiparous 1.5 cm/hr (Friedman, 1978). Progress of the active phase depends on strength and frequency of uterine contractions, size, position, and attitude of the fetal head, as well as size and shape of the bony pelvis. Because of the different diameters of the pelvic inlet, midplane, and outlet, the fetal head must turn at different times of descent to negotiate the bony structure. Flexion of the fetal head during this process is crucial because this diminishes its anteroposterior (AP) diameter and permits easier descent. The cardinal movements of the fetal head during labor include engagement, descent, flexion, internal rotation, extension, external rotation, and expulsion.

Either continuous electronic fetal monitoring (EFM) or intermittent auscultation can be used to monitor the fetus in the active phase of labor (ACOG, 1995a). Instead of continuous EFM in this phase, in low-risk mothers with normal labor, the fetal heart may be auscultated after a contraction and recorded every 30 minutes; the frequency should be increased to every 15 minutes in higher-risk labors. Fetal heart rate decelerations should prompt even more frequent auscultation or continuous EFM. Auscultation rather than continuous EFM will allow mobility during labor, which may improve maternal comfort. IV fluids in the normal gravida can be reserved for women with long labor who become dehydrated despite oral liquids, those who require conduction anesthesia or large doses of pain medication, and those in whom complications develop or are suspected.

Second Stage of Labor

The second stage of labor involves maternal expulsive forces during uterine contractions to aid in the descent and ultimate delivery of the fetus. Instead of continuous monitoring, the fetal heart should be auscultated and recorded every 15 minutes in normal, low-risk pregnancies, and every

Figure 21-7 Composite curves of normal and abnormal labor progress. (From Scherger J, Levitt C, Acheson L: *Teaching family-centered perinatal care in family medicine. Part 2. Fam Med 1992;24:369.*)

10 minutes in higher-risk pregnancies. The second stage of labor averages 20 minutes for the multipara and 50 minutes for the nullipara. Although pushing for longer than 2 hours without an epidural or 3 hours with an epidural in a nullipara should alert the practitioner to possible cephalopelvic disproportion, pushing can continue longer in cases of adequate fetal heart rate and continued progress in descent.

Third Stage of Labor

The third stage of labor begins with the delivery of the baby. Appropriate equipment for resuscitation should be available. Maternal pushing with contractions will cause the fetal head to bulge the perineal tissues with increasing pressure to distend the opening of the vaginal canal and allow the fetal head to deliver. It is only when the head is stretching these tissues should the decision for episiotomy be made. The fetal head delivers with extension, after which the practitioner suction the fetal mouth, pharynx, and nose. If meconium is present, wall suction to a DeLee trap is used for suctioning, and the fetus is not stimulated to breathe before a laryngoscope is used to assess the presence of meconium below the cords. After delivery of the fetal head and suctioning is complete, the neck of the fetus is explored for nuchal cords, which are preferably reduced if possible. If too tight to reduce, the cord must be clamped, then cut. The anterior shoulder of

the fetus is then delivered with gentle downward traction, but predominantly with maternal expulsive forces to avoid excessive pulling on the fetal neck, which can be associated with brachial plexus injury. Hyperflexion of the legs at the hip joint will allow the anterior shoulder to deliver more easily. After delivery of the anterior shoulder, the posterior shoulder is delivered usually quite easily with gentle upward traction. Excessive maternal efforts at this point can cause perineal lacerations. Thus the mother is instructed to push hard for the delivery of the anterior shoulder and gently for the posterior shoulder. Once the shoulders are delivered the remainder of the body escapes easily. The baby can then be placed on the mother's abdomen where warm towels await. The timing of clamping of the cord is controversial. As long as the baby is kept on the maternal abdomen, excessive blood shifts through an unclamped cord will usually not occur. The cord can then be clamped. Cord blood is obtained, as well as cord pH if desired.

The placenta should then be allowed to separate spontaneously. During this time, inspection of the vaginal canal and cervix for tears can be started, but adequate inspection for lacerations should be done after delivery of the placenta. Signs of placental separation include lengthening of the cord, gush of blood, and change in contour of the uterine fundus. Separation of the placenta from the maternal decidua is most likely from shearing forces as the now-smaller uterus

contracts. After separation, uterine contractions decrease the size of the implantation site to arrest bleeding from this area. Maternal expulsive forces may be required to deliver the placenta along with gentle traction on the cord. Uterine massage and immediate breastfeeding will aid in maintaining a contractile state of the uterus and decrease uterine atony. In some cases, oxytocin may be required to maintain uterine contractility. After separation of the placenta, the episiotomy (if cut) and any lacerations should be repaired.

Fourth Stage of Labor

Some consider the first hour after delivery of the placenta the fourth stage of labor. Risk of uterine atony is highest during this period. The patient should be watched carefully for excessive vaginal bleeding, an enlarging boggy fundus, and hypotension. Massage of the uterine fundus most often is sufficient to return it to a contracted state and stop bleeding. Oxytocin may be added to the IV fluids in doses of 20 or 40 units/L of fluid and the IV rate increased, or if no IV fluid is needed, 20 units of oxytocin can be given intramuscularly (IM). Alternately, methylergonovine (Methergine), 0.2 mg, can be given IM every 20 minutes if the mother is not hypertensive. Finally, if no resolution to bleeding, 250 µg of prostaglandin E_{2α} (Hemabate) can be given IM every 15 to 20 minutes as needed for up to 3 doses.

Induction of Labor

Physicians have turned to induction of labor as a means of preventing complications from conditions such as prolonged rupture of membranes, fetal demise in utero or severe preeclampsia, or a post-term pregnancy. For example, post-term delivery beyond 42 weeks' gestation poses risks to both mothers and babies, including increased perinatal death, increased cesarean deliveries, perineal injuries from macrosomia, and labor dystocias. The onset of labor can be stimulated in different ways. Less interventional approaches, such as stripping of the amniotic membranes, may be effective but not predictable and thus may not be sufficient in women who need prompt delivery. Stripping of the membranes requires the cervix to be dilated sufficiently to introduce the examining finger. Potential risks include rupture of membranes, infection, and bleeding. However, this technique appears safe, in particular for those gravidas approaching postdates (El-Torkey and Grant, 1992).

In most cases the pharmacologic induction of pregnancy should be reserved for a medical or obstetric indication, such as hypertension, diabetes, premature rupture of membranes, postdates, fetal demise, and IUGR. Logistic and psychosocial factors, such as distance from the hospital and rapid labors, are also indications. Absolute contraindications for induction of labor are similar to those for spontaneous labor and vaginal delivery. In pregnancy, at term before induction of labor, fetal maturity should be confirmed. Gestational age of at least 39 weeks should be confirmed by early positive pregnancy test, early ultrasound, or early fetal heart tone auscultation. In some cases, fetal lung maturity studies from amniotic fluid may be required.

Success of induction is mainly a factor of parity and cervical readiness at the time of induction. A scoring system developed by Bishop in 1964 to assess the cervix has become popular (Table 21-13). A Bishop's score of 9 or greater is

favorable for induction. Women with low scores benefit from cervical ripening with prostaglandins before induction.

Prostaglandin E₂ is now approved by the FDA for cervical ripening. Dinoprostone (Prepidil) is 0.5 mg of modified PGE₂ in 2.5 mL of gel that is placed intracervically and repeated once in 6 to 12 hours if the Bishop's score does not change appreciably. Intracervical dinoprostone may or may not cause uterine contractions. Its effect on cervical consistency appears unrelated to the number of contractions. Alternately, dinoprostone may be given intravaginally (Cervidil) as a slow-release, 12-hour vaginal insert that may be removed if uterine hyperstimulation occurs. Previous cesarean section is not a contraindication for use. If spontaneous labor does not ensue, an oxytocin infusion may then be used.

Misoprostol (Cytotec), a synthetic PGE₁ FDA approved for prevention of gastric ulcers, has been used off-label for cervical ripening and labor induction. Several protocols have been developed. It is a potent uterotonic agent that may be associated with increased incidence of uterine rupture. Misoprostol is best not used in women with prior cesarean section or uterine surgery.

EVIDENCE-BASED SUMMARY

- Patients should be counseled that walking during labor does not enhance or improve progress in labor and that it is not harmful (SOR: A).
- Continuous support during labor from caregivers should be encouraged because it is beneficial for women and their newborns (SOR: A).
- Active management of labor may shorten labor in nulliparous women, although it has not consistently been shown to reduce the rate of cesarean delivery (SOR: B).
- Amniotomy may be used to enhance progress in active labor but may increase the risk of maternal fever (SOR: B).
- Intrauterine pressure catheters may be helpful in the management of dystocia in select patients, such as obese women (SOR: C).
- Women with twin gestations may undergo augmentation of labor (SOR: C).

KEY TREATMENT

Prostaglandin E (PGE) analogs are effective for cervical ripening and inducing labor (SOR: A).
 Low-dose or high-dose oxytocin regimens are appropriate for women in whom induction of labor is indicated (SOR: A)
 Before 28 weeks' gestation, vaginal misoprostol appears to be the most efficient method of labor induction regardless of Bishop's score, although high-dose oxytocin infusion is also acceptable (SOR: A).
 Approximately 25 µg of misoprostol should be considered as the initial dose for cervical ripening and labor induction; frequency of administration should be no more than every 3 to 6 hours (SOR: A).
 Intravaginal PGE₂ for induction of labor in women with premature rupture of membranes appears to be safe and effective (SOR: A).
 The use of misoprostol in women with prior cesarean delivery or major uterine surgery has been associated with an increase in uterine rupture and therefore should be avoided in the third trimester (SOR: A).
 Misoprostol (50 µg every 6 hours) to induce labor may be appropriate in some situations, although higher doses are associated with an increased risk of complications, including uterine tachysystole with fetal heart rate decelerations (SOR: B).

Data from ACOG, 2009.

Table 21-13 Bishop's Pelvic Scoring for Elective Induction of Labor

| Score | Dilation | Effacement | Station | Position | Consistency |
|-------|----------|------------|---------|-------------|-----------------|
| 0 | Closed | 0-30% | -3 | | |
| 1 | 1-2 cm | 40%-50% | -2 | Posterior | Firm |
| 2 | 3-4 cm | 60%-70% | -1, 0 | Midposition | Moderately firm |
| 3 | 5+ cm | 80+% | +1, +2 | Anterior | Soft |

The Bishop's score generally follows this scale:

Modifiers

A point is added to the score for each of the following:
Preeclampsia
Each prior vaginal delivery

A point is subtracted from the score for:
Postdates pregnancy
Nulliparity
Premature or prolonged rupture of membranes
Interpretation

Indications for Cervical Ripening with Prostaglandins

1. Bishop's score <5
2. Membranes intact
3. No regular contractions

Indications for Labor Induction with Pitocin

1. Bishop's score \geq 5
2. Rupture of membranes

| Cesarean Rates | First-Time Mothers | Women with Past Vaginal Deliveries |
|-------------------|--------------------|------------------------------------|
| Scores of 0 to 3 | 45% | 7.7% |
| Scores of 4 to 6 | 10% | 3.9% |
| Scores of 7 to 10 | 1.4% | 0.9% |

Points for each parameter are added. A score of 9 or greater is favorable for induction.

Modified from Bishop EH. Pelvic scoring for elective induction. *Obstet Gynecol* 1964;24:266.

Oxytocin has been available for labor induction for 40 years. Administered appropriately, it is as safe as spontaneous labor. Many protocols are available for IV oxytocin infusion for induction of labor, from low-dose constant infusion (Mercer et al., 1990) to higher-dose incremental infusion (Muller et al., 1992; Satin et al., 1994). Steady-state levels after IV infusion occur about 40 minutes after the start of infusion. Starting doses range from 0.5 to 2 mU/min with incremental increases of 1 to 2 mU/min every 30 to 60 minutes (ACOG, 1995b). The goal is to achieve two to four uterine contractions in 10 minutes. All protocols share certain precautions. Continuous fetal heart rate and uterine contraction monitoring is mandatory. Hyperstimulation can occur even after a stable infusion rate has been established. Often, contraction intensity and frequency will increase spontaneously after the pregnant woman reaches the active phase or if the amniotic membranes rupture, necessitating a decrease in the oxytocin infusion rate. Hyperstimulation associated with fetal heart rate decelerations requires discontinuing or lowering of the infusion until recovery. Prolonged use of high doses of oxytocin can

cause water intoxication because of its biochemical similarity to antidiuretic hormone.

Amniotomy alone or in conjunction with oxytocin has been shown to decrease the length of labor. In some cases, amniotomy alone can stimulate normal labor, omitting the need for oxytocin. Risks of early amniotomy is cord prolapse and chorioamnionitis. In clinical practice, the decision between induction and expectant management should include favorability of the cervix, maternal parity, and complicating medical or obstetric issues, as well as patient or physician convenience and preferences.

Abnormalities of Labor and Delivery

Dysfunctional Labor

A dysfunctional pattern of labor is defined as a deviation from the norm for the different phases of labor described earlier (see Fig. 21-7). In the latent phase of the first stage of labor, a prolonged or protracted course can be seen. In the active phase of the first stage of labor, both a protracted

course and an arrested course can be seen (O'Brien and Cephalo, 1991). The disorders for each of these phases are examined separately.

Prolonged Latent Phase

The latent phase of the first stage of labor is variable in length, but usually less than 20 hours for a nullipara and 14 hours for a multipara. It is defined by the onset of regular contractions and is terminated by the onset of the active phase. The rate of dilation is usually 0.6 cm/hr or less. This phase is considered prolonged if it falls outside these parameters. The possible etiologies include an unripe cervix, false labor, sedation, and uterine inertia. The management of this condition is primarily conservative unless there is an expeditious need to deliver the fetus. This includes rest, observation, and possibly oxytocin augmentation. Maternal rest can be induced by a therapeutic dose of morphine, to provide a respite from the stresses of early labor and to promote sleep. The vast majority of these patients will declare themselves and either progress into labor or cease contractions, and then the diagnosis of false labor can be made. Amniotomy should be avoided in this phase because it increases the risk for chorioamnionitis. A prolonged latent phase in itself is not an indication for cesarean section.

Protracted Active Phase

The active phase of labor is defined as dilation of the cervix occurring at a rate of at least 1.2 cm/hr for nulliparous women and 1.5 cm/hr for multiparous women. A slower rate of dilation is known as protracted active phase or *primary dysfunctional labor*. The etiologies of a protracted active phase include fetal malposition (e.g., occiput posterior), relative cephalopelvic disproportion (CPD), inadequate uterine contractions, and anesthesia. Historically, debate has surrounded its management. The current trend is active management with oxytocin to optimize uterine contractions. A protracted active phase is a frequent predecessor of secondary arrest of cervical dilation and is associated with an increased risk of operative delivery.

Secondary Arrest of Cervical Dilation

The cessation of cervical dilation for 2 hours with a history of previously normal dilation is termed *secondary arrest*. The management of this condition varies considerably; however, an initial assessment and examination of the patient (including vaginal) are probably warranted, to document cervical dilation, fetal station, presentation, and position. Placement of an intrauterine monitor should be considered to assess the adequacy of uterine contractions. Alternative measures include ambulation, amniotomy, and oxytocin augmentation if the uterine contractions are judged inadequate. There is a high association with CPD, and a significant number of these patients will need operative delivery.

Abnormalities of the Second Stage of Labor

The second stage of labor is defined as the interval between the complete dilation of the cervix to the delivery of the infant. As with previous stages of labor, abnormalities in

Figure 21-8 Shoulder dystocia. Impaction of the anterior shoulder against the pubic symphysis.

this stage include a protracted rate or a complete “arrest of descent,” or the more common term *failure of descent*, used to describe an unchanged station. The evaluation of descent disorders should include maternal and fetal well-being, adequacy of contractions, obstructive etiologies (e.g., distended bladder), and cephalopelvic relationships. Other mitigating factors include maternal exhaustion, ineffective pushing, conduction anesthesia, and perineal resistance. There is also a high incidence of CPD with this condition and an increased risk of operative deliveries.

A *protracted descent* is more difficult to gauge but is defined by a rate of less than 1 cm/hr in nullipara women and less than 2 cm/hr in multiparous women. This diagnosis should prompt an evaluation for such causes as CPD, macrosomia, and inadequate pushing.

Shoulder Dystocia

Shoulder dystocia is defined as the impaction of the anterior shoulder against the pubic symphysis after the delivery of the head and occurs when the breadth of the shoulder is greater than the biparietal diameter of the head (Fig. 21-8). It is a life-threatening event associated with significant morbidity and mortality that needs to be recognized early and managed promptly. The overall incidence of shoulder dystocia is 0.3% to 1% but increases to 5% to 7% for newborns with macrosomia (birth weight >4500 g). Although a number of factors are associated with its occurrence, their predictive values are low, making it incumbent on the practitioner to be ever vigilant.

Several maternal and fetal complications are associated with shoulder dystocia (Carlan, 1991). Maternal complications are usually a consequence of soft tissue damage. The attempt to deliver the baby can result in an extension of an episiotomy to a fourth-degree laceration, with disruption of the anal sphincter and rectal mucosa. Other complications include hemorrhage secondary to uterine atony, vaginal lacerations, and rarely uterine rupture.

Fetal complications tend to be more profound. Brachial plexus injury can occur. Most resolve within 6 months with adequate physical therapy. However, the injury may persist as a source of lingering disability. Erb's palsy is the most common brachial plexus injury and involves the fifth and sixth cervical roots. Klumpke's palsy involves injury to the

Figure 21-9 Shoulder dystocia. Release of the anterior shoulder from behind the pubic symphysis.

eighth cervical root and the first thoracic fibers. Clavicular fracture may occur spontaneously or intentionally and may rarely result in damage to the underlying tissue. Prolonged fetal hypoxia secondary to a delay in the delivery can result in severe neurologic damage and even death.

Conditions that predispose to development of shoulder dystocia are related to either a macrosomic fetus or a contracted pelvis. Importantly, however, approximately one half of all shoulder dystocias occur with normal-weight fetuses and are unanticipated. Predisposing conditions include prepregnancy weight of greater than 180 pounds, excessive maternal weight gain, a history of diabetes or abnormal glucose tolerance, advanced maternal age, or a post-term pregnancy.

The key to management of this condition is anticipation and preparation. Warning signs include a prolonged second stage of labor or use of a vacuum or forceps. Once a shoulder dystocia becomes apparent, a number of maneuvers can be used to disimpact the shoulder (Fig. 21-9). The McRoberts maneuver is a time-honored and proven technique that is ideal in initial management (Gherman et al., 1997). It involves the flexion of the maternal thighs onto the abdomen, which increases the inlet diameter, straightens the lumbosacral lordosis, and removes the sacral prominence as a possible obstruction to delivery. This procedure is often done with suprapubic pressure to dislodge the offending shoulder from behind the maternal pubic symphysis. In contrast to suprapubic pressure, fundal pressure, which often serves to exacerbate the condition, should not be exerted. Other measures include the Woods' screw maneuver, an attempt to apply pressure to the back of the posterior shoulder to rotate the fetus, free the anterior shoulder, and attempt delivery obliquely. Alternately, delivery of the posterior arm can be attempted. Finally, as a measure of last resort, the Zavanelli maneuver, the cephalic replacement of the fetus followed by cesarean delivery, can be attempted.

Electronic Fetal Monitoring

Electronic fetal monitoring, developed at Yale University in the 1960s, was introduced into clinical practice in the early 1970s as an indirect measure of fetal oxygenation. EFM allowed the early detection of abnormal fetal heart

Box 21-8 Indications for Electronic Fetal Monitoring

Maternal

- Hypertension
- Insulin-dependent diabetes
- Asthma
- Other maternal diseases
- Advanced maternal age
- Epidural analgesia
- Absence of prenatal care
- Multiple gestations

Fetal

- Premature rupture of membranes
- Abnormal presentation
- Prematurity
- Postdates pregnancy
- Oxytocin use
- Intrauterine growth restriction
- Meconium

rate patterns potentially associated with hypoxia and metabolic acidosis. Use of EFM has quickly become the standard of care for the management of high-risk pregnancies and a standard practice for low-risk pregnancies. In 2002 the National Center for Health Statistics estimated that approximately 85% of women in labor had EFM (NCHS, 2003). When used, EFM is predictive of a good outcome but not accurate or predictive of a bad outcome. In other words the false-positive rate of EFM is high for predicting adverse fetal outcomes. Recognizing the limitations of this technology, ACOG (2005) concurred that EFM appears to have no inherent benefit over auscultation properly performed in low-risk women. Furthermore, USPSTF (1996) could not recommend its routine use for the management of low-risk deliveries.

The use of EFM is associated with an increase in the rate of surgical interventions (vacuum, forceps, cesarean delivery), increased cost, and possibly increased legal risk; however, it is not associated with a decrease in the incidence of cerebral palsy. If the monitoring is done internally, there is increased risk of uterine perforation and scalp abscess in the neonate.

The multiple reasons for EFM may be subdivided into maternal and fetal indications (Box 21-8). EFM is indicated mainly for the monitoring of high-risk patients in labor, as well as for abnormalities in structured intermittent auscultation and when inadequate staffing is available to maintain the protocol for intermittent auscultation.

Interpretation of Fetal Heart Rate Recordings

A systematic approach in evaluation of the fetal heart rate (FHR) recordings is recommended to optimize interpretation. Studies have demonstrated poor reliability and consistency among various expert interpreters, even in controlled settings. The initial recommendations in 1997 by a National Institute of Child Health and Human Development (NICHD) work group have been revised and updated by a 2008 work group cosponsored by the Society for Maternal-Fetal Medicine, in part to simplify and standardize FHR

Figure 21-10 Accelerations of the fetal heart rate above a baseline rate of 130 to 140 beats per minute. Good variability is present.

interpretation. Five features of the FHR that need to be assessed: baseline, variability, accelerations, decelerations and its sub-classifications, and corresponding contractions. As of 2008, FHR recordings can be considered as belonging to one of three categories: normal (NICHHD Category I), indeterminate (Category II), and abnormal (Category III). *Normal* tracings are associated with a normal pH and fetal well-being, and current management should continue. *Indeterminate* tracings and *abnormal* tracings suggest the need for further evaluation and possible intervention. This evaluation may include vaginal examination, checking maternal vital signs, giving oxygen, changing maternal position, administering fluids, scalp stimulation, and determination of scalp pH measurement. An NICHHD Category II tracing will represent a significant fraction of those encountered in clinical care and will include all tracings that do not belong in categories I and II. An abnormal (NICHHD III) tracing usually indicates the need for the previous measures and consideration of expedited delivery.

Baseline Fetal Heart Rate

Normal baseline FHR ranges from 110 to 160 beats/min. A baseline change is interpreted as one that persists for 10 minutes or more and occurs between or in the absence of contractions. An FHR of less than 110 beats/min is considered *bradycardia*. FHR is a function of the autonomic nervous system. The vagus nerve provides an inhibitory affect, whereas the sympathetic nervous system provides an excitatory influence. As the gestation advances, the vagal system gains dominance, resulting in a gradual decrease in the baseline. Stressful events such as hypoxia, uterine contractions, and head compression evoke a baroreceptor reflex, with resulting peripheral vasoconstriction and hypertension causing bradycardia. Stimulation of peripheral nerve receptors can cause acceleration of FHR (Fig. 21-10). An FHR baseline greater than 160 beats/min is defined as *tachycardia*. This is

seen with certain maternal and fetal conditions, such as chorioamnionitis, maternal fever, and fetal tachyarrhythmias.

Variability of Fetal Heart Rate

The baseline FHR fluctuates constantly under normal conditions, described as its *variability*. This variability is often a good indicator of a healthy nervous system. Variability is the oscillation of the FHR around the baseline with amplitude of 6 to 25 beats/min. Variability reflects vagal efferent impulses only. Uncomplicated loss of variability is often caused by fetal quiescence (sleep state), CNS depressants (e.g., diazepam, morphine, magnesium sulfate), or parasympatholytic agents (e.g., atropine). The uncomplicated loss of variability is associated with no risk or minimal risk of acidosis and low Apgar scores. The presence of decreased variability in combination with late or severe variable deceleration is an ominous finding. Clinically variability is one of the most important indicators of fetal well-being, and the majority of babies with good variability do well regardless of the presence of decelerations.

Recent guidelines do not recommend the use of or differentiation between short-term and long-term variability in the assessment of fetal well-being (NICHHD, 2008). In the assessment of variability, the following categories are now recommended, reflecting the amplitude of the FHR tracing around the baseline (Fig. 21-11):

Absent: Amplitude range is undetectable.

Minimal: Amplitude range is detectable, but 5 beats/min or less.

Moderate: Amplitude is 6 to 25 beats/min.

Marked: Amplitude range is greater than 25 beats/min.

Bradycardia

Bradycardia is defined as FHR less than 110 beats/min for at least 10 minutes. *Mild* bradycardia ranges between 100 and 110 beats/min. Mild bradycardia with normal variability is

Figure 21-11 Variability in fetal heart rate (FHR). Definitions from National Institute of Child Health and Human Development. (Redrawn from Cunningham FG, Leveno KL, Bloom SL, et al. *Williams Obstetrics, 2nd ed.* New York, McGraw-Hill, 2005. <http://www.accessmedicine.com>.)

not associated with fetal acidosis and is considered reassuring. *Moderate* bradycardia of 80 to 100 beats/min is considered a nonreassuring pattern. Bradycardia less than 80 beats/min is considered ominous and is often a terminal event (Fig. 21-12). There are numerous etiologies for fetal bradycardia (Box 21-9).

Tachycardia

Fetal tachycardia is defined as a baseline FHR of greater than 160 beats/min for at least 10 minutes. *Mild* tachycardia is a FHR of 160 to 180 beats/min; in *severe* tachycardia the FHR is greater than 180 beats/min. Fetal tachycardia greater than 200 beats/min is usually caused by fetal tachyarrhythmia or rarely a congenital anomaly and seldom results from fetal hypoxia. There are numerous etiologies of fetal tachycardia (Box 21-10).

Accelerations

Accelerations are transitory increases in FHR associated with fetal movement, scalp or acoustic stimulation, and uterine contractions. Accelerations are considered reassuring and are

associated with fetal well-being. Accelerations form the basis of a reactive NST, defined as the presence of two or more accelerations of 15 beats/min above baseline for at least 15 seconds (see Fig. 21-10).

Early Decelerations

Early decelerations are caused by a vagal response to fetal head compression resulting in a slowing of FHR. These decelerations have a smooth, uniform shape that is a mirror image of the corresponding contraction. They begin with the onset of a contraction, nadir at the peak of the contraction, and promptly return to baseline. Early decelerations are considered reassuring and are associated with a good outcome.

Variable Decelerations

Variable decelerations are characterized by an acute fall in FHR with a rapid down slope and a variable recovery. These have variable shapes, at times described as being “v,” “u,” or “w” (Fig. 21-13). They also have a variable relationship with contractions. Variable decelerations may be classified according to their depth and duration as *mild* when the

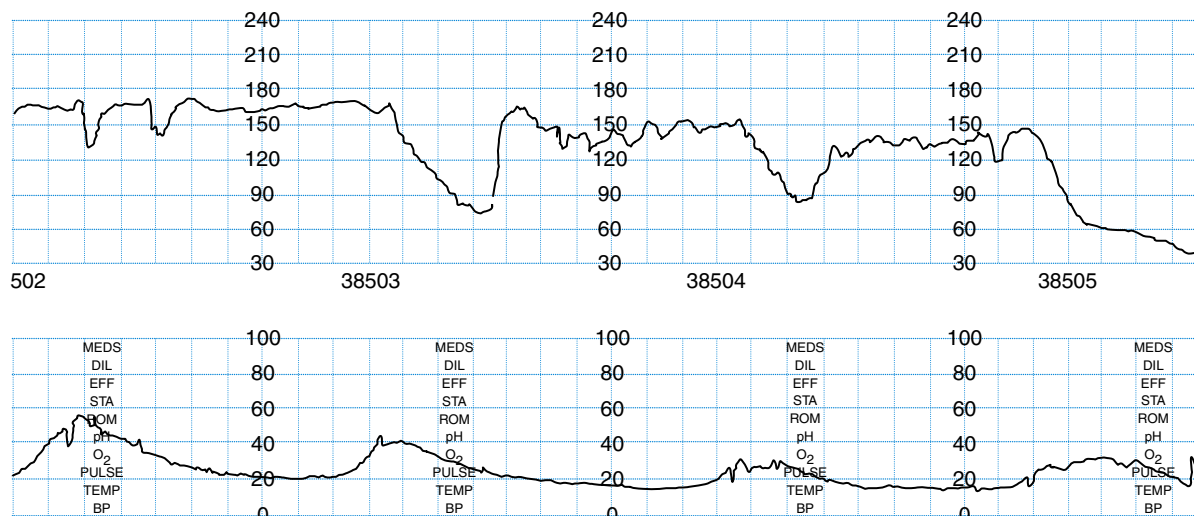

Figure 21-12 Fetal heart rate decelerations with contractions. Bradycardia occurred after the last contraction (only the initial segment is visible).

Box 21-9 Etiology of Fetal Bradycardia

- Prolonged cord compression/cord prolapse
- Hypothermia
- Tetanic uterine contractions
- Paracervical block
- Epidural and spinal analgesia
- Maternal seizure
- Rapid descent
- Vigorous vaginal examinations
- Congenital heart disease
- Fetal heart block
- Severe hypoxia

Box 21-10 Etiology of Fetal Tachycardia

- Chorioamnionitis
- Hyperthyroidism
- Parasympatholytic drugs (atropine, atarax)
- Sympathomimetic drugs (terbutaline)
- Fetal tachyarrhythmia
- Maternal anxiety
- Maternal fever
- Fetal infection
- Prematurity
- Fetal hypoxia
- Idiopathic

depth is greater than 80 beats/min and duration less than 30 seconds. Variable decelerations are considered *moderate* when the depth is 70 to 80 beats/min and duration is 30 to 60 seconds. Variable decelerations are *severe* when the depth is less than 70 beats/min and duration longer than 60 seconds.

Variable decelerations are the most commonly encountered pattern, occurring in 50% to 80% of all deliveries. They are almost always caused by umbilical cord compression. Variable decelerations are noted to be common with nuchal cord, short or prolapsed cord, or when the membranes have been ruptured. Segments of FHR accelerations just before and after the variable deceleration (shoulders) indicates a healthy response.

Late Decelerations

Late decelerations are consistent with NICHHD Category III, abnormal FHR tracing, and are associated with uteroplacental insufficiency. These are provoked by uterine contractions and are associated with decrease in uterine blood flow or placental dysfunction. A late deceleration is a symmetric, gradual fall in FHR beginning at or after the contraction peak, with a slow return to baseline only after the contraction has passed (Fig. 21-14). Postdate gestation, preeclampsia, chronic hypertension, and diabetes mellitus are among the many causes of placental dysfunction. The management

of late decelerations include turning the patient on her side to physiologically increase cardiac output and uterine blood flow, administering IV fluids to correct hypotension, discontinuing oxytocin infusion, and administering oxygen.

Sinusoidal Patterns

Sinusoidal patterns are rare but particularly ominous, belong to the NICHHD Category III, and are associated with a high rate of fetal morbidity and mortality. Sinusoidal patterns are characterized by a smooth, undulating, sine-wave pattern of 2 to 5 cycles/min and amplitude of 5 to 15 beats/min, with a notable absence of variability (Fig. 21-15). They occur with fetal anemia or severe hypoxia and need to be differentiated from a “pseudosinusoidal” pattern, which is a benign, uniform variability pattern with the preservation of beat-to-beat variability. Sinusoidal patterns are often ominous but are occasionally seen after the administration of narcotics to the mother.

Contractions

Contractions are classified as *normal* (no more than five contractions in a 10-minute period) or *tachysystole* (more than five contractions in a 10-minute period, averaged over a 30-minute window). The term “hyperstimulation” is no

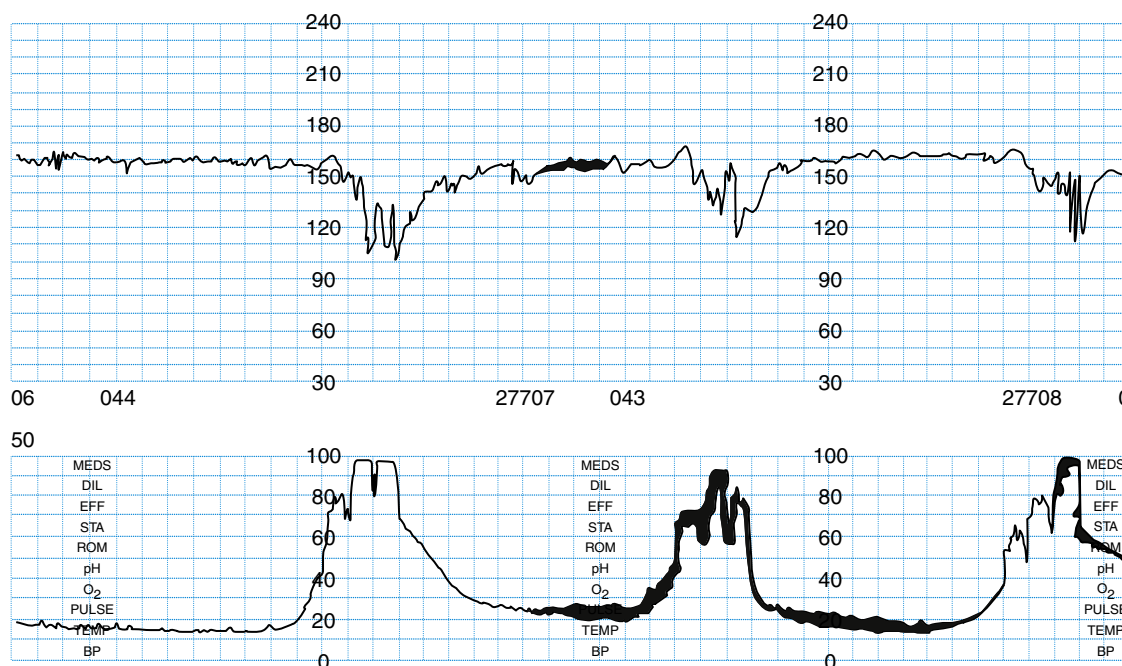

Figure 21-13 Variable decelerations of fetal heart rate.

longer accepted and should be discontinued. Tachysystole is qualified by the presence or absence of decelerations, and it applies to both spontaneous and stimulated labor.

EVIDENCE-BASED SUMMARY

- The false-positive rate of electronic fetal monitoring (EFM) for predicting adverse outcomes is high (SOR: A).
- The use of EFM is associated with an increase in the rate of surgical interventions (SOR: A).
- Compared with structured intermittent auscultation, continuous EFM shows no difference in overall neonatal mortality (SOR: A).
- Continuous EFM reduces neonatal seizure rates (SOR: A).
- Fetal pulse oximetry has not shown a reduction in cesarean delivery rates (SOR: A).
- The use of EFM does not result in a reduction of cerebral palsy rates (SOR: A).
- The labor of women with high-risk conditions should be monitored continuously (SOR: B).
- Reinterpretation of the fetal heart rate tracing, especially knowing the neonatal outcome, is not reliable (SOR: B).
- The use of fetal pulse oximetry in clinical practice cannot be supported at this time (SOR: B).

Data from ACOG, 2005, 2009b; Alfirevic et al., 2006; East et al., 2007; and Macones et al., 2008.

Vaginal Birth after Cesarean

A trial of vaginal birth after a previous cesarean delivery (VBAC) is an accepted method of delivery for most women with a prior low-transverse cesarean delivery. Factors that increase morbidity in VBAC should be understood so that practical decisions can be made regarding the best route of delivery for each patient. ACOG (2004) suggests the following criteria for selection of appropriate candidates: one

previous cesarean delivery, adequate pelvis, no uterine scars, and immediate availability of both a physician to perform an emergency cesarean delivery and facilities and anesthesia to support an immediate cesarean delivery. Use of prostaglandin cervical ripening is discouraged in these women because of the small increased risk of uterine rupture associated with these medications when used with a scarred uterus.

The AAFP (2005) reviewed a trial of labor after cesarean (TOLAC) and compared TOLAC with elective repeat cesarean section (ERCS) and formulated the following recommendations:

Most women with one previous cesarean delivery with a low-transverse incision are candidates for VBAC and should be counseled about VBAC and offered a trial of labor; epidural anesthesia may be used for VBAC (SOR: A).

Women with a vertical incision within the lower uterine segment that does not extend into the fundus are candidates for VBAC (limited or inconsistent scientific evidence, SOR: B).

The use of prostaglandins for cervical ripening or induction of labor in most women with a previous cesarean delivery should be discouraged. Because uterine rupture may be catastrophic, VBAC should be attempted in institutions equipped to respond to emergencies with physicians immediately available to provide emergency care. After thorough counseling that weighs the individual benefits and risks of VBAC, the ultimate decision to attempt this procedure or undergo a repeat cesarean delivery should be made by the patient and her physician. This discussion should be documented in the medical record. VBAC is contraindicated in women with a previous classic uterine incision or extensive transfundal uterine surgery (primarily consensus and expert opinion, SOR: C).

After careful patient selection, preparation, and management, 7 or 8 of 10 women with uterine scars deliver vaginally. The strongest predictor of the safety of VBAC is the

Figure 21-14 Late deceleration of fetal heart rate.

location of the previous uterine scar. Safety of TOLAC in women with history of one cervical low-transverse cesarean has been documented. Rupture of these incisions is low,

0.5% (Pridjian, 1992). Information is insufficient to determine whether TOLAC is safe for VBAC candidates with two or more prior low-transverse cesarean sections, previous low-vertical incision, multiple gestation, breech presentation, or suspected macrosomia.

Oxytocin use and epidural anesthesia are not contraindicated in women attempting VBAC, although they should be used cautiously in this setting. An internal uterine pressure monitor is recommended when labor is enhanced or induced medically. The most common signs and symptoms of uterine rupture are fetal decelerations and distress, heavy vaginal bleeding, decreasing station or complete loss of the presenting part, loss of contraction intensity as documented by internal pressure monitor, uterine or pelvic pain in between contractions, and bloody urine.

Women who are most likely to have a successful VBAC are less than 40 years old, have had one prior cesarean delivery, undergo spontaneous labor, have a baby no greater than 4000 g, and had a prior cesarean section that was not for failure to progress or CPD in the active phase of labor. Based on the available data, the overall outcomes from TOLAC and ERCS are so similar that the two birthing methods appear medically equivalent. As a consequence, women's preferences for the method of delivery must be explored

EVIDENCE-BASED SUMMARY

- Most women with one previous cesarean delivery with a low-transverse incision are candidates for vaginal birth after cesarean (VBAC) and should be counseled about VBAC and offered a trial of labor (SOR: A).
- Epidural anesthesia may be used for VBAC (SOR: A).
- Women with a vertical incision within the lower uterine segment that does not extend into the fundus are candidates for VBAC (SOR: B).
- The use of prostaglandins for cervical ripening or induction of labor in most women with a previous cesarean delivery should be discouraged (SOR: B).
- After thorough counseling about benefits and risks of VBAC, the decision to attempt this procedure or undergo a repeat cesarean delivery should be made by the patient and her physician (SOR: C).
- VBAC is contraindicated in women with a previous classic uterine incision or extensive transfundal uterine surgery (SOR: C).

and respected throughout pregnancy and during the delivery process. Women should be encouraged to undergo a TOLAC, but they should also have the opportunity to weigh the potential harms and benefits of TOLAC versus ERCS. A decision to have a cesarean delivery should be supported.

Intrapartum Procedures

Obstetric Anesthesia

At present, many pregnant women are choosing to receive analgesia to relieve the pain of childbirth through several methods. More than 50% of women in labor are reported to choose intrapartum epidural analgesia at many U.S. institutions. This probably reflects changing societal expectations and increasing participation in the birth process on the part of both anesthesiologists and certified registered nurse anesthetists.

Pain during the first stage of labor is attributable to uterine contractions and cervical dilation. Afferent impulses from the cervix and uterus are transmitted to the spinal cord via the tenth thoracic to first lumbar (T10-L1) segments. Pain is conducted along the paracervical and inferior hypogastric plexus. During the second stage, pain also occurs from distention and stretching of pelvic structures and the perineum. Second-stage pain is principally somatic in nature and is transmitted through the spinal second to fourth sacral (S2-S4) segments.

Therapeutic modalities to manage the pain of childbirth include systemic narcotics, local anesthesia, and psychological methods (Howell, 2000). Systemic narcotics used to manage pain during labor include meperidine (Demerol, 25 mg IM or IV) and nalbuphine (Nubain, 10 mg IV). Narcotics should be avoided at or near delivery because they can cause nausea, vomiting, decreased gastric motility, and respiratory depression and can interfere with the mother's ability to concentrate and cooperate. Fetal effects include respiratory and CNS depression and temperature instability. Naloxone (0.01 mg/kg) can be administered to depressed newborn as an IV bolus for counteracting the effect of narcotics.

A pudendal block provides analgesia to the vaginal introitus and perineum. Usually done in the second stage of labor, 5 mL of 1% lidocaine is injected into the pudendal canal, the location of the pudendal nerves and vessels. Care is taken to aspirate for blood before instilling the anesthetic solution. It takes approximately 10 minutes for anesthesia to establish. Infection at the injection site, intravascular injection, and maternal overdose are the major potential complications.

Neuraxial or epidural analgesia is popular among both physicians and patients (Vincent and Chestnut, 1998). The anesthesiologist's goal for epidural analgesia during the first stage of labor is to provide segmental sensory anesthesia of the T10 to L1 dermatomes. The dose of anesthetic necessary to achieve effective labor analgesia will depend on the intensity and location of the patient's pain. These in turn depend on the amount and rate of cervical dilation; the strength, frequency and duration of uterine contractions; and the position of the fetal head at the time epidural analgesia is placed. Typically, bupivacaine (Marcaine) or ropivacaine (Naropin), with or without a small dose of a lipid-soluble opioid such as fentanyl (Sublimaze) or sufentanil (Sufenta), establishes effective analgesia with minimal motor block. Maintenance of epidural analgesia may be achieved with intermittent bolus injections, continuous infusion, or patient-controlled dosing frequency.

Although epidural analgesia provides superior pain relief during labor, much controversy surrounds its drawbacks. These include the increased duration of labor, increased need for oxytocin augmentation, and increased rate of cesarean section for failure to progress. The most common complications, however, are maternal hypotension and headache from inadvertent puncture of the dura.

Contraindications to epidural analgesia include patient refusal, active maternal hemorrhage, maternal septicemia or untreated febrile illness, infection at or near needle insertion site, and maternal coagulopathy.

Psychological methods of pain relief include Lamaze, natural-childbirth methods, acupuncture, biofeedback, and

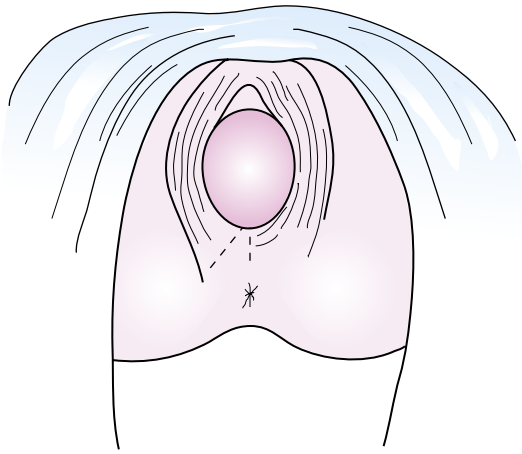

Figure 21-16 Crowning fetal head distending the perineal tissues. Broken lines depict the location of the incision for a midline (median) or mediolateral episiotomy.

Box 21-11 Categories of Perineal and Vaginal Lacerations

First degree: Confined to the superficial skin or mucosa; repair usually not required unless extensive or bleeding.

Second degree: Involves the mucosa and deeper tissues of the vagina and perineum.

Third degree: Involves the anal sphincter.

Fourth degree: Involves the rectal mucosa and usually transects the anal sphincter.

self-hypnosis. These techniques are useful in decreasing maternal anxiety and may reduce the amount of analgesia needed.

Episiotomy

An episiotomy is a surgical incision in the perineum to enlarge the introitus at delivery. Episiotomy is one of the most common medical procedures performed in the United States. There are two types of episiotomies (Fig. 21-16). The midline or *median* episiotomy is the most common in the United States. It involves an incision from the posterior aspect of the vagina downward, directly toward the anus, approximately half the length of the perineum. The *mediolateral* episiotomy is a diagonal incision toward either side of the midline, done to prevent tearing into the rectum. The mediolateral incision may serve to decrease the incidence of third- and fourth-degree extensions but is more difficult to repair and is associated with more blood loss, pain, slow healing, and dyspareunia. It is performed when the fetal head is crowning 3 to 4 cm. An average incision extends 5 to 6 cm into the vagina. Lacerations and extensions of episiotomies are described according to the extent of tissue involvement (Box 21-11).

Historically, episiotomies were performed for a number of indications. These include the substitution of an anticipated ragged spontaneous laceration for a more controlled straight surgical incision, reduction in the second stage of a labor, and reduction in subsequent pelvic relaxation and trauma to pelvic musculature.

The literature since 1980 does not substantiate the alleged benefits of episiotomy (Argentine Episiotomy Trial Collaborative Group, 1993), as supported by more recent

review by the Agency for Healthcare Research and Quality (Viswanathan et al., 2005). The reputed long-term and short-term benefits have not been substantiated. Episiotomy is used in approximately one third of vaginal deliveries to hasten birth and prevent tearing of the perineum during delivery, but in fact it fails to accomplish any of the other maternal or fetal benefits traditionally ascribed to it (Klein et al., 1994). Episiotomies fail to prevent perineal damage, pelvic floor relaxation, reduction of the second stage of labor, and protection of the newborn from either intracranial hemorrhage or intrapartum asphyxia. Also, episiotomy does not protect women against urinary or fecal incontinence, pelvic organ prolapse, or difficulties in sexual function in the first 3 months to 5 years after delivery. Furthermore, in primigravid women, episiotomy appears to be causally associated with third-degree and fourth-degree lacerations.

In summary, episiotomy is an unproven, controversial surgical procedure best restricted to specific fetal and maternal indications. Most data do not support its routine application, making its use a decision best left to the individual physician and patient (Sleep et al., 1984).

The repair of an episiotomy should be approached with standard surgical principles. After appropriate positioning of the patient and with adequate lighting, the practitioner should determine the extent of the wound. Efforts should be made to assess the adequacy of the anesthesia. Sites of uncontrolled bleeding should be identified and hemostasis ensured. In the repair the practitioner should aim to use the least amount of suture material possible and achieve wound approximation without dead space. Several techniques of repair are accepted. Typically, an anchoring, hemostatic stitch of an absorbable or delayed-absorbable material such as 2-0 chromic catgut or polyglycolic acid is placed at the apex of the vaginal incision, and the vaginal mucosa is approximated in a continuous interlocking fashion to the hymenal ring (Fig. 21-17, A). Polyglycolic acid sutures may be superior to chromic catgut for episiotomy suturing. Compared with surgical repair using catgut or chromic suture, repair using 3-0 polyglactin 910 (Vicryl) suture results in decreased wound dehiscence and less postpartum perineal pain. This suture can then be tied or brought through to repair the deep layer of the perineum (Fig. 21-17, B). The deep perineal tissues are then approximated with interrupted or continuous stitches in the muscle and fascia. Finally the skin is approximated with a subcuticular stitch, knotted and buried inside the vagina above the hymenal ring (Fig. 21-17, C).

Diagnostic Ultrasound

Sonographic examination with the appropriate indication is an appropriate skill that enhances the diagnostic and therapeutic capabilities of family physicians who practice obstetrics. Even physicians who do not deliver babies are faced with clinical questions for which diagnostic ultrasound is indicated. Studies do not support the routine use of sonography in low-risk prenatal care; however, societal expectations and the relative ease of access to this technology have made it an established aspect of obstetric care. The Radius study group evaluated the use of screening ultrasounds in 15,151 low-risk pregnancies and found no difference in perinatal mortality, birth weight, or preterm birth. The study did not evaluate its use in high-risk pregnancy (Ewigman et al., 1993).

Box 21-12 Indications for Obstetric Ultrasound

1. Determination of gestational age
2. Diagnosis
 - Suspected miscarriage or fetal demise
 - Vaginal bleeding
 - Pelvic pain
 - Suspected multiple gestation
 - Suspected hydatidiform mole
 - Suspected ectopic pregnancy
 - Size-date discrepancy
 - Uterine or pelvic mass or abnormality
 - Congenital anomalies
 - Fetal presentation
3. Antenatal monitoring
 - a. Biophysical profile (BPP)
 - b. Intrauterine growth retardation (IUGR)
 - c. Fetal macrosomia
4. Adjunct to obstetric procedures
 - Chorionic villus sampling
 - Amniocentesis
 - Cephalic version
5. ACOG* recommends ultrasound at 18 weeks for all patients.
 - Confirm dates and fetal survey.

From <http://www.fpnotebook.com/OB/Rad/ObstrcUltrasound.htm>.

*American College of Gynecologists and Obstetricians.

The obstetric ultrasound has numerous indications and benefits in prenatal care (Box 21-12). Benefits include estimation of fetal age through biometry (accurate to within 1 week under 20 weeks, ± 2 weeks at 20-28 weeks, and ± 4 weeks after 28 weeks). In the hands of an experienced sonographer, the gestational sac size or the crown-rump length has proved a reliable measure of gestational age (Fig 21-18). Again, early ultrasound may provide more accurate dating,

which is important for timing screening tests and interventions and for optimal management of complications such as post-term pregnancies (Neilson, 2004). Prenatal diagnosis and evaluation of fetal anomalies, growth anomalies (e.g., size vs. date discrepancies), fetal assessment (e.g., BPP, confirmation of fetal demise), maternal factors (e.g., diagnosis of ectopic pregnancy), and uterine anomalies are other indications and benefits.

The overutilization or recreational use of ultrasound technology may pose a medical-legal risk, particularly in the hands of an inexperienced provider.

Operative Vaginal Deliveries

Indications for operative vaginal delivery in a low-risk mother are nonreassuring FHR, maternal exhaustion, and prolonged second stage, which is generally 3 hours for a nulliparous woman and 2 hours for a parous woman.

Essential for safe operative vaginal delivery is optimal readiness. The laboring woman should understand the reasons why operative delivery has been chosen, with documentation in the chart. She should then be placed in a position in which her legs are maximally open, preferably in stirrups, with the perineum at the edge of the bed. Usual washing and draping is performed. The bladder is emptied. Adequate anesthesia makes placement of instruments easier and improves maternal cooperation. Pudendal block is often adequate for procedures when the fetal head is at the outlet. However, conduction anesthesia is often used. The cervix should be completely dilated and the membranes ruptured. Station, position, and attitude of the fetal head should be known. The fetal head should be engaged. Palpation, maternal sensation, or contraction monitoring can help identify the timing of contractions. Facilities for cesarean section should be available. Decision to use forceps or vacuum is based on operator skill, availability of instruments, and fetal-maternal considerations, including pelvic shape and size, fetal head position, and availability of anesthesia.

Figure 21-18 The crown-rump length (CRL) is denoted by crosses. Care should be taken to view the entire fetus in the midsagittal plane so as not to undermeasure. Conversely, the yolk sac is not a part of the CRL, so its inclusion will falsely increase the measurement.

Forceps Delivery

Currently, forceps deliveries are divided into outlet, low, mid, and high forceps, determined by the station of the fetal head. In an *outlet* forceps delivery the fetal head has reached the pelvic floor and is seen at the introitus without separating the labia. The fetal head may be right, left, or straight occiput anterior or posterior, and delivery is accomplished without rotation of greater than 45 degrees. A *low* forceps delivery is one in which the fetal head is at least +2 cm (on a 0 to +5 cm scale of station), but not on the pelvic floor. Rotation may be greater than or less than 45 degrees. A *mid* forceps delivery occurs when the head is engaged, but less than +2 cm station. A *high* forceps delivery, when the fetal head is unengaged, is no longer performed in modern obstetrics.

The choice of forceps to use is based on the operator's training and the type of forceps delivery. Typically, Simpson (or Simpson-DeLee) or Elliot forceps are used for low and outlet deliveries. After requirements for operative vaginal deliveries are met, the operator faces the maternal perineum with forceps held in the position desired. The left blade is generally placed first. The operator's right hand is fitted between the fetal head and the left vaginal side wall, and the left blade is placed by holding the handle at 12 o'clock and rotating counterclockwise as the blade slips between the fetal head and the operator's right hand. After adequate placement, the majority of the blade is no longer visible. In a similar fashion, the operator's left hand then aids in placement of the right blade. When properly placed, the handles should come together easily. Appropriate placement is then ascertained. The sagittal suture should be equidistant from both blades and perpendicular to the shanks, with the posterior fontanelle exactly between the two blades. The posterior fontanelle should be palpable about 1 fingerbreadth above the interdigitated shanks. Failure to apply the forceps symmetrically will increase risk of injury and failure of the technique.

Holding the handles together with moderate pressure, the operator rotates the fetal head if needed so that the occiput is directly anterior or posterior (sagittal suture is perpendicular

Figure 21-19 Outlet forceps delivery. The direction of traction is first downward so that the fetal head negotiates the pubic symphysis and then upward to deliver in extension.

to the floor). This rotation should be done during uterine muscle relaxation, just before a contraction. A mild degree of flexion of the fetal head during rotation will make rotation easier. With a contraction and additional expulsive forces from the mother, the operator applies traction. Traction direction should be guided by the maternal pelvis. Initial traction is downward (toward the floor) until the fetal head clears the symphysis pubis. Then, traction is directed more upward as the fetal head delivers with extension (Fig. 21-19). Although in some cases early episiotomy is beneficial to forceps delivery, most often episiotomy should be cut if needed when the fetal head is bulging the perineal tissues. In many cases, removal of the forceps at this time will preclude need for episiotomy. Removal of the forceps before delivery of the head should be in the opposite direction and order of placement. Maternal expulsive forces during a contraction can then often deliver the remainder of the fetal head. The vagina and cervix should be carefully inspected for lacerations.

Vacuum Extraction

Vacuum extractors currently in widespread use in the United States are those with a soft cup made of silicone or plastic. They are smaller and more flexible than the classic Malstrom metal cup. Vacuum can be easily applied. Although these cups tend to dislodge somewhat more frequently than the Malstrom metal cup, less scalp trauma is noted with their use. Often, vacuum delivery can be performed with little to no anesthesia. However, requirements of operative vaginal delivery still apply. For the best results, the vacuum cup should be placed over the sagittal suture about 3 cm from the posterior fontanelle. This can be difficult in fetal heads descending with asynclitism (lateral deflection). After placement of the cup, an examining finger is used to ascertain that no cervical, vaginal, or perineal tissue is trapped in the cup. With a contraction, after adequate vacuum is generated, downward and then upward traction should be applied to the fetal head (Fig. 21-20). The fetal head should be allowed to rotate if needed during descent. Forceful rotation of the fetal head using the suction cup is generally not recommended because of the increased risk of scalp injury. Removal of the cup is easily accomplished once suction is

Figure 21-20 Vacuum extraction with J-shaped direction of traction, similar to forceps delivery.

discontinued. The cervix and vagina should be examined carefully for lacerations.

The Puerperium

The postpartum period, or puerperium, is the time during which the mother's altered anatomy, physiology, and biochemistry returns to the nonpregnant state. This process has its onset at the third stage of labor and is completed 6 weeks after delivery. These changes are normal and should not be confused with a pathologic condition. The woman undergoes physiologic and emotional changes that need to be monitored by her primary care physician.

Within the first 24 hours, the mother's pulse rate drops and her temperature may be slightly elevated. Generally, the white blood cell count increases during labor, with a marked leukocytosis (to 20,000/ μ L) occurring in the first 24 hours postpartum. The vaginal discharge is grossly bloody (lochia rubra) for the first 3 or 4 days. During the next few to 10 days, the lochia becomes more serous and pinkish brown and decreases in amount (lochia serosa). Finally, 7 to 10 days postpartum, the lochia becomes pale yellow-white and decreases even more in volume. Urine output temporarily increases and might contain protein and sugar, reflecting a maternal diuresis. This loss of fluid with the accompanying decrease in intravascular volume artificially elevates the hematocrit for a few days. The uterus involutes progressively; after 5 to 7 days, it should be firm and nontender, extending midway between the symphysis and umbilicus. By 2 weeks the uterus should no longer be palpable abdominally. Contractions of the involuting uterus are often painful and can require analgesics. Care should be exercised in choice of analgesia so as not to interfere with the maternal-infant bond or breastfeeding.

The mother is observed for 1 hour after completing the third stage of labor and given periodic uterine massage to make sure that the uterus contracts and remains contracted, preventing excess bleeding. If desired, breastfeeding can be initiated at this stage to promote uterine contraction, minimize bleeding, and promote involution of the uterus. If the uterus does not remain contracted with massage alone, oxytocin can be administered, either 10 units IM or dilute oxytocin with IV drip (10 or 30 U/1000 mL of IV fluid) at 125 to 200 mL/hr for 1 to 2 hours. Recent trends in the active

management of labor encourage the administration of oxytocin before delivery of the placenta. This has been found to promote the delivery of the placenta and decrease incidence of uterine atony and postpartum hemorrhage (Prendiville et al., 2000). If general anesthesia was used for operative delivery, the mother is monitored (preferably in a recovery room or a labor, delivery, recovery, and postpartum room); oxygen and blood are tested for compatibility, and IV fluids must be readily available after delivery.

After the first 24 hours, postpartum recovery is rapid. A regular diet after a normal vaginal delivery can be offered as soon as the patient requests food. Full ambulation is encouraged as soon as possible. Showers can be encouraged, but vaginal douching is prohibited during the early postpartum period. Discomfort from an episiotomy can be relieved with hot sitz baths several times a day and analgesia. Drugs may be offered for pain as necessary but should be limited in breastfeeding mothers, because most drugs are secreted in breast milk. Meperidine (Demerol) is not the preferred analgesic for use in breastfeeding women because of the long half-life of its metabolite in infants. Repeated exposure to analgesics, especially meperidine, can result in drug accumulation and toxic effects in young or compromised infants because of their underdeveloped hepatic conjugation.

Bladder care is important. Urine retention, bladder overdistention, and catheterization should be avoided if possible. Rapid diuresis can occur, especially when oxytocin is discontinued. The woman must be encouraged to void and must be monitored to prevent asymptomatic bladder overfilling. The woman should be encouraged to defecate before leaving the hospital, although with early discharge, women often leave before a bowel movement has occurred. Laxatives may be needed for constipation. If a bowel movement has not occurred within 3 days, a mild cathartic may be given. Hemorrhoids can be minimized by maintaining an appropriate diet and good bowel function and can be treated with warm sitz baths. Regional anesthesia (spinal or epidural) delays ambulation and can delay spontaneous urination. Catheterization is recommended if significant urine output is not achieved by 12 hours and a distended bladder is apparent.

A complete blood count should be performed before discharge to verify that the woman is not significantly anemic. Women who have been determined to be seronegative should be immunized against rubella on the day of discharge. If the woman has Rh-negative blood, is not sensitized, and has an infant with Rh-positive blood, she should be given Rh₀D immune globulin 300 μ g within 72 hours of delivery to prevent sensitization.

Rh(D) blood typing and antibody testing are strongly recommended for all pregnant women during their first visit for pregnancy-related care. The USPSTF found good evidence that Rh(D) blood typing, anti-Rh(D) antibody testing, and intervention with Rh(D) immunoglobulin are appropriate, prevent maternal sensitization, and improve outcomes for newborns. The benefits substantially outweigh any potential harm (USPSTF, 1989).

The breasts might become painfully engorged during early lactation, when the amount of milk is beginning to increase. If the mother is not going to breastfeed, lactation can be suppressed by firmly supporting the breasts, because gravity stimulates the let-down reflex and encourages milk flow. Many mothers find that tight binding of the breasts and

restriction of oral fluid intake followed by firm support are effective, with symptoms lasting only 3 to 5 days.

The postpartum period can be complicated by the “baby blues,” a common self-limited mood disorder. This is characterized by mild depressive symptoms, tearfulness (often for no discernible reason), anxiety, irritability, mood lability, increased sensitivity, and fatigue. The “blues” typically peak 4 to 5 days after delivery, can last hours to days, and usually resolve by the tenth postnatal day.

The “blues” is distinct from postpartum major depression, which occurs in approximately 10% of childbearing women (O’Hara et al., 1990). It can begin from 24 hours to several months after delivery. Its onset can be abrupt and symptoms severe, and it can be associated with lack of interest in the infant, suicidal or homicidal thoughts, hallucinations, or psychotic behavior. True psychosis probably reflects the exacerbation of preexisting mental illness in response to the physical and the psychological stress of pregnancy and delivery. Psychotherapy or pharmacotherapy is indicated, alone or in combination. Selective serotonin reuptake inhibitors may be associated with congenital heart anomalies and should be used with caution in pregnancy. All women should be routinely assessed during the antenatal period for a history of depression.

Prevention of pregnancy for several months to allow complete recovery is in the woman’s best interest. *Rubella immunization mandates a delay of 3 months before a woman becomes pregnant.* Therefore, although intercourse may be resumed as soon as desired and comfortable, contraception is required because pregnancy is possible. Oral contraceptives may be started at discharge. A low-dose estrogen or progesterone-only preparation is desirable. A diaphragm should be fitted only after complete involution of the uterus, at 6 to 8 weeks; meanwhile, foams, jellies, and condoms may be used. In mothers who are not breastfeeding, earliest ovulation usually occurs about 4 weeks postpartum, 2 weeks before the first menses. However, conception has been reported as early as 2 weeks postpartum, so ovulation can occur earlier. Breastfeeding mothers tend to ovulate, then menstruate, usually at 10 to 12 weeks postpartum. The duration of anovulation is influenced by the frequency of breastfeeding, the duration of feedings, and the proportions of supplemental feeding.

Postpartum Hemorrhage

Traditionally, postpartum hemorrhage (PPH) was defined as blood loss greater than 500 mL in a vaginal delivery and greater than 1000 mL in a cesarean delivery. However, studies have revealed that an uncomplicated delivery often results in blood loss of more than 500 mL without any compromise of the mother’s condition (Pritchard et al., 1962). Clinically, these findings led some authors to adopt a broader definition for PPH. Any bleeding that results in signs and symptoms of hemodynamic instability, or bleeding that could result in hemodynamic instability if untreated, is considered PPH. The loss of these amounts within 24 hours of delivery is termed *early* or *primary* PPH, and such losses are termed *late* or *secondary* PPH if they occur 24 hours after delivery or later. This section focuses primarily on early PPH.

The most common causes of PPH are uterine atony and lacerations of the vagina and cervix. Other causes include

retained placental fragments, lower genital tract lacerations, uterine rupture or inversion, placenta accreta, and hereditary coagulopathy. Causes of late PPH (24 hours to 6 weeks after delivery) include infection, placental site subinvolution, retained placental fragments, and hereditary coagulopathy (ACOG, 1998a).

Risk factors for uterine atony include uterine overdistention secondary to hydramnios, multiple gestation, use of oxytocin, fetal macrosomia, high parity, rapid or prolonged labor, intra-amniotic infection, and use of uterine-relaxing agents (Combs et al., 1991). Uterine rupture occurs in approximately 1 in 2000 deliveries. Previous uterine surgery is a significant risk factor for uterine rupture, placenta accreta, and PPH. Other risk factors include obstructed labor, multiple gestations, abnormal fetal lie, and high parity.

Risk factors for hemorrhage at the time of cesarean delivery include preeclampsia, disorders of active labor, a history of previous hemorrhage, obesity, use of general anesthesia, and intra-amniotic infection.

Adequate intravascular access should be obtained in women who have significant risk factors for PPH. Active management of the third stage of labor has been shown to decrease the incidence of PPH. Early administration of oxytocin, early cord cutting and clamping, and controlled cord traction have been shown to decrease PPH by two-thirds (Soriano et al., 1996).

In the event of hemorrhage, supplemental oxygen should be administered to enhance cellular oxygen delivery. Heart rate and blood pressure should be monitored closely. Initial laboratory evaluation includes a complete blood count with platelet concentration. Blood type and crossmatch should be performed if not previously obtained. Fibrinogen, fibrin split products, prothrombin time, and partial thromboplastin time should be measured (ACOG, 1998a).

Excessive vaginal bleeding after placental delivery should prompt vigorous fundal massage while the patient is rapidly given 10 to 30 units of oxytocin in 1 L of IV fluid. If the fundus does not become firm, uterine atony is the presumed (and most common) diagnosis. Uterine atony should be initially managed by bimanual uterine massage and compression in addition to the oxytocin. If IV or IM oxytocin proves ineffective, other uterotonic agents, such as methylergonovine and prostaglandin derivatives (15-methyl PGF_{2α}), may be used as second-line treatment (ACOG, 1998a). Methylergonovine may be administered in a dose of 0.2 mg IM every 2 to 4 hours. Methylergonovine can cause cramping, headache, and dizziness. This agent is contraindicated in hypertensive disease states because it induces vasoconstriction, which can lead to severe hypertension.

15-Methyl prostaglandin F_{2α} (Hemabate), may be given in a dose of 0.25 mg IM every 15 to 90 minutes (no more than eight doses). PGF_{2α} may also be given by intramyometrial injection at cesarean delivery or transabdominally after vaginal delivery. Prostaglandin E₂ can cause vasodilation and exacerbation of hypotension; therefore, 15-methyl PGF_{2α} is preferred. Because oxygen desaturation has been reported with use of PGF_{2α}, patients should be monitored by pulse oximetry.

Continuing hemorrhage in a patient with a firm uterine fundus can indicate a hidden vaginal or cervical laceration. This type of injury is usually easy to identify and repair with adequate lighting, exposure, and assistance. If no laceration

is present and the fundus is firm, the uterus requires gentle but thorough manual exploration for retained placenta, which should be removed. Uterine rupture is occasionally evident and requires immediate surgery.

An occult uterine inversion might also be discovered on vaginal examination, or it can manifest frankly. Uterine inversion is somewhat more common in primiparas and has no clear association with the mismanagement of labor. Because uterine inversion can quickly lead to shock, the physician should order brisk IV hydration and grasp the uterus in the palm, with the thumb anterior. The uterus is then firmly pushed back up into the abdominal cavity and held in place for several minutes (Brar et al., 1989). Magnesium sulfate, 0.25 mg IV, has been reported to assist in the repositioning of the uterus (Catanzarite et al., 1986).

If uterine and vaginal exploration is nondiagnostic, if uterine inversion is excluded, and if the fundus is firm, rarer causes of hemorrhage should be considered. Puerperal *hematomas* typically cause a vulvar or vaginal mass, and an occult retroperitoneal hematoma can manifest with severe abdominal pain and shock after delivery. The diagnosis is confirmed on laparotomy. Visible hematomas less than 4 cm and not expanding may be managed with ice packs and observation. Larger or expanding hematomas must be

incised, irrigated, and packed, and any obvious bleeding vessels must be ligated. If venipuncture sites are oozing, coagulopathy should be considered.

Surgical intervention is undertaken for direct indications, such as uterine curettage for suspected retained placental tissue or for hemostasis if medical therapy fails. The most common indications for emergency hysterectomy include uterine atony, placenta accreta, uterine rupture, and the extension of a low-transverse uterine incision.

KEY TREATMENT

Uterotonic agents should be the first-line treatment for postpartum hemorrhage caused by uterine atony (SOR: C). Management of PPH may vary greatly among patients, depending on etiology and available treatment options, and often a multidisciplinary approach is required (SOR: C). When uterotonics fail following vaginal delivery, exploratory laparotomy is the next step (SOR: C). In the presence of conditions known to be associated with placenta accreta, the obstetric care provider must have a high clinical suspicion and take appropriate precautions (SOR: C).

Whether present at the delivery or taking care of a new infant in the newborn nursery, the family physician plays an important part in newborn care during the early days of life. At the moment of birth, the newborn infant undergoes many changes and is vulnerable in the new environment. This chapter discusses these physiologic changes as well as the basics of neonatal resuscitation. The initial examination, common benign findings in the newborn period, developmental dysplasia of the hip, and audiology screening are described. Signs and symptoms of concern and common problems in the newborn period, including group B streptococcal infection and hyperbilirubinemia, are discussed, as well as infant safety, parent education, hospital follow-up, and care after discharge from the neonatal intensive care unit.

Preconception and Intrapartum Health

Key Points

- Oral folic acid supplementation before conception prevents neural tube defects.
- All pregnant women should be offered prenatal screening for trisomy 21 (Down syndrome) and neural tube defects.

- Pregnant women should be counseled against using tobacco, alcohol, or illicit drugs.
- Routine prenatal screening for group B streptococcal colonization significantly reduces early-onset neonatal GBS infection.
- Preexisting maternal illness (e.g., diabetes, hypo- and hyperthyroidism, hypertension) should be monitored closely during pregnancy.

A healthy newborn baby begins with a healthy pregnant mother. Family physicians are in the unique position of caring for women as they plan their families, during pregnancy, during childbirth, and after their infant is born. Preconception and intrapartum health care increase the likelihood of delivering a happy and healthy newborn.

Preconception Counseling

Preconception counseling regarding genetic diseases such as cystic fibrosis and Huntington's disease, as well as the dangers of tobacco, alcohol, and substance abuse, should be addressed with women of childbearing age. All women considering pregnancy should be encouraged to take in 400 µg (0.4 mg) of folic acid per day. Oral folic acid supplementation before conception can significantly decrease the risk of neural tube defects

(Czeizel and Dudas, 1992; MRC Vitamin Study Research Group, 1991). Women who have had a previous pregnancy affected by a neural tube defect should take 4000 µg (4.0 mg) of folic acid daily beginning 1 month before pregnancy (Centers for Disease Control and Prevention [CDC], 1992).

During pregnancy, maternal illness can adversely affect the fetus and lead to adverse neonatal outcomes. Maternal hypertension, preeclampsia, alcohol and tobacco use, illicit drug use, and autoimmune diseases can cause *intrauterine growth restriction* (IUGR) and preterm birth. Children born to women with diabetes mellitus or gestational diabetes are at risk for shoulder dystocia, operative delivery, hypoglycemia, and birth trauma (American College of Obstetricians and Gynecologists [ACOG], 2005). Maternal hyperglycemia at delivery also puts the infant at risk for hypoglycemia. Poorly controlled maternal hypothyroidism and hyperthyroidism are associated with low birth weight (LBW) and preterm delivery (ACOG, 2005). Fetal alcohol syndrome is directly caused by maternal alcohol use and abuse, and other illicit drug use is associated with preterm birth, congenital abnormalities, neurobehavioral abnormalities, and neonatal drug withdrawal syndromes (ACOG, 2005). **Box 22-1** lists the more common human teratogens seen in the United States.

Intrapartum care should include regular fundal height measurements to monitor the growth of the fetus. Routine screening obstetric ultrasound is not recommended because of insufficient evidence of benefit or harm (ACOG, 2005). However, ultrasound is a useful and safe diagnostic test for investigating concerns about fetal growth, estimating gestational age, observing fetal anomalies, and studying other intrapartum conditions.

All pregnant women should be offered prenatal screening for trisomy 21 (Down syndrome) and neural tube defects. For most women, maternal serum quadruple analyte screen (quad screen) is the most appropriate screening test. The quad screen measures serum levels of alpha fetoprotein (AFP), human chorionic gonadotropin (hCG), unconjugated estriol, and inhibin-A. Inhibin-A was added to the prior triple screen to improve the detection of trisomy 21. For women younger than 35, the triple screen detects approximately 75% of trisomy 21, 90% of anencephaly, and 80% of spina bifida if measured between 16 and 18 weeks' gestation (Benn et al., 2003; Graves et al., 2002). Using the quad screen, approximately 85% of trisomy 21 cases can be detected. The quad screen also has a false-positive rate for trisomy 21 of 8.2% after correction of major gestational errors, so a positive quad screen indicates a 1.9% risk for true trisomy 21 (Benn et al., 2003).

Routine prenatal screening for group B streptococci (GBS) significantly reduces early-onset neonatal GBS infection (Schrage et al., 2002b). Women who test positive for GBS or who have had a previous child with invasive GBS disease should receive intrapartum antibiotics for at least 4 hours before delivery (Schrage et al., 2002a). Management of the infant born to a mother colonized with GBS is discussed later.

KEY TREATMENT

Oral folic acid supplementation before conception prevents neural tube defects (Czeizel and Dudas, 1992; MRC Vitamin Study Research Group, 1991) (SOR: A).
 Routine prenatal screening for colonization by group B *Streptococcus* species significantly reduces early-onset neonatal GBS infection in neonates (Schrage et al., 2002b) (SOR: A).

Box 22-1 Selected Teratogenic Agents in Humans

Drugs and Environmental chemicals

Androgenic hormones
 Angiotensin-converting enzyme (ACE) inhibitors
 Angiotensin receptor blockers (sartans)
 Antiepileptics
 Carbamazepine*
 Diphenylhydantoin
 Trimethadione
 Valproic acid
 Phenobarbital*
 Antineoplastics
 Cigarette smoking
 Cocaine
 Coumarin anticoagulants (warfarin)
 Diethylstilbestrol
 Etretinate
 Fluconazole, high dose
 Iodides and goiter
 Lithium*
 Mercury, organic
 Methimazole
 Methylene blue via intra-amniotic injection
 Misoprostol
 Penicillamine
 1,3-*cis*-Retinoic acid (isotretinoin)
 Tetracyclines
 Thalidomide
 Toluene abuse

Infections

Cytomegalovirus

*Denotes agents that produce less than 10 defects in 1000 exposures.

Transition from Fetus to Newborn

Key Points

- A separate provider trained in neonatal care and resuscitation should be present and responsible only for the infant during every delivery.

- The ABC principles of neonatal resuscitation are airway, breathing, and circulation.
- The Apgar score should not be used as a substitution for assessing the ABCs in neonatal resuscitation.
- Resuscitation efforts should not be delayed or interrupted to assign an Apgar score.
- Routine endotracheal intubation and tracheal suction do not prevent meconium aspiration syndrome and may harm the vigorous infant.

During the first hours after delivery, the newborn must adapt to extrauterine life. This adaptation includes a highly coordinated series of physiologic changes during which the infant is particularly vulnerable. Health care providers trained to assess and manage newborns should be available during the delivery and immediate neonatal transition period for all infants.

Circulatory Changes

In utero, a series of central shunts moves oxygenated blood coming from the placenta through the umbilical vein to supply the brain and other organs. Most oxygenated blood bypasses the liver via the ductus venosus and enters the left side of the heart (bypassing the lungs) through the foramen ovale. The poorly oxygenated blood returning from the lungs bypasses the heart through the ductus arteriosus and returns to the placenta to obtain oxygen from the maternal circulation (Moore and Persaud, 1993).

On delivery, the fetal circulation must adapt to self-oxygenation, and the central shunting must cease. When the umbilical cord is clamped and cut, absent blood flow within the umbilical vein leads to the closure of the ductus venosus. The umbilical vessels functionally close by 2 to 3 days of life.

With the initial newborn breath, the aeration of the lungs drives fluid within the air space of the lungs into the pulmonary interstitium. An increase in the partial pressure of oxygen (P_{O_2}) within the pulmonary vasculature causes vasodilation and a progressive decrease in pulmonary vascular resistance. Increasing P_{O_2} , along with circulating prostaglandins, stimulates the constriction and closure of the ductus arteriosus. Pulmonary blood now flows preferentially to the heart, rather than directly into the aorta through the ductus arteriosus (Moore and Persaud, 1993; Thureen et al., 2005).

In the normal infant the ductus arteriosus might remain partially open during the first several hours of life and cause a soft systolic murmur. It can take the normal infant a few hours to clear the lungs of excess fluid, causing fine crackles to be heard on lung examination and a transient elevation of the respiratory rate. As pulmonary vascular resistance falls, systemic vascular resistance increases. When left atrial and ventricular pressures increase above right atrial pressures, the foramen ovale closes. Poorly oxygenated blood from the superior and inferior vena cava can now flow into the pulmonary arteries (Moore and Persaud, 1993). The foramen ovale typically becomes fully sealed within the first month of life.

Neonatal Resuscitation

The successful transition to extrauterine life depends heavily on the ability of the neonatal pulmonary system to adapt quickly and provide oxygen to the infant. Any illness or injury

Box 22-2 Neonatal Resuscitation Supplies and Equipment for Delivery of a Term Infant

Suction equipment

Bulb syringe
Mechanical suction and tubing
Suction catheters
8-F feeding tube and 20-mL syringe
Meconium aspirator

Bag and mask equipment

Neonatal resuscitation bag with a pressure-release valve or pressure manometer
Face masks, newborn and premature sizes
Oxygen source with flow meter and tubing

Medications and supplies to be immediately available if necessary

Epinephrine 1:10,000
Isotonic crystalloid for volume expansion
Sodium bicarbonate 4.2%
Naloxone hydrochloride (0.4 mg/mL)
Dextrose 10%
Normal saline for flushes
Umbilical vessel catheterization supplies
Syringes and needles

Miscellaneous

Gloves and appropriate personal protection
Radiant warmer or other heat source
Firm, padded resuscitation surface
Clock
Warmed linens and dry blankets
Stethoscope
Oropharyngeal airways

Intubation equipment

Laryngoscope with straight blades, no. 1
Extra bulbs and batteries for laryngoscope
Endotracheal (ET) tubes, sizes 2.5, 3.0, 3.5, and 4.0 mm
Materials to secure ET tube in place

Modified from Kattwinkel J (ed): Textbook of Neonatal Resuscitation, 5th ed. Elk Grove Village, Ill, American Academy of Pediatrics and American Heart Association, 2006.

that interferes with oxygenation puts the infant at great risk and should be identified and treated promptly. It is important that with every delivery, at least one person trained in neonatal care and resuscitation be assigned to care specifically for the infant. Caregivers should have immediate access to the necessary equipment for a complete resuscitation. If there is concern that the newborn will be at high risk for complications (e.g., thick meconium, fetal heart rate decelerations, known fetal anomalies), appropriate equipment should be set up and ready to use immediately (Box 22-2).

The American Academy of Pediatrics and American Heart Association developed specific protocols for neonatal resuscitation (AAP and AHA, 2006). An adapted resuscitation algorithm is given in Figure 22-1. This chapter does not cover the protocol in sufficient detail to produce competency in neonatal resuscitation and should not be used as a substitute

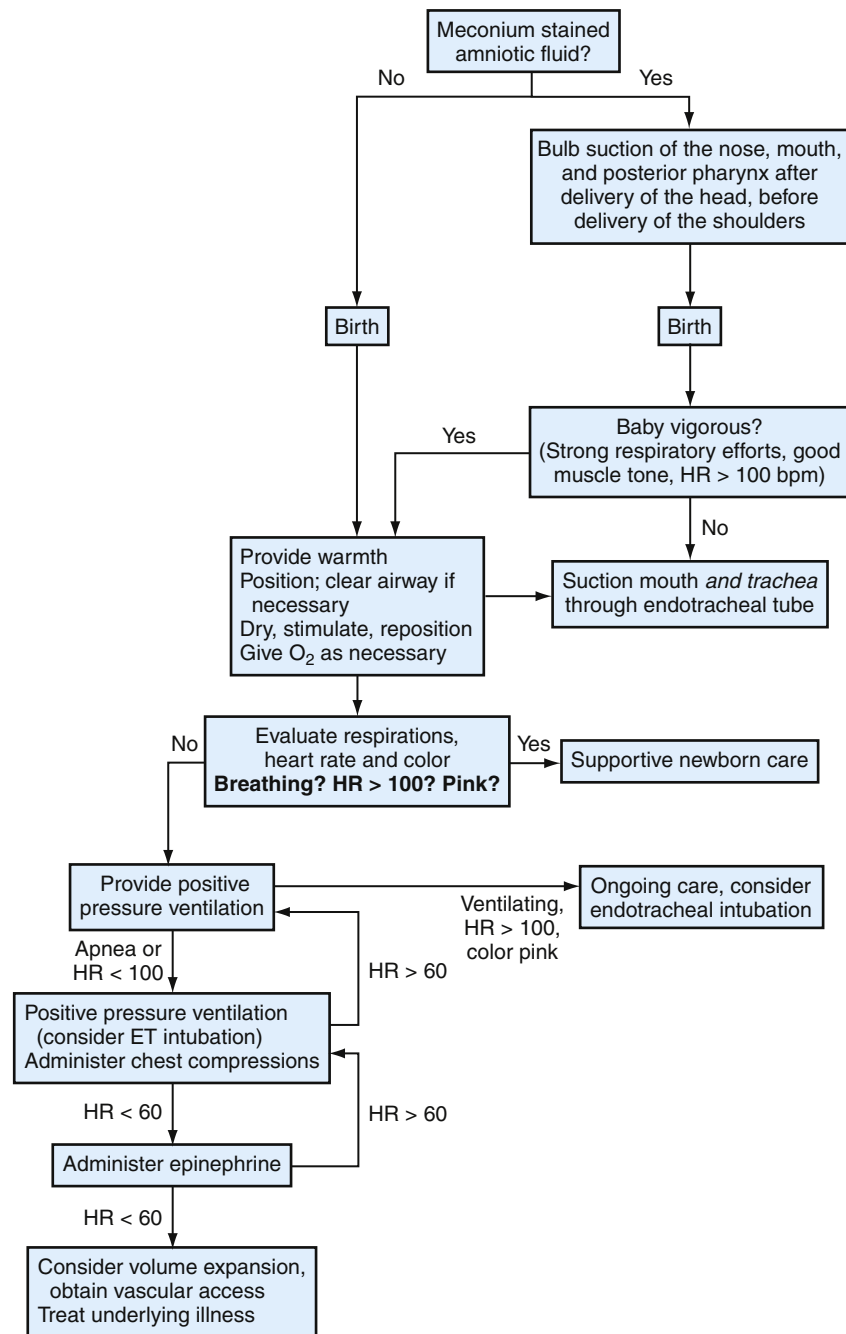

Figure 22-1 Algorithm for neonatal resuscitation. ET, Endotracheal; HR, heart rate.

(Modified from John Kattwinkel J (ed). *Textbook of Neonatal Resuscitation*. 5th ed. American Academy of Pediatrics and American Heart Association, Elk Grove Village, Ill, 2006.)

for participation in the AAP/AHA Neonatal Resuscitation Program (NRP). The ABCs of neonatal resuscitation are the same as adult resuscitation: clear and position the *airway*, make sure the infant is *breathing* (whether spontaneously or with support), and ensure *circulation* of oxygenated blood.

Initial stabilization procedures after every delivery should include warming and drying the infant, removing wet towels quickly, and providing tactile stimulation to encourage vigorous breathing and good muscle tone. After necessary resuscitation is completed, all neonates should receive chemoprophylaxis for ophthalmia neonatorum with 1% tetracycline ophthalmic ointment, 0.5% erythromycin ophthalmic ointment, or 1% silver nitrate aqueous solution. All three

medications have similar efficacy; however, silver nitrate is preferred in areas with appreciable incidence of penicillinase-producing *Neisseria gonorrhoeae*. Silver nitrate is more likely than tetracycline or erythromycin to cause a transient chemical conjunctivitis in the first 1 or 2 days of life (AAP, 2003a).

Infants should also receive 1.0 mg of vitamin K intramuscularly early after delivery to prevent vitamin K–deficiency bleeding (VKDB, previously hemorrhagic disease of the newborn) (AAP, 2003b; Puckett and Offringa, 2000). Concerns about a correlation between intramuscular (IM) vitamin K and childhood leukemia have not been validated, and there is insufficient data to show that oral vitamin K prevents

late-onset VKDB; therefore, IM vitamin K should be administered to all newborns (AAP, 2003b).

The Apgar Score

The Apgar score is widely used as a part of the early assessment of the newborn (Table 22-1). A score of 0, 1, or 2 is assigned to each of the five physical signs at 1 and 5 minutes after birth. The Apgar score should not be used as a substitute for assessing the ABCs in neonatal resuscitation, and resuscitation efforts should not be delayed or interrupted to assign an Apgar score. However, the Apgar score does allow a quick and consistent way for different providers to describe an infant's condition. A score of 7 to 10 is considered normal. If the 5-minute Apgar score is abnormal, less than 7, appropriate resuscitation measures should be continued and Apgar scores assigned every 5 minutes until the infant is stabilized.

Although the Apgar score provides a systematic way for different providers to describe an infant's condition in the first minutes of life, it correlates poorly with future neurologic outcomes (AAP and ACOG, 1996). A poor Apgar score alone cannot be used to diagnose asphyxia in the newborn or predict the development of cerebral palsy. However, the Apgar score is correlated with early infant death. In a large population study of term infants, an abnormal 5-minute Apgar score correlated with a significantly increased risk of death in the first 28 days of life. Even in infants with the lowest scores, however, death within 28 days is uncommon, occurring in 244 of 1000 infants with 5-minute Apgar scores of 0 to 3 (Casey et al., 2001).

Resuscitation of the Infant Born through Meconium-Stained Amniotic Fluid

Meconium staining of the amniotic fluid is a common complication during delivery of term infants, and approximately 5% to 12% of these infants develop *meconium aspiration syndrome* (MAS) (Wiswell et al., 2000). Risk factors for meconium staining of the amniotic fluid include maternal hypertension, maternal diabetes, maternal chronic respiratory or cardiovascular disease, maternal heavy smoking, preeclampsia or eclampsia, oligohydramnios, IUGR, poor biophysical profile, and abnormal fetal heart rate patterns (Gelfand et al., 2004). MAS is a life-threatening disease for otherwise healthy term newborns, and appropriate resuscitation of the infant at risk for MAS is important (see later discussion). All infants at risk for MAS and showing respiratory distress or bradycardia after delivery should undergo standard neonatal resuscitation procedures. In the depressed infant, tracheal suctioning to remove visible meconium can decrease the incidence and the severity of MAS (AAP and AHA, 2006). However, when the infant is *vigorous* at birth—defined as heart rate greater than 100, spontaneous respiration, and spontaneous movements or extremity flexion—routine endotracheal intubation and tracheal suction does not prevent MAS (Wiswell et al., 2000).

syndrome (MAS) (Wiswell et al., 2000). Risk factors for meconium staining of the amniotic fluid include maternal hypertension, maternal diabetes, maternal chronic respiratory or cardiovascular disease, maternal heavy smoking, preeclampsia or eclampsia, oligohydramnios, IUGR, poor biophysical profile, and abnormal fetal heart rate patterns (Gelfand et al., 2004). MAS is a life-threatening disease for otherwise healthy term newborns, and appropriate resuscitation of the infant at risk for MAS is important (see later discussion). All infants at risk for MAS and showing respiratory distress or bradycardia after delivery should undergo standard neonatal resuscitation procedures. In the depressed infant, tracheal suctioning to remove visible meconium can decrease the incidence and the severity of MAS (AAP and AHA, 2006). However, when the infant is *vigorous* at birth—defined as heart rate greater than 100, spontaneous respiration, and spontaneous movements or extremity flexion—routine endotracheal intubation and tracheal suction does not prevent MAS (Wiswell et al., 2000).

KEY TREATMENT

In the vigorous infant, routine endotracheal intubation and tracheal suction do not prevent meconium aspiration syndrome and can harm the infant (Wiswell et al., 2000) (SOR: A).

Initial Newborn Evaluation

Key Points

- A comprehensive physical examination of the newborn should be completed and discussed with the parents within the first 12 to 18 hours of life.
- The newborn examination should include observation of the infant at rest, including resting muscle tone, skin color, and respiratory effort.
- Periodic breathing is a normal breathing pattern in the newborn.
- A normal infant may need several hours to clear the lungs of excess fluid, and fine pulmonary crackles can be a normal physical finding.
- A soft systolic murmur can be a normal physical finding in the first hours of life, as the ductus arteriosus remains partially open.
- Asymmetric limb movements and reflexes should prompt further evaluation.
- All newborns should be screened for hearing loss before discharge.

Once the infant has been stabilized immediately after delivery, maternal and infant bonding should be encouraged. Initiating breastfeeding within the first 60 minutes after birth can increase the chances of successful breastfeeding (Sinusas and Gagliardi, 2001).

Within the first 12 to 18 hours of life, a comprehensive physical examination should be completed and discussed with the parents. During the examination, the infant should be kept in a comfortable environment. Keeping the infant quiet and calm is important for adequate examination in the newborn period. The examination should begin with observation of activity, skin color, muscle tone, and respiratory effort while the infant is quiet. Listening to the heart and lungs should be completed next, disturbing the infant as little

Table 22-1 Apgar Score

| Sign | Score* | | |
|--|--------------|-----------------------------|-----------------------------|
| | 0 | 1 | 2 |
| Heart rate | Absent | <100 beats/min | ≥100 beats/min |
| Respirations | Absent | Irregular and slow | Strong breaths, crying |
| Muscle tone | Limp | Some flexion | Good flexion, active motion |
| Reflex irritability to tactile stimulation | No response | Grimace | Cough, sneeze, cry, |
| Color | Blue or pale | Blue extremities, pink body | Completely pink |

*Apgar scoring should be completed at 1 and 5 minutes. The normal Apgar score at 5 minutes is 7 or higher. If the 5-minute Apgar is less than 7, continue resuscitative efforts and assign additional scores every 5 minutes for up to 20 minutes after birth. Modified from Kattwinkel J (ed). *Textbook of Neonatal Resuscitation*. 5th ed. Elk Grove Village, Ill, American Academy of Pediatrics and American Heart Association, 2006.

as possible. An infant often begins to cry at the touch of a cold stethoscope or cold hands, making the cardiopulmonary examination particularly difficult. The rest of the examination can then be completed in a calm and thorough manner.

As with the examination of adults and children, a complete history should be obtained on every patient. For the newborn, this includes the maternal history, antepartum course, course of delivery and any complications, and any postpartum complications. Specific attention to maternal medication and drug use, maternal medical conditions, traumatic events during delivery, neonatal resuscitation measures required, and maternal postpartum course assist in developing an appropriate assessment and plan for the neonate.

General Appearance

After collecting the history, it is important to observe the calm newborn. The normal term newborn rests with all extremities in some degree of flexion. Breathing should be quiet and effortless, but it can be very irregular. Episodes without breathing lasting 5 to 10 seconds are common and normal in newborns. Skin should be warm to the touch, soft, and smooth. [Table 22-2](#) lists normal vital signs in the first days of life. [Box 22-3](#) lists some common benign findings on the newborn examination. These are generally self-limited and require no further evaluation or treatment in the otherwise asymptomatic newborn.

Infants typically lose up to 10% of their birth weight in the first few days but should regain this weight by 2 weeks of age (Thureen et al., 2005). Excessive weight loss can indicate systemic disease or feeding difficulties and should be evaluated before discharge.

Skin

Examination of the skin should identify signs of systemic illness, signs of trauma from delivery, and birthmarks. Pallor, mottling, and central cyanosis can be signs of infection or respiratory distress. Petechiae on the face, scalp, and upper chest can occur as a result of a compressed nuchal cord during delivery. Bruising on the face and molding of the cranium are common in vaginal deliveries and often resolve in the first few days of life.

Several common benign skin conditions in the newborn period often cause significant worry for parents and

caregivers. Accurate diagnosis and reassurance can be an important part of the physician-patient relationship. *Macular hemangiomas* (also known as “stork bites” and “salmon patches”) are extremely common, particularly on the forehead and eyelids, and usually disappear before 1 year of age. *Milia* are tiny epidermoid cysts on the face that disappear within a few weeks. *Erythema toxicum* is a benign rash of yellowish papules on an erythematous base and resolves spontaneously in 4 to 5 days (Thureen et al., 2005).

Neurologic Examination and Newborn Reflexes

The neurologic examination of the newborn begins with the general appearance of the infant. The newborn should have a strong cry and exhibit symmetric movements; a high-pitched or weak cry can be associated with current illness or neurologic deficits. Asymmetric movements can indicate musculoskeletal or focal neurologic injury. Complete absence or asymmetry of any newborn reflex can indicate neurologic deficit or injury. The following developmental reflexes are present at birth in the normal newborn (Thureen et al., 2005):

Rooting reflex: When the cheek is stroked, the infant turns the head toward the stimulus and opens the mouth as if preparing to feed.

Sucking reflex: Stroking the lips causes the infant to open the mouth and begin to make sucking movements. The strength and coordination of suck can be assessed using a gloved finger placed in the mouth.

Moro reflex (or startle reflex): The infant’s head is raised several centimeters above the examination table while supporting the head and neck. The head is allowed to drop a short distance into the examiner’s other hand, and the infant responds by abduction and extension of the arms and opening of the hands. The infant then flexes arms and closes the fists and brings them back in toward the body.

Tonic neck reflex: With the infant lying supine, the head is turned to one side. The infant’s arm on the side where the face is directed extends, and the opposite arm flexes.

Box 22-3 Common Benign Findings in the Newborn (Partial List)

- Caput succedaneum (edema crossing suture lines)
- Epstein’s pearls (retention cysts) on hard palate
- Erythema toxicum
- Enlarged breasts (male or female)
- Hydrocele
- Mild diastasis recti
- Mild esotropia/exotropia
- Milia
- Miliaria
- Mongolian spots
- Nasolacrimal duct blockage (usually spontaneously resolves)
- Neonatal pustular melanosis
- Petechiae on presenting part (nonprogressive)
- Protruding xiphoid
- Salmon patches
- Shortened tongue frenulum (does not need cutting)
- Subconjunctival hemorrhage at birth
- Umbilical hernia
- Vaginal discharge or bleeding

Table 22-2 Vital Signs in the First Days of Life

| Vital sign | Normal value |
|--------------------------|---|
| Heart rate | 100-180 beats/min |
| Respiratory rate | 24-60 breaths/min |
| Systolic blood pressure | 65-90 mm Hg |
| Diastolic blood pressure | 50-70 mm Hg |
| Temperature | <101.4° F (38.0° C) >96.8° F (36.0° C) |

Data from Gunn VL, Nechyba C. *The Harriet Lane Handbook*, 16th ed, St Louis, Mosby, 2002; Rudolph AM, Kamei RK, Sagan P. *Rudolph’s Fundamentals of Pediatrics*, 2nd ed. Norwalk, Conn, Appleton & Lange, 1998.

Palmar and plantar grasp: Stroking the palm of the hand causes the infant to grip the examining finger. This grip tightens as the examiner pulls away. When firm pressure is placed on the plantar surface of the foot, the toes curl in toward the examining thumb.

Stepping reflex: The infant is held with both feet touching the examination table. The infant should exhibit alternating stepping movements.

Truncal incurvation (Galant reflex): The infant is held in the prone position above the examination table. Stroking one side of the spine with a finger or cotton swab should cause the infant to flex the pelvis toward the side of the reflex.

Head, Face, and Neck

Examination of the head and neck should include evaluation of cranial sutures, anterior and posterior fontanelles, facial symmetry, hard and soft palate, patency of the ear canal, patency of both nares, position of the nasal septum, placement of the ears, and intercanthal distance of the eyes.

The fontanelles should be flat and soft, and cranial sutures should be slightly mobile. The cranial sutures may override each other, and there may be temporary skull asymmetry after prolonged labor or vaginal delivery. Caput succedaneum and cephalohematoma (subperiosteal hemorrhage) are also common complications of labor and vaginal delivery. A *cephalohematoma* is a result of bleeding in the subperiosteal space and does not extend across a suture line, whereas caput succedaneum is caused primarily by subcutaneous edema and can involve any amount of the scalp. *Caput succedaneum* is present at delivery, and cephalohematoma is not evident until a few hours of age.

Many infants have transient skin lesions on the face and neck, and these should be noted and discussed with caregivers. Some birthmarks, however, can be a sign of underlying disease. For example, a port-wine stain occurring in the distribution of the first branch of the trigeminal nerve may be associated with Sturge-Weber syndrome. Hemangiomas are not always present at birth and might not be visible until 1 month of age. Most hemangiomas spontaneously regress during childhood and need no specific management. Periocular hemangiomas, however, should be managed with ophthalmologic consultation and aggressive therapy (Thureen et al., 2005).

The eyes, nose, mouth, and ears should be symmetric. Using a gloved finger, the hard and soft palate should be palpated and found to be fully merged. The oropharynx should be visualized, and the uvula should be single and midline. The ear canals should be inspected with an otoscope and found to be patent, and a small nasogastric tube should pass freely through each nare to the oropharynx. The helix of the ear (top portion) should be above the position of the inner canthi of the eyes.

Eyes

The newborn eye examination can be difficult immediately after birth, when the face may be edematous, and an assistant may help to hold the eyelid open. The sclera should be white but may appear a faint blue in premature infants. The pupils should be symmetric and reactive. A red reflex (reflex off the retina as viewed through ophthalmoscope) should be present bilaterally. In dark-skinned infants the retinal reflex can appear pale or grayish white (Tappero and Honeyfield,

2003). Absence of a retinal reflex can indicate a congenital cataract, and a bright white or asymmetric reflex may be seen with retinoblastoma. Subconjunctival hemorrhage can be seen, more frequently with traumatic labor or delivery, and often clears within the first few days of life. Prominent epicanthal folds over the medial upper aspect of the eye can be seen in Down syndrome but can also be a familial trait.

Chest and Lungs

Initial observation of the quiet infant should include assessment of respiratory rate and effort. Skin retraction between the ribs during inspiration is abnormal and usually indicates respiratory distress. The abdomen may move with each breath, but it should appear effortless. Breath sounds should be equal and clear in all lung fields. Fine crackles (wet lungs) can be normal, particularly in the infant who was delivered by cesarean section, as the infant is trying to clear the interstitial fluid left over from intrauterine life. This can also be associated with a transient tachypnea that resolves spontaneously.

Heart

The newborn cardiac examination should include inspection for adequate perfusion and palpation of the radial, brachial, and femoral pulses. Capillary refill time in the neonate is normally less than 2 seconds, and all pulses should be strong and equal bilaterally. Cyanosis or diaphoresis with crying, feeding, or Valsalva maneuver can be a sign of congenital heart disease and should be evaluated further. On auscultation, the heart rate should be regular and without murmur, and both heart sounds should be heard distinctly.

In the first 24 hours of life, the continuous rumbling murmur of a patent ductus arteriosus (PDA) is often heard in the second left intercostal space (Tappero and Honeyfield, 2003). In an otherwise asymptomatic infant, PDA can be observed and should resolve quickly. Coarctation of the aorta often produces a systolic ejection murmur radiating to the cardiac apex and to the back and may also be associated with asymmetric or absent femoral pulses.

Abdomen

The infant abdomen is normally round, soft, and symmetric. Abdominal masses, hepatomegaly, duodenal atresia, and other intra-abdominal abnormalities can cause asymmetry. Bowel sounds should be heard in all quadrants. The umbilical cord should be clamped and should be dry, showing no signs of infection. The abdomen should be palpated when the infant is not crying or upset, and the liver, kidneys, and spleen should be normal in size. The normal infant liver is 1 to 3.5 cm below the costal margin, and the left lobe often crosses the midline. The normal spleen should be slightly below the left lateral costal margin and should feel firm and small. The kidneys are felt with deep palpation as small, firm, lobular masses on either side of the abdomen.

Genitalia and Anus

The genitalia of the female child should have a visibly patent vaginal orifice, with the labia majora covering the labia minora, clitoris, and vaginal opening. The labia majora

should be completely separate from each other (ensuring the absence of labioscrotal fusion). The labia majora should be palpated to evaluate the presence of inguinal hernia or ectopic gonads.

The male infant should have two palpable testicles of similar size within the scrotum. If the infant is cold during the examination, the testicles may be retracted and might even be found at the distal end of the inguinal canal. Each testicle, however, should be able to be easily brought down into the scrotum. The testicles should be similar in size and shape, although presence of significant hydrocele is a common transient finding in newborns. A hydrocele should transilluminate, and any testicular mass that does not transilluminate should be further evaluated.

The glans of the penis is normally covered completely by foreskin, and the urethral meatus should be located at the tip of the glans. A child with the urethral meatus opening on the ventral (hypospadias) or dorsal (epispadias) surface of the penis *should not be circumcised* until pediatric urologic consultation has been completed.

Most male and female infants urinate within the first 24 hours of life. Delay in urination should prompt an evaluation of the kidneys, bladder and urethra (Tappero and Honeyfield, 2003).

The anus should be inspected for patency during the initial examination, and the infant should pass stool within the first 24 hours of life. The first several bowel movements are meconium stools, dark and black with a tarry consistency. These eventually change to the thin, yellowish stools of the newborn.

Muscles, Skeleton, and Hips

The initial musculoskeletal examination should be the observation of the infant. All limbs should appear symmetric and move equally, and any deficit should lead to further evaluation.

Palpate both clavicles to evaluate for fracture or dislocation that might have occurred during delivery. In the event of a traumatic vaginal delivery, it is important to pay special attention to the potential for a brachial plexus injury. An infant with brachial plexus injury often has the affected arm straight down at the side and might have the wrist slightly bent, the fingers straight, and the forearm pronated (Thureen et al., 2005). Inspect hands and feet for syndactyly (fusion of fingers or toes), polydactyly (extra digits), clubfoot, and other congenital anomalies.

The incidence of *developmental dysplasia of the hip* (DDH) is estimated to be between 1.5 and 20 cases per 1000 infants (Shipman, 2006). Female gender, breech position, and family history are all reported risk factors for DDH; however, only a minority of cases of DDH are found in infants with identifiable risk factors (Shipman, 2006). In addition, as many as 80% of infants with an abnormal hip examination at birth resolved by 6 weeks, and 90% of mild dysplasia identified by ultrasound resolved between 6 weeks and 6 months (Shipman, 2006). The U.S. Preventive Services Task Force concluded that there was insufficient evidence to recommend routine screening for DDH in newborns (USPSTF, 2006). AAP (2000b) continues to recommend serial clinical examinations of the hip for the first 12 months of life.

There are two maneuvers in the neonatal hip examination: the Ortolani maneuver and the Barlow maneuver (Fig. 22-2). Each hip should be examined separately using gentle but firm pressure. Too much force can injure the hip in a normal infant.

The *Barlow maneuver* begins with flexion and adduction of the hip. The examiner should place the palm of the hand just below the infant's knee and the fingertips over the greater trochanter of the femur. The examiner exerts gentle pressure toward the examination table, and in a positive test the examiner can feel and often hear the femur slip posteriorly out of the acetabulum (Weinstein et al., 2004). This is often

Figure 22-2 Physical examination maneuvers for developmental dysplasia of the hip.

called the “clunk of exit” or “click of exit” (Vain et al., 2004). The terminology used to describe the positive test can cause confusion to the inexperienced examiner. Benign adventitial sounds and high-pitched clicks often occur with flexion and extension of the extremities in a normal newborn and are mistaken for hip dysplasia (AAP, 2000b). If the newborn hip is already dislocated, the Barlow test will be negative because the femur is already outside the acetabulum.

The *Ortolani maneuver* is performed by abducting the hip and firmly pressing the greater trochanter up away from the examination table. In a positive test, a “clunk of entry” is heard and felt as the head of the femur reenters the acetabulum (Weinstein et al., 2004).

Newborn infants with any positive or equivocally positive result should be reexamined at 2 weeks of age. If at 2 weeks the examination remains positive, pediatric orthopedic consultation should be considered. Some newborns have ligamentous laxity that can be mistaken for hip dysplasia, but this should resolve in the first 2 weeks of life. A child with a history or physical examination suspicious for developmental dysplasia of the hip can be evaluated with serial hip examinations, hip ultrasound at 6 weeks of age, or pelvic radiographs at 4 months of age, and pediatric orthopedic referral should be considered (AAP, 2000b).

Postnatal Assessment of Gestational Age

Before delivery, gestational age is estimated using the date of the last menstrual period or obstetric ultrasound measurements. After birth, however, physical and neurologic criteria should be used to estimate the gestational age of the infant. The *new Ballard score* accurately estimates gestational age within 2 weeks for infants older than 20 weeks' gestation (Ballard et al., 1991). Identifying the preterm (less than 37 weeks) and post-term (more than 42 weeks) infant is important for appropriate risk management and observation after delivery.

The assessment of gestational age should be performed within 96 hours of birth by two separate examiners to ensure objectivity (Thureen et al., 2005). **Box 22-4** and **Figure 22-3** describe the new Ballard score and examination.

Audiology Screening

Congenital hearing loss affects approximately 1 to 3 infants per 1000 live births. At least 37 states and the District of Columbia have legislatively mandated universal newborn hearing screening programs in the United States (National Center for Hearing Assessment and Management [NCHAM], 2005). In a 2008 update, USPSTF changed its recommendation on newborn hearing screening to a B recommendation, indicating that the evidence shows moderate certainty that there is a moderate net benefit to universal newborn hearing screening.

There are three acceptable screening tests to detect congenital hearing loss: automated auditory brainstem response (AABR), transient evoked otoacoustic emissions (TEOAE), and distortion product otoacoustic emissions (DPOAE) (Hayes, 2002; NCHAM, 2006). The AABR is a more expensive test but has a lower audiology referral rate than testing for TEOAE or DPOAE. TEOAE might have higher false-negative results in particularly vulnerable populations such as premature infants

Box 22-4 Examination Technique for the New Ballard Score

Neuromuscular maturity

Posture: Assign score when infant is relaxed and quiet.

Square window: Measure the angle of the wrist in flexion, between the hypothener eminence and the forearm.

Arm recoil: Score the position of the arm after flexing the forearms for 5 seconds, fully extending the arm and releasing quickly.

Popliteal angle: Measure the angle of the popliteal fossil with the hip fully flexed and the knee extended with gentle pressure.

Scarf sign: Maneuver arm over opposite shoulder keeping scapulae on the exam table.

Heel to ear: Keeping the pelvis on the exam table and without forcing the leg, move the infant's foot toward the head.

Physical maturity

Skin: With increasing gestational age, the skin becomes thicker, tougher, and less transparent.

Lanugo: Describe the fine, downy lanugo hair as seen over the infant's back and scapulae.

Plantar surface of foot: Measure from the tip of great toe to the back of the heel.

Breast tissue: Describe nipple size, stage of development, and amount of breast tissue.

Eye/ear: Loosely fused eyelids open with gentle traction; the pinna in a term infant is well formed and quickly recoils after bending.

Genitalia: Describe the development of the external genitalia.

Modified from Thureen PJ, Deacon J, Hernandez JA, Hall DM. *Assessment and Care of the Well Newborn*. 2nd ed. Philadelphia, Saunders, 2005.

or those hospitalized in the intensive care unit (Hayes, 2002). Many screening programs using TEOAE or DPOAE employ a two-stage screening program, where an infant who fails the initial screen will be tested with AABR before discharge (NCHAM, 2006). Infants who fail a hearing screening program should be promptly referred to a pediatric audiologist for further diagnostic testing.

Signs and Symptoms of Concern

Key Points

- The inability to maintain body temperature may be an early sign of sepsis in the newborn.
- Tachypnea, expiratory grunting, intercostal retractions, subcostal retractions, apnea, and cyanotic spells are signs of respiratory distress in the infant.
- Petechiae that become generalized or develop hours after delivery should prompt further evaluation.
- Most infants will pass urine and meconium stool by 24 hours of age.
- Group B streptococcal sepsis can be prevented through appropriate antepartum antibiotic use and appropriate management of the infant born to a high-risk mother.

General Observation

Using careful observational skills, the examiner can obtain much useful information without even touching the infant. One can assess the infant's skin color, respiratory effort, and

Figure 22-3 Maturation assessment of gestational age (new Ballard score). See Box 22-4 for a description of the technique. (From Ballard JL, Khoury JC, Wedig K, et al: New Ballard score, expanded to include extremely premature infants. J Pediatr 1991;119:417-423).

activity state; the muscle tone can be assessed by observing whether the infant lies in a flexed position and spontaneously moves the extremities.

Vital Signs

Heart Rate

Variations of the heart rate (HR) or rhythm are relatively common in the newborn period and, if isolated, are usually benign. HR abnormalities fall into one of two main categories: *tachycardia* (HR >180 beats/min) and *bradycardia* (HR <80 beats/min). Persistent tachycardia is abnormal

and should be evaluated for conditions such as sepsis, anemia, hypoxemia, hypovolemia, and hyperthermia. Persistent bradycardia is abnormal and may be associated with sepsis, asphyxia of the fetus, hypoxemia, congenital heart block, increased intracranial pressure, and hypothyroidism (Hoekelman, 2001, Thureen et al., 2005).

Blood Pressure

It is unusual for blood pressure (BP) abnormalities to be isolated findings in the newborn. *Hypotension* (systolic BP <60 mm Hg in term infant) is usually accompanied by tachycardia and a physical examination consistent with poor

perfusion. Hypotension usually is a complication of some other serious underlying problem, such as overwhelming sepsis or acute hemorrhage. In infants who had umbilical arterial catheters, occasionally a renal vascular occlusion leads to hypertension. A combination of poor femoral pulses and elevated pressures in the upper extremities calls for evaluating for coarctation of the aorta (Hoekelman, 2001; Thureen et al, 2005). Normal BP ranges for term infants vary by method obtained and birth weight (Versmold et al., 1981).

Temperature

An infant who is ill is more likely to have *hypothermia* than a fever. The newborn a few hours old often has difficulty maintaining body temperature and should not be allowed to become cold. This is particularly true in the delivery room when the infant is still wet. The newborn is particularly susceptible to environmental conditions. An infant who becomes cold-stressed has increased metabolic demands that could lead to metabolic acidosis, pulmonary hypertension, and hypoxemia. One of the early signs of sepsis is an inability to maintain body temperature. Hypothermia can also quickly lead to hypoglycemia. The infant's body temperature must be stable before giving the first bath (Hoekelman, 2001).

Respiratory Symptoms

Tachypnea

Tachypnea is a persistent respiratory rate greater than 60 breaths per minute. The respiratory rate should be determined while the infant is quiet, and the examiner should observe chest excursions for a full 60 seconds because newborns tend to be periodic breathers (Thureen et al., 2005). Tachypnea may be associated with cardiovascular, pulmonary, or metabolic diseases. Tachypnea is also often associated with other respiratory symptoms, as discussed later.

Expiratory Grunting

Audible expiratory grunting may be present during the first hour of life as lung fluid is cleared. Grunting can occur in association with intercostal or substernal retractions. However, if the grunting persists beyond the first hour of life, it can signal a significant pulmonary problem and should be promptly evaluated.

Retractions

Retractions (intercostal or substernal) are a common finding in newborns with respiratory problems. Retractions are seen in the preterm infant with *respiratory distress syndrome* (RDS) and in term infants with conditions such as GBS pneumonia and MAS. Retractions indicate that the infant is having difficulty breathing, and the cause should be defined and promptly treated.

Apnea

Episodes of apnea persisting for longer than 20 seconds are abnormal and should be promptly investigated. There might or might not be associated bradycardia and cyanosis. Apnea can have several causes, including medications administered

to the mother during labor, sepsis, airway obstruction, severe hypoxemia, central nervous system (CNS) abnormalities, and metabolic disorders.

It is important to distinguish apnea from periodic breathing (Hoekelman, 2001). *Periodic breathing* is almost always a normal finding in the newborn, particularly in the preterm infant.

Cyanosis

One needs to differentiate *central* cyanosis, which is always pathologic, from *peripheral* cyanosis involving the hands and feet (acrocyanosis). Acrocyanosis is normal in the first few days of life. The infant with true generalized or central cyanosis should be given oxygen immediately and the cause of cyanosis should be investigated. The major causes of cyanosis are cardiac anomalies, respiratory problems, and sepsis. The approach to evaluation and management of cyanosis has been well described (Sasidharan, 2004).

Other Signs and Symptoms that Should Raise Concern

Refusal to Feed or Intolerance to Feedings

Most infants with a serious illness do not feed well. They might refuse to nurse or to take a bottle of formula, or they take much longer than usual to feed. One should be concerned about the infant who is vomiting, particularly if projectile, or if the vomitus is bilious. Most infants regurgitate or spit up, and this normal finding needs to be distinguished from true vomiting. Normal regurgitation is effortless, but vomiting is more forceful. In an infant who is septic, intolerance to feedings is very common. One of the early signs of congestive heart failure in a newborn is a change in ability to feed. The infant will tire during feeding and may also become diaphoretic.

Lethargy

Lethargy is a decrease in activity. Infants born to mothers who were given certain medications during labor may be quite inactive until the drug effect dissipates. Magnesium sulfate and narcotics have this potential effect on the newborn. Most infants who develop sepsis become lethargic, so this possibility needs to be considered in any infant who has prolonged lethargy. Some inborn errors of metabolism also manifest with persistent lethargy.

Hypotonia

Any acutely ill infant can demonstrate some degree of decreased muscle tone. Infants with trisomy 21 typically have decreased muscle tone. Magnesium sulfate given to the mother during labor can lead to a transient state of hypotonia in the newborn. An infant with low muscle tone usually has little to no resting limb flexion.

Hypertonia

Increased muscle tone is usually a manifestation of a CNS abnormality, such as hypoxic-ischemic brain injury, intracranial hemorrhage, or infection (meningitis). Persistent arching of the back may be a manifestation of hypertonia.

Jitteriness

Jitteriness is defined as rhythmic tremors of equal amplitude and is frequently seen in the healthy infant. These tremors can be easily initiated in the susceptible newborn by external stimuli such as handling or loud noise. One can stop the tremor by gently holding the affected extremity. Although jitteriness often occurs in the healthy infant, tremors may be a manifestation of a variety of neonatal problems, including hypoglycemia, hypocalcemia, drug withdrawal from maternal drug use, and perinatal asphyxia. In the infant with persistent or exaggerated tremors, possible causes must be investigated (Hoekelman, 2001).

Pallor

Pallor is skin color that is paler than normally expected in an infant of that race. Pallor can be secondary to vasoconstriction or significant anemia.

Petechiae

Petechiae are pinpoint hemorrhages into the skin that do not blanch when pressure is applied. Petechiae are typically seen on the presenting part of the infant after a vaginal delivery, and these are of no concern. If the petechiae later become generalized, however, platelet abnormalities should be considered and a platelet count obtained. Petechiae can be seen in a variety of scenarios, including sepsis and hematologic and immunologic conditions.

Absence of Femoral Pulses

Femoral pulses should be palpated in all newborns because absent or delayed femoral pulses are often associated with coarctation of the aorta. It is important to obtain four extremity BP readings in this situation. If BP is greater in the arms than in the legs, a coarctation is likely present.

Abdominal Distention

Abdominal distention may be an isolated finding, or it may be associated with emesis. Abdominal distention may be present because of a septic ileus, obstruction in the gastrointestinal (GI) tract, or enlargement of an abdominal organ. It is important to diagnose and treat the underlying cause. Infants with diaphragmatic hernias can present with a *scaphoid abdomen* (abdomen seems empty of much of its contents) because much of the bowel is in the chest cavity.

Delayed Passage of Meconium or Urine

More than 90% of term infants pass their first meconium stool by 24 hours of age, and 99% pass one by 48 hours of age (Hoekelman, 2001). Delay in passage of meconium can be caused by Hirschsprung's disease, meconium plug, or meconium ileus. When the infant has not passed a stool by 24 to 48 hours of age, a plain radiograph of the abdomen, taken with the infant in the prone position, often reveals the source of the problem. The absence of intraintestinal air in the pelvis suggests Hirschsprung's disease, and air trapped within meconium (characteristic soap bubble appearance) is highly

suggestive of meconium ileus (Rudolph et al., 1998). Meconium ileus has a high association with cystic fibrosis. Early recognition of Hirschsprung's disease is essential to reduce the morbidity and mortality associated with late diagnosis.

More than 90% of newborns void by 24 hours of age, and 99% by 48 hours of age (Hoekelman, 2001). Failure to pass urine by 48 hours of age should lead to evaluation of the kidneys, ureters, and bladder, including renal sonography.

No infant should be discharged from the nursery without documentation of voiding and stooling. Before initiating any evaluation, however, talk with parents and with nursing staff to make certain that the infant did not have a stool or a wet diaper that was not recorded.

Differential Diagnosis of Concerning Signs and Symptoms

Group B Streptococcal Sepsis

Group B *Streptococcus* is a leading cause of neonatal morbidity and mortality in the United States (Schrage et al., 2002b). Newborns with GBS sepsis can present with respiratory symptoms (tachypnea, grunting, or retractions) or with symptoms such as poor feeding, intolerance to feeds, lethargy, or inability to maintain body temperature. If this disease is in the differential, prompt evaluation and treatment are necessary to prevent severe morbidity or mortality. Treatment protocols are available to manage the at-risk pregnant patient and evaluate and manage the newborn infant (Figs. 22-4 and 22-5).

Other Neonatal Infections

Newborns can be infected with organisms other than GBS, and thus blood cultures are an integral part of the diagnostic evaluation. These organisms include *Listeria monocytogenes*, *Chlamydia* species, and *Escherichia coli*. Infants with these diseases can present with respiratory symptoms or other symptoms depending on whether the infection is localized to the lungs or generalized.

Respiratory Distress Syndrome

Respiratory distress syndrome, sometimes referred to as "hyaline membrane disease," is seen in the surfactant-deficient preterm infant. RDS is also seen in the infant of a diabetic mother delivered before 38 weeks' gestation. These infants present with respiratory distress, including tachypnea, grunting, and retractions. They often become cyanotic as the disease worsens. The preterm infant is at higher risk for developing GBS sepsis, and the symptoms of both diseases are similar, as are the early radiographic findings. Thus, if symptomatic, the preterm infant should receive antibiotic therapy.

Pneumonia

The infant with pneumonia generally presents with respiratory symptoms, particularly with tachypnea. Pneumonia has various causes, including aspiration and infection. Meconium aspiration syndrome can lead to severe pneumonia, with subsequent development of persistent pulmonary hypertension. It becomes difficult to oxygenate

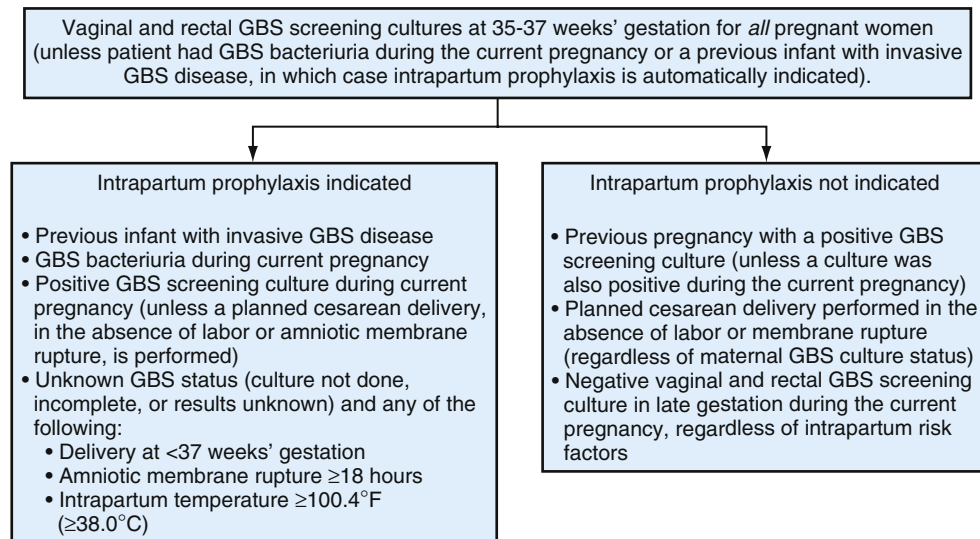

Figure 22-4 Indications for intrapartum antibiotic prophylaxis to prevent perinatal group B streptococcal (GBS) disease under a universal prenatal screening strategy based on combined vaginal and rectal cultures collected at 35 to 37 weeks' gestation from all pregnant women.

(Modified from Schrag S, Gorwitz R, Fultz-Butts K, Schuchat A. Prevention of perinatal group B streptococcal disease: revised guidelines from CDC. *MMWR* 2002;51(RR-11):1-22.)

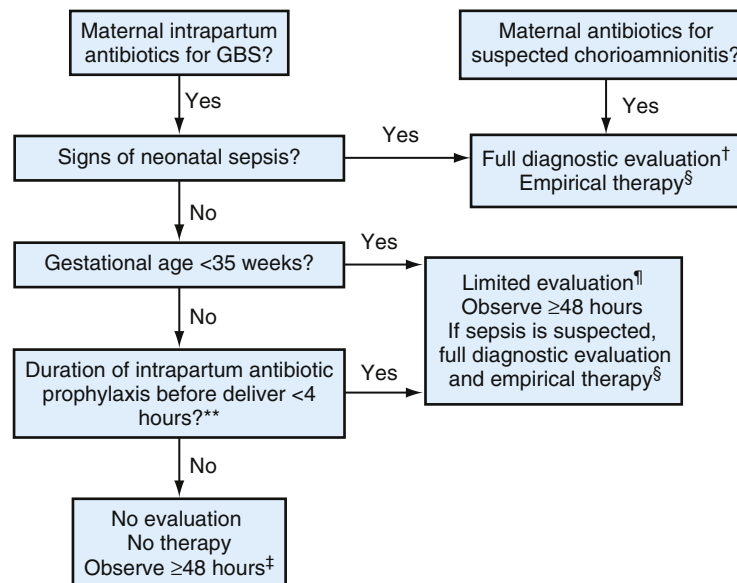

Figure 22-5 Sample algorithm for management of a newborn whose mother received intrapartum antimicrobial agents for prevention of early-onset group B streptococcal disease* or suspected chorioamnionitis. This algorithm is not an exclusive course of management. Variations that incorporate individual circumstances or institutional preferences may be appropriate.

*If no maternal intrapartum prophylaxis for GBS was administered despite an indication being present, data are insufficient on which to recommend a single management strategy.

†Includes complete blood cell count (CBC) and differential, blood culture, and chest radiograph if respiratory abnormalities are present. When signs of sepsis are present, a lumbar puncture, if feasible, should be performed.

§Duration of therapy varies depending on results of blood culture, cerebrospinal fluid findings, if obtained, and the clinical course of the infant. If laboratory results and clinical course do not indicate bacterial infection, duration may be as short as 48 hours.

¶CBC with differential and blood culture.

**Applies only to penicillin, ampicillin, or cefazolin and assumes recommended dosing regimens.

‡A healthy-appearing infant who was ≥38 weeks' gestation at delivery and whose mother received ≥4 hours of intrapartum prophylaxis before delivery may be discharged home after 24 hours if other discharge criteria have been met and a person able to comply fully with instructions for home observation will be present. If any one of these conditions is not met, the infant should be observed in the hospital for at least 48 hours and until criteria for discharge are achieved.

(Modified from Schrag S, Gorwitz R, Fultz-Butts K, Schuchat A. Prevention of perinatal group B streptococcal disease: revised guidelines from CDC. *MMWR* 2002;51(RR-11):1-22.)

and sufficiently ventilate the most severely affected infants. Infants with pneumonia should be treated with appropriate antibiotics and respiratory support. Meconium aspiration often requires endotracheal intubation and prolonged ventilatory support in addition to antimicrobial treatment.

Transient Tachypnea of the Newborn

The most common cause of tachypnea in the term newborn is transient tachypnea of the newborn (TTN). It likely represents delayed clearing of the fetal lung fluid and is

particularly common in the infant who is delivered by cesarean section without labor. The symptoms are present from birth and can persist for up to 72 hours. TTN can be difficult to differentiate from other respiratory entities such as pneumonia; however, infants with TTN rarely exhibit signs of serious illness other than tachypnea.

Congenital Heart Disease

In an infant who is tachypneic and cyanotic, it may be difficult clinically to distinguish between cardiac and pulmonary disease. The physical examination is important, but an infant can have a congenital heart lesion and not have an audible murmur. The oxygen challenge test (OCT) can help to distinguish between pulmonary and cardiac causes. The OCT helps determine whether a significant cardiac anomaly is causing a right-to-left shunt, or whether oxygenated blood is mixing with unoxygenated blood. Arterial blood gases (ABGs) are tested while the infant is breathing room air and after the infant has been breathing 100% oxygen for at least 15 minutes. On 100% oxygen, the P_{O_2} should increase to greater than 150 mm Hg in the infant without cardiac disease (Sasidharan, 2004). If congenital heart disease is strongly suspected, the infant should be readily transferred to a facility with pediatric echocardiography and neonatal intensive care facilities.

Common Problems Encountered in the Term Newborn

Key Points

- The incidence of hypoglycemia in the infant of a diabetic mother is 25% to 40%.
- About 50% of healthy term newborns develop visible jaundice.
- Unconjugated (indirect) hyperbilirubinemia is caused by increased bilirubin production, decreased hepatic uptake of bilirubin, and increased enterohepatic circulation.
- Bilirubin levels should be interpreted according to the age of the infant, measured in hours.
- Breastfeeding should be encouraged throughout phototherapy if clinically possible, regardless of the cause of hyperbilirubinemia.

In the newborn, certain signs and symptoms of illness are readily apparent while others are much subtler. It is important to detect the subtle signs in an infant's illness to initiate early therapy. This section discusses many of the signs and symptoms in a newborn that may indicate potential disease processes.

Hypoglycemia

Hypoglycemia is relatively common in the newborn infant. In the healthy term newborn, low blood glucose concentrations are often encountered and usually reflect normal metabolic adaptation to extrauterine life. However, with prolonged or recurrent hypoglycemia, the newborn risks neurologic sequelae (Fluge, 1975).

The blood glucose level that defines clinically significant hypoglycemia is controversial. Cornblath and associates (2000) believe that a plasma glucose concentration less than 36 mg/dL warrants close monitoring. If the plasma

glucose remains below this level or does not rise after a feeding, intervention is recommended. Liver glycogen stores are rapidly depleted within a few hours after birth. In the newborn, serum glucose levels decline after birth until 1 to 3 hours of age, when levels tend to begin spontaneously rising.

Serum glucose levels are higher than whole-blood glucose levels. Whole-blood measurements of glucose (bedside testing using finger or heel stick) often underestimate the plasma glucose concentration by as much as 10% to 15%.

Infants who are known to be at higher risk for hypoglycemia should have blood glucose concentrations routinely measured. Infants at high risk for hypoglycemia include infants of diabetic mothers (IDMs), small-for-gestational-age (SGA) newborns, infants with a history of perinatal hypoxia or ischemia, and infants who become hypothermic from cold stress. Infants who become septic are also at higher risk for hypoglycemia. For infants at risk, glucose monitoring should be initiated as soon as possible after birth, and within the first hour of life in IDMs. Healthy term newborns delivered after a normal pregnancy, with no known risk factors for hypoglycemia and with no clinical signs of low blood sugar, do not need monitoring of blood glucose concentrations (Cornblath et al., 2000). Routine blood glucose monitoring of large-for-gestational-age (LGA) infants who have no additional risk factors is not necessary (de Rooy and Hawdon, 2002).

If the infant is asymptomatic and alert, low blood sugar can be treated by breastfeeding or by giving formula and repeating the serum glucose concentration after the feeding. If the infant is symptomatic, intravenous (IV) glucose is recommended. The exact concentration and amount of IV glucose to deliver depends on the amount of decrease in the serum glucose concentration. Guidelines for management can be found in the *Harriet Lane Handbook* (Robertson and Shilkofski, 2005).

Infant of a Diabetic Mother

About 6% of pregnancies are complicated by maternal diabetes mellitus, and about 80% of these women have gestational diabetes. Almost 100,000 infants are born to diabetic and gestational diabetic women in the United States each year, and IDMs account for 5% of all neonatal intensive care unit (NICU) admissions (Tyralla, 1996).

Many IDMs are macrosomic. *Macrosomia* is defined as a birth weight of more than 4000 grams or greater than the 90th percentile for gestational age. The problems associated with being an IDM relate to the effects of hyperinsulinism and macrosomia. IDMs have higher rates of perinatal mortality and morbidity. Macrosomia is a predisposing factor for a variety of birth trauma-related injuries, including shoulder dystocia, clavicle fracture, facial nerve palsy, and brachial plexus injury. Poor intrauterine growth occurs at a higher incidence in diabetic pregnancies than in the nondiabetic pregnancy. Women with severe preexisting diabetic vascular disease and decreased uterine blood flow are at significant risk to deliver a growth-retarded infant (Tyralla, 1996).

The incidence of hypoglycemia in the IDM ranges from 25% to 40%. Many nurseries have protocols for the IDM that include checking a bedside whole-blood glucose measurement at 30 minutes of age and again at 1 and 2 hours of age. If the whole blood cell glucose value is reported as less than 40 mg/dL, a serum glucose should be obtained and the

infant fed. If the infant is unable to feed orally, IV glucose should be initiated (Tyralla, 1996).

Polycythemia and hyperviscosity are more common in the IDM because of increased erythropoiesis secondary to fetal hypoxia related to hyperinsulinism. A greater amount of blood is shifted from the placenta to the fetus during hypoxia. *Polycythemia* is defined as a venous hematocrit of 65% or greater (Tyralla, 1996).

The risk of RDS in an IDM is five to six times greater than in the infant of the nondiabetic mother before 38 weeks' gestation. Animal studies have implicated hyperglycemia and hyperinsulinemia within the uterine environment as causing the delay of pulmonary maturation (Tyralla, 1996). Lung maturation studies (e.g., lecithin/sphingomyelin ratio by amniocentesis) should be considered before an elective cesarean section in a diabetic mother.

Poor blood sugar control during the early weeks of pregnancy can result in a fourfold to eightfold increase in congenital malformations, such as cardiac defects and CNS anomalies. The higher the hemoglobin A_{1c}, the greater is the incidence of congenital anomalies (Tyralla, 1996). There are no anomalies that are found only in the offspring of diabetic women. The most common cardiac malformations include transposition of the great vessels, ventricular septal defect, coarctation of the aorta, hypoplastic left ventricle, and pulmonic stenosis. CNS malformations include anencephaly, microcephaly, holoprosencephaly, and neural tube defects. Caudal regression syndrome is 600 times more common in IDMs. The IDM is also at increased risk for developing hyperbilirubinemia.

Jaundice

Jaundice is the most common condition requiring medical attention in the term newborn. *Hyperbilirubinemia* is one of the primary reasons for hospital readmission during the first week of life (Brown et al., 1999). Visible jaundice refers to a yellow coloration of the skin and sclera in infants with elevated levels of bilirubin and may be difficult to detect in infants with darker skin. Visible jaundice occurs in more than 50% of healthy term newborns. Although rare, high levels of bilirubin occurring in the first week of life can cause *kernicterus*, a permanent and devastating form of brain damage (Palmer et al., 2003). Neonatal hyperbilirubinemia results from the accelerated production of bilirubin in newborns and their limited ability to excrete it. The newborn liver has limited ability to conjugate bilirubin, and unconjugated bilirubin is not readily excreted.

The primary concern regarding exaggerated levels of bilirubin is the potential for neurotoxic effects. The concentration of bilirubin in the brain and the duration of exposure to bilirubin are important determinants of the neurotoxic effects. Bilirubin can enter the brain if it is not bound to albumin, if it is unconjugated, or if there has been damage to the blood-brain barrier (Dennery et al., 2001). Increased production of bilirubin, deficiency of hepatic uptake, impaired conjugation of bilirubin, and increased enterohepatic circulation of bilirubin account for most cases of pathologic jaundice in newborns.

Increased production of bilirubin can result from hemolytic and nonhemolytic causes. Examples of hemolytic causes include Rh incompatibility, ABO incompatibility, red blood cell membrane defects, and enzyme disorders. Nonhemolytic causes are conditions such as resolving cephalohematoma and polycythemia. The propensity toward

hyperbilirubinemia in certain racial groups is not well understood (Dennery et al., 2001).

Deficient hepatic uptake of bilirubin is seen in certain inborn errors of metabolism such as Gilbert's syndrome, Crigler-Najjar syndrome, tyrosinemia, and galactosemia. The result is decreased clearance of bilirubin, which can also be seen with hormone deficiencies such as hypothyroidism.

Increased enterohepatic circulation of bilirubin can lead to hyperbilirubinemia. Newborn infants who are not feeding well or who are exclusively breastfed have low levels of the intestinal bacteria that are needed for the conversion of bilirubin to nonresorbable derivatives, and the enterohepatic circulation of bilirubin may be increased in these infants (Dennery et al., 2001).

Compared to *unconjugated* (indirect) hyperbilirubinemia, *conjugated* (direct) hyperbilirubinemia is rare and is usually caused by obstructed bile flow or hepatocyte injury with normal bile ducts. Hepatocyte injury may be seen in infectious causes, such as intrauterine viral infections. Obstructed bile flow occurs with biliary atresia and biliary stenosis.

The AAP Subcommittee on Hyperbilirubinemia established a clinical practice guideline in 2004. The guideline recommendations have 10 key elements. One recommendation is to establish nursery protocols for identifying and evaluating hyperbilirubinemia. Another key recommendation is to interpret all bilirubin levels according to the infant's age in hours. All infants should be assessed for the risk of severe hyperbilirubinemia before discharge. Factors that put the infant at high risk include jaundice in the first 24 hours of life, blood group incompatibilities, other known hemolytic diseases, prematurity, exclusive breastfeeding when feeding is going poorly, cephalohematoma, and extensive bruising. The history of a previous sibling requiring treatment with phototherapy also places the infant at higher risk (AAP, 2004b). The recommended method for assessing the risk of subsequent hyperbilirubinemia is to measure the total serum bilirubin or transcutaneous bilirubin and plot the results on a nomogram, as provided in Figure 22-6.

Guidelines for treatment with phototherapy are described in Figure 22-7. In breastfed infants who require phototherapy, the AAP recommends that, if possible, breastfeeding should be continued. Home phototherapy devices do not deliver the same degree of irradiance of surface-area exposure as hospital models. Therefore, home phototherapy should be used only for infants whose bilirubin levels are in the optional phototherapy range, according to the clinical guideline; home phototherapy is not appropriate for infants with higher bilirubin concentrations (AAP, 2004b). The infant must have bilirubin levels monitored even while receiving home phototherapy. The total serum bilirubin level at which one can discontinue phototherapy depends on the age of the infant when the treatment began and the cause of the hyperbilirubinemia (Maisels and Kring, 2002). For infants who can be safely discharged before 48 hours of age, the AAP guidelines recommend follow-up with the postdischarge physician within 48 to 72 hours of discharge (AAP, 1994).

Birth Trauma

Infants who present with shoulder dystocia are at risk for clavicle fracture during delivery. The fracture is usually at the midclavicle and may first be noticed when the infant does

Figure 22-6 Nomogram for designation of risk in 2840 well newborns at 36 or more weeks' gestational age with birth weight of 2000 g or more or 35 or more weeks' gestational age and birth weight of 2500 g or more based on the hour-specific serum bilirubin values. The serum bilirubin level was obtained before discharge, and the zone in which the value fell predicted the likelihood of a subsequent bilirubin level exceeding the 95th percentile (high-risk zone). This nomogram should not be used to represent the natural history of neonatal hyperbilirubinemia.

not move the arm on the involved side as much as the opposite arm. A fracture can also be detected when an asymmetric Moro reflex is found on neurologic examination. Most of these fractures heal rapidly and normally and do not require specific therapy.

Brachial plexus injuries usually result from pulling on the arm at delivery. Injuries can be caused by stretching of the nerve, hemorrhage within a nerve, or tearing of the nerve or nerve root. *Erb's palsy* is an upper brachial plexus (C5-6) injury that leads to adduction and internal rotation of the shoulder with resulting pronation of the forearm. *Erb's palsy* can also be accompanied by an ipsilateral paralysis of the diaphragm. *Klumpke's palsy* is a lower plexus

Box 22-5 Guidelines for Phototherapy in Hospitalized Infants ≥ 35 Weeks' Gestation (see Fig. 22-7)

- Use total serum bilirubin (TSB). Do not subtract direct-reacting or conjugated bilirubin.
- Risk factors: isoimmune hemolytic disease, glucose-6-phosphate dehydrogenase (G6PD) deficiency, asphyxia, significant lethargy, temperature instability, sepsis, acidosis, or albumin <3.0 g/dL (if measured).
- For well infants at 35 to 37 6/7 weeks, can adjust TSB levels for intervention around the medium-risk line. It is an option to intervene at lower TSB levels for infants closer to 35 weeks and at higher TSB levels for those closer to 37 6/7 weeks.
- It is an option to provide conventional phototherapy in hospital or at home at TSB levels of 2 to 3 mg/dL (35-50 $\mu\text{mol/L}$) below those shown, but home phototherapy should not be used in any infant with risk factors.

Note: These guidelines are based on limited evidence, and the levels shown are approximations. The guidelines refer to the use of intensive phototherapy, which should be used when the TSB exceeds the line indicated for each category. Infants are designated as "higher risk" because of the potential negative effects of the conditions listed on albumin binding of bilirubin, the blood-brain barrier, and the susceptibility of the brain cells to damage by bilirubin.

"Intensive phototherapy" implies irradiance in the blue-green spectrum (wavelengths of approximately 430-490 nm) of at least 30 $\mu\text{W/cm}^2$ per nm (measured at infant's skin directly below center of phototherapy unit) and delivered to as much of the infant's surface area as possible. Note that irradiance measured below the center of the light source is much greater than that measured at the periphery. Measurements should be made with a radiometer specified by the manufacturer of the phototherapy system.

If total serum bilirubin levels approach or exceed the exchange transfusion line, the sides of the bassinet, incubator, or warmer should be lined with aluminum foil or white material. This will increase the surface area of the infant exposed and increase the efficacy of phototherapy. If the TSB does not decrease or continues to rise in an infant who is receiving intensive phototherapy, this strongly suggests the presence of hemolysis.

From American Academy of Pediatrics, Subcommittee on Hyperbilirubinemia. Management of hyperbilirubinemia in the newborn infant 35 or more weeks of gestation. *Pediatrics* 2004;114:297-316.

(C7-8 and T1) injury leading to paralysis of the hand and the wrist. Neither of these conditions is usually associated with demonstrable sensory loss more suggestive of a tear or avulsion. Both conditions usually improve rapidly, and in most patients, no deficits persist (Beers and Berkow, 1995). If a significant neurologic deficit persists for longer than 3 months, magnetic resonance imaging (MRI) may be helpful to determine the extent of injury to the plexus, roots, and cervical spinal cord.

Bleeding beneath the periosteum of the skull (cephalohematoma) is often seen with minor trauma sustained during labor and delivery. Cephalohematomas usually have a parietal location on the right or left side of the head and are unilateral in most cases. Treatment is not required, but the infant needs to be watched for signs of anemia or hyperbilirubinemia. Infants with a large cephalohematoma are more likely to develop hyperbilirubinemia as the blood cells within the hematoma break down and are reabsorbed.

Parental Education and Anticipatory Guidance before Discharge

Key Points

- Parental education before discharge should include infant feeding, safety at home, tobacco exposure, and recognizing neonatal illness.
- Breastfeeding support should be provided throughout hospitalization and continuing after discharge.
- All infants should be secured in a rear-facing car seat, with accessibility of the car seat verified before hospital discharge.
- Parents should be encouraged to place their children in the supine position while sleeping to prevent sudden infant death syndrome.

Caring for an infant can seem like an overwhelming task for new parents. Complete and accurate parental education can help alleviate parental stress. Often, parents are particularly concerned with feeding and elimination habits, how to tell if their baby is sick or needs medical attention, and how to ensure safety for their baby. It is difficult to anticipate all upcoming questions, but thorough anticipatory guidance before hospital discharge can help alleviate some of the natural anxiety of caring for an infant.

Feeding and Elimination Habits

Breastfeeding support should be provided throughout hospitalization, beginning in the first several hours of the infant's life. Assisting the mother in holding the baby at the breast and establishing a good latch-on are important in facilitating successful breastfeeding (Sinusas and Gagliardi, 2001). Trained obstetric nurses, lactation consultants, or other trained providers should be available to help the nursing mother begin breastfeeding.

Breastfeeding mothers are often worried that they will not produce enough milk for their baby. In the first 2 or 3 days, as milk production is being established, the infant is primarily receiving low volumes of high-calorie colostrum, and mothers may think their baby is not receiving enough from the breast. Parents should be reassured that the normal newborn does not need supplementation with formula unless there is a specific medical indication (e.g., true dehydration, sepsis) (AAP, 1997b). A trained professional should observe the breastfeeding mother and baby before discharge from the hospital to help correct any problems.

All infants should be fed whenever they are hungry, and for the first few weeks of life, this may be every 1 to 3 hours for breastfed infants and slightly less frequently for those receiving formula. The infant should feed a minimum of every 4 hours and should be awakened from sleep if necessary (AAP, 1997b). Infants may lose up to 10% of their birth weight in the first few days of life, but they should be back to birth weight within 2 weeks of life. In the first few weeks of life the formula-fed infant should take 1 to 2 ounces per feeding, approximately 12 to 24 ounces per day. Formula and expressed breast milk should never be warmed in a microwave oven because hot spots can develop within the milk and burn the newborn's oropharynx. Expressed breast milk or liquid formula that has been at room temperature

for more than 1 hour should be discarded (Thureen et al., 2005). Formula should always be mixed strictly according to the manufacturer's instructions, never diluted or concentrated.

After the first 48 hours, the normal infant has 6 to 8 wet diapers and 1 to 2 stools per day. The infant may appear to be uncomfortable as he or she has a bowel movement, possibly straining or turning red in the face. If the stool remains soft, parents should be reassured that the baby is not constipated (Thureen et al., 2005). Normal infant stools are soft, loose, and yellow or yellow-green, and they may be confused with diarrhea. Diarrheal stools are more watery and often leave a water ring in the diaper surrounding the more solid parts of the stool. Parents should be instructed to contact the family physician for true constipation (firm, small, pellet-like stools), diarrhea lasting more than 1 day, and blood or mucus in the stool.

Safety at Home

Sleep Position

Since the implementation of the AAP's Back to Sleep program, the incidence of sudden infant death syndrome (SIDS) has decreased by 40% (AAP, 2000a). Infants should be put to sleep on the back, on a firm mattress, in a crib without any soft or compressible structures (stuffed toys, crib bumpers, bedding) within the sleeping space to help prevent accidental suffocation, which is one cause of SIDS. Sleeping on quilts, comforters, waterbeds, sheepskin, pillows, or any other compressible surfaces increases the risk for SIDS.

Bed Sharing

Cosleeping of infants with other family members can be hazardous and can increase the risk of infant death (AAP, 2000a). Specifically, the risk of SIDS associated with cosleeping is significantly increased when the caregiver is a smoker (AAP, 2000a). Parents should be encouraged to move the bassinette or crib into their room to have the infant close by, but should be strongly discouraged from having the infant sleep in the same bed. Also, adults who smoke or use sedating substances (alcohol or other drugs) should not share a bed with an infant.

Car Seats

Every infant should be secured in a rear-facing car seat whenever riding in a moving vehicle. An infant car seat should never be placed in a seat equipped with an air bag, including front passenger-side and side-impact air bags (AAP Committee on Injury and Poison Prevention, 2002). In many vehicles, therefore, the safest place for the infant is the middle portion of the rear seat. Parents should be given information on how to secure the seat in their vehicle and how to secure the baby into the seat before discharge from the hospital.

Bathing

Parents should be particularly conscientious of safety while bathing the newborn. The infant (and toddler) should never be left unattended near standing water, to prevent accidental

drowning. As long as the infant's face and diaper area are kept clean, the infant does not require daily bathing. Frequent bathing with soap can dry out sensitive newborn skin, and creams, lotions, and powders can irritate a baby's skin. If the infant has unusually dry skin, unscented, non-alcohol-based lotions can be used (Thureen et al., 2005). The parent can test the bathwater by dipping an elbow in the water. The water should be comfortably warm and not hot to the touch. The temperature of the water heater within the home should be kept below 120° F (49° C) to prevent accidental scalding injuries (Consumer Products Safety Commission, 2005).

Tobacco Exposure

Children exposed to environmental tobacco smoke are at higher risk for SIDS, otitis media with effusion, and lower respiratory illness in the first year of life (AAP, 1997a). Family physicians should encourage all adults to quit smoking, particularly when children may be exposed to tobacco smoke.

Shaken Baby Syndrome

All parents should be informed of the serious problem of shaken baby syndrome. A baby should never be shaken for any reason. The most common reason for shaking a baby is inconsolable crying (National Exchange Club Foundation, 2005). Discussing normal crying behavior and giving some suggestions for how to calm the baby and how parents can calm themselves is an important part of anticipatory guidance. A parental time-out is one suggestion for parents who find themselves angry, frustrated, or having thoughts about hurting their baby. After placing the infant in a safe place such as a crib or bassinet, parents can leave the room for a few minutes, sit down, close their eyes, and count to 20. After they have calmed themselves, they can once again try to calm their baby using one of many techniques (e.g., feeding, diaper change, rocking, stroller or car ride, soft music).

The symptoms of shaken baby syndrome are caused by the trauma to the brain during the forceful back-and-forth movement of the skull. Vomiting, irritability, and poor feeding can be signs of mild to moderate brain damage, and more severe injury can manifest with seizures, a bulging fontanelle (secondary to significant intracranial hemorrhage), or other CNS deficits (National Center on Shaken Baby Syndrome, 2005).

Circumcision

Parents and guardians of male infants are faced with the decision of whether or not to circumcise their infant. For some families, this is an easy decision based on culture,

tradition, or specific preferences. Others, however, might not have strong opinions and might look to the family physician for information on the risks and benefits of this procedure. Epidemiologic studies have shown some potential medical benefits to circumcision, but real risks are associated with the surgery itself. Parents and guardians should be given full information on the risks and benefits before making a decision (AAP Circumcision Policy Statement, 1999).

The circumcised penis can take 7 to 10 days to heal. Parents should gently clean the penis with each diaper change, being careful not to be too aggressive and reopen the wounded glans. Any new or significant bleeding from the penis should be reported to the family physician. Bleeding from the circumcision site occurs in about 0.1% of cases and often can be treated in an office setting with local pressure, chemical cautery (silver nitrate), or sutures (AAP, 1999).

The uncircumcised penis does not require any particular care. Many parents may be anxious to retract the foreskin and clean between the glans and the foreskin. Early retraction, however, is unnecessary and can lead to paraphimosis. The foreskin should not be retracted until it can be retracted easily, without any force and without causing pain to the child. This can take 3 to 5 years, and at that time parents can teach the boy to clean under the foreskin daily (Thureen et al., 2005).

Preventing and Recognizing Illness

Before discharging the infant from the hospital, it is helpful to discuss with caregivers specific examples of when to be concerned about serious illness and how they can reach their family physician for questions or concerns during and after normal business hours. Parents should be encouraged to limit exposure of the infant to adults or children who are sick, especially in the first few months of life. It is good practice to ask family and friends to wash their hands before handling the newborn infant to prevent the spread of disease.

Parents can learn to take an infant's axillary temperature, recognize respiratory retractions, identify infection around the umbilicus or circumcision, and tell the difference between normal and abnormal muscle tone. Some normal infant behavior, such as sneezing, hiccups, effortless regurgitation after feeding, the startle reflex, and irregular breathing, can cause concern in parents. Anticipating and discussing these concerns can help put parents at ease.

Children are distinguished from people in other age groups by physical growth and developmental changes that are ongoing, normative, and expected. These changes usually proceed in an orderly progression that allows for individual variation. The family physician must be familiar with the range of normal physical and developmental changes that occur in the process of providing health supervision to children.

Growth is a dynamic process in which increasing cell size and number in various tissues result in a physical increase in the size of the body as a whole. Simultaneously, development occurs as tissues differentiate in form and mature in function, reflecting the person's genetic heritage and environmental interaction. Nutritional, family, emotional, sociocultural, and community influences as well as physical factors play a role in shaping the child's psychological and physiological development (Vaughan and Litt, 1992). The child responds emotionally to a particular stimulus in an apparently innate and characteristic style that reflects his or her temperament.

Knowledge of normal as well as abnormal patterns of growth and development enables the physician to assist the child in maximizing his or her fullest potential. Growth in height and weight is a sensitive reflection of a child's general health. Deviations from normal can reflect the presence of physical illness or a disturbance in the child's environment. **Box 23-1** lists some significant causes of growth abnormalities.

Care of Children in Family Medicine

Family physicians have the opportunity to provide family-centered pediatric care in the context of the child's family and community. The office should be "child friendly" and child safe with at least one room equipped to evaluate the child's physical growth. Blood pressure cuffs should be available to measure a child's blood pressure, at least from age 36 months and older. Electrical outlets and cords should be secured and potentially hazardous chemicals and biohazard

bins stored either out of reach or under lock and key from curious young toddlers. Guidelines for the frequency of "well child" or "well teen" visits are available from the American Academy of Pediatrics (AAP) *Bright Futures: Guidelines for Health Supervision of Infants, Children, and Adolescents* (Hagan et al., 2008).

Initial history for a new infant or child includes the birth history, nutritional history (e.g., breastfed vs. bottle-fed), developmental milestones achieved, immunization record, and environmental history (e.g., do parents smoke?) Later, the physician or staff will also perform anticipatory guidance, including injury prevention and the need to immunize against vaccine-preventable diseases.

Observation of the parent-child interaction informs the physician about the relationship between parent(s) and the child, especially with infants and young children. The parent sitting in a chair reading a magazine while her young infant teeters on an exam table engenders more concern than the parent who is standing next to the child or has him in her lap. Observation of the child's appearance, alertness, muscle tone, state of hydration, and respiratory status also raise or lower the index of concern about a child. The cardiorespiratory examination is often done best if the child is sitting or lying on a parent's lap, whereas examination of the abdomen, genitalia, and hips is generally done on the exam table. The HEENT examination is often done last because it is the most likely to provoke discomfort.

Blood Pressure Monitoring

Hypertension has become increasingly common in children and adolescents. Since 1988, the prevalence of high blood pressure has increased, especially for certain populations, such as Mexican-Americans and blacks (Din-Dzietham et al., 2007). The rising rate of obesity, particularly truncal obesity, at least partly accounts for this. Because of potential end-organ damage and cardiovascular risk in adulthood, auscultatory monitoring of blood pressure (BP) is recommended during health care visits for all children 3 years and older and for younger children with certain high-risk features (Box 23-2). Automatic devices may be needed to measure BP in young infants. Elevated BP should be confirmed on repeat visits. The guidelines define *hypertension* as average systolic or diastolic BP of 95% or higher for gender, age, and height on three or more occasions. *Prehypertension* is defined as values of 90% or greater and less than 95%. For adolescents, BP greater than or equal to 120/80 mm Hg but less than 95% is defined as prehypertensive. Because of the inclusion of a diverse population, these guidelines and tables appear applicable to all ethnic groups (see eTables 23-1 and 23-2 online at www.expertconsult.com).

The approach to confirmed hypertension in children should be individualized and should consider variables such as comorbidities and family history. In overweight or obese children, the possibility of metabolic syndrome should be investigated. Lifestyle changes, including diet and exercise, may be sufficient for overweight children with stage 1 hypertension (BP at 95% to 99% plus 5 mm Hg). Children with stage 2 hypertension (BP >99% plus 5 mm Hg) and those with end-organ damage likely require medical therapy (National High Blood Pressure Education Program Working Group, 2004).

Box 23-2 Indications for Blood Pressure (BP) Measurement in Children Under 3 Years Old

History of prematurity, very low birth weight, or other neonatal complication requiring intensive care
 Congenital heart disease (repaired or nonrepaired)
 Recurrent urinary tract infections, hematuria, or proteinuria
 Known renal disease or urologic malformations
 Family history of congenital renal disease
 Solid-organ transplant
 Malignancy or bone marrow transplant
 Treatment with drugs known to raise BP
 Other systemic illnesses associated with hypertension (e.g., neurofibromatosis, tuberous sclerosis)
 Evidence of elevated intracranial pressure

Data from National High Blood Pressure Education Program Working Group on High Blood Pressure in Children and Adolescents: The Fourth Report on the Diagnosis, Evaluation, and Treatment of High Blood Pressure in Children and Adolescents. *Pediatrics* 2004;114:555-576.

Measuring Physical Parameters of Growth

Key Points

- Measure height and weight at all well-child visits.
- Measure head circumference in children up to 24 months of age and blood pressure in children 3 years and older.
- Plot measurements on NCHS growth charts to demonstrate normal growth.
- Investigate significant deviations if the child's growth crosses multiple percentile lines on the growth chart.

Weight, length, and head circumference are the most useful routine measurements in infants. Total body length in children up to age 2 is obtained most accurately by placing them in the recumbent position and measuring from crown to heel. The child's head is placed perpendicular to the surface touching a fixed plate, the hips and knees are fully extended, and the soles of the feet are placed against a sliding board. Older children should have their shoeless standing height measured with a stadiometer with their heels and back touching the wall. Regardless of age, the head should be positioned so that the outer canthus of the eye is aligned with the external auditory canal and perpendicular to the measuring surface (Halac and Zimmerman, 2004). Children should ideally be weighed on the same scale at each visit. Infants should preferably be weighed nude; older children may wear light clothing but not shoes. Height and weight are then plotted on age- and gender-appropriate growth charts developed by the National Center for Health Statistics (NCHS) (see eFig. 23-1, A-H, and Web Resources).

Body mass index (BMI) is a reliable indicator of body fatness for most children and teenagers that is age and gender specific. A BMI less than the 5th percentile for age is *underweight*, from the 5th to 85th percentile is *healthy weight*, from the 85th up to 95th percentile is *overweight*, and the 95th percentile or greater is considered *obese* (CDC, 2009). BMI charts are also available from the same website.

Head circumference reflects the growth of the cranium and its contents. It should be determined and recorded at all routine

physical examinations during the first 2 years of life. This also may be done as part of the initial examination at any age. A nonstretchable measuring tape (usually paper or flexible plastic) is used to obtain the greatest circumference encompassing the occipital, parietal, and frontal prominences. A small head circumference (microcephaly) may be familial; caused by craniosynostosis, congenital viral infections, fetal drug syndromes, or underlying structural abnormalities; or secondary to trauma, infection, or dysmorphic syndromes. A large head circumference (macrocephaly) most often is caused by hydrocephalus, but it may be familial, caused by intracranial bleeding or masses or thickening of the skull, or associated with fragile X syndrome and other conditions (Green, 1986).

Proper Use and Interpretation of Growth Charts

The growth charts shown in eFigure 23-1 online were revised by NCHS (2000) from surveys of generally well-nourished children representing a cross section of ethnic and economic groups in the United States. These graphs provide a normal range of weight and length or height for a given chronologic age. Recumbent length is recorded on the chart for children from birth to 36 months, and standing height is recorded on the chart for children from 2 to 18 years. Premature infants should have their chronologic age adjusted according to their degree of prematurity up to age 2 years, because most catch-up growth is complete by this time. Although a height or weight above the 95th percentile or below the 5th percentile should alert the physician to a possible problem, these can represent the outer fringe of the normal range.

Linear growth in infants has been shown to occur in incremental bursts rather than continuously (Lampl et al., 1992). A growth curve constructed by a series of heights and weights taken over time allows the physician to compare current growth with the child's previous pattern. The *linear growth velocity*, or rate of gain in height, decreases from 25 cm per year during the first year of life to a prepubertal rate of 5 to 6 cm/yr by age 6 or 7 years (Miller and Zimmerman, 2004). The rate accelerates during puberty. A child whose growth curve parallels the normal curve regardless of the child's absolute percentile has a normal rate of growth for that particular child. In comparison, a child whose height or weight crosses multiple percentile lines or whose linear growth rate drops below 4 cm/yr requires further evaluation for nutritional, psychosocial, or organic problems that could impede or accelerate growth (Lipsky and Horner, 1988). Children with genetic short stature have normal length and weight at birth, but their growth percentiles decline within the first 2 to 3 years of life as they reach their genetic potential (Halac and Zimmerman, 2004).

Although careful measuring and plotting of growth parameters is the most accurate method by which to follow a child's physical growth, approximate growth guidelines are helpful to the physician in remembering and forming an overall impression of the child's progress (Table 23-1).

Familial Short Stature and Constitutional Growth Delay

Each child has a different rate of maturation, or what Boas termed "tempo of growth" (Tanner, 1986). Persons with *short stature* are more than 2 standard deviations (SD) below the

Table 23-1 Approximate Growth Guidelines for Children

| Age | Length or Height (ht) | Weight (wt) |
|---------------------|---|--|
| Newborn | 50 cm (20 inches) average | 3.4 kg (7.5 pounds) average |
| Newborn to 3 months | — | 1 kg/month (1 oz/day) average wt gain |
| 3-12 months | — | Wt (kg) = [Age (mo) + 9] ÷ 2 Wt (lb) = Age (mo) + 11* |
| 12 months | 75 cm (30 in) average | Triples birth weight |
| 12-24 months | Increases by >10 cm/yr | 0.25 kg/month |
| >5 years | >5 cm (2 in)/yr until adolescent growth spurt | 2.3 kg (5 lb)/yr until adolescent growth spurt |
| 2-12 years | Ht (cm) = [Age (yr) × 6] + 77 Ht (in) = [Age (yr) × 2.5] + 30* (e.g., 4-year-old = 40 inches) | Ages 1-6: Wt (kg) = [Age (yr) × 2] + 8 Wt (lb) = Age (yr) × 5 = 17* Ages 7-12: Wt (kg) = [Age (yr) × 7 - 5] ÷ 2 Wt (lb) = Age (yr) × 7 + 5* |
| Puberty | 8-14 cm/yr | |

*Modified from Needleman RD. The first year. In Behrman RE, Kliegman RM, Jenson HB (eds). Nelson Textbook of Pediatrics, 17th ed. Philadelphia, Saunders, 2004, p 31.

mean in height and constitute approximately 2.5% of children (Miller and Zimmerman, 2004). If a child's growth falls outside the range of normal, it is useful to obtain a bone-age radiograph, usually of the left hand and wrist, and compare it to age-specific standards. Children must be at least 2 years of age to reliably identify epiphyseal ossification centers. **Box 23-3** lists some causes of retarded or accelerated bone age. Calculation of mean predicted adult height is also useful in determining whether a child is fulfilling her or his genetic potential. The mean predicted adult height is calculated as follows (Rogol, 2004):

$$\begin{aligned} \text{Boy's mean height} &= \\ &[\text{Father's height} + (\text{Mother's height} + 13 \text{ cm})] \div 2 \\ \text{Girl's mean height} &= \\ &[(\text{Father's height} - 13 \text{ cm}) + \text{Mother's height}] \div 2 \end{aligned}$$

Children and adolescents of short stature whose bone age is delayed relative to their chronologic age have more growth potential than do children with a skeletal age appropriate for their chronologic age. If an organic cause of short stature has been excluded, children with delayed bone age are likely to have *constitutional growth delay*. The majority of these children are boys who were of normal length and weight at birth. Their growth rate decelerates during the first 2 years of life and subsequently returns to normal. The children then follow a lower percentile on the growth curve until the onset of their pubertal growth spurt and development, which often

Box 23-3 Causes of Short Stature and Relationship to Bone Age and Growth Rate

Bone age less than chronologic age

Growth rate normal or slightly decreased

Growth rate initially increased but short adult

Congenital adrenal hyperplasia
Exogenous androgenic steroids
Precocious puberty

occurs later than their peers. There is usually a family history of delayed growth and development (Bareille and Stanhope, 1998). The bone age of these children equals their height age, which is the age at which their height plots on the 50th percentile of the growth chart.

Children with familial short stature usually have parents or close relatives who are short. They often have normal birth weight and length, but their growth rate declines during the first 2 to 3 years of life. Their growth curve subsequently parallels the normal curve but falls below the fifth percentile (Bareille et al., 1998). Their bone age is approximately equal to their chronologic age but less than their height age. These children usually enter puberty at the appropriate age. The U.S. Food and Drug Administration (FDA) has approved the use of recombinant growth hormone for the treatment of idiopathic short stature. This can result in an increase of predicted height of more than 7 cm (Miller and Zimmerman, 2004). Because of potential side effects and the high cost, treatment should be undertaken in consultation with a specialist in pediatric growth disorders.

Pubertal Growth and Development

All children grow at a different tempo, with some maturing earlier than others and some later. This difference is most apparent during puberty. The NCHS growth charts now extend to age 20 years. Tanner and Davies (1985) took the

Table 23-2 Sexual Maturity Stages in Boys and Girls

| Stage | Male genitalia | Pubic hair | Female breasts |
|-------|--|--|---|
| 1 | Preadolescent: testes, scrotum, and penis are childlike in size. | None; may be vellus hair, as over abdomen. | Preadolescent: elevation of papilla only. |
| 2 | Slight enlargement of scrotum with reddening of skin; little or no enlargement of penis. | Sparse growth of long, slightly pigmented, downy hair, straight or slightly curled, primarily at base of penis or along labia. | Breast bud stage; breast and papilla form a small mound; areolar diameter enlarges. |
| 3 | Further enlargement of scrotum; penis enlarges, mainly in length. | Hair considerably darker, coarser, and more curled; spreads sparsely over junction of pubes. | Further enlargement of breast and areola with no separation of their contours. |
| 4 | Further enlargement and darkening of scrotum; penis enlarges, especially in breadth; glans develops. | Adult-type hair that does not extend onto thighs, covering a smaller area than in adult. | Areola and papilla project to form a secondary mound above the contour of the breast; stage 4 development of the areolar mound does not occur in 10% of girls and is slight in 20%; when present, it may persist well into adulthood. |
| 5 | Adult in size and shape. | Adult in quantity and type with extension onto thighs but not up linea alba. | Mature female; papilla projects and areola recesses to general contour of breast. |
| 6 | — | Spreads up linea alba (80% of men, 10% of women). | |

Modified from Tanner JM. Normal growth and techniques of growth assessment. Clin Endocrinol Metab 1986;15:436.

earlier NCHS data and constructed height and weight velocity curves for American boys and girls that account for those groups who mature earlier and later. These charts also allow for notation of the various stages of puberty described by Tanner (1986) (Table 23-2).

The onset of puberty generally occurs at age 9 in American girls, with the peak height velocity occurring at age 11.5 years (range, 9.7 to 13.5 years for early to late maturers). American boys have onset of puberty at age 11 and peak height velocity at 13.5 years (range, 11.7 to 15.3 years) (Tanner and Davies,

1985). Because boys have two additional years of prepubertal growth and a peak height velocity greater than that of girls, their ultimate height is usually taller. Head, hands, and feet are first to reach their adult size, followed by leg length, trunk length (which accounts for much of the spurt), and body breadth. Pubertal boys develop greater shoulder breadth than do pubertal girls, who develop wider hips. Adolescents can be reassured that their bodies eventually will become more proportionate with their hands and feet. Boys ultimately gain greater muscle size and strength than do girls, while losing limb fat. This results from their increased secretion of testosterone, which also increases red cell mass and hemoglobin (Tanner, 1986).

The adolescent growth spurt in skeletal and body dimensions is associated closely with the development of the reproductive system. Although the onset and rate of maturation vary according to the individual, the sequence is usually the same within genders (Figs. 23-1 and 23-2). Girls who demonstrate signs of puberty before 7 to 8 years of age and boys who show signs before 9 years should be evaluated for *precocious puberty*. Conversely, girls who do not show signs of puberty by age 13 and boys by age 14 should be evaluated for *pubertal delay* (Plotnick, 1999).

The first sign of puberty in boys is an increase in growth of the testes and scrotum, with reddening and wrinkling of the scrotal skin. Pubic hair appears within 6 months, followed by phallic enlargement in 12 to 18 months and peak height velocity 2 to 2.5 years after testicular enlargement (Copeland, 1986). Axillary hair usually appears 2 years after the beginning of pubic hair growth (stage 4 pubic hair), but there is considerable variability. Some boys may have enlargement of the breasts midway through adolescence. Following the attainment of peak height velocity, boys develop mature spermatozoa, full facial hair, and voice change. However, breaking of the voice is a late and often gradual process.

In girls, the breast bud is the first sign of puberty, and the pubertal growth spurt typically occurs concurrently, peaking at stage 3 breast and pubic hair. The uterus and vagina develop simultaneously with the breast, but menarche usually does not occur until stage 4 breast and pubic hair. Although the peak height velocity has been passed, girls may grow an average of 6 cm more after menarche. Early cycles may be irregular and anovulatory, but early sterility should never be presupposed (Tanner, 1986).

Screening Healthy Children

Key Points

- All newborns should have a hearing screen within the first month of life.
- Examine eyes at all well care visits; screen vision beginning at age 3 years.
- Provide anticipatory guidance regarding discipline starting at 15 months of age.

Preventive care services for children often include screening for health conditions in which early detection and early treatment can prevent or ameliorate more serious disease in the future. Screening tests should detect most persons with

the condition (*sensitivity*) while excluding most persons who do not have the condition (*specificity*) in a cost-effective manner. In an inner-city Medicaid population, high continuity of care in infancy was associated with improved screening for anemia, lead, and tuberculosis (Flores et al., 2008).

Hearing and Vision Screening

Early detection and intervention for hearing and vision deficits are important for maximal long-term functioning. Without appropriate opportunities to learn language, children with significant hearing deficits fall behind peers in terms of communication, cognition, reading, and social-emotional development, with long-term effects on educational attainment and adult employment (AAP Joint Committee on Infant Hearing, 2007). It is now recommended that all infants be screened for hearing loss by 1 month of age, regardless of risk factors. Those who do not pass the screening should have a complete audiologic evaluation by 3 months of age, and those with confirmed hearing loss should receive appropriate treatment by 6 months to ensure optimal outcome. Regardless of the outcome of newborn screening, ongoing surveillance of hearing status is recommended. Developmental delays and other risk factors (Box 23-4), particularly in language, as well as the presence of parental concern about hearing, should prompt referral for a complete audiologic evaluation, even if the newborn screen was normal and there are no risk factors for hearing impairment (Hagan et al., 2008). Gradations of hearing loss are presented in Table 23-3.

Eyesight evaluation is a recommended part of routine health maintenance examinations in children beginning in the newborn period. In young children (<3 years) the

Box 23-4 Risk Factors for Delayed Onset of Hearing Loss in Young Children

- Caregiver concern regarding hearing, speech, language, or developmental delay
- Family history of permanent childhood hearing loss
- Neonatal intensive care longer than 5 days
- In utero infections (e.g., cytomegalovirus)
- Craniofacial anomalies (e.g., ear pits, ear canal defects)
- Syndromes known to be associated with hearing loss (e.g., neurofibromatosis)
- Neurodegenerative disorders (e.g., Friedreich's ataxia)
- Postnatal infections (e.g., meningitis)
- Head trauma (e.g., basal skull/temporal bone fracture)
- Chemotherapy

Modified from Hagan JF, Shaw JS, Duncan PM (eds). *Bright Futures: Guidelines for Health Supervision of Infants, Children, and Adolescents*, 3rd ed. Elk Grove Village, Ill, American Academy of Pediatrics, 2008, p 232.

Table 23-3 Hearing Loss Scale

| Hearing impairment | Hearing threshold (dB) |
|--------------------|------------------------|
| None | 10-25 |
| Mild | 26-40 |
| Moderate | 41-55 |
| Moderate to severe | 56-70 |
| Severe | 71-90 |
| Profound | >91 |

evaluation, besides the actual eye examination, is somewhat subjective and based on parental history. Children with risk factors, such as prematurity, family history of retinoblastoma or glaucoma, or significant developmental delays or neurologic difficulties, should be referred to an experienced pediatric ophthalmologist. More formal testing of visual acuity should begin at age 3 years, using standardized systems such as the Allen Cards, which have easily recognized pictures (AAP Committee on Practice and Ambulatory Medicine, 2003). Normal visual acuity is in the 20/30 to 20/40 range for children 3 to 4 years old, but increases to 20/20 by early school age. Eye-specific screening should be attempted in an effort to detect amblyopia (more than one line difference on the chart) (SOR: B). The suspicion of amblyopia or strabismus requires further evaluation to prevent long-term visual loss (AAP Committee on Practice and Ambulatory Medicine, 1996). Routine screening should be done at least through early school age, at puberty and whenever there are other signs, such as squinting or complaints of inability to see the board at school (Hagan et al., 2008).

Screening for Iron Deficiency Anemia

The U.S. Preventive Service Task Force currently has found insufficient evidence to recommend for or against routine screening asymptomatic infants age 6 to 12 months for iron deficiency anemia (USPSTF, 2006). Venous hemoglobin is more accurate than capillary hemoglobin for detecting anemia; however, true iron deficiency is much more common than iron deficiency anemia. In addition, there is evidence that even children with severe anemia who are treated with iron supplementation continue to demonstrate behavioral and developmental deficits 10 years afterwards (Lozoff et al., 2000). Nevertheless, the AAP Committee on Nutrition presents two options for screening for iron deficiency anemia. If a community has a significant level of iron deficiency anemia or infants who are at risk by virtue of their diet, universal screening is recommended for all full-term infants between 9 and 12 months old, with a second screening 6 months later at 15 to 18 months old. Selective screening may be done on a similar schedule only for children deemed to be at risk for iron deficiency anemia, including low-birth-weight infants, infants not receiving iron-containing formula, or breastfed infants over 6 months old who lack adequate iron in their diet.

Screening for Lead Toxicity

Lead is neurotoxic and affects both intellectual and behavioral function, even below the 10 µg/dL level established by the U.S. Centers for Disease Control and Prevention (CDC) and World Health Organization (WHO) (Canfield et al., 2003). Federal Medicaid law has required lead screening of young children eligible for Medicaid at ages 12 months and 24 months, and for children ages 36 to 72 months not previously tested. However, 1999–2004 NHANES data demonstrate that the percentage of children with blood lead levels of 10 µg/dL or higher had decreased to 3.4% for black and 1.2% for white children age 1 to 5 years. The USPSTF finds insufficient evidence to recommend for or against screening asymptomatic children 1 to 5 years old who are at increased risk. The CDC recommends targeted screening of specific

groups of children, except in areas where universal screening is still recommended because of a prevalence of elevated lead levels. Specific state information can be obtained at <http://www.cdc.gov/nceh/lead>. Children considered at risk who require screening include (1) those suspected by a parent or health care provider to be at risk for exposure; (2) those with a sibling or frequent playmate with an elevated blood lead level; (3) those with a parent or caregiver who works professionally or recreationally with lead; (4) a household member uses traditional folk or ethnic remedies or cosmetics; or (5) family designated at increased risk for lead exposure by the health department because of local risk factors for lead exposure, such as residing in a high-risk zip code (Wengrovitz and Brown, 2009).

Screening for Tuberculosis

In 2007, there were approximately 10 million cases of new and recurrent tuberculosis (TB) and 1.8 million deaths worldwide, with the highest rates occurring in low-income countries (Marais et al., 2009). The incidence of active TB is much lower in the United States, but an estimated 10 to 15 million persons have *latent tuberculosis infection* (LTBI). Six groups considered at high risk are children, foreign-born persons, HIV-infected persons, homeless persons, detainees and prisoners in correctional facilities, and close contacts of infectious persons (CDC, 2005). Targeted rather than universal testing of children for TB is now recommended. Risk factors for LTBI include (1) previous positive tuberculin skin test; (2) birth in foreign country with high prevalence of TB (e.g., China, India, Mexico, Philippine Islands, Vietnam, certain African countries); (3) nontourist travel to a high-prevalence country for more than 1 week; (4) contact with TB-infected person, and (5) presence in the household of another person with LTBI (CDC, 2005). The Mantoux TB skin test is recommended for children because its correlation with results of interferon-γ release assays is often discordant in children (Connell et al., 2008).

Discipline

Parents frequently ask their primary care physician about discipline. Discipline should be a priority topic for anticipatory guidance at 15 months and 18 months (Hagan et al., 2008). Effective discipline requires three essential components: (1) a positive, loving relationship between the parent(s) and child, (2) positive reinforcement strategies to increase desired behaviors, and (3) punishment or removal of reinforcement to reduce or eliminate undesired behaviors (AAP Committee on Psychosocial Aspects, 1998). Although often confused with punishment, discipline actually means to *teach*. All children benefit from guidance and structure, and most children require occasional discipline. The best discipline is consistent and considers the child's developmental level as well as the child's point of view. Effective strategies include environmental modifications (e.g., child-proofing the house), distraction, redirection, giving appropriate choices, and time-out. Although many parents spank (Regalado et al., 2004), corporal punishment is controversial and has potential long-term negative effects (Smith, 2006). Other methods of discipline are more effective over time and

should be used. Some families may require more intensive assistance, and clinicians should be aware of local resources for teaching parents.

Nutrition

Key Points

- Breast milk is the recommended food for infants and the standard to which infant formulas are compared.
- Give vitamin D supplements to all breastfed infants and those taking less than 1 L of vitamin D–fortified milk or formula per day.
- Begin iron-fortified cereal for infants older than 4 to 6 months or low-birth-weight infants older than 2 weeks.
- Obtain a fasting lipid profile in children with a family history of dyslipidemia, premature atherosclerotic vascular disease, or personal risk factors such as overweight, hypertension, smoking, and diabetes mellitus.

Infancy through Adolescence

Proper physical growth and appropriate cognitive development depend on adequate nutrition. Infants and young children with severe iron deficiency anemia were found to have significantly lower verbal and full-scale IQ scores and lower achievement test scores in arithmetic and writing than non-iron-deficient infants, even 10 years after treatment (Lozoff et al., 2000). An increase in behavioral problems was also reported, although this could not be directly linked to the preceding iron deficiency. In the Third National Health and Nutrition Examination Survey (NHANES III, 1988–1994), 7.2% of 12- to 16-year-old girls had iron deficiency, but only 1.5% demonstrated anemia (Halterman et al., 2001). Adolescent iron-deficient girls scored significantly lower math scores compared with non-iron-deficient girls. Vitamin D deficiency and insufficiency in children and adolescents has been reported worldwide, including North America (Wagner and Greer, 2008). Mealtime also represents a time for social interaction within the family unit, whether this is the bonding of mother and child during breastfeeding or discussion of the day's events during dinnertime.

Although malnutrition is still a problem in the United States, *inappropriate nutrition*, especially calorie-nutrient imbalance leading to overweight and obesity, has become commonplace. Recent NHANES studies demonstrate that the prevalence of overweight (BMI $\geq 95\%$) in girls 2 to 19 years old increased from 13.8% in 1999–2000 to 16% in 2003–2004, and the prevalence of overweight in boys 2 to 19 years old increased from 14% to 18.2% (Ogden et al., 2006). Increased pediatric BMI is associated with high blood pressure, sleep apnea, asthma, polycystic ovarian syndrome, type 2 diabetes, gastroesophageal reflux, and orthopedic problems (Benson et al., 2009). A nationwide survey of more than 6000 children and adolescents found that at least 30% consumed “fast food” on a typical day. These children consumed more total fat, total carbohydrate, more added sugars and sugar-sweetened beverages, less milk, and fewer fruits and nonstarchy vegetables than children who did not eat fast food (Bowman, 2004). The odds of having a BMI of 85th percentile or higher was more than four times that for 10- to

15-year-old children viewing more than 5 hours of television per day compared with those watching for 0 to 2 hours (Gortmaker et al., 1996). A survey of low-income preschool children in New York State found that children with a TV set in their bedroom watched 4.8 hours more TV/video than those without a bedroom TV. In this group the prevalence of child overweight (BMI $>85\%$) was associated with an odds ratio of 1.06 for each additional hour per day of TV/video viewed (Dennison et al., 2002). Frequent television viewing can lead to decreased activity, excessive snacking on high-calorie junk foods, and subsequent obesity (Dietz and Gortmaker, 1985). In contrast, dieting in pursuit of the media's representation of the ideal woman can lead to eating disorders, such as bulimia or anorexia. The CDC has proposed 24 strategies to prevent obesity in the United States, including increasing the availability of healthier food and beverage choices, restricting the availability of less healthy foods and beverages in public service areas, and increasing the amount of physical activity in schools (Khan et al., 2009).

Infants and Toddlers

Infants require approximately 120 kcal/kg/day to meet basal metabolic requirements and the energy demands of growth and activity during the first 6 months of life. Low-birth-weight (LBW) newborns may require 130 to 150 cal/kg/day for catch-up growth (Klish, 2009). Weight gain should be 25 to 30 g/day during the first 3 months of life, decrease to 15 to 20 g/day between 3 and 6 months of age, and decrease to 10 to 15 g/day between 6 and 12 months (AAP, 2009). Energy requirements are increased by greater physical activity, stress imposed by disease processes (e.g., cystic fibrosis), or symptoms (e.g., fever). Fever can increase the fluid requirements of infants younger than 6 months beyond the usual 130 to 190 mL/kg/day (Barness and Curran, 1996).

The composition of human milk varies by time, day, and maternal nutrition and from woman to woman. Infant formulas contain about 50% more protein than human milk and, like breast milk, provide 40% to 50% of energy as fat (Table 23-4). Beginning at 2 years of age, fat calories should decrease to approximately 30% of total energy consumption, with less than 10% of calories from saturated fat, and dietary cholesterol less than 300 mg/day (AAP, 2009).

The ideal food for full-term infants during the first 12 months of life is human milk. Oliver Wendell Holmes once noted, “A pair of substantial mammary glands has the advantage over the two hemispheres of the most learned professor's brain in the art of compounding a nutritious fluid for infants” (Cone, 1979, p. 138). Human milk is fresh, readily available at the proper temperature, and generally free of contaminating bacteria. Its acid-resistant whey proteins include secretory immunoglobulin A (sIgA), α -lactalbumin, and lactoferrin, a whey protein that transports iron and inhibits the growth of a range of organisms in the intestine. The protein in human milk consists predominantly of whey proteins that are of higher nutritional quality and digested and absorbed more easily than cow's milk proteins (AAP, 2009).

Commercial cow's milk and soy-based formulas must contain higher levels of protein to compensate for their lower quality (see Table 23-4). However, they are quite acceptable for mothers who are unable to nurse their infants or for parents who wish to bottle-feed their children. Soy formulas are

Table 23-4 Comparison of Common Milks and Infant Formulas

| Milk/formula | kcal/30 mL | Protein (g/dL) | CHO (g/dL) | CHO type | Fat (g/dL) | Iron (mg/L) | comments |
|------------------------------------|------------|----------------|------------|---|------------|-------------|---|
| Human milk | 20 | 1.0 | 6.9 | Lactose (primary), glucose, oligosaccharides | 4.4 | <0.1 | Small flocculent curd is easily digestible, and iron is absorbed. |
| Whole cow's milk | 19 | 3.3 | 4.7 | Lactose | 3.7 | Trace | Curd is less easy to digest. Can cause intestinal blood loss. Do not use before age 12 months. |
| Evaporated whole milk | 43 | 6.9 | 10.0 | Lactose | 7.6 | Trace | Curd is softer, smaller and may be less allergenic. Dilute and add dextrose to make 20 kcal/oz formula. |
| Prepared formula, cow's milk based | 20 | 1.4-1.7 | 6.9-7.5 | Lactose | 3.4-3.8 | 4.7-12.2* | AAP recommends only iron-fortified formulas. |
| Prepared formula, soy based | 20 | 1.7-1.8 | 6.8-7.4 | Corn syrup, corn syrup solids, sucrose, corn maltodextrin | 3.4-3.7 | 12-12.2 | May use if lactase-deficient vegetarian, galactosemic, or allergic to cow's milk. [†] |

Modified and compiled from Kleinman RE (ed). Pediatric Nutrition Handbook, 6th ed. Elk Grove Village, Ill, American Academy of Pediatrics (AAP), 2008, pp 1250-1265.

*Iron-fortified formula.

[†]However, cross-reactivity with cow's milk protein sometimes occurs.

CHO, Carbohydrate.

recommended for infants with hereditary lactase deficiency or galactosemia and may be tried in infants intolerant to cow's milk, but soy formula should not be used in preterm infants. Because some infants allergic to cow's milk protein will develop an allergy to soy protein, it is advisable to use an extensively hydrolyzed protein formula in cases of true milk allergy or malabsorption. These are lactose free and may contain medium-chain triglycerides to improve fat absorption (AAP, 2009).

Human breast milk or iron-fortified infant formula is recommended for the first 12 months of life. Cow's milk is not suitable for infants because the higher intake of protein, sodium, potassium, and chloride increases renal solute load. In addition, the lower concentrations of iron, zinc, essential fatty acids, vitamin E, and other micronutrients can result in deficiencies. Significant intestinal blood loss can occur in infants younger than 12 months of age receiving cow's milk. Very-low-fat milks lack adequate calories for growth despite promoting excessive volume ingestion. Breastfed full-term infants seldom develop iron deficiency anemia before 4 to 6 months of age because the iron present in breast milk is well absorbed. Iron-fortified infant cereal or meats are then good sources of the 1 mg/kg/day of elemental iron required by full-term infants. All preterm or LBW infants should receive at least 2 mg/kg/day of elemental iron from 2 weeks until 12 months of age (AAP, 2009). Parents should be warned that iron is toxic in excessive amounts, and appropriate precautions should be taken.

Children 6 months to 3 years old who do not drink fluoridated water or other beverages may be given 0.25 mg/day of supplemental fluoride. Human milk contains only small amounts of biologically active vitamin D, and rickets has

been reported in breastfed infants, infants with darker skin pigmentation, and even older children with minimal exposure to sunlight. Consequently, all breastfed infants, partially breastfed, non-breastfed infants, and older children ingesting less than 1000 mL/day of vitamin D–fortified formula or milk should receive 400 IU/day of supplemental vitamin D daily beginning within the first few days of life until the infant or child is ingesting 1000 mL/day of vitamin D–fortified formula or milk (AAP, 2009). Higher doses of vitamin D may be required in children with chronic fat malabsorption. Vitamin B₁₂ supplementation should be given to breastfed infants whose mothers are strict vegetarians.

Both WHO and AAP promote exclusive breastfeeding for the first 6 months of life. However safe, nutritious solid foods may be introduced between 4 and 6 months of age, when the infant is developmentally ready. The order of introduction of solid foods is generally not critical; however, single-ingredient foods should be tried for 1 week at a time to observe for possible allergic reactions before introducing another food or mixtures of foods. Single-grain infant cereals such as rice (which lacks gluten) are usually well tolerated and provide a source of fortified iron. Homemade infant foods should not have added salt or sugar. Honey is associated with infant botulism and should not be given to infants younger than 1 year. Teething biscuits or finely chopped foods may be given by 8 to 10 months of age. However, foods such as popcorn, nuts, or rounded candies should not be offered to infants or toddlers because of the risks of choking, aspiration, and even death. Potentially hazardous foods such as hot dogs and grapes must be cut into small pieces, and the caregiver should always be present during mealtime. Children should be weaned from the bottle to a "sippy cup" by 12 to 15

months of age and bedtime bottles discouraged because they are associated with dental caries (AAP, 2009).

A toddler's food intake may be quite variable from day to day or even meal to meal. Because young children cannot choose a well-balanced diet, parents must provide nutritious, safe, developmentally appropriate foods at regular meals and snacks. Children should be sitting in a designated area for mealtime, without distractions such as television (AAP, 2009). Small portions of food should be offered to preschool children, allowing the child to determine how much he or she will eat and offering more as necessary. Excessive portion sizes can contribute to obesity later in life. Guidelines about types and quantities of foods from the basic food groups are available from the U.S. Department of Agriculture (USDA) MyPyramid website (www.mypyramid.gov), which provides recommendations on the amount of grain products, vegetables, fruits, and milk products based on the person's age, gender, and activity level.

Parents should be counseled that toddlers and preschool children are often picky eaters but generally grow well despite this. Parents need to guide children in their selection of food by offering a variety of nutritious items such as fruits and vegetables, keeping in mind that it can require 8 to 10 exposures to a new food before a child accepts it (AAP, 2009). Mealtime should not turn into a battleground because forcing a child to clean the plate can lead to specific food dislikes or promote obesity in later life. Snacking or eating while watching television should be discouraged, and physical activity should be encouraged.

Healthy children eating a varied diet usually do not require a multivitamin supplement. Children who do not eat dairy products, meat, or eggs require supplemental vitamin B₁₂ and are at risk for vitamin D deficiency, especially if they lack adequate sunlight exposure or have darkly pigmented skin. Children following strict vegetarian diets often have low intakes of iron and calcium that can require supplementation. They often have a low intake of zinc that may be obtained from zinc-fortified infant and adult cereals. The recommended fiber intake is 19 g/day for children 1 to 3 years old and 25 g/day for those 4 to 8 years old. Excessive fiber consumption may decrease the intake of energy-dense foods and inhibit the absorption of some minerals (AAP, 2009).

Children with malabsorption or hemolytic anemia can require additional folic acid. Parents who insist on using a vitamin supplement without any obvious deficiency on the part of the child should be counseled to use a preparation that does not exceed the dietary reference intakes (DRIs) established by the Institute of Medicine and the National Academy of Sciences. In particular, vitamins A and D can produce toxicity if given in excessive doses.

Adolescents

Adolescents are at greater risk than other age groups for nutritional deficiencies because they may skip meals, snack more, eat more fast foods, and follow fad diets for reasons ranging from weight loss to cultural differentiation. Teenage boys and girls often replace milk and juice with soft drinks, coffee, tea, and alcoholic beverages, thereby lowering their intake of calcium as well as vitamins A and C. Adolescents' iron intake may be lower than required for their rapid increases in lean body mass and hemoglobin mass in addition to menstrual blood loss in girls. Zinc is also required for growth and

sexual maturation. Most teenagers do not ingest the recommended 1300 mg of calcium daily (AAP, 2009).

Energy requirements vary greatly in teenagers, depending on their gender, activity, and stage of adolescence. Sedentary adolescent girls require 1600 to 1800 cal/day and sedentary boys 1800 to 2200 kcal/day. As much as 200 kcal/day may be added for moderate physical activity and 200 to 400 kcal/day added for those who are very active (Daniels and Greer, 2008). Healthy pregnant women of normal BMI should tailor their prenatal diet to achieve a total weight gain of 11.5 to 16 kg (26-35 lb), or an additional 300 kcal/day during the second and third trimesters. Additional protein requirements are about 15 and 27 g/day during the second and third trimesters, respectively. Most will require some form of iron supplementation, about 30 mg/day during the second and third trimesters. Because zinc deficiency has potential teratogenic effects, pregnant adolescents should receive about 13 mg/day of zinc supplementation along with 1 mg/day of copper supplementation. All women of childbearing potential should take 400 to 600 µg of folic acid supplement per day in addition to 400 µg of dietary folate to decrease the risk of giving birth to children with neural tube defects. Pregnant women also require 1300 mg/day of calcium in their diet (AAP, 2009).

Universal screening for hypercholesterolemia in children is not currently recommended. A fasting lipid profile should be obtained in children who have a family history of dyslipidemia or premature (men ≤55 years, women ≤65 years) coronary heart disease or peripheral vascular or cerebrovascular disease. Children for whom the family history is not known or who have other risk factors such as overweight (BMI ≥85% and <95%), obesity (BMI ≥95%), hypertension (BP ≥95%), cigarette smoking, or diabetes mellitus should also be screened. This screening should be done between 3 and 10 years of age. The National Cholesterol Education Program (NCEP) guidelines indicate that a total cholesterol less than 170 mg/dL is acceptable, 170 to 199 mg/dL is borderline, and 200 mg/dL or greater is high. Similarly, a low-density lipoprotein (LDL) level less than 110 mg/dL is acceptable, 110 to 129 mg/dL is borderline, and higher than 130 mg/dL is elevated (Daniels and Greer, 2008). The American Heart Association has designated triglyceride (TG) levels greater than 150 mg/dL and high-density lipoprotein (HDL) level less than 35 mg/dL as abnormal. If initial lipid values are within acceptable levels, retesting should be done in 3 to 5 years.

It is recommended that all healthy children older than 2 years follow a diet in which a wide variety of foods provide adequate caloric intake to achieve proper growth and development as well as desirable weight. Total fat and saturated fat intake should be no more than 30% and 10%, respectively, of total calories; dietary cholesterol should be less than 300 mg/day. Children who are overweight or obese and have a high TG or low HDL level should be counseled regarding proper diet and increased physical activity. Children at especially high risk based on familial hyperlipidemias or premature cardiovascular disease may undertake a diet restricting saturated fat to 7% of total calories and cholesterol to 200 mg/day (Daniels and Greer, 2008). Children 10 years and older may be considered for pharmacologic therapy with LDL of 190 mg/dL or higher without additional risk factors, 160 mg/dL or greater with a family history of early heart disease or two or more other risk factors, or 130 mg/dL or higher if diabetes mellitus is present (AAP, 2009).

KEY TREATMENT

Ensure vitamin D intake of at least 400 IU/day, either by diet or supplementation (Wagner and Greer, 2008) (SOR: A).
 Children 2 years and older should follow a diet with less than 30% of calories from total fat and 10% from saturated fat (Daniels and Greer, 2008) (SOR: B).
 Communities should improve the availability of affordable healthier food and beverage choices and restrict the availability of less healthy choices in public service areas, by decreasing the cost of healthy foods and increasing the cost of less healthy foods (Khan et al., 2009) (SOR: B).

Behavior and Neurodevelopment**Key Points**

- Development is a product of factors intrinsic and extrinsic to the child.
- Basic knowledge of child development enables clinicians to guide and educate families.
- Development proceeds in a basic sequence.
- Delays in one area of development may affect another.
- In preterm infants, correct for prematurity until age 2 years.

One of the rewards of providing primary care for a child is sharing with the family in the development of cognitive, motor, social, and language skills. Clinicians need to understand the theoretic framework on which the scientific understanding of child development is based in order to individualize the approach to the unique needs and concerns of each family. Physicians should develop strategies for clinically assessing child development and managing identified developmental abnormalities.

Theories of Development

Child development was widely studied in the 20th century. A general understanding of the common theories can enrich the clinician's relationship with young patients. Most researchers in child development believe that developmental outcomes are a product of intrinsic child factors, including genetic potential and temperament, and extrinsic environmental factors, such as intrauterine, infectious, traumatic, chemical, and sociocultural factors (Vaughan and Litt, 1992). The relative weights of each of these factors vary considerably among persons, thus frustrating the attempts of researchers to develop a formula for predicting developmental outcome for any individual person.

A clinician who is familiar with the key elements of theoretic models can develop expertise in applying them appropriately to meet the needs of countless clinical scenarios. For example, a physician might use Erikson's theory of psychosocial stages to explain to a vexed parent of a 2-year-old that the child's constant temper tantrums represent a normal expression of the child's need to exert autonomy over the environment. In the next room, the physician might refer to Piaget's concept of concrete operational thought to explain why a 10-year-old might not be capable of considering remote consequences of present actions (e.g., "If I don't study for my science test, I might not meet my goal of becoming an astronaut").

Features of the most widely accepted developmental theories are found in many pediatric references (Dixon and Stein, 2000). A summary of the salient features of each theory and potential clinical applications is presented in Table 23-5.

Erikson's psychosocial stages theory is particularly relevant (Table 23-6). According to his theory, at each discrete life stage, persons are confronted with a crisis requiring integration of personal needs with sociocultural demands. Successful integration of needs and development indicates normal adaptation. A practitioner who is familiar with these stages can counsel families about the emotional needs of children at different ages and explain the appropriateness of challenging but normal childhood behavior.

The concept of temperament is also clinically relevant for primary care. *Temperament* is a set of consistent, inborn characteristics that influence how people interact with and learn from their environment (Thomas et al., 1968). The person's temperament characteristics are innate to his or her personality. Three basic temperament profiles based on nine separate infant characteristics are outlined in Table 23-7. These are broad generalizations, and not all infants fit easily into one of these three categories.

Each family's personal value system influences their reaction to a child of a particular temperament. For example, a highly competitive, athletically oriented family may view high-energy, high-intensity characteristics more positively than a family who values studiousness. Qualities such as introversion or extroversion are often based on characteristics of temperament and are not modified readily by the environment. In a family in whom "goodness of fit" between individual members' temperaments does not exist, knowledge of the inborn nature of temperament can help the family accept a child's unique characteristics. Anticipatory guidance can then focus on achieving a better relationship between family and child.

Guidelines for Clinical Assessment

Although individual children develop at their own rate, with great variability in the normal range, general rules for neurodevelopmental maturation can serve as guidelines to help practitioners formulate a developmental trajectory for each child (Sturner and Howard, 1997). The developmental trajectory can be envisioned as an individualized growth chart of anticipated developmental progress based on normal neurodevelopmental milestones and moderated by child, parent, and environmental factors such as temperament, parental mental health, and exposure to lead.

Development usually is categorized into the domains of language, fine motor, gross motor, personal-social, and cognitive. Delays can occur in one or any combination of these domains. For example, a child with mental retardation is likely to have delays in all domains, although gross motor skills may be fairly well preserved. Conversely, a child with cerebral palsy may have normal or near-normal cognitive development with significant delays in gross and fine motor function. Many of the neurodevelopmental rules of thumb address the relationships among these domains.

Children acquire developmental tasks in a predictable sequence. For example, children typically do not learn to walk until they have mastered crawling and then standing.

Table 23-5 Summary of Developmental Theories of Child Development

| Theory (proponents) | Key features | Potential clinical applications |
|--|---|--|
| Normative approach: development as maturation (Gesell) | Behavior depends on neurologic and physical maturation. Universal progression of developmental sequence. Minimal rule of environment/temperament. | Basis for age norms for developmental milestones typically used in clinical setting. |
| Psychosexual and psychoanalytic theory: development as resolution of conflict (Freud, Erikson) | Emotional life exerts strong influence on development and behavior. Unconscious conflicts between biologic drive and social expectations continuously shape behavior and self-concept. Parents are primary interactors with child, influencing behavior into adulthood. Mastery of major developmental tasks at different stages is required for emotional growth. | Interpersonal relationships, especially with primary caregivers, influence present and future adjustment, functioning, and self-concept. Importance of “bonding.” |
| Behaviorism and social learning: development as learning (Pavlov, Skinner, Bandura) | Behavior, but not its underlying influences and motives, can be studied and changed. Environmental stimuli are the major forces shaping development and behavior. Environmental stimuli act as positive and negative reinforcements to existing behavior. | Children imitate what they see, so environmental models are important to learning (e.g., influences of media). Basis for behavioral management approaches. |
| Constructivist views: development as cognitive change (Piaget) | Cognitive development depends on both nature and nurture. Child uses physical and mental abilities to observe and act on the environment. Observation and action advance cognitive development. Child’s mental processing develops with age, influencing how child perceives and interacts with the world. | Children possess an innate drive to learn. Play is the medium by which children learn and develop. Parents can be guided in choosing appropriate playthings/settings to allow their children to learn. |
| Ecologic system: development as cultural and ecologic adaptation (Bronfenbrenner) | A set of interrelated systems (e.g., family, school, community, health services) influences development. These systems exert reciprocal influence on one another. Development is determined by interactions of child and family. | Child’s needs must be considered in context of the family and the environment. |

Table 23-6 Using Erikson’s Psychosocial Stages to Guide Development

| Psychosocial Stage | Guidance |
|---|---|
| Basic trust and mistrust (0-2 years; infancy) | Parent can provide consistent nurturing to aid development of attitude of trust. |
| Autonomy vs. shame and doubt (2-4 years) | Parent should allow safe exploration of environment and encourage decision making. |
| Initiative vs. guilt (5-7 years) | Limits on child should be for protection of child, family, and society, and not random or condemning. |
| Industry vs. inferiority (8-12 years) | Caregiver must work with the school to ensure that child is achieving to his or her abilities and feeling sense of competence vs. inferiority. |
| Identity vs. role confusion (13-17 years) | Selection of career goal; establishment of relationship with opposite sex; independence from family should be encouraged by caregiver; failures to adapt in previous stages make this stage more difficult. |
| Intimacy vs. isolation (18-22 years) | Need to make personal and occupational commitment. |

Although most children are able to crawl by 9 months of age and walk by 14.5 months, even severely delayed children follow the sequence of crawl, stand, and walk (Milani-Comparetti and Gidoni, 1967). This predictable sequence is dictated by building on previously learned skills, as well as by maturation of the central nervous system (CNS) (Springate, 1981). Before a critical stage in the maturation of the intellectual potential or will of the child or parent. For example, because CNS control of the external anal sphincter is incomplete before 18 to 24 months of age, it is impossible to toilet-train even the most precocious toddler before this age.

Responses to stimuli proceed from generalized, symmetric, whole-body reflexes to discrete, cortically controlled, voluntary actions. Newborn reflexes can be thought of in terms of their role in survival of the individual; an example is the rooting reflex, which helps the newborn seek out nutrition. Voluntary movements develop as the child learns to control the environment.

Development proceeds in head-to-toe (cephalocaudal) and proximal-to-distal directions. Therefore, the infant bears weight on the arms before bearing weight on the legs. As proximal-to-distal progression occurs, the infant becomes more precise in fine-tuning the smaller muscles involved in reaching, grasping, and manipulating an object with his or her hand. Vocalization skills follow this pattern as well. A newborn infant vocalizes with “grunts” originating in the

Table 23-7 Temperament Characteristics and Profiles

| Feature | Description |
|--|--|
| Characteristics | |
| Activity | Frequency and speed of involvement |
| Rhythmicity | Regularity of physiologic functions (e.g., hunger, sleep, elimination) |
| Approach/withdrawal | Immediate reaction of child to new stimuli |
| Adaptability | Degree of ease or difficulty with which child adjusts to new stimuli |
| Intensity | Energy level of responses, without regard to positive or negative quality of the response |
| Mood | Predominance of pleasant and friendly versus unfriendly behavior during waking |
| Attention span/persistence | Length of time the child will engage in a single activity with or without interruption |
| Distractibility | Degree of ease with which extraneous stimuli interfere with child's task performance |
| Sensory threshold | Amount of external stimulation required to evoke a response |
| Profiles | |
| Easy (40% of children) | Regularity of biologic functions; positive approach responses to new stimuli; high adaptability to change; mild to moderately intense mood that is predominantly positive |
| Difficult (10% of children) | Irregularity of biologic functions; negative withdrawal responses to new stimuli; no or slow adaptability to change; intense expressions of mood that are predominantly negative |
| Slow to warm up (15% of children) | Negative responses of mild intensity to new stimuli, with slow adaptability with repeated contact; mild intensity of reactions |
| Modified from Chess S, Thomas A. Dynamics of individual behavior development. In Levine MD, Carey WB, Crocker AC (eds). <i>Developmental-Behavioral Pediatrics</i> . Philadelphia, Saunders, 1992, p 86. | |

chest. As proximal-to-distal maturation develops, vocalizations originate more distally in the larynx (cooing), glottis (guttural syllables, “ga”), tongue (“da”), and lips (“ba”).

Delays in one developmental domain can impair development in another domain. For example, an 18-month-old infant with motor impairments secondary to spina bifida lacks the freedom to explore the environment to learn how two pieces of furniture are oriented in space. Likewise, delays in one developmental domain can impair the practitioner's ability to evaluate skills in other domains. A 4-year-old toddler with cerebral palsy might understand the concept of sorting by shape but lack the motor control to manipulate the shapes to pass a standardized test.

An outline of salient features of development in each domain based on age is presented in Table 23-8. This guide to normal development should be considered by the physician

along with past history, parental concerns, clinical observations, and developmental screening in the ongoing surveillance of child development. Until chronologic age 2 years, the development of a premature infant should be judged on corrected age, that is, the chronologic age minus the number of weeks premature.

Developmental Screening in Young Children

Key Points

- Always refer the child to audiology if language is delayed.
- Never ignore parents' concerns.
- Suspect delays and refer early.
- Developmental screening, using parent report measures, is more accurate than clinical judgment.
- Autism usually manifests as language delay.

Every encounter between a physician and child involves developmental and behavioral issues. Attention to such matters can benefit every child. By monitoring development, the primary care physician has the opportunity to customize anticipatory guidance based on the child's current abilities and temperament (Sturner and Howard, 1997).

Additionally, the family physician has a responsibility to identify children with delayed development. Federal law (Individuals with Disabilities Education Act [IDEA]) mandates physicians to refer children with suspected delays to early intervention (birth to 3 years) or early childhood services (3 to 5 years). The specifics of these services vary from state to state but are free and individualized according to the child's and family's needs (AAP Committee on Children with Disabilities, 1999). As the professional with the most frequent—and sometimes only—contact with young children, the family physician is in the ideal position to detect possible developmental problems. Additionally, parents may feel more comfortable sharing concerns and seeking advice from a trusted physician.

Early detection of delays is important, because brain development is most malleable in the early years of life (Shonkoff and Phillips, 2000). Early intervention has been shown to be cost-effective, resulting in better intellectual, social, and adaptive behavior, increased high school graduation and employment rates, and decreased criminality and teen pregnancy (Gomby et al., 1995; Reynolds et al., 2001). Unfortunately, less than half of children with developmental difficulties are identified before kindergarten (Pelletier and Abrams, 2002).

Research shows that clinical impression alone is quite poor at detecting developmental delays (Glascoe, 2000). This has led the AAP to recommend routine monitoring (surveillance) at all preventive care visits and use of standardized developmental screening tests at 9, 18, and 24 or 30 months of age, with the addition of autism-specific screening at 18 and 24/30 months (AAP Council on Children with Disabilities, 2006). Newer screening tools based on parent report can facilitate fulfilling this recommendation. Parent report has been found to be a reliable way to identify children in need of further developmental assessment, particularly if the concerns are elicited and interpreted in a standardized manner (Glascoe, 2003).

Table 23-8 Developmental Milestones in Young Children

| Age | Gross motor | Fine motor/Reflex motor | Social/Adaptive/Cognitive | Language |
|---------|---|---|--|---|
| Neonate | Flexed attitude, turns head side to side when prone without lifting, head sags if unsupported, body sags on ventral suspension | <i>Reflex:</i> Moro symmetric, grasp reflex, stepping reflex, suck reflex, placing reflex | Fixates on face or light, moves in cadence with sound | Alerts to voice |
| 1 mo | Extends legs more, holds chin up briefly when prone, head lag persists | <i>Reflex:</i> Persistence of neonatal reflexes, tonic neck posture | Watches person, visually tracks to midline, begins to smile, body moves in cadence with voice | Throaty noises, range of cries to signal hunger, pain, etc. |
| 2 mo | Raises head from prone position, sustains head in plane with body or ventral suspension, head lag on pull to sit | <i>Reflex:</i> Stepping reflex fades | Smiles on social contact, attracts to voice | Coos |
| 4 mo | Head up to vertical axis in prone position, bears weight on arms, extends legs, symmetric posture with hands in midline in supine position, no head lag on pull to sit, pushes with feet in standing position, holds head erect in sitting position | <i>Fine:</i> Grasps and attains object, brings to mouth <i>Reflex:</i> Grasps, Moro, tonic neck fade; downward parachute present | Laughs out loud, voices displeasure if contact is broken, excites at sight of food, regards a small pellet | Vowel sounds, visually searches for speaker |
| 6 mo | Sits alone with rounded back, rolls over, pivots, creeps | <i>Fine:</i> Rakes at pellet, transfers, turns body to reach <i>Reflex:</i> Sideways parachute present | Prefers mother, responds to emotion, imitates banging, visually follows dropped objects | Polysyllabic babble, blows bubble ("raspberry"), laughs |
| 9 mo | Sits with erect back, crawls, walks holding both hands, pulls to stand, can get to sitting position | <i>Fine:</i> Pokes with forefinger, uses assisted pincer grasp <i>Reflex:</i> Forward (7 mo) and backward parachute present, plantar grasp fades | Plays "peekaboo," "pat-a-cake"; waves bye-bye; finds an object after watching it hidden; may cry at sight of unfamiliar person | Responds to some verbal commands: "no"; imitates some sounds; uses "mama," "dada" nonspecifically |
| 12 mo | Cruises holding on, stands alone, may take several steps, walks holding hand | <i>Fine:</i> Neat pincer grasp, releases on request; puts 2 cubes in cup, pellet in bottle | Plays ball, adjusts posture when dressing, drinks from a cup, imitates activity (talks on toy phone) | 1-2 true words, symbolic gestures (e.g., shakes head "no"), points to indicate wants |
| 15 mo | Walks alone, crawls up stairs, walks backward, rises after stooping | <i>Fine:</i> Dumps pellet from bottle or draws line with crayon when demonstrated, scribbles spontaneously, stacks 2 cubes | Feeds self with utensils, performs simple household tasks (pick up toys), hugs parent | Points to body parts, jargons, follows 1-step command without gestures |
| 18 mo | Runs stiffly, sits on small chair, walks up stairs with hand holding rail | <i>Fine:</i> Tower of 4 cubes, dumps pellet on request, imitates line with crayon | Feeds self with utensils; kisses parent with pucker; explores drawers, wastebaskets; removes garment; seeks help when in trouble | 10 words, says "no," names pictures, points to 1 body part |
| 24 mo | Runs well; walks up and down stairs, one at a time; jumps in place, climbs on furniture; kicks ball | <i>Fine:</i> Tower of 7 cubes, "train" of 4 cubes; imitates vertical and circular crayon stroke; imitates folding paper | Listens to story with pictures, helps to undress, dresses with help, parallel play, uses spoon well | 30-50 words; 2- or 3-word sentences; uses pronouns, sometimes incorrectly; relates recent experience; speech 50% intelligible |
| 36 mo | Alternates feet climbing stairs, stands on one foot briefly, broad jumps with both feet, pedals tricycle, throws ball overhand | <i>Fine:</i> Tower of 10 cubes, imitates "bridge" of 3 cubes, imitates cross, copies circle, attempts to draw person | Knows age and gender, counts 3 objects, repeats 3 serial numbers, understands turn-taking, washes and dries hands, helps with dressing | States full name; uses complete sentences; speech 75% intelligible to stranger; uses plurals, past tense, pronouns correctly |

Continued

Table 23-8 Developmental Milestones in Young Children—cont'd

| Age | Gross motor | Fine motor/Reflex motor | Social/Adaptive/Cognitive | Language |
|-------|---|---|---|--|
| 48 mo | Hops on one foot, throws ball overhand, balances on each foot 2-3 seconds | <i>Fine:</i> Uses scissors to cut out pictures; copies cross, square; draws man with head and 2-4 body parts (pairs count as 1 part); tells a story | Counts 4 objects correctly, group play with role playing, toilets independently, dresses with little supervision | — |
| 60 mo | Skips, balances on each foot 4-5 seconds | <i>Fine:</i> Copies triangle, 8- to 10-part person | Counts 10 objects, prints first name, domestic role playing, asks meaning of words, dresses and undresses independently | Uses complete sentences, names 4 colors, repeats 10-syllable sentence, follows 3-stage command |

Compiled from Vaughn VC, Litt IF. Growth and development. In Behrman RE, Kliegman RM, Nelson WE, Vaughn VC (eds): Nelson Textbook of Pediatrics, 14th ed. Philadelphia, Saunders, 1992, pp 41-42.

Parent report measures can be used in a variety of ways. They can be completed in the waiting room, sent out to be returned at the next appointment, or completed via an interview, either in person or by telephone with a staff member. It is helpful to have a staff member routinely inquire if the parents would like someone to go over the measure with them; this ensures that literacy or language issues are not barriers to screening. Even if staff administer the parent report, parent report measures are the most accurate and time-effective and cost-efficient method of developmental screening currently available. Accurate screening tools with acceptable sensitivity and specificity (70%-80%) are listed in Table 23-9. Physicians can bill for screening, although reimbursement varies widely (Glascoe, 2003). More information regarding developmental screening, including coding and billing aspects, can be found at the Developmental Behavioral Pediatrics website.

Evaluation of Developmental Delay

The estimated prevalence of developmental delay is 10%. Some children present with delays in multiple areas, or global developmental delay. *Global developmental delay* is defined as significant delay in two or more areas of development (gross or fine motor, speech and language, cognition, social and personal, and activities of daily living). The more severe the delay, the more likely a cause can be determined (Roberts et al., 2004). Once significant delay is recognized, parents are often eager to know the cause. The family physician can be instrumental in referring for appropriate intervention, as well as overseeing an initial workup.

Although many physicians refer to specialists (e.g., developmental pediatricians, neurologists) for further evaluation, these specialists may have long waiting lists. Some aspects of the workup can easily be ordered by the family physician. Guidelines from the American Academy of Neurology and Child Neurology Society for the workup of the child with global developmental delay are shown in Table 23-10 (Shevell et al., 2003). The guidelines listed in the table are evidence based and could be readily used by family

Table 23-9 Developmental Screening Tools

| Tool | Age range | Time | Source |
|---|------------|---------|---|
| Ages and Stages Questionnaire | 0-60 mo | ~7 min | Paul H. Brooks, Publishers www.pbrookes.com |
| Child Development Inventories | 3-72 mo | ~10 min | Behavior Science Systems* |
| Parents' Evaluations of Developmental Status (PEDS) | Birth-8 yr | ~2 min | Ellsworth & Vandermeer www.pedstest.com |

*PO Box 580274, Minneapolis, MN 55458.

physicians to start the workup while waiting for a specialist appointment. Results of the workup may facilitate more specific referrals. Even if not globally delayed, all children with language delay should have a formal audiology assessment to rule out hearing impairment.

Autism Screening

Autism is a developmental disability involving difficulties with communication and social interaction as well as unusual and restricted behavior. The prevalence of autism appears to be rapidly increasing, for reasons not yet clear (Fombonne, 2003; Yeargan-Allsopp et al., 2003). The latest prevalence estimates are 1.1 per 100 children (Kogan et al., 2009). This makes it essential that any primary care physician seeing children be able to recognize signs and symptoms suggesting autism and refer for further evaluation promptly. Early diagnosis allows earlier initiation of intensive behavioral intervention, which has been shown to be very helpful (Butter et al., 2003). Table 23-11 lists "red flags" that should prompt referral for further evaluation

Table 23-10 Evaluation of Global Developmental Delay

| Indication | Workup |
|---|--|
| Everyone | |
| First-line workup | Comprehensive history and physical Hearing and vision screening Metabolic studies and T ₄ (if newborn screen results not known) EEG if symptoms of seizures Screen for autism if language delayed |
| Positive family history | |
| Genetic, metabolic, or CNS disorder | Test for specific condition |
| Nonspecific developmental delays | Chromosomes and fragile X |
| Signs or Symptoms present | |
| Specific genetic disorder | Specialized genetic testing |
| Hypothyroidism | Thyroid studies |
| CNS abnormality | MRI |
| Other | |
| Possible lead exposure | Lead level |
| Regression of skills or parental consanguinity | MRI, chromosomes, fragile X, metabolic testing, EEG, genetics evaluation |
| No specific signs/symptoms (stepwise in order) | MRI, chromosomes, fragile X, metabolic testing, Rett's syndrome testing |
| <small>Data from Roberts G, Pafrey J, Bridgemohan C. A rational approach to the medical evaluation of a child with developmental delay. <i>Contemp Pediatr</i> 2004;21:76-100; and Shevell M, Asheval S, Donley D, et al: Practice parameter: evaluation of the child with global developmental delay. <i>Neurology</i> 2003;60:367-380. CNS, Central nervous system, EEG, electroencephalogram; MRI, magnetic resonance imaging.</small> | |

(Filipek et al., 2000). A formal audiology evaluation is also indicated, as well as lead screening if the child has pica. It is important to keep in mind that most young children with autism are presented to their physician with the chief complaint of language delay. The physician should consider autism in the differential diagnosis for a child with language delay.

Assessing Development in the School-Age Child

Developmental surveillance in a school-age child should focus on identification of unsuspected learning problems, including attention-deficit/hyperactivity disorder (ADHD), mild mental retardation, and learning disabilities, as well as detection of emotional problems such as anxiety, depression, or school phobia. Emotional problems can be screened for using the Pediatric Symptom Checklist (PSC). The PSC is a one-page questionnaire that is relatively easy to administer and interpret during routine well-child care. Positive results should prompt the physician to probe

Table 23-11 Red Flags and Absolute Indications for Immediate Evaluation

| Age | Sign |
|--|---|
| 12 months | No babbling No pointing No gestures |
| 16 months | No single words |
| 24 months | No 2-word phrases |
| Any age | Loss of language or social skills |
| <small>Modified from Filipek PA, Accardo PJ, Ashwal S, et al. Practice parameter: screening and diagnosis of autism. <i>Neurology</i> 2000;55:468-479.</small> | |

further with questions regarding school, friends, family, moods, and activities. Referrals to other professionals can then be made if necessary. More information regarding the PSC is available on the Massachusetts General Hospital PSC website.

Asking the child and parent about school progress and reviewing report cards and standardized testing results are simple ways for the physician to monitor school progress. Checklists completed by the parent and teacher can provide further information about specific issues (e.g., attention) or behavior in general (Table 23-12).

Federal law (IDEA) mandates a free and appropriate education for all children, regardless of handicapping condition. Therefore, if a child is suspected to have a learning disability, the school is obligated to evaluate and provide necessary services, free of charge (AAP, 1999). The parent should be advised to request the evaluation, called the Multi-Factored Evaluation (MFE), in writing. Federal law requires the MFE be done within 60 days. The MFE consists of standardized assessments of various aspects of learning. Once the MFE is completed, school personnel meet with the parents to review testing results and determine if the child is eligible for special education services. These services may occur in the regular classroom or in a separate one, although the law requires that services be provided in the least restrictive environment. The goal is to keep children with their typical peers as much as possible.

Once a child is deemed eligible for services, an individualized education plan (IEP) is developed. Parent input is required as part of the process. If the parent disagrees with the suggested IEP, the parent has the right to due process. An explanation of due process must be given to all parents at the beginning of the MFE/IEP process. Once developed, the IEP is updated annually. Parents should receive progress reports throughout the school year. They may request interim changes to the IEP if needed. Reevaluations are conducted at least every 3 years (Henderson, 2001).

All this is often overwhelming for families. The physician can assist by providing simple explanations of the process as well as periodically reviewing the IEP and helping parents understand it. The physician should also encourage parents to become knowledgeable advocates for their child.

Some children have conditions that can benefit from extra assistance but that do not qualify as handicaps according to

Table 23-12 School-Age Checklists

| Purpose | Ages | Description | Website/ Contact |
|---|---|--|--|
| Pediatric symptom checklist | | | |
| Brief screening for behavioral concerns | 4-16 years | 35 items completed by parents | psc.partners.org |
| Child behavior checklist | | | |
| In-depth screening for behavioral/emotional problems | Separate forms for 1-5 years and 6-18 years | Parents, teachers, caregivers, youth (11-18 yr); 99-118 items depending on form used | www.aseba.org |
| Conners scales | | | |
| More specific for ADHD and learning difficulties | 3-17 years | Parent, teacher, youth (12-17 yr); short and long forms, 27-87 items | www.pearsonassessments.com |
| Clinical attention problem scale | | | |
| Brief, specific for attention and overactivity symptoms | 6-12 years | 24-item checklist Teacher version | www.dbpeds.org/handouts |
| Vanderbilt | | | |
| Symptoms of ADHD; common comorbidities | 6-12 years | Teacher/parent; initial (43-55 items) and follow-up (26 items) forms | http://www.nichq.org/NlaCHQ/Topics/ChronicConditions/ADHD/Tools/ |
| ADHD, Attention-deficit/hyperactivity disorder. | | | |

the IDEA. Conditions such as ADHD are covered by Section 504 of the Rehabilitation Act of 1973 (Henderson, 2001). The qualifications are broader under this law, allowing children with less serious issues to still receive special services. This assistance, though helpful, is often less extensive than if the child qualified for an IEP.

Regardless of the issues, communication with school personnel is often helpful. Teacher rating scales (general or specific for certain concerns) may be useful, as well as direct communication, either verbally or in writing. Such dialogue also illustrates for families the advantages of cooperative teamwork with school personnel. It is always important for physicians to follow the Health Insurance Portability and Accountability Act (HIPAA) guidelines, obtain written permission from parents, and show discretion (“need to know”) when sharing information with schools.

Immunizations

Key Points

- Avoid missed opportunities to vaccinate by reviewing the child’s immunization record at every visit.
- Schedule adolescents for an immunization visit at age 11 to 12 years to catch up on missed vaccines and administer new ones.
- Provide current vaccine information statements to parents or guardians for each vaccine given during the visit.

Indications and Contraindications

Routine immunizations are essential for the control and prevention of previously common childhood infectious diseases. During 2008, more than 76% of U.S. children age 19 to 35 months received 4 or more doses of diphtheria, tetanus toxoids, and pertussis vaccines (DTP/DT/DTaP); 3 or more doses of poliovirus vaccine; 1 or more doses of any measles-containing vaccine; at least 3 doses of *Haemophilus influenzae* type b (Hib) vaccine; at least 3 doses of hepatitis B vaccine; and at least 1 dose of varicella vaccine (CDC, 2009). However, there is still considerable disparity in immunization rates among states and communities. Young children might not be immunized at the recommended age because of missed opportunities to vaccinate, deficient health care delivery in the public sector, lack of insurance, inadequate access to medical care, lack of public awareness about the necessity for immunizations, or concern about potential or alleged adverse effects of immunizations. Both AAP and AAFP endorse the Childhood and Adolescent Immunization Schedules (see eTables 23-3 to 23-5 online) (SOR: A).

Parents or guardians should be questioned about possible contraindications, precautions, and any previous adverse events in response to vaccine administration (see eTable 23-6). They should be informed about the potential benefits and risks of the vaccine and the risks of the natural disease should the immunization not be given. Health care providers administering any vaccine covered by the National Vaccine Compensation Injury Act or purchased by federal contract must provide the most current *vaccine information statements* (VISs) detailing the potential benefits and risks of each vaccine to the parents or guardians each time that vaccine is given (AAP Red Book, 2009, 5-6). Copies of VISs may be obtained from the CDC (www.cdc.gov/vaccines/pubs/VIS/default.htm), the Immunization Action Coalition (www.immunize.org), or state health departments.

Vaccines have become “victims of their own success” (Cooper et al., 2008). Because they no longer are confronted with the presence of vaccine-preventable diseases, some individuals, parents, and groups have become more concerned about the alleged adverse effects of immunization. A Danish study is one of many that has confirmed the effectiveness of vaccines such as Hib and pertussis and did not find an association of MMR or thimerosal-containing vaccines with autism spectrum disorders (Hviid, 2006). Physicians serve as the primary source of information about immunizations, and the family physician should explain the potential benefits and risks of immunizations to parents and older patients such as adolescents (Gellin et al., 2000). If parents still do not wish

to have their child vaccinated, further information and documentation may be obtained at <http://www.aap.org/immunization/pediatricians/pdf/RefusaltoVaccinate.pdf>.

Before administering vaccines, the physician should ask about the child's current state of health, as well as that of other family members. An immunosuppressed member of the household might contraindicate the administration of certain live-virus vaccines, such as nasal live, attenuated influenza vaccine (LAIV). Minor febrile illnesses are not contraindications to vaccine administration. General contraindications are a previous anaphylactic reaction to the specific vaccine or a severe hypersensitivity reaction to vaccine constituents such as gelatin or antibiotics such as neomycin, streptomycin, or polymyxin B. Latex allergy may also be a contraindication if the vaccines are supplied in vials or syringes containing natural rubber (AAP Red Book, 2009, 848-853).

Vaccine Administration

Most immunizations must be given by deep intramuscular (IM) or subcutaneous (SC) injection. IM injections should be given in the anterolateral thigh for infants or the deltoid muscle of the arm for older children. The sciatic nerve may be injured by deep intragluteal injections. Although acetaminophen (paracetamol) administered for 24 hours has been demonstrated to decrease mild to moderate reactions, such as temperature of 38° C (100.4° F) or greater, it may reduce antibody responses to some vaccine antigens (Prymula et al., 2009). Topical local anesthetics, sweet-tasting solutions, and breastfeeding may decrease injection pain for childhood immunizations (HELPinKIDS, 2009).

Immune responses may be impaired if two live-virus vaccines are given within 28 days of each other. Live-virus vaccines must be given simultaneously or at least 4 weeks apart (AAP Red Book, 2009, 22). If immune globulin (IG) is given, live-virus vaccine administration should be delayed for up to 3 to 6 months to allow optimal antibody production (AAP Red Book, 2009, 448). An even longer period may be required if high doses of intravenous (IV) gamma globulin have been given.

Schedule of Immunizations

The recommended schedule for childhood and adolescent immunizations are given online in eTables 23-3 to 23-5. A lapse in the immunization schedule does not require starting over the entire series. Doses of any vaccine should not be divided or reduced, because this can result in an inadequate response. Premature infants should receive the same vaccine dose, usually at the same chronologic age as full-term infants. Most vaccines can be administered simultaneously using separate syringes at separate sites (AAP Red Book, 2009, 33).

Poliovirus Vaccine

The last indigenous case of wild-type poliomyelitis in the United States occurred in 1979, and the last identified imported case occurred in 1993. From 1980 to 1996, there were approximately eight cases per year of vaccine-associated paralytic poliomyelitis (VAPP) caused by oral poliovirus vaccine (OPV) in the United States. In 2000, inactivated

poliovirus vaccine (IPV) was recommended for all routine childhood polio vaccinations in the United States, and only one case of VAPP was imported from Central America in 2005 (AAP Red Book, 2009, 541).

Measles, Mumps, and Rubella Vaccine

The measles-mumps-rubella (MMR) vaccine should be given to children 12 to 15 months of age. The second MMR or measles-mumps-rubella-varicella (MMRV) vaccine is recommended before school entry at 4 to 6 years of age, but it can be given earlier in the event of an outbreak or as a requirement for travel, provided the second dose is given at least 28 days after the first. Physicians should review their records to ensure that all children receive the second MMR or MMRV by 11 to 12 years of age. Children may be immunized with MMR even if there is a pregnant or immunosuppressed family member, because the vaccine viruses are not transmitted (AAP Red Book, 2009, 47).

Haemophilus Influenzae Type b Conjugate Vaccine

The use of *H. influenzae* type b (Hib) conjugate vaccines has lowered the U.S. incidence of invasive Hib disease in children younger than 5 years of age by 99%. Vaccines currently available in the United States, such as HbOC (HibTITER), PRP-OMP (PedvaxHIB), and PRP-T (ActHIB, OmniHIB), are given beginning at age 2 months. ActHIB reconstituted with Tripedia as Trihibit is licensed only for the fourth dose of Hib and DTaP, while PRP-T (Hiberix) is licensed for use as a booster in children 15 months through 4 years of age (CDC, 2009). PRP-OMP-HepB (Comvax) is administered at 2, 4, and 12 to 15 months of age and DTaP-IPV/PRP-T (Pentacel) at 2, 4, 6, and 15 to 18 months of age (AAP Red Book, 2009, 318-321).

The schedule of administration varies according to the type of vaccine, as shown in eTables 23-3 and 23-4. Children age 15 to 59 months of age usually need only 1 dose of any Hib conjugate vaccine. Children with conditions predisposing to invasive Hib disease, such as sickle cell anemia, asplenia, human immunodeficiency virus (HIV) infection, chemotherapy for malignancies, and immunologic impairment, are given 2 doses of vaccine 2 months apart. Children age 60 months or older are generally not vaccinated unless they also have a chronic illness associated with an increased risk of Hib disease and require 2 doses of Hib conjugate vaccine 1 to 2 months apart (AAP Red Book, 2009, 321).

Acellular Pertussis Vaccine

Acellular pertussis vaccines combined with diphtheria and tetanus toxoids (DTaP) are used in the United States for the primary and booster doses in children. These vaccines (DAP-TACEL, Infanrix, Tripedia) are immunogenic and produce fewer adverse local and systemic reactions, such as fever and irritability, than do whole-cell pertussis vaccines. Whenever possible, the same DTaP vaccine should be used throughout the entire vaccination series, because there are no data on safety or efficacy when different formulations of these vaccines are interchanged. However, if the previously used vaccine is not known or is unavailable, any of the DTaP vaccines licensed for use in children may be given to complete the immunization

series. Combination vaccines such as DTaP-IPV-HepB (Pediarix) and DTaP-IPV-Hib (Pentacel) are licensed for use as the first 3 doses and first 4 doses, respectively, of their components, whereas DTaP-IPV (Kinrix) is licensed only as the booster fifth dose of DTaP and fourth dose of IPV at ages 4 to 6 years (AAP Red Book, 2009, 508, 510).

Two vaccines containing reduced concentrations of diphtheria toxoid and pertussis antigens combined with tetanus toxoid (Tdap) are now licensed for use in adolescents and adults (Boostrix and ADACEL). The vaccines are recommended for adolescents 11 to 18 years of age in place of the Td booster to decrease the reservoir of *Bordetella pertussis* in this population. Increasing reports of pertussis in many U.S. states has led to a recent recommendation to give one dose of these vaccines to children 7 to 10 years of age who are incompletely immunized against pertussis.

Rotavirus Vaccine

Rotavirus is responsible for up to 500,000 deaths from diarrhea worldwide and 20 to 60 U.S. deaths in each year. Before the introduction of rotavirus vaccines (RV1 or Rotarix, RV5 or RotaTeq), rotavirus caused 3 million infections per year in the United States, resulting in more than 400,000 physician visits and 55,000 to 70,000 hospitalizations per year (CDC Pink Book, 2009, 245-256). RV1 is given as 2 oral doses at 2 and 4 months of age, and RV5 is given as 3 oral doses at 2, 4, and 6 months of age. The minimum interval between doses of either vaccine is 4 weeks. Neither vaccine should be started for infants age 15 weeks, 0 days or older, and all doses must be given by 8 months, 0 days of age. The vaccine-specific package insert should be seen for full prescribing indications and contraindications.

Varicella Vaccine

Two SC doses of monovalent varicella (VZV) vaccine or MMRV are indicated in children age 12 months through 12 years. The doses should be separated by at least 3 months, with the second dose routinely recommended at age 4 to 6 years before kindergarten or first grade. Persons 13 years or older who do not have evidence of immunity to varicella should receive 2 doses of VZV vaccine at least 28 days apart because MMRV is not licensed in this age group. A second dose of varicella vaccine should be given to people who previously received only 1 dose. The vaccine is generally contraindicated in pregnant women, immunodeficient persons, or those receiving high doses of systemic corticosteroids (≥ 20 mg/day of prednisone or equivalent) for 14 days or more. However, VZV vaccine may be considered for HIV-infected patients with a CD4+ T-lymphocyte count of 15% or greater. Vaccine-strain VZV has been rarely transmitted, and vaccinated patients who develop a rash should avoid contact with immunocompromised persons (AAP Red Book, 2009, 724-726). Zoster vaccine is not interchangeable with varicella vaccine and is not used in children.

Hepatitis A Vaccine

Hepatitis A virus (HAV) is usually transmitted person to person through the fecal-oral route and by ingestion of contaminated food or water, but it has rarely been transmitted by transfusion of blood or blood products. Two HAV

inactivated vaccines, HAVRIX and VAQTA, are licensed in the United States for use in children age 1 year and older. TWINRIX is a combined hepatitis A and hepatitis B vaccine licensed for use in persons at least 18 years old. Physicians should consult the package insert for proper dosing because there are different formulations of these vaccines.

Childhood vaccination against HAV is recommended for all U.S. children 12 to 23 months of age and should be considered for unimmunized children ages 2 to 18 years old. Indications for immunization with hepatitis A vaccine include travel to or residence in countries or areas endemic for hepatitis A, residence in Native American or Alaskan Native communities with high rates of HAV infection, persons who receive clotting-factor concentrates, persons with chronic liver disease, injection drug users (IDUs), men who have sex with men (MSM), and people at risk of occupational (e.g., handlers of primates), household, and sexual exposure (AAP Red Book, 2009, 329-337).

Hepatitis B Vaccine

Hepatitis B virus (HBV) is endemic in Southeast Asia, the Pacific Islands, China, Africa, parts of the Middle East, and the Amazon Basin. More than 350 million people worldwide have chronic HBV infection. Although transmission in U.S. children is less likely because of high coverage with HBV vaccine, the risk of perinatal transmission of HBV from an infected mother to her infant varies from 10% to as high as 90%, depending on whether the mother is negative or positive for hepatitis B e antigen (HBeAg) (CDC Pink Book, 2009, 99-122).

Immunization with the pediatric formulations of hepatitis B vaccine is recommended for all infants soon after birth or before hospital discharge. HBV vaccine should be given to newborns of mothers positive for hepatitis B surface antigen (HBsAg) or infants of mothers whose HBsAg status is unknown. An infant born to an HBsAg-positive mother should receive an initial dose of 5 μ g Recombivax HB or 10 μ g Engerix-B and 0.5 mL of hepatitis B immune globulin (HBIG) IM at separate sites within 12 hours of birth. Repeat vaccine doses should be given at ages 1 month and 6 months. For infants of HbsAg-negative mothers, the combination DTaP-HBV-IPV (Pediarix) or PRP-OMP-HBV vaccine (Comvax) may also be used, beginning at 6 to 8 weeks of age. Practitioners should consult the package insert for the appropriate dose according to the formulation and intended use. Any adolescents who have not yet received HBV vaccine should also be immunized with 2 doses at least 4 weeks apart, with a third dose 4 to 6 months after the second dose (CDC Pink Book, 2009, 99-122).

Hepatitis B vaccine should be given to susceptible high-risk children or adults who are institutionalized; those who have end-stage renal disease, chronic liver disease, or HIV infection; those who receive clotting-factor concentrates; those who have an HIV-infected household or sexual contact; MSM; IDUs; and adoptees from or long-term travelers to countries endemic for hepatitis B (AAP Red Book, 2009, 337-356).

Conjugate Pneumococcal Vaccine

The 13-valent conjugate pneumococcal vaccine (PCV13) covers 64% of the serotypes that cause invasive pneumococcal disease in children younger than 5 years old. The vaccine

stimulates effective antibodies to all 13 serotypes in over 90% of recipients after three doses and is given to infants at 2, 4, 6, and 12 to 15 months of age. Children 7 to 11 months old require 2 doses 2 months apart, followed by a third dose at 12 to 15 months of age (2 or more months later). Children 12 to 23 months old require 2 doses 2 months apart. Only 1 dose is required for all healthy children 24 to 59 months of age. Children age 24 to 71 months at high risk for invasive pneumococcal disease should receive 2 doses of vaccine at least 8 weeks apart if they have not been previously immunized (CDC, 2010).

Influenza Vaccine

Routine annual immunization with trivalent inactivated influenza (TIV) vaccine is now recommended for all persons 6 months of age and older, including these with high-risk conditions such as HIV, chronic pulmonary (including asthma), cardiac, renal, or metabolic diseases; those receiving immunosuppressive or long-term aspirin therapy; those who have hemoglobinopathies, and those with any condition (e.g., cognitive dysfunction, seizure disorder, neuromuscular disorder) that could compromise respiratory function. TIV vaccine is also recommended for pregnant women and persons who are household contacts of high-risk patients, including health care workers. Several TIV products are now available, and providers should read the prescribing information regarding the appropriate age and dosing of these vaccines. Live, attenuated influenza vaccine (LAIV) is approved for use in healthy persons age 2 through 49 years and not pregnant. LAIV should not be used in persons with asthma or those in close contact with severely immunosuppressed hospitalized patients receiving care in a protected environment. Neither vaccine should be given to persons with a history of severe allergy to egg or any other vaccine component (CDC Pink Book, 2009, 141-154).

Conjugate Meningococcal Vaccine

Tetravalent meningococcal polysaccharide-protein conjugate vaccine (MCV4, Menactra, Sanofi Pasteur; and Menveo, Novartis) has been licensed in the United States for use in persons 2 to 10 years old and 11 to 55 years old. Routine immunization of all children age 11 to 18 years and especially 11 to 12 years at a health-care visit is recommended. The vaccines contain serogroups A, C, Y, and W-135, as does the current meningococcal polysaccharide vaccine (MPSV4). Serogroups C, Y, and W-135 cause 75% of all cases of meningococcal disease in persons older than 11 years in the United States (Bilukha and Rosenstein, 2005). Neither vaccine is protective against serogroup B, which accounts for most of the remaining cases. Persons 2 to 55 years with terminal complement or properdin deficiencies, anatomic or functional asplenia, and HIV should receive two doses 2 months apart (CDC, 2011). Travelers to countries with hyperendemic or epidemic *Neisseria meningitidis* (e.g., sub-Saharan Africa, Mecca during the Hajj) should also be immunized with MCV4 (CDC Pink Book, 2009, 177-188). College freshmen students living in dormitories have a higher risk of meningococcal infection than students living off campus and should be immunized with MCV4. MCV4 is given to all U.S. military recruits (AAP Red Book, 2009, 461-463). Revaccination

is recommended for persons at prolonged increased risk who were vaccinated at age 7 years or older and were vaccinated 5 years previously, or for those at ages 2 to 6 years old and vaccinated 3 years previously (CDC, 2009). A booster dose of MCV4 is also recommended for adolescents at age 16 years who received their previous dose at age 11 or 12 years and at age 16 through 18 years for those who received their first dose at age 13 through 15 years (CDC, 2011).

Human Papillomavirus Vaccine

Although most human papillomavirus (HPV) infections spontaneously resolve, high-risk HPV types are found in 99% of cervical cancers with types 16 and 18, accounting for about 70% of cervical cancers worldwide. HPV is also believed to account for 90% of anal cancers; 40% of vulvar, vaginal, or penile cancers; and 12% of oral and pharyngeal cancers. Types 6 and 11 HPV account for 90% of genital warts and laryngeal papillomatosis. The bivalent HPV (types 16, 18) vaccine (Cervarix) and the quadrivalent HPV (types 6, 11, 16, 18) vaccine (Gardasil) are licensed for use in U.S. females age 10 to 25 and 9 to 26 years, respectively. Both are recommended for routine vaccination at age 11 or 12 years and are ideally given before onset of sexual intercourse. The bivalent HPV vaccine is given in a 3-dose series at time 0, 1, and 6 months and the quadrivalent HPV vaccine in a 3-dose series at time 0, 2, and 6 months, with the third dose following the first dose by at least 24 weeks (CDC Pink Book, 2009, 123-133). These vaccines are prophylactic only for the HPV types they contain and do not treat preexisting infection with these HPV types. They may be given at the same visit at different sites with the MCV4 and Tdap vaccines. The FDA (2009) has also approved the quadrivalent HPV vaccine for use in males 9 to 26 years old to prevent genital warts.

Special Clinical Situations

Children who are immunocompromised or infected with HIV usually should not be given live-virus vaccines. However, measles can cause severe disease and death in symptomatic HIV-infected patients. MMR (but not MMRV) is recommended at age 12 months for HIV-infected children with CD4+ T-lymphocyte counts of 15% or greater. The second dose can be given 28 days later to improve the immune response. Children with age-specific low CD4+ counts should not be given measles virus-containing vaccine (AAP Red Book, 2009, 447-455). All HIV-infected children or children of unknown status born to HIV-infected women should receive immune globulin at 0.5 mL/kg to a maximum dose of 15 mL, regardless of vaccination status, if exposed to wild-type measles. HIV-infected children are also at increased risk from complications of chickenpox and zoster, and those children with CD4+ counts of at least 15% should receive two doses of varicella vaccine 3 months apart. The MMRV vaccine is not used in this situation (AAP Red Book, 2009, 726).

Conjugate pneumococcal vaccine (PCV13) is recommended for all children younger than 60 months and children 24 to 71 months who have high-risk conditions such as sickle cell disease, functional or anatomic asplenia, HIV infection, other immune deficiencies or immunosuppressive therapies, chronic cardiac or pulmonary disease, chronic renal

insufficiency, diabetes mellitus, cerebrospinal fluid leaks, or cochlear implants. High-risk children who have received 4 doses of PCV13 should also receive 1 dose of the 23-valent polysaccharide pneumococcal vaccine (PPSV23, Pneumovax-23) at 24 months. Children 24 to 71 months old who have received less than 3 doses of PCV13 should receive 2 doses of PCV13 followed by 1 dose of PPSV23 at 8 weeks later. Immunosuppressed children and those with sickle cell disease or functional asplenia should receive a second dose of PPSV23 vaccine 5 years after the first dose (AAP Red Book, 2009, 524-535).

National Childhood Vaccine Injury Act

The National Childhood Vaccine Injury Act of 1986 was passed to provide compensation for children inadvertently injured by any of the routinely recommended childhood vaccines and to provide liability protection for manufacturers and for health care providers who administer the vaccines. The intent of the law is to ensure a stable supply of vaccine and allow routine immunizations to continue. The physician or other health care provider must maintain permanent documentation of the date, vaccine type, manufacturer, lot number, and name, address, and title of the person administering the vaccine. A list of reportable but not necessarily compensable events is available from the Health Resources and Services Administration. Significant adverse events

should be reported to the Vaccine Adverse Event Reporting System (VAERS) at 1-800-822-7967 or www.vaers.hhs.gov.

Behavioral problems are common reasons for parents to bring their child to see the family physician. In addition, addressing behavioral issues is an important component of the well-child visit. Childhood behavioral problems are a complex assortment of individual mental disorders, genetic and medical disorders, family interaction difficulties, social and school problems, and combinations of these. The rates of many psychosocial problems in children and adolescents, including depression, suicide, conduct disorders, and drug and alcohol abuse, have been rising in recent years throughout Western culture (Fombonne, 1998). This increase is only partly explained by changes in diagnostic criteria and reporting. The trend is particularly troubling when economic conditions and physical health of the population have been improving. The implication for office physicians is that psychosocial problems will encompass a growing proportion of patient care both as presenting problems and as cofactors in other medical conditions.

This chapter is arranged in problem-focused fashion along a developmental continuum from infancy through adolescence based on when various problems are most frequently encountered in practice. For conditions encountered at different developmental stages, discussions include similarities and differences in recognition and treatment at different ages. Management focuses on early, brief interventions the physician can make with the patient and family as well as suggestions about referral.

Regardless of the behavioral concern or the child's age, general principles for evaluation and management include the following:

1. Obtain specific examples of the problem behaviors rather than general conclusions. For example, "Child is out of his seat, walking around the classroom every few minutes," rather than, "Disruptive in class"; and "Screams inconsolably at 2 AM," rather than, "Doesn't sleep well."
2. Obtain as complete information from as many observers as possible. Unusual seizure disorders and other neurologic problems are included in the differential diagnosis of many behavioral disorders. Keys to their diagnosis are found in a careful history.
3. For the same reason just stated, include a careful neurologic and age-appropriate mental status examination.
4. Emotional stressors and abuse, whether physical, verbal, or sexual, can be important precipitators or exacerbators of behavioral problems. Therefore, explore these, including an interview of the child apart from their parents once the child is verbal.
5. Consider multiple diagnoses simultaneously. Multifactorial etiologies are common for many behavioral complaints, and many psychiatric diagnoses carry a high risk of comorbid conditions. Therefore, avoid a linear approach of working up one potential diagnosis at a time.
6. Use a multidimensional treatment approach. Many behavioral problems respond best to combinations of psychotherapy, medication, parent and teacher education, and other therapies, rather than only one of these at a time.

- Familiarize yourself with the mental health regulations for the various insurance plans in which you participate. Many plans have “carve-outs” (separately contracted providers) for mental health services. If you are the initial contact regarding a concern, you may either assist or hinder your patient obtaining the appropriate assistance based on your knowledge of available service channels. This is particularly important in crisis situations; know the services in your area, including specific providers available on various insurance plans, and how to access them during evenings and weekends.

Sleep Problems

Key Points

- Many sleep problems can be prevented with good sleep hygiene.
- For obstructive sleep apnea syndrome, criteria to order a sleep study in the evaluation of a child are similar to criteria for adults, but interpretation of the results requires special pediatric expertise.
- The most common cause of obstructive sleep apnea in children is adenotonsillar hypertrophy, and the treatment of choice is surgery.

Normal sleep has a well-characterized pattern of rapid eye movement (REM) and non-REM sleep that changes with age. Non-REM sleep is further categorized into stages 1, 2, 3, and 4, on the basis of electroencephalographic (EEG) characteristics, with the deepest non-REM sleep occurring in stages 3 and 4. A normal nighttime sleep cycle is about every 90 minutes, with multiple brief arousals and quick returns to sleep without memory of having awakened. Deep non-REM sleep predominates in the first several hours of sleep, and REM is most prominent in the last few hours. Children have substantial periods of very deep sleep that lessen with age. There is a gradual decrease in the amount of REM sleep and a significant decrease in deep non-REM sleep, especially in adolescence.

Children and adolescents in American society sleep less than those in other societies and less than children in the past (Dahl, 1998). Because of the wide variations in normal sleep patterns and development, the physician should avoid rigid expectations in counseling parents, but the following are some useful guidelines. A typical infant is able to sleep 6 to 8 hours through the night by age 2 months and 10 to 12 hours by age 6 months. The child usually no longer requires a morning nap by about 1 year of age and outgrows the afternoon nap around age 3. The total daily sleep requirement decreases with age, from 16 ½ hours at 1 week of age to 14 hours by age 1 year, 13 hours by age 2 years, 12 hours by age 3 years, 11 hours by age 5, and 10 hours by age 9 years (Blum and Carey, 1996).

An important aspect of preventing sleep problems is guidance regarding good sleep hygiene (Box 24-1). *Sleep hygiene* refers to the conditions that are most conducive to healthy, restorative sleep. Some children are reassured by a low-wattage night-light, but more light than that may disturb sleep. Parents of newborns should be counseled to put their infant to sleep supine rather than prone, unless

Box 24-1 Good Sleep Hygiene

Activities

No frightening TV or stories
No vigorous physical activities in the hour before bedtime
Consistent bedtime routine
Consistent soothing methods
Child put into bed awake

From Blum NJ, Carey WB. Sleep problems among infants and young children. *Pediatr Rev* 1996;17:87-92.

there is a specific medical indication to the contrary. This results from the association of the prone sleeping position with sudden infant death syndrome (SIDS) in young infants (Guntheroth and Spiers, 1992) (SOR: A). Many children rest better with a “transitional object,” a favorite blanket or toy. However, parents should avoid putting the child to bed with a bottle left in the mouth because it may lead to severe dental caries. Finally, the child should be put to bed awake, so that the child develops self-soothing skills to initiate sleep and resume sleep after nighttime disruptions.

About 20% to 30% of children and adolescents have sleep problems that are a serious concern to them and their families (Dahl, 1998). Problems with sleep initiation and nighttime awakenings are most common during infancy. Parasomnias and obstructive sleep apnea syndrome are most common in the 3- to 8-year-old group. Sleep deprivation, delayed sleep-phase syndrome, and narcolepsy are important considerations in the adolescent age group (Carskadon and Roth, 2000).

Besides sleep problems being common, family physicians need to be alert to these conditions because they have such a negative impact on many aspects of physical, mental, and social well-being. Sleep problems early in life are predictive of many later behavioral and emotional problems (Dahl, 1998). Children with frequent nighttime awakenings are at increased risk for physical abuse, perhaps because parents of these children show increased levels of fatigue, irritability, and depression.

The assessment and management of sleep problems in general should include consideration of potential sleep interrupters as primary causes or as exacerbators. One important category of interrupters is conditions that cause pain or itching (e.g., juvenile rheumatoid arthritis, migraine, atopic dermatitis). Another category is problems that lead to respiratory symptoms, including nocturnal asthma, gastroesophageal reflux (GERD), and obstructive sleep apnea.

Sleep Refusal

Toddlers often resist going to bed when their parents want them to go. Parents may have difficulty recognizing whether the resistance is related to true needs and fears or whether it is attention seeking or oppositional. The resistance often takes the form of repeated requests for a snack, a drink, or a trip to the toilet and may include fears of noises, shadows, or imaginary monsters.

A sleep diary can be helpful to sort out the etiology for the sleep refusal and direct management efforts. The parents record bedtimes and waking times for 2 weeks and indicate specific problem behaviors and their responses to each situation. Parents are often able to recognize patterns and problems themselves as they review the diary.

Many common refusal patterns can be addressed by focusing on the problem aspects of good sleep hygiene (Box 24-1). If the problem seems to be oppositional, the best approach is for parents to ignore it. If the child gets out of bed, a parent should place the child back in bed without conversation other than a firm, "It's time for bed." When the parents actively ignore their child's efforts to get attention, the behaviors often get worse before they improve. However, even persistent children eventually respond (Blum and Carey, 1996). If standard ignoring is too stressful on the family, a "gradual ignoring" technique is also effective (Reid et al., 1999) (SOR: B). This involves briefly checking on the child every few minutes until they are asleep and gradually lengthening the interval between checks.

For a child who is fearful, having parents ignore them may make the fears worse. A gradual withdrawal of the parent's presence after the bedtime routine works better. The parent may sit in the room while the child falls to sleep but should avoid lengthy discussion of the child's fears. Once the child is able to get to sleep without fear, the parent begins to move their chair closer to the child's door and eventually outside the bedroom. Fearful children who do not respond to this technique should be considered for referral for more intensive treatment similar to that applied toward phobias.

Night Waking

Most children wake up in the night but are able to get back to sleep without arousing their parents. The exceptions can have a serious impact on the entire family, as previously noted. As with sleep refusal, a sleep diary can help, and parent education regarding good sleep hygiene is beneficial. However, two common problems deserve particular attention: night terrors and nightmares (Table 24-1).

Night terrors come about as a sudden partial arousal from the deepest non-REM sleep. Essentially, part of the brain snaps into wakefulness, but part remains soundly asleep. Because deep non-REM sleep predominates in the first four hours of sleep, night terrors usually happen during the early part of the night. The child bolts upright in bed, screaming, sweating, tachycardic, and tachypneic. The episodes usually last only a few minutes, ending as abruptly as they began, with the child falling back to sleep quickly unless fully awakened by the parents. Not fully awake, these children do not respond to the parents' efforts to comfort them. The child appears disoriented and confused, often with a blank stare, and has no recall of the event the next morning. Night terrors

Table 24-1 Diagnostic Features of Night Terrors vs. Nightmares

| Feature | Night Terrors | Nightmares |
|---------------------|--|-----------------------|
| Time of night | Early; usually within 4 hours of bedtime | Late |
| State on waking | Disoriented or confused | Upset or scared |
| Response to parents | Unaware of presence; not consolable | Comforted |
| Memory of event | None, unless fully awakened | Vivid recall of dream |
| Return to sleep | Usually rapid, unless fully awakened | Often delayed by fear |
| Sleep stage | Partial arousal from deep non-REM sleep | REM sleep |

From Blum NJ, Carey WB. Sleep problems among infants and young children. *Pediatr* Rev 1996; 17(3):87-92.
REM, Rapid eye movement.

usually occur in children ages 2 to 6 years and are more common during times of illness, stress, or sleep deprivation. A nocturnal seizure should be considered in the differential diagnosis if the events are more likely right at sleep onset or if there is a personal or family history of seizures (Dahl, 1998).

Nightmares, on the other hand, are frightening dreams that awaken the child from REM sleep. Therefore, they tend to occur during the second half of the night, leaving the child upset or scared with a vivid recall of the dream. The child responds to comforting efforts by the parent but may be slow to go back to sleep because of fear. As with night terrors, nightmares occur most often during the toddler to preschool years and are more common during stressful times.

Management

In general, sedative medications are not indicated for night waking. Instead, behavior management techniques similar to those outlined for sleep refusal are appropriate for most cases.

There is no specific treatment for night terrors. Parents should be reassured with the explanation that the problem is common and self-limited. They should not try to wake the child up because this may only frighten the child or slow the child's return to sleep. For children who thrash violently, the parent should take precautions to provide protection for them. If the child sleepwalks into potentially dangerous situations, the parents can hang a bell or electronic movement alarm on the child's bedroom door to warn them. Because overtiredness is a major factor in the tendency to have night terrors, increasing the total amount of sleep and keeping a consistent sleep-wake cycle should be emphasized.

Because nightmares tend to occur at times of emotional stress, the focus of treatment should be on assisting parents with effective ways to manage the underlying stress. When a nightmare has occurred, the child is awake and frightened. The parent should comfort the child *without* a detailed review of the nightmare contents or "flashlight searches for monsters" (Blum and Carey, 1996) which can further increase the child's fears.

Obstructive Sleep Apnea Syndrome

Habitual snoring occurs in 3% to 12% of preschool-age children. The childhood incidence of obstructive sleep apnea syndrome (OSAS) is estimated to be 2%. The American Academy of Pediatrics has published an evidence-based guideline for the diagnosis and management of OSAS (AAP, 2002).

In children, OSAS is most often associated with large adenoids and/or tonsils, as well as specific facial features such as micrognathia, macroglossia, and Down syndrome. Unlike adults with sleep apnea, children can be affected without large drops in blood oxygen levels, because children can have frequent brief awakenings to quickly reestablish their airway. Thus, the primary clinical issue may be sleep fragmentation. In the context of a child with snoring and restless sleep, OSAS should be considered any time there are symptoms or signs suggesting sleep deprivation, such as difficulty paying attention, emotional lability, partial arousals during the night (night terrors, sleepwalking), or difficulty waking up in the morning (Dahl, 1998).

Because only a portion of children with snoring and adenotonsillar hypertrophy have OSAS, a sleep study is recommended to avoid unnecessary surgery. A caution, however, is that sleep studies in children require special expertise that may not be available at an adult sleep center.

Treatment of a child with OSAS on the basis of adenotonsillar hypertrophy is surgery. Continuous positive airway pressure (CPAP) is effective in children but is reserved for when adenotonsillectomy is contraindicated or unsuccessful (AAP, 2002) (SOR: A).

Sleep Deprivation and Delayed Sleep-Phase Syndrome

Sleep deprivation and delayed sleep-phase syndrome are common problems in adolescents for several reasons. The total sleep requirement is as much or more in adolescence as in pre-adolescence (Carskadon and Roth, 2000), but adolescents tend to receive less sleep for both biologic and cultural reasons. School-age children are more likely to be “larks,” preferring to wake up early even if they are up late at night. At puberty, a circadian rhythm change occurs that results in a switch from larks to “owls,” the preference for a late-night bedtime and late-morning awakening. This biologic tendency is encouraged by the availability of stimulating activities late into the night, whether social events, part-time jobs, or technologic advances (e.g., TV, Internet). Stimulants such as caffeine and tobacco also act to delay sleep. Despite these factors that act to delay sleep, school schedules often require the adolescent to awaken early. Thus, sleep deprivation develops. Also, jet lag–like shifts often develop between the weekday and weekend or holiday schedule. These schedule shifts probably play a role in the most common adolescent sleep problem, delayed sleep-phase syndrome (Dahl, 1998).

The assessment is by history. The main differential diagnosis to consider from delayed sleep-phase syndrome is the teenager who is choosing a late-night schedule for some secondary gain. This person is not distressed by the dysfunctional sleep pattern and is unmotivated to change it. Therefore, the adolescent with secondary gain requires treatment directed at the underlying school or family issues rather than the sleep disturbance.

Treatment of the cooperative adolescent involves attempting a schedule shift and consistently maintaining it. Those with marked difficulty initiating timely sleep may respond to staying awake through an entire night, then reestablishing a regular schedule. Mindell and Owens (2009) provide a practical clinical guide for pediatric sleep.

Narcolepsy

Although rare, narcolepsy is an important cause of daytime sleepiness because it can affect personal safety and school performance but is readily treatable. Normally, REM sleep only occurs when a person has been asleep for 60 to 90 minutes and follows all four stages of non-REM sleep. Narcoleptic patients, on the other hand, experience sudden episodes of REM sleep in the middle of a wakeful state or immediately after falling asleep.

The key feature of narcolepsy is recurrent *sleep attacks*: sudden, unintentional, irresistible bouts of sleep that occur in inappropriate situations, such as during conversations or while driving. Other common findings include *cataplexy* (sudden bilateral loss of muscle tone without loss of consciousness), *hypnagogic hallucinations* (vivid dreamlike imagery just before falling asleep), and *sleep paralysis* (inability to move or speak just after morning awakening). Any child or adolescent with unexplained daytime sleepiness who does not respond to initial management with good sleep hygiene, or who has a family history of narcolepsy, should be considered for evaluation. A sleep study is required to make the diagnosis.

Narcolepsy treatment combines behavioral approaches with medications. The patient should adhere to good sleep hygiene. Therapeutic naps enhance daytime alertness and reduce the necessary dose of stimulants. Stimulant medications, such as methylphenidate, dextroamphetamine, or modafinil are very helpful for daytime sleepiness (Vgontzas and Kale, 1999) (SOR: A). The antidepressants are REM suppressants that help prevent cataplexy or hypnagogic hallucinations. The nonsedating antidepressants, especially the selective serotonin reuptake inhibitors (SSRIs), work synergistically when combined with stimulants (Vgontzas and Kale, 1999) (SOR: B).

Autism

Key Points

- Autistic disorder has onset before age 3 years and is characterized by impaired social interaction, impaired communication, and repetitive, stereotyped patterns of behavior.
- Autism is *not* caused by thimerosal-containing vaccines.
- Standard developmental screening tests have poor sensitivity for autism.
- Early intervention with a multidisciplinary approach improves autism outcomes.

The term *autism* refers to a spectrum of pervasive developmental disorders characterized by various degrees of impaired social interaction and communication and repetitive, stereotyped patterns of behavior. Patients may have

relatively good skills in one area and very poor skills in others. The specific diagnosis of “autistic disorder” has an onset before 3 years of age and requires the presence of impairments in all three categories, whereas “Asperger’s disorder” includes impaired social interaction and autistic behaviors but excludes language delay. The incidence of autistic disorder is 5 to 20 per 10,000 persons, with a much higher occurrence among siblings of affected patients (3%-7%) (Schaefer and Mendelsohn, 2008). Mental retardation, typically in the moderate range (IQ 35-50), accompanies the disorder in 75% of affected children (DSM-IV-TR, 2000).

Evidence is mounting that both genetic and environmental factors influence the etiology of autism (Kolevzon 2007; Schaefer and Mendelsohn, 2008). Assertions that autism is caused by thimerosal-containing vaccines have been discounted by a comprehensive meta-analysis (Parker et al., 2004) (SOR: A).

Assessment

Developmental screening should be part of each well-child examination. The Denver Developmental Screening tools have often been used for this purpose but they lack sensitivity and specificity for autism. The AAP provides a thorough examination of screening instruments for autism (Johnson and Myers, 2007). A variety of screening tools aimed specifically at autism are available but also lack sensitivity (Bryson et al., 2003). Therefore, physicians should take parental concerns about delayed speech and language development seriously, especially beyond 18 months of age, even in the context of normal screening. In addition to delayed speech development, the other common presenting symptom is *challenging behavior*. The behaviors may include a violent reaction to minor changes in the environment or routine, stereotypic movements such as clapping or rocking, and preoccupation with narrow interests or inanimate objects.

When autism is suspected, a thorough evaluation should be performed, including appropriate intellectual testing, speech-language assessment, Autism Diagnostic Interview-Revised (ADI-R) (Western Psychological Services [WPS], 2003) and the Autism Diagnostic Observation Schedule (ADOS) (WPS, 2001). Because hearing loss can mimic autism, the evaluation should also include formal audiologic testing. Common comorbidities include anxiety, depression, and obsessional behavior (Prater and Zylstra, 2002). Many autistic patients develop *infantile spasms* in the first year of life, a severe seizure disorder.

Management

Early intervention is important because the younger children are treated, the better the outcome. The most successful programs utilize a multidisciplinary approach that includes behavior modification, development of social communication, active involvement of parents and families, and use of psychotropic medications for dangerous behaviors that do not respond to behavior modification (Myers et al., 2007). Referral to an established program is recommended. Despite anecdotal reports of efficacy of alternative and complementary treatments, none of these has shown benefit in clinically

controlled trials. Less than 5% of autistic people become self-sufficient adults, although one-third achieve some degree of independent living (Prater and Zylstra, 2002). Clear gain in language is the most important predictor of adult outcomes (Bryson et al., 2003)

KEY TREATMENT

Comprehensive treatments that address both the autistic child and the child’s parents are “possibly efficacious” per meta-analysis (Rogers and Vismara, 2008) (SOR: B). Risperidone effectively treats irritability, repetition, and social withdrawal in autism, with weight gain as the most prominent side effect (Jesner et al., 2007) (SOR: A).

Encopresis and Enuresis

See the discussion online at www.expertconsult.com.

Attention-Deficit/Hyperactivity Disorder

Key Points

- Consider ADHD in a child presenting with hyperactivity, impulsivity, inattentiveness, academic underachievement, or behavior problems.
- Use the DSM-IV-TR diagnostic criteria when assessing for ADHD.
- Obtain information from the parents, child, and teacher, using standardized behavior reports, if possible.
- When planning treatment, recognize that ADHD is a chronic condition for which medication only temporarily decreases symptoms and improves functioning.
- Stimulants are the first and second lines of medication treatment.

Attention-deficit/hyperactivity disorder (ADHD) is the most frequently diagnosed behavioral disorder of childhood, with a prevalence of 4% to 12% (DSM-IV-TR, 2000). At least 10% of behavior problems seen in a general pediatric practice are caused by ADHD. Boys are seen more frequently than girls. ADHD should be considered and assessed in a child who presents with inattention, hyperactivity, impulsivity, academic underachievement, or behavior problems (AAP, 2000; AHCP, 1999). ADHD is a chronic disorder persisting from childhood into adolescence and adulthood. In general, symptoms decrease by half every 5 years between ages 10 and 25 (Goldman et al., 1998). Obvious hyperactivity disappears while inattention persists.

Research suggests that ADHD has a central nervous system (CNS) basis; however, no specific etiology has been discovered. Family genetic studies have shown up to 92% concordance in monozygotic twins and 33% concordance in dizygotic twins. Clinicians should keep in mind that the child’s parents may also have ADHD. Various brain imaging studies of ADHD patients have demonstrated abnormalities of brain metabolism, supporting the validity of ADHD as a disorder. However, the strongest evidence of validity has been course prediction and treatment response to medication.

Box 24-2 DSM-IV-TR Diagnostic Criteria For Attention-Deficit/Hyperactivity Disorder**A. Either (1) or (2)**

1. Inattention: six (or more) of the following symptoms of inattention have persisted for at least 6 months to a degree that is maladaptive and inconsistent with developmental level:
 - (a) Often fails to give close attention to details or makes careless mistakes in schoolwork, work, or other activities
 - (b) Often has difficulty sustaining attention in tasks or play activities
 - (c) Often does not seem to listen to what is being spoken to directly
 - (d) Often does not follow through on instructions and fails to finish schoolwork, chores, or duties in the workplace (not due to oppositional behavior or failure to understand instructions)
 - (e) Often has difficulties organizing tasks and activities
 - (f) Often avoids, strongly dislikes or is reluctant to engage in tasks (such as schoolwork or homework) that require sustained mental effort
 - (g) Often loses things necessary for tasks or activities (e.g., school assignments, pencils, books, tools, or toys)
 - (h) Is often easily distracted by extraneous stimuli
 - (i) Often forgetful in daily activities
2. Hyperactivity-impulsivity: six (or more) of the following symptoms of hyperactivity-impulsivity have persisted for at least 6 months to a degree that is maladaptive and inconsistent with developmental level:

Hyperactivity

- (a) Often fidgets with hands or feet or squirms in seat
- (b) Often leaves seat in classroom or in other situations in which remaining seated is expected
- (c) Often runs about or climbs excessively in situations where it is inappropriate (in adolescents or adults, may be limited to subjective feelings of restlessness)
- (d) Often has difficulty playing or engaging in leisure activities quietly
- (e) Is often "on the go" or often acts as if "driven by a motor"
- (f) Often talks excessively

Impulsivity

- (g) Often blurts out answers to questions before the question has been completed
- (h) Often has difficulty awaiting turn
- (i) Often interrupts or intrudes on others (e.g., butts into conversations or games)

- B. Some hyperactive-impulsive or inattentive symptoms that caused impairment were present before seven years of age.
- C. Some impairment from the symptoms is present in two or more settings (e.g., at school [or work], and at home).
- D. There must be clear evidence of clinically significant impairment in social, academic, or occupational functioning.
- E. The symptoms do not occur exclusively during the course of a pervasive developmental disorder, schizophrenia or other psychotic disorder, and are not better accounted for by a mood disorder, anxiety disorder, dissociative disorder, or a personality disorder.

From American Psychiatric Association. *Diagnostic and Statistical Manual of Mental Disorders*, 4th ed, Text Revision (DSM-IV-TR). Washington, DC, American Psychiatric Association, 2000.

Comorbidity is common in ADHD; 65% of children diagnosed with ADHD have more than one psychiatric diagnosis (Biederman et al., 1991), including about 30% with more than one comorbid condition. Of children diagnosed with ADHD, 35% also have oppositional defiant disorder; 25% have conduct disorder; 18% have a depressive disorder; 25% have an anxiety disorder; and 12% to 60% have a learning disorder (AHCPR, 1999).

Assessment

There is no independent valid test to determine that a child has ADHD. The diagnosis can only be obtained reliably by using well-established diagnostic assessment methods. This involves using the standardized diagnostic criteria of the American Psychiatric Association's *Diagnostic and Statistical Manual of Mental Disorders* (DSM-IV-TR; Box 24-2), rather than the clinical description of the World Health Organization's *International Classification of Diseases* (ICD-9) (AHCPR, 1999). Unfortunately, only 30% of family physicians routinely use the DSM criteria (Rushton et al., 2004). This must be part of a comprehensive diagnostic evaluation that involves obtaining information from the parents, child, and teacher. The baseline assessment of target ADHD symptoms can be assisted by using standardized behavior reports, such as the Conners Rating Scales (1997 revision), NICHQ Vanderbilt forms, or the SNAP checklist. Broadband behavioral rating scales, such as the Child Behavior Check List (CBCL, Achenbach), do not effectively discriminate between ADHD and non-ADHD children but do assist in identifying comorbid disorders (AAP, 2000). Because of the significant prevalence of comorbid psychiatric disorders, the assessment should include inquiring about these conditions (AHCPR, 1999). In addition to psychiatric symptoms, the ability of the child to function normally in different domains must also be assessed. These domains include family relationships with adults, sibling relationships, peer social relationships, community behavior, school academic performance, school behavior, interests and play activities, and subjective psychological distress.

The physician should conduct a medical screening examination, including hearing and vision tests, if this has not already been done. Other diagnostic tests, including laboratory screening tests for lead intoxication, abnormal thyroid function, neuroimaging for brain tumor, or seizure disorder, should be conducted when indicated by the history and physical examination (AHCPR, 1999). Computerized continuous performance tests should not be used as a clinical screening or diagnostic tool for ADHD.

Management

The clinician should establish a comprehensive management program that recognizes ADHD as a chronic condition and works with the parents, child, and teachers to identify the most important problems as targets of treatment (AHCPR, 1999). Indications for referral to a specialist include (1) children with ADHD plus a comorbid psychiatric disorder and (2) children with ADHD who do not respond to initial treatment. More specific guidance in assessment and management may be obtained by consulting practice guidelines or parameters (AAP, 2000; McDonagh et al., 2009;

Pliszka et al., 2007) and health care guidelines (Moore, 2007; O'Brien, 2005). An initial effort must be made to educate the parents and child about ADHD (see Web Resources).

Psychosocial Therapy

The physician or staff should review techniques of parent behavioral management to assess how well they are understood and effectively implemented. This includes the proper use of positive reinforcers and punishment. A structured and standardized system, called the "token economy," can be very effective but requires considerable time and effort by the parents. Common mistakes made by parents include too much punishment versus positive reinforcement, too long a delay in receiving a reward, making the system too difficult initially so that the child never achieves success, inconsistent implementation, and poor supervision.

Assessing for proper educational placement is important. At a minimum, the parents should consult with the child's classroom teacher and confirm close supervision of the child, a structured classroom, good behavioral management, and good communication with parents. If this effort is not sufficient, the parents can request educational accommodations under Section 504 of the 1973 Rehabilitation Act. This federal law provides for special accommodations and services in a person with a chronic handicapping condition, including psychiatric disorder. The request must be accompanied by a physician statement documenting the handicapping condition and directed to the building principal or school district "Section 504 compliance officer." If this is not enough and the child is failing in one or more subjects, the parents can request a comprehensive evaluation by the Child Study Team for possible Special Education placement ("Other Health Impaired" eligibility condition—Federal Public Law 94-142, currently the Individuals with Disabilities Education Act, IDEA). The request should be in writing and directed to the building principal. The evaluation may take up to 85 school days but could result in an *individualized education program* (IEP), a description and contract of what special services the school will provide.

For children with ADHD alone, other psychosocial treatments have not been shown to be more effective than aggressive use of stimulant medication, or even to provide an additional benefit (MTA Cooperative Group, 1999). However, psychosocial treatments are beneficial in children with ADHD and other comorbid disorders or those from families with chaotic functioning.

Pharmacotherapy

The stimulants are the medications of first choice at any age (AHCPR, 1999); they do not have a paradoxical reverse effect at puberty. Methylphenidate was also shown to be beneficial for very young children with ADHD through the National Institutes of Mental Health (NIMH) Preschoolers with ADHD Treatment Study (PATS); however, the benefit was not as robust as in older children, and adverse effects were more prominent (Abikoff et al., 2007; Gleason et al., 2007). Table 24-2 provides measures for successful stimulant administration, and Table 24-3 lists specific dosing recommendations. Of ADHD children, 70% show significant

Table 24-2 Keys to Successful Pediatric Stimulant Administration

| Recommendation | Comment |
|--|---|
| Be aggressive with titration of medication. | Increase dose until benefit clearly seen or side effects prevent further dose increases. |
| Frequency of doses: cover the day as much as possible and normalize functioning as much as possible. | Give doses at breakfast, lunch, and after school, depending on duration of benefit of the specific stimulant. |
| Monitor closely the beneficial and adverse effects of medication. | Obtain information from both parents and teachers. Use standardized behavior report.* |
| See patients at least every 3 months for maintenance treatment. | Try to head off problems before they develop into serious ones. |
| Consider annual discontinuation of medication to see if it is still needed. | However, this is unnecessary if parents still see a clear worsening when medication wears off. |

*For example, NICHQ Vanderbilt Assessment Follow-up forms.

improvement on the first trial of a stimulant, and 85% to 90% improve significantly taking at least one of the listed stimulants. When the medication is in effect, motor activity decreases, certain cognitive processes improve, motivation improves, academic performance improves, and oppositional and aggressive behaviors decrease. However, the medication works only for as long as it is given, with no long-lasting or curative effect.

The physician should use a systematic approach. If the first stimulant is not effective after an adequate trial of maximum doses, a sequential trial of each available stimulant is appropriate before moving to another class of medication. At a minimum, at least one methylphenidate preparation and one amphetamine preparation should be tried. Follow-up appointments should be regular and scheduled and should include information from the parents, teachers, and child (AHCPR, 1999). Adverse effects are similar for all stimulants and can affect up to 20% of children. Important side effects include anorexia, weight loss, irritability (more likely in younger children), abdominal pain, insomnia (only if given after 5 PM), dysphoria (more likely in younger children), "behavioral rebound" after wearing off, impaired cognitive performance on laboratory tests (methylphenidate at single doses >1 mg/kg), tachycardia, and increased tic symptoms (if patient has tic disorder). In general, growth suppression is not a concern, except in children with dramatic anorexia. There is no evidence that the legitimate prescribed use of stimulants by ADHD children and adolescents lead to future drug abuse, and proper use may actually have a protective effect. Sudden death in children taking stimulant medication was recently a concern (Gould 2009). The U.S. Food and Drug Administration (FDA) issued a 2009 communication recommending caution but not stopping the use of stimulants for ADHD. A more definitive study involving 500,000 stimulant medication users is expected soon.

Table 24-3 Stimulant Medications Used in Treatment of Attention-Deficit/Hyperactivity Disorder (ADHD)

| Drug | Brand Name | Dosage Forms | Duration of Behavioral Effects | Suggested Dosage |
|--------------------|-----------------------------|---|--------------------------------|--|
| Methylphenidate | Ritalin regular Methylin | 5-, 10-, 20- mg tablet Methylin also in chewable tablet and solution | 1-4 hours | 0.6-2.0 mg/kg/day in divided doses FDA approved for use in children age ≥ 6 years PDR: 60 mg max dose |
| | Ritalin SR | 20-mg tablet | 3-9 hours | Titrate quickly up to 0.5 mg/kg in a single dose. Observe for benefit and titrate to max dose if necessary. |
| | Methylin ER | 10-, 20-mg tablet | — | — |
| | Ritalin LA | 10-, 20-, 30-, 40- mg tablet | 10-12 hours | — |
| | Metadate ER | 10-, 20-mg tablet | — | — |
| | Metadate CD | 10-, 20-, 30-, 40-, 50-, 60-mg capsule | 8-12 hours | — |
| | Concerta | 18-, 27-, 36-, 54-mg tablet | 12 hours | Child: up to 54 mg daily Adolescent and adult: 72 mg daily |
| Dexmethylphenidate | Daytrana skin patch | 10-, 15-, 20-, 30-mg patch | 9 hours while patch applied | — |
| | Focalin | 2.5-, 5-, 10-mg tablet | — | 0.3-1.0 mg/kg/day |
| Amphetamine salts | Focalin XR | 5-, 10-, 15-, 20-, 30-mg capsule | — | PDR: 30 mg max daily dose |
| | Adderall | 5-, 7.5-, 10-, 12.5-, 15-, 20-, 30-mg scored tablet | 6-8 hours | 0.3-1.0 mg/kg/day |
| Dextro-amphetamine | Adderall XR | 5-, 10-, 1-, 20-, 25-, 30-mg capsule | 10-12 hours | PDR: Max daily dose — child: 30 mg; adolescent/adult: 40 mg |
| | Dexedrine | 5-mg tablet | 1-8 hours | 0.3-1.0 mg/kg/day FDA approved for use in children age ≥ 3 years |
| Lisdexamfetamine | Dexedrine SR | 5-, 10-, 15-mg Spansule | 8-9 hours | PDR: 40 mg max dose |
| | Vyvanse | 20-, 30-, 40-, 50-, 60-, 70-mg capsule | — | Up to 70 mg daily |
| Methamphetamine | Desoxyn | 5-mg tablet | — | 0.3-1.0 mg/kg/day, typically 20-25 mg daily |
| | | CR tablets are no longer available. | — | Up to 40 mg in morning |

FDA, U.S. Food and Drug Administration; PDR, *Physicians' Desk Reference*; CR, controlled-release.

The third line of treatment (after two trials of stimulants) is atomoxetine, which has an FDA indication for the treatment of ADHD. It is initially given at 0.5 mg/kg/day, either in the early morning or as a divided dose (morning and late afternoon). It is titrated up to a maximum dose of 1.4 mg/kg/day (or 100 mg maximum). The full benefit may not be seen for 4 weeks (ICSI, 2005). Common adverse effects include nausea, vomiting, gastrointestinal pain, anorexia, headache, fatigue, and sleepiness. Atomoxetine is not a U.S. Drug Enforcement Administration (DEA) scheduled medication, has no potential for abuse, and therefore can be written with refills.

Bupropion, tricyclic antidepressants (TCAs, e.g., imipramine, nortriptyline), and the alpha-adrenergic agent clonidine do not have an official FDA indication for the treatment of ADHD. The evidence for their benefit is based on randomized controlled trials (RCTs) and nonrandomized trials with controls (ICSI, 2007). Two alpha agents, guanfacine and clonidine, in extended-release forms, have received FDA approval for treatment of ADHD. Further information can be found by referring to the Texas Children's Medication Algorithm Project (most recent algorithms, May 2006; see Web Resources), developed by expert consensus (Pliszka 2000). Atypical antipsychotic medication (i.e., risperidone), mood stabilizers (lithium,

KEY TREATMENT

The stimulants are the medications of first choice for ADHD at any age (AHCPR, 1999) (SOR: A)
 Although not a first-line drug, atomoxetine is effective for treatment of ADHD (Hammerness et al., 2009) (SOR: A).
 Behavioral treatments for children with ADHD are effective adjuncts to pharmacologic therapy (Fabiano et al., 2009) (SOR: A).

valproic acid), or clonidine can be used in children with comorbid severe aggression or suspected bipolar disorder after an adequate trial of a standard ADHD medication (Barzman and Sorter, 2009).

Oppositional Defiant Disorder**Key Points**

- The provider must establish a therapeutic alliance with both the child and the family to be successful in treating oppositional defiant disorder.
- The diagnosis of ODD is based on reports from the parents and child; carefully consider the possibility of comorbid conditions.
- The best treatment of ODD usually is parent training in behavior management techniques.
- Medication may be helpful in treating the symptoms of comorbid conditions.

The prevalence of oppositional defiant disorder (ODD) in children under 18 years old is widely reported as 2% to 16%. Before puberty, males outnumber females, but after puberty the rates are more equal. The disorder is usually evident by 8 years of age (APA, 2000). ODD is a chronic persistent disorder; however, approximately 67% of childhood cases have resolved 3 years later. About 30% of children with early-onset ODD develop conduct disorder (Connor et al., 2002).

The characteristics predisposing to ODD are biologic, social, and psychological, involving the parents and child. The parents usually employ poor, ineffective, inconsistent, and indiscriminate behavioral management methods, which are often combined with unusually harsh but inconsistent discipline and poor monitoring of activities. These children are usually temperamental, impulsive, active, and inattentive. The parents themselves are frequently immature, temperamental, and impulsive. The family members usually experience significant marital, financial, health, and personal distress (Barkley, 1997).

Assessment

There are two periods of developmentally normal oppositional behavior: the “terrible twos,” between 18 and 24 months of age, when the toddler behaves negatively as an expression of developing autonomy, and sometimes in adolescence, when the teenager is trying to separate from the parents and establish an autonomous identity. Unlike ODD, these stages usually last less than 6 months (see eBox 24-1).

A child with ODD reported by the parents may not show much oppositional behavior while being examined in the

office. The symptoms of ODD that these children display are much more evident in interactions with people and situations that they know well. The child takes a self-defeating position in arguments with adults. The struggle becomes more important than the reality of the situation, such that the child may be willing to risk losing the object or activity rather than lose the argument. Even a significant delay by the child in complying with a parental request is seen as a victory by the child. The assessment of ODD should include direct information from the child and parents regarding symptoms, age of onset, duration, and degree of functional impairment.

If oppositional behavior is confined mostly to school and not much at home (except as it relates to schoolwork), additional diagnoses must be considered in the differential, including mental retardation, borderline intellectual functioning, a specific developmental disorder (e.g., learning disability), and most often, ADHD. No specific laboratory tests or pathologic findings can assist the clinician in making the specific diagnosis of ODD.

Management

With methodologically sound RCTs lacking and recommendations based on clinical consensus, the appropriate psychosocial interventions for ODD include parenting training in behavior management techniques: improved parent/child relationship, positive reinforcement, closer supervision, giving more effective commands, time-out, and token economies. Despite the usually chaotic family situation and high emotions involved, the family physician needs to establish a therapeutic alliance with both the child and the family to have the best chance of success (Steiner and Rensing, 2006). Interventions should be family based, targeted to specific concerns, and oriented to problem solving. Traditional individual psychotherapy, unstructured/nondirected family therapy, or short-term treatment is usually not helpful. Psychoactive medications are used to treat comorbid conditions and targeted symptoms but have not demonstrated benefit for ODD alone. Intense and prolonged treatment may be necessary for severe and persistent ODD. One-time crisis interventions (e.g., “scared straight” attempts) are not effective.

Conduct Disorder**Key Points**

- Poorer prognosis for conduct disorder is associated with earlier age at onset, lower IQ, more conduct symptoms, greater frequency, and severity of symptoms.
- Suspect alcohol and drug use in a teenager with conduct disorder.
- Talking to the CD adolescent is not sufficient; collateral sources of information (parents, teachers, courts) are essential.
- Diligently search for another, more treatable condition, if it exists, because CD does not have effective treatment.
- Involvement by the juvenile court or placement outside the home may be the best option for some patients.

The prevalence of conduct disorder (CD) in children under 18 years old is 6% to 16% in males and 2% to 9% in females. At all ages, boys outnumber girls. Males usually exhibit more

aggression, whereas females usually commit more covert crimes and prostitution. CD is more common in urban than rural settings and is one of the most frequent diagnoses in outpatient and inpatient psychiatric facilities for children. The mortality rate for seriously disturbed delinquents is 50 times higher than for normal youths. Adolescents with CD are more likely to die by homicide, suicide, violent accident, or drug overdose.

Generally, the natural history of children with severe CD is marked by the development of ADHD at a very early age, followed by ODD, then finally the onset of CD. In adolescence, alcohol and substance abuse occur. The factors that determine a poorer prognosis in the patient with CD are an early age of onset of symptoms, greater number of symptoms, and greater frequency of expression of these CD symptoms. The factors that determine a better prognosis are minimum number of CD symptoms, absence of comorbid psychiatric diagnoses, and normal intellectual functioning. Characteristics more common in childhood-onset versus adolescent-onset CD are greater frequency of neuropsychiatric disorders, lower IQ, higher levels of aggression, male gender, and greater frequency of externalizing behavior disorders in other family members. From 25% to 40% of children with CD go on to develop *antisocial personality disorder*, a chronic pattern of lawlessness.

Current views posit an interaction among genetic, biologic, and environmental factors (i.e., parental, sociocultural, psychological, prolonged abuse). No single factor accounts for more than 50% of the variance in the occurrence of CD, and no combination of factors accounts for more than 70% of the variance. Many children with risk factors do not develop CD.

Assessment

The diagnostic criteria for CD are summarized in **eBox 24-2**. The clinician should not quickly accept the diagnosis of CD in a youth, because no specific effective treatment exists, and instead should diligently search for other, more treatable psychiatric conditions. Other psychiatric diagnoses that should be considered as the primary disturbance in a child presenting with CD symptoms include ADHD, ODD, intermittent explosive disorder, psychoactive substance use disorder, mood disorders (bipolar and depressive disorders), posttraumatic stress disorder (PTSD), dissociative disorder, borderline personality disorder, and adjustment disorder with disturbance of conduct. A manic episode must be seriously considered in a teenager presenting with frequent lying, physical aggression against others, impulsive sexual activity, stealing, sneaking out in the middle of the night, grandiosity, and persistent pervasive irritability.

The interview of an adolescent with CD is not sufficient, in itself, for the psychiatric evaluation. Lying is a common problem for these teenagers, as is conscious and unconscious underreporting of their problem behaviors. Other sources of information, including parents, teachers, other professionals, past records, and court personnel, are essential to obtain a valid evaluation. Complications seen in association with CD symptoms include impairment in school performance, poor social and family relationships, problems with the legal system, poor work performance, physical injuries from fighting or carelessness, sexually transmitted diseases, teenage

pregnancy, drug problems, suicide, and homicide. Common examples of interpersonal impairment in these children include suspiciousness or paranoia, misperception of others' actions as hostile, difficulty relating to peers and adults, lack of guilt, and lack of empathy.

Children with CD respond differently to punishment than normal children. The frequency of negative behavior of normal children decreases when they are punished, whereas the negative behavior of children with CD increases when they are punished.

There are no specific laboratory tests that assist in making the diagnosis of CD. However, the differential diagnosis for CD symptoms includes conditions for which tests may be important. These include head trauma, seizure disorder, birth injury to the brain, and encephalitis.

Management

One-time interventions affecting a single domain will be ineffective in treating CD. Interventions need to target all affected domains in a naturalistic setting for a long period in a consistent manner. Family interventions (parenting training/guidance, functional family therapy) and social skill training with a behavioral approach seem to be the most effective treatments for the CD patient (Dillon et al., 2007, Steiner, 1997). The focus should be on the child and the family. Individual therapy that focuses on problem-solving skills can also be useful. An environment with consistent rules and consequences is helpful. Proper school placement using behavioral techniques to encourage prosocial behavior and discourage antisocial incidents is appropriate.

Factors that can cause a cognitive-behavioral treatment program to fail include the following: the situation is "too hot to handle"; the youth is "too brittle"; the parents covertly support the youth's behavior; the parents have given up on the youth; the parents are inconsistent and are unable to supervise adequately; the program is poorly designed; rewards are too costly; or the parents have little social support. Factors that can interfere with limit setting of the child or adolescent at home include parental conflict, parental absence, parental psychiatric illness, inconsistent discipline, and vague or minimal expectations regarding appropriate behavior.

Several legal options are available if parents are unable to control their children. Most state laws have a special status that can be petitioned by the county district attorney to the juvenile court judge (i.e., Child/Person in Need of Care laws), that can allow the court to supervise the child by having hearings, placing a child on probation, mandating treatment and monitoring, or eventually taking the child away from the parents and placing the child in a residential treatment facility. However, some dangers must be kept in mind when teenagers with CD are confined to a juvenile detention facility. These patients prefer to be unrestricted and active; they can become depressed and at risk for impulsively attempting suicide when placed in confinement. Inpatient psychiatric hospitalization can be used to assess and initiate treatment for comorbid psychiatric disorders. A homicidal or suicidal patient can be stabilized and then moved to a less restrictive long-term setting. However, the stay is usually too brief to effectively treat CD itself.

Medications used as the sole treatment for conduct disorder have not been demonstrated to be effective. Psychoactive medications are used for the treatment of concurrent psychiatric disorders and concurrent target symptoms (aggression, impulsiveness, mood instability). Some of these medications are lithium, antidepressants, carbamazepine, propranolol, stimulants, clonidine, and antipsychotics (usually haloperidol). The physician should be cautious when prescribing medication to a youth with CD. Medication can be “cheeked,” sold or traded, hoarded, and taken all at once in an impulsive suicide attempt.

Eating Disorders

Key Points

- When considering a diagnosis of feeding disorder, consultation with a physician familiar with growth problems in children may be necessary because of the extensive differential diagnosis.
- Long-term mortality for anorexia nervosa is 6% to 20%, the highest rate for any psychiatric disorder.
- The most useful measure to assess for extreme weight loss in adolescents is age-adjusted BMI less than the fifth percentile.
- For anorexia nervosa, vomiting is a poor prognostic feature, as is purgative use for bulimia nervosa.
- Patients with eating disorders should be managed by a multidisciplinary team that includes a primary physician, mental health professional, and nutritionist.

The most common and most serious eating disorders, anorexia nervosa and bulimia nervosa, typically have their onset in adolescence. However, several eating problems are associated with infants and children as well.

Feeding and Eating Disorders of Infancy and Early Childhood

Feeding difficulties are common in infants and young children. Most are minor and self-limited and can be addressed through education and reassurance of caregivers. However, physicians must be alert for specific feeding and eating disorders that can lead to malnutrition or chronic toxicity from ingested substances. The most important of these are listed in DSM-IV-TR as “Feeding Disorder of Infancy or Early Childhood.” The diagnosis has previously been described as “psychosocial failure to thrive” and “psychosocial dwarfism.” The key feature of the diagnosis is that the child fails to gain weight appropriately over a prolonged time, which is not fully explained by a gastrointestinal, endocrinologic, or neurologic condition. Of children admitted to the hospital for failure to thrive, as many as half have a psychosocial etiology.

The other important consideration in this category is *pica*, the persistent eating of nonnutritive substances, such as hair, soil, paint, animal droppings, or sand. Pica can result in vitamin deficiencies, lead or other heavy metal intoxication, phytobezoars, and other complications. The prevalence of pica is not certain, but it is probably fairly common in preschool children, especially those with mental impairment.

The most important aspect in assessing feeding difficulties in infants and children is tracking height and weight with each office visit. Children who are not maintaining expected gains should be observed more closely, keeping in mind that a significant proportion of these children have a psychosocial basis. The diagnosis of feeding disorder is suggested by improvement in feeding and weight gain following a change in caregivers. When a diagnosis of feeding disorder is entertained, consultation with a physician familiar with growth problems in children should be considered, because the differential diagnosis for growth problems is extensive, and diagnostic implications include child abuse and neglect.

The important aspect to assessment of pica is to *ask*. Evaluation and treatment then depend on the specific substance ingested and symptoms the child exhibits, if any.

Anorexia Nervosa and Bulimia Nervosa

In adolescent girls, eating disorders are the third leading chronic illness, after obesity and asthma. The number of young people diagnosed with eating disorders (anorexia nervosa or bulimia nervosa) and eating disturbances (some but not all criteria for diagnosis of a “disorder”) is increasing, the result of a combination of improved recognition and reporting, as well as an apparent true increased incidence. About 95% of cases are female, and the prevalence of eating disorders has been directly correlated to the rates of dieting behavior. High-risk groups include female athletes and diabetic patients.

An individual with anorexia nervosa refuses to maintain a minimally normal body weight, is fearful of gaining weight, and exhibits a distorted body self-image. If she is postmenarchal, she is amenorrheic. The long-term mortality rate for anorexia nervosa is 6% to 20%, the highest rate for any psychiatric disorder (Roerig et al., 2002), often as an acute suicidal act rather than slow bodily destruction alone (Pompili et al., 2006). Bulimia nervosa is characterized by binge eating and inappropriate compensation attempts to avoid weight gain, such as self-induced vomiting, misuse of laxatives or diuretics, fasting, or excessive exercise. The prevalence of bulimia nervosa is 1% to 3% in adolescent and young adult women, more common but less often fatal than anorexia nervosa (DSM-IV).

Assessment

A prime objective in assessment is to distinguish “normal dieters” from individuals with eating disorders. In addition to the characteristics outlined in Table 24-4, patients with eating disorders have a pathologic reaction to weight gain. To explore this possibility, a useful question to ask is, “What would it be like to find you weighed one pound more next week when you get on the scales?” This may provoke an overly emotional response in a person with an eating disorder (Selzer et al., 1995).

Another important aspect to evaluation is to exclude certain medical conditions in the differential diagnosis as the primary cause of the symptoms. This includes such diverse problems as inflammatory bowel disease, hyperthyroidism, chronic infections, diabetes mellitus, and Addison’s disease. The erythrocyte sedimentation rate (ESR) and serum albumin tend to remain normal in patients with eating disorders,

Table 24-4 Characteristics of Normal Dieting vs. Eating Disorders

| Feature | Normal dieting | Eating disorder |
|---------------------------|---|---|
| Communication with others | Dieters tell those around them that they are dieting, seeing it as “something to be proud of.” | Dieters are reluctant to discuss their diets even when it is obvious to those around them that they are restricting their intake. |
| Intake regulation | They use internal cues and the rules of their diet plan. | They often use external cues, such as eating less than the person at the table who eats the least, to avoid feeling selfish or gluttonous. |
| Behavior | When weight loss goal achieved, they want to show off their “new body,” often in new and more revealing clothes or situations (e.g., new swimsuit, sunbathing). | They usually avoid exposing their bodies, often with baggy clothing, or regard their physical dimensions with disgust, no matter how much weight they lose. |
| Self-esteem | They exhibit a feeling of accomplishment and increased self-esteem when they achieve planned weight loss. | They tend to become self-critical, often depressed or irritable, and avoid social occasions. |

so an elevated ESR or a reduced albumin suggest an organic cause for weight loss (Selzer et al., 1995).

It is important to assess the acuteness and severity of malnutrition or fluid and electrolyte abnormalities. Indications for immediate referral include any patient with abnormal findings on physical examination or laboratory studies because these indicate severe and entrenched eating disorders. Laboratory studies should include a complete blood count, electrolytes, magnesium, calcium, phosphorus, urea nitrogen, creatinine, glucose, albumin, and electrocardiogram (Walsh et al., 2000).

Extreme weight loss is difficult to define in growing adolescents. The usual criteria of less than 85% of average body weight (ABW) and body mass index (BMI) less than 17.5 kg/m² used to diagnose anorexia nervosa in adults can be

misleading. The most clinically useful measure is BMI percentile adjusted for age (Hebebrand et al., 1996). A reading less than the fifth percentile is considered extreme (Selzer et al., 1995). Finally, for anorexia nervosa, the presence of vomiting is a poor prognostic feature, as is the use of purgatives for bulimia nervosa (Wilhelm and Clarke, 1998).

Management

Indications for inpatient management include “extremely low weight ($\leq 75\%$ of expected body weight) or rapid weight loss; severe electrolyte imbalances, cardiac disturbances, or other acute medical disorders; severe or intractable purging; psychosis or a high risk of suicide; and symptoms refractory to outpatient treatment” (Becker et al., 1999).

Patients with eating disorders should be managed by a multidisciplinary team that includes a primary physician, mental health professional, and nutritionist. Family physicians should be aware of the resources available in their area and should be prepared to refer any adolescent suspected of an eating disorder or with abnormal eating behaviors who does not respond to initial efforts at diet education. A valuable resource for developing a treatment plan is a practice guideline published by the American Psychiatric Association (Yager, APA Work Group, 2006).

Various antidepressants are effective for treatment of bulimia nervosa but have not shown definite benefit for anorexia nervosa. Cognitive-behavioral therapy has been shown to be the most effective psychological approach to bulimia nervosa (Berkman et al., 2006).

KEY TREATMENT

Primary prevention programs have greatly improved knowledge, but with “small net effects on reducing maladaptive eating attitudes and behaviors.” Studies targeted at high-risk groups produced greater benefits. “Concerns about iatrogenic effects of including psychoeducational material on eating disorders were not supported by the data” (Fingeret et al., 2006) (SOR: A).

“Anorexia nervosa (AN): The literature regarding medication treatments for AN is sparse and inconclusive. . . . Cognitive behavioral therapy may reduce relapse risk for adults with AN after weight restoration. Family therapy focusing on parental control of renutrition is efficacious in treating AN in adolescents” (Berkman et al., 2006) (SOR: B).

“Bulimia nervosa (BN): Fluoxetine (60 mg/day) reduced core bulimia symptoms in the short term. . . . The optimal duration of treatment is unknown. Cognitive behavioral therapy is effective in both short and long term” (Berkman et al., 2006) (SOR: A).

Patient-Centered Approach to the Well-Woman Examination

The well-woman examination is an opportunity for the family physician to promote health, prevent disease, and strengthen the physician–female patient relationship. Although women have traditionally been advised to see their doctors for an “annual examination,” which includes a Papanicolaou smear, new screening guidelines have widened the scope of the visit and deemphasized the Pap smear (which may not be needed on an annual basis). Building a trusting relationship is important because women may be more likely to volunteer sensitive problems with a physician they trust. In addition, some women may have had previous negative experiences with pelvic examinations.

Evidence-Based Screening Guidelines

Screening guidelines published by the U.S. Preventive Services Task Force (USPSTF) provide an evidence-based guide for family physicians to follow. Recommendations with A and B levels of evidence for adult women are included in Table 25-1. Unfortunately, many established components of the well-woman examination are not supported by evidence. Screening for intimate-partner violence, routine breast self-examination, testing for lipid disorders in average-risk women, type 2 diabetes screening, and physical activity counseling are examples of “uncertain” recommendations, according to the USPSTF. A physician may choose to cover these areas in a well-woman visit, but it is important

to ensure that the areas with stronger evidence of benefit are thoroughly discussed. USPSTF also lists areas of screening that have the potential to cause harm and therefore are not recommended. These include cervical cancer screening in women with previous hysterectomy for benign causes, screening for gonorrhea in low-risk women, and screening for ovarian cancer.

Immunizations are an important part of well-woman care. All patients benefit from disease prevention, and women are often caregivers for children or elderly persons, who are at higher risk from vaccine-preventable illnesses. Vaccines recommended by the U.S. Centers for Disease Control and Prevention (CDC) Advisory Committee on Immunization Practices (ACIP) include tetanus/diphtheria/pertussis (Tdap), herpes zoster, and influenza for adults over age 50 and human papillomavirus vaccine for women 26 and younger.

Pap Smear Guidelines

Key Points

- Pap screening should begin at age 21. Women should have Pap smears every 2 years.
- Women who have had a hysterectomy for benign disease should not have Pap smear screening.
- Women are not required to have a Pap smear before starting hormonal contraception.
- Women do not need a pap smear over age 65 if they have had normal results in the past.

Although the Pap smear is still the mainstay of cervical cancer screening, recent advances in the understanding of human papillomavirus (HPV) have revolutionized this field. HPV is the most common sexually transmitted infection (STI), with its highest prevalence among the 20- to 24-year-old age group (44.8%) (Dunne et al., 2007). Although HPV is typically spread through sexual activity, 5.2% of women in this study who reported that they had never had sex were infected with HPV. Physicians should keep in mind that some of these women may have been uncomfortable disclosing their sexual activity, even on an anonymous survey, whereas others may have had sexual contact they did not consider intercourse. Risk factors for

HPV infection include lifetime number of sexual partners, age at first intercourse, smoking, and lack of condom use (Burchell et al., 2006).

Strength of recommendation taxonomy (SORT) level A recommendations for cervical cancer screening include starting Pap test screening at age 21 and repeating every 2 years. "Low-risk women" are defined as those with three consecutive normal Pap tests, no history of cervical intraepithelial neoplasia type II (CIN-II) or higher, and no immunocompromise. A screening option for women age 30 and older is to perform Pap smear and HPV testing together, with repeat Pap tests every 3 years if both are normal. The recommendations for fewer Pap tests in women under 21 and over 30 are consistent with the epidemiology of HPV. Younger women acquire HPV infections more frequently, but most will clear the infection without intervention. Older women are less likely to develop new HPV infections, and only persistent HPV is a concern for cervical cancer. Women are not required to have a Pap smear before starting hormonal contraception. Physicians can use visits when a Pap test is not needed as an opportunity to educate female patients about STIs and reproductive health, as well as perform the other, evidence-based screening recommendations previously cited (ACOG, 2003).

Table 25-1 USPSTF Level A and B Recommendations for Adult Women

| Condition | Recommendation | SORT* |
|---------------------|---|-------|
| Alcohol misuse | Screening and behavioral counseling | B |
| High blood pressure | Office sphygmomanometry | A |
| Breast cancer | Mammogram, with or without clinical breast exam, every 1-2 years for women 40 and older | B |
| Pap smear | Screening at least every 3 years, starting within 3 years of sexual activity or at age 21 | A |
| Chlamydia | Women age 24 and younger who have ever been sexually active | A |
| Lipid disorders | Women age 45 and older at increased risk for heart disease | A |
| | Women age 20-45 at increased risk for heart disease | B |
| Colorectal cancer | Adults age 50-75, using fecal occult blood testing, sigmoidoscopy, or colonoscopy | A |
| Depression | Screening in adults as part of clinical practices with systems to ensure accurate diagnosis, effective treatment, and follow-up | B |
| Type 2 diabetes | Adults with blood pressure >135/80 mm Hg | B |
| Obesity | Screening adults; behavioral and counseling interventions | B |
| | Routine screening of women age 65 and older | B |
| Osteoporosis | Screening of women age 60 and older at increased risk | B |
| Tobacco use | Screening adults; cessation interventions | A |

US Preventive Services Task Force recommendations, available at www.ahrq.gov/clinic/uspstfix.htm.

*Strength of recommendation taxonomy (level of evidence).

Abnormal Pap Smear Management

Guidelines for management of abnormal Pap tests have also been updated to reflect understanding of the epidemiology of HPV infection (Wright et al., 2007). These guidelines include recommendations for the management of special populations, such as adolescents, pregnant women, and postmenopausal women, and are available online at the American Society for Colposcopy and Cervical Pathology (ASCCP) at www.asccp.org. Most women with low-grade squamous intraepithelial lesions (LSIL), atypical squamous cells of undetermined significance (ASCUS) with positive HPV testing, and high-grade SIL (HSIL) should have colposcopy.

Abnormal Vaginal Bleeding

Key Points

- Anovulation is common in adolescents.
- Bleeding disorders typically present as menorrhagia in adolescence.
- Anovulation is the most common cause of abnormal vaginal bleeding in reproductive-age women.
- The four most common causes of secondary amenorrhea are pregnancy, hyperprolactinemia, thyroid disorders, and iatrogenic.
- Evaluation of abnormal bleeding in women over age 35 should include an endometrial biopsy.
- Anovulatory women are at risk for endometrial hyperplasia or carcinoma from unopposed estrogen and should have regular progesterone-induced withdrawal bleeds.
- Any bleeding after menopause in a woman who is not taking hormone therapy is abnormal.
- Evaluation with an endometrial biopsy or a pelvic ultrasound can exclude endometrial cancer.

Normal menstrual bleeding is defined as regular vaginal bleeding that occurs at intervals from 21 to 35 days. A normal menstrual cycle begins with the follicular phase before ovulation and then the luteal phase after ovulation. Abnormal vaginal bleeding is a common complaint in primary care. The prevalence of some type of abnormal bleeding is 10% to 30% among women of reproductive age. The estimated annual direct and indirect costs of abnormal bleeding are \$1 and \$12 billion, respectively (Liu et al., 2007). Abnormal bleeding is also a common reason for women to be referred to gynecologists and is an indication for up to 25% of all gynecologic surgery (Goodman, 2000). A life cycle approach to abnormal vaginal bleeding is helpful in determining etiology and treatment options.

Adolescents

In adolescents the three most common presentations of abnormal vaginal bleeding are anovulation, menorrhagia, and amenorrhea. It is normal for menstrual cycles to be anovulatory for an average of 18 months after menarche in adolescents while the hypothalamic-pituitary axis matures. *Menorrhagia* (heavy bleeding) is quite common in adolescent patients and is most often caused by anovulation (Rimza, 2002). In some young women, however, menorrhagia at menarche can be a sign of a bleeding disorder. Up to 24% of adolescents with menorrhagia may have an undiagnosed bleeding disorder (Strickland, 2004). Evaluation of menorrhagia in adolescents includes a complete blood count (CBC), coagulation profile, and von Willebrand's screening test if clinically indicated. Treatment of both anovulation and menorrhagia in adolescents is usually hormonal contraception for cycle control.

The most common causes of primary amenorrhea include pregnancy, chromosomal abnormalities, (e.g., Turner's or Sawyer's syndrome); hypothalamic hypogonadism; congenital absence of the uterus, cervix, or vagina; and structural abnormalities (e.g., transverse vaginal septum or imperforate hymen). Evaluation of primary amenorrhea includes a careful history, pelvic examination, pelvic ultrasound to document the presence of pelvic organs, and chromosome analysis if clinically indicated.

Reproductive-Age Women

The most common causes of abnormal bleeding in reproductive-age women are pregnancy complications, anovulatory disorders, and benign pelvic pathology. Characteristics of ovulatory cycles include regular cycle length, presence of premenstrual syndrome (PMS) symptoms, and changes in cervical mucus. In contrast, anovulatory cycles tend to be unpredictable, with varying bleeding amounts and intervals.

Abnormal bleeding in ovulatory cycles includes menorrhagia, polymenorrhea, oligomenorrhea, and intermenstrual bleeding. Menorrhagia can be associated with structural lesions (uterine leiomyomas, endometrial polyps or hyperplasia), coagulation disorder, liver failure, or chronic renal failure. *Polymenorrhea* (bleeding at short intervals) can be caused by a luteal-phase disorder (not enough progesterone is produced after ovulation to stabilize the endometrium) or a short follicular phase. *Oligomenorrhea* (infrequent bleeding) is usually caused by a prolonged follicular phase.

Intermenstrual bleeding can be caused by cervical pathology (dysplasia or infection) or an intrauterine device (IUD). Evaluation of a woman with abnormal bleeding is based on the type of bleeding (Box 25-1).

Anovulation is the most common cause of abnormal vaginal bleeding in reproductive-age women. The majority of anovulation is related to hypothalamic abnormalities or polycystic ovarian syndrome (PCOS) (Box 25-2). By definition, anovulatory cycles are unpredictable and cannot be classified by any one type of vaginal bleeding pattern. A woman may experience 14 days of heavy bleeding one month, light spotting intermittently for the next month, and then go for 3 months without a cycle. The pathologic abnormality in these cycles is a lack of ovulation, which produces an unopposed-estrogen state. The lack of progesterone

Box 25-1 Clinical Evaluation of Reproductive-Age Woman with Abnormal Bleeding

Ovulatory abnormal bleeding

History, physical exam, pregnancy test

Menorrhagia

Consideration of liver function tests, BUN/Cr, CBC, coagulation profile
Pelvic ultrasound to exclude uterine fibroids
Endometrial biopsy (especially if over 35) to exclude endometrial hyperplasia

Intermenstrual bleeding

Pap smear, cervical cultures
Basal body temperature chart to determine length of follicular and luteal phases

Anovulatory bleeding

History, physical exam, pregnancy test

Laboratory studies

Thyroid-stimulating hormone level
Prolactin level
CBC (if acute bleeding episode or frequent heavy bleeding)
Fasting glucose and insulin levels
Screening for eating disorder, stress, and female-athlete triad

BUN/Cr, Blood urea nitrogen/creatinine; *CBC*, complete blood count.

Box 25-2 Causes of Anovulatory Cycles

Hypothalamic

- Weight loss
- Eating disorders
- Female-athlete triad
- Chronic illness
- Stress
- Excessive exercise

Polycystic ovarian syndrome

- Thyroid disorders
- Hyperprolactinemia
- Idiopathic chronic anovulation
- Medication induced (discontinuation of hormonal contraceptives)

production resulting from no ovulation contributes to irregular endometrial growth and non-uniform bleeding. In a normal cycle, the entire endometrium sloughs off during menstruation. In an anovulatory cycle, different sections of endometrium outgrow their blood supply at different times and bleed erratically.

Treatment of women with either ovulatory bleeding or anovulatory bleeding is not necessary unless the woman wants to become pregnant, is bothered by her bleeding pattern, or has systemic symptoms from anemia. However, anovulation is an unopposed-estrogen state, and treatment with some type of progesterone is necessary to reduce the risk of endometrial hyperplasia or carcinoma. *Unopposed estrogen* is a risk factor for endometrial cancer, along with obesity, diabetes, nulliparity, and age over 35. To protect against the development of endometrial hyperplasia, a precursor to endometrial cancer, all women with chronic anovulation should have a progesterone-induced withdrawal bleed at least four times a year (Albers et al., 2004). Women may take medroxyprogesterone acetate, 10 mg daily for 10 days, and then expect a withdrawal bleed within a few days of stopping the medication.

Treatment of abnormal bleeding consists of ovulation induction if pregnancy is desired or cycle control with hormonal contraceptives if it is not. In women who are not candidates for estrogen-containing contraceptives, a monthly cycling of progesterone or continuous administration of progestin contraception (e.g., depot medroxyprogesterone acetate or levonorgestrel IUD) can also be an effective treatment. For women who do not want to take hormonal medications, some nonsteroidal anti-inflammatory drugs (NSAIDs) can decrease the amount of bleeding (Ely et al., 2006) (Box 25-3).

Another common presentation of abnormal bleeding is an *acute bleeding* episode. In this situation, a woman is most likely anovulatory. Evaluation in an acute bleeding episode should include hemoglobin (Hb) and hematocrit (Hct), assessment of volume status, and an endometrial biopsy in women over 35.

If a woman presents with heavy bleeding and exhibits any signs or symptoms of *hypovolemia*, she should be admitted to hospital and either treated with intravenous (IV) estrogen to stop the bleeding or have a surgical procedure, such as dilation and curettage (D&C). If the woman is stable and her Hb and Hct are near normal, outpatient treatment with high-dose oral contraceptives (OCs), estrogen, or progesterone may be attempted (Ely et al., 2006).

A woman may also present with *amenorrhea*. The four most common causes of secondary amenorrhea (when a woman who previously had normal menses stops having menses for at least 6 months) are pregnancy, hyperprolactinemia, thyroid disorders, and iatrogenic (from medications). Other reasons for amenorrhea include outflow obstruction (e.g., Asherman's syndrome, caused by scarring of uterus from instrumentation, or cervical stenosis) and primary ovarian failure. Evaluation of a woman with amenorrhea begins with a history and physical examination. Laboratory studies should include a pregnancy test and thyroid-stimulating hormone (TSH) and prolactin levels. The next step is an induced withdrawal bleed after administering progesterone for 10 to 14 days. If a woman has a menstrual bleed after the progesterone, outflow obstruction and low estrogen state

Box 25-3 Treatment Options for Abnormal Vaginal Bleeding

Pregnancy desired

Ovulation induction with clomiphene citrate.
Referral to gynecologist.

Contraception desired

Cycle control with estrogen/ progestin method, depot medroxyprogesterone acetate, or levonorgestrel intrauterine device (IUD).

Acute bleeding episode

Outpatient

Administration of high-dose oral contraceptives (OCs), up to 4 pills daily for 5 to 7 days, with subsequent continuous OC cycling for at least a month.

Administration of oral estrogen or oral progesterone to stop the bleeding acutely.

Inpatient

IV fluids, supportive care, IV estrogen therapy.

Consultation for surgical intervention.

Contraception regimen used

Estrogen/Progestin

Supportive care for first 3 months.

Assessment of adherence to OC regimen.

Add supplemental estrogen.

Change to method with higher dose of estrogen or different class of progestin.

Progestin only

Add supplemental estrogen or combination OC.

Administer NSAID to decrease bleeding.

Modified from Ely JW, Kennedy CM, Clark EC, Bowlder NC. Abnormal uterine bleeding: a management algorithm. *J Am Board Fam Med* 2006;19:590-602; and Schragger S. Abnormal uterine bleeding associated with hormonal contraception. *Am Fam Physician* 2002;65:2073-2080.

IV, Intravenous; NSAID, nonsteroidal anti-inflammatory drug.

(as in primary ovarian failure) are excluded as the causes of amenorrhea. If a woman does not have a withdrawal bleed after progesterone administration, a trial of estrogen supplementation for 3 weeks should be given before another course of progesterone is attempted. In this situation, if a woman has a withdrawal bleed, the diagnosis of primary ovarian failure is considered, and levels of gonadotropins (FSH, LH) should be obtained. If a woman does not have a withdrawal bleed after estrogen and progesterone administration, a hysterosalpingogram (radiograph of uterus and ovaries after dye injection) should be obtained to evaluate for outflow obstruction.

Perimenopausal Women

Abnormal bleeding in the 5 to 10 years before menopause is very common. The most common pathology is anovulation caused by declining numbers of ovarian follicles and decreasing inhibin B levels (Jain and Santoro, 2005). Perimenopausal women may also bleed from structural lesions (most often uterine fibroid tumors) or bleeding disorders. Evaluation of a perimenopausal woman with abnormal

KEY TREATMENT

Unstable women with acute heavy vaginal bleeding should be admitted to hospital for IV estrogen therapy or surgical intervention.

Treatment of abnormal bleeding includes ovulation induction if a woman desires pregnancy and hormonal cycle control if she does not.

To protect against the development of endometrial hyperplasia, a precursor to endometrial cancer, all women with chronic anovulation should have a progesterone-induced withdrawal bleed at least four times a year (Albers et al., 2004).

If hemoglobin and hematocrit are near normal, outpatient treatment with high-dose oral contraceptives, estrogen, or progesterone may be attempted (Ely et al., 2006).

SOR: C.

bleeding should include an endometrial biopsy to exclude endometrial hyperplasia or cancer. The risk of endometrial cancer increases in women who are nulliparous, diabetic, or obese (Espindola et al., 2007). Nonsmoking women in this age group can be effectively managed with hormonal contraception for cycle control. Smokers can use cyclic progestin to provide a monthly withdrawal bleed.

Postmenopausal Women

Menopause is defined as 12 months without a menstrual period. After that 12-month period, any bleeding is abnormal. A large Danish study found a 10% prevalence of postmenopausal bleeding (Astrup, 2004). Bleeding episodes decreased as the time since menopause increased. The main concern in a postmenopausal woman with bleeding is endometrial carcinoma. Between 10% and 20% of all postmenopausal bleeding will be caused by malignancy (Hale and Fraser, 2007). Evaluation of postmenopausal bleeding can be done effectively with either a pelvic ultrasound or an office endometrial biopsy. A pelvic ultrasound can assess the thickness of the endometrium, the *endometrial stripe*. A stripe less than 4 mm in diameter is the cutoff to exclude endometrial cancer (Tabor et al., 2002). An office endometrial biopsy is an excellent diagnostic test to evaluate endometrial tissue (Dijkhuizen et al., 2000). In some postmenopausal women, however, cervical stenosis precludes a successful biopsy. In this situation, if the ultrasound is nonreassuring, a surgical procedure may be indicated.

Pelvic Mass**Key Points**

- Pelvic examination is not sensitive or specific for the diagnosis of a pelvic mass.
- Initial evaluation of a pelvic mass should include a focused history, physical exam, and pelvic ultrasound.
- Pelvic ultrasound with cyst morphology and Doppler flow studies can distinguish benign cysts from ovarian carcinoma, especially in postmenopausal women.
- Although combination oral contraceptives can reduce the risk of functional ovarian cysts, OCs are not useful for treatment.

Diagnosis

A patient may report a symptomatic pelvic mass, or it may be discovered as part of a pelvic examination or ultrasound done for other reasons. A pelvic mass can be associated with the uterus, ovaries, or nongynecologic organs. The first step in evaluation is to review the patient's age, history, and risk factors. For example, an ovarian cyst is more likely to be a functional cyst in a younger woman, but it has a higher potential to be ovarian cancer in postmenopausal women. Additional historical details include menopausal status, menstrual history, family history, STI risk, symptoms of hyperandrogenism, and dysmenorrhea.

Pelvic examination is not sensitive or specific for diagnosis of a pelvic mass, especially as body mass index (BMI) increases (Myers et al., 2006). However, pelvic examination can provide other information helpful in the diagnosis, such as location of the mass, mobility of the mass, cervical motion tenderness, pelvic tenderness, and vaginal discharge. Initial evaluation of a pelvic mass should include a pelvic ultrasound, which can be transabdominal or transvaginal, depending on the size and location of the mass. Premenopausal women should be tested to exclude pregnancy. Doppler ultrasound, cyst morphology, and CA-125 testing are useful in ruling out ovarian cancer in a postmenopausal woman with an adnexal mass. Table 25-2 lists the differential diagnosis and common features of pelvic masses.

Uterine Fibroids

Uterine fibroids are present in approximately one third of reproductive-age women (Viswanathan et al., 2007). Although often asymptomatic, fibroids may cause pelvic pain, pressure, and heavy or irregular vaginal bleeding and are the most common reason for hysterectomy in the United States. Treatment options for fibroids include watchful waiting, since most fibroids will decrease in size after menopause. Although hysterectomy is definitive treatment, it carries the risks of major surgery. Myomectomy and other uterine-sparing procedures have a high rate of symptom recurrence (up to 50% within 5 years) and may be more effective for symptom control in perimenopausal women. Women with fibroids are more likely to be infertile, although it is not clear if the association is causative. Removal of fibroids has not been shown to improve fertility (Griffiths et al., 2009). Medical treatments such as NSAIDs and OCs have not been well studied. The levonorgestrel intrauterine system (Mirena) has been shown to prevent hysterectomy in women with heavy vaginal bleeding related to fibroids, but women with more than three fibroids or with one fibroid larger than 3 cm were excluded from this study (Lahteenmaki et al., 1998). Low-dose mifepristone (5 mg daily for 26 weeks) was found to decrease symptoms and improve quality of life (Fiscella et al., 2006).

Ovarian Cysts and Carcinoma

As mentioned, the initial evaluation of an ovarian cyst includes a transvaginal ultrasound. Premenopausal women should have pregnancy testing, and postmenopausal women should have CA-125 testing. Simple cysts are more likely to be benign, whereas complex cysts (with thick walls, irregularity, papillations, septa, and echogenicity) have a higher risk of

Table 25-2 Differential Diagnosis of Pelvic Mass

| Diagnosis | Features |
|--------------------------------------|--|
| Uterus | |
| Uterine fibroid | Pelvic pressure, heavy vaginal bleeding |
| Intrauterine pregnancy | Positive pregnancy test, amenorrhea |
| Fallopian tubes | |
| Ectopic pregnancy | Positive pregnancy test, adnexal pain or tenderness, hemodynamic instability |
| Tubo-ovarian abscess | STI risk, pelvic pain, cervical motion tenderness, vaginal discharge, fever |
| Ovaries | |
| Simple cysts | More common in premenopausal women; sharp, may have pelvic pressure |
| Endometriomas | Dysmenorrhea |
| Dermoid cysts (teratomas) | Pelvic pressure |
| Ovarian carcinoma | Postmenopausal women |
| Polycystic ovarian syndrome | Hyperandrogenism, irregular menses, multiple cysts on ultrasound |
| Germ cell tumors | Pelvic pressure, chromosomal abnormalities, younger women (teens and 20s) |
| Intestines | |
| Appendicitis | Anorexia, right lower quadrant pain/tenderness, elevated white blood cell count, fever |
| Diverticulitis | Left lower quadrant pain/tenderness, cramping, constipation, older age, fever |
| Urinary tract | |
| Bladder tumor | Hematuria |
| Pelvic kidney | Usually asymptomatic |
| STI, Sexually transmitted infection. | |

malignancy. Malignant neoplasms also display increased vascularity on Doppler ultrasound. Women with complex cysts, cysts larger than 10 cm in diameter, or elevated CA-125 levels should have a surgical referral (Modesitt et al., 2003). Although combination OCs can reduce the occurrence of functional ovarian cysts, OCs are not helpful for treatment (Grimes et al., 2007).

KEY TREATMENT

Most simple ovarian cysts can be managed expectantly (Modesitt et al., 2003) (SOR: B).
 The levonorgestrel intrauterine system can avoid hysterectomy in some women with fibroids and heavy vaginal bleeding (Lahtenmaki et al., 1998) (SOR: B).
 Low-dose mifepristone decreases symptoms and improves quality of life (Fiscella et al., 2006) (SOR: B).

Vaginal Discharge

Key Points

- Douching is not helpful for prevention or treatment of vaginitis.
- Signs and symptoms of vaginitis are not specific, but a cause can usually be diagnosed on office microscopy.
- Speculum exam is not necessary for diagnosis of vaginitis; a blind swab in the vaginal vault is equally sensitive
- Self-diagnosis of vaginal infection by the patient is unreliable.

Vaginitis is the most common gynecologic diagnosis made in the primary care setting. Common symptoms include increased vaginal discharge without pelvic pain or systemic symptoms, vulvar itching and burning, dysuria, and possible odor. Physiologic leukorrhea varies and may change with a woman's menstrual cycle. If purulent cervicitis is present on examination, testing for *Chlamydia* and *Neisseria gonorrhoeae* should be performed (French et al., 2004). In postmenopausal women, vaginal irritation, dryness and superficial bleeding are often caused by atrophic vaginitis (see Menopause). A medication history is important because isotretinoin and some contraceptives may also cause dryness and itching. Personal hygiene habits of excessive washing with soap and use of highly absorbent panty liners may cause irritation. If a woman has self-diagnosed and treated with an antifungal and symptoms persist, a clinical examination should be encouraged (ACOG, 2006). Table 25-3 and Box 25-4 review differential diagnosis and findings in vaginitis.

Office microscopy is used most often to make a diagnosis of vaginitis. A finding of many leukocytes is uncommon in candidiasis or bacterial vaginosis (BV) and suggests trichomoniasis. If trichomonads are not present, consider gonorrhea or chlamydial infection (Anderson et al., 2004). Fem V, an over-the-counter (OTC) diagnostic kit, can be used; a positive test suggests BV or trichomoniasis; a negative test is likely a yeast infection (Prescriber's Letter, 2006).

Bacterial Vaginosis

Bacterial vaginosis is caused by a shift from the normal lactobacilli-dominated vaginal flora to a polymicrobial flora dominated by gram-positive anaerobes. Although BV is the most common cause of vaginal discharge and foul odor, more than half of women with BV are asymptomatic (CDC, 2006). BV is associated with postoperative infection, pelvic inflammatory disease (PID), premature delivery in women with certain risk factors (French et al., 2004), and an increased risk of human immunodeficiency virus type 1 (HIV-1) transmission (Oduyebo et al., 2009). Risk factors for acquisition of BV include tobacco use, intrauterine contraception (IUC) use, new male sexual partner, sex with another woman, and use of vaginal foreign bodies, perfumed soaps, or douching (Allsworth and Peipert, 2007).

The diagnosis of BV can usually be made by history and laboratory microscopy (Fig. 25-1). Self-diagnosis by the patient is unreliable (ACOG, 2006). A strong "musty cheese" odor predicts BV, whereas lack of a perceived odor makes BV unlikely (Anderson et al., 2004). Use of the Amsel criteria on a vaginal (not cervical) sample can be used to diagnose BV in clinical practice (Box 25-5).

Table 25-3 Comparison of Findings for Vaginitis

| Type | Symptoms | Signs | pH | KOH | Saline Wet Mount |
|-----------------------------|-----------------------|-------------------------------------|---------|-----------------------------|---------------------------|
| Bacterial vaginosis | Malodorous discharge | Thin, gray adherent discharge | >4.5 | Amine/fishy odor | Clue cells |
| Vulvovaginal candidiasis | Itching, burning pain | Curdlike discharge, vulvar erythema | 3.8-4.5 | Pseudohyphae; budding yeast | Occasional hyphae; yeast |
| Trichomoniasis | Fish-odor discharge | Erythema, tenderness | 6-7 | Negative | Trichomonads, many WBCs |
| Atrophic vaginitis | Dryness, pain | Pale, friable | >4.5 | Negative | RBCs, WBCs; many bacteria |
| Aerobic vaginitis | Foul odor | Heavy purulent discharge | >4.5 | Negative | Cocci or coarse rods |
| Irritant/allergic vaginitis | Itching, swelling | Erythema | Any | Negative | Negative |

WBCs, White blood cells; RBCs, red blood cells.

Box 25-4 Differential Diagnosis of Vaginal Discharge: Vaginitis

Candida spp. (*C. albicans*, *C. glabrata*)
 Bacterial vaginosis (anaerobic bacteria: *Gardnerella vaginalis*, *Bacteroides* spp.)
 Desquamative inflammatory vaginitis (DIV): aerobic bacteria
Trichomonas vaginalis
 Allergic vaginitis/contact dermatitis
 Chlamydial infection/gonorrhea
 Erosive lichen planus vaginitis
 Actinomyces Behçet's syndrome (associated with IUC use)
 Vulvar vestibulitis
 Physiologic (leukorrhoea)
 Atrophic vaginitis

IUC, Intrauterine contraceptive.

Box 25-5 Amsel Criteria for Bacterial Vaginosis*

1. Vaginal pH >4.5 (most sensitive) (89% sens, 74% spec)
2. Clue cells >20% on wet-mount (74% sens, 86% spec)
3. Homogeneous discharge, gray, adherent, but wipes off easily (79% sens, 54% spec)
4. Whiff test (amine odor when KOH added; 67% sens, 93% spec)

Modified from Gutman RE et al. Evaluation of clinical methods for diagnosing bacterial vaginosis. *Obstet Gynecol* 2005;105:551-556.

*A score of 3 of 4 is diagnostic.

sens, Sensitivity; spec, specificity; KOH, potassium hydroxide.

Figure 25-1 Bacterial vaginosis. Typical clue cells of vaginal epithelium are heavily covered by coccobacilli, with loss of distinct cell margins. (Magnification $\times 400$). (From Holmes KK. *Lower genital tract infections in women: cystitis/urethritis, vulvovaginitis, and cervicitis*. In Holmes KK, Mårdh PA, Sparling PF, et al [eds]. *Sexually Transmitted Diseases*. New York, McGraw-Hill, 1984.

There are many effective options for the treatment of BV. A 2009 Cochrane review states that clindamycin and metronidazole have equivalent efficacy, regardless of regimen. The standard oral dose of metronidazole for BV is 500 mg

twice daily for 7 days. Both metronidazole and clindamycin vaginal cream are dosed daily. Clindamycin has lower adverse event rates. Intravaginal lactobacilli gelatin tablets are also effective (Oduyebo et al., 2009). The 2006 CDC guidelines do not recommend treatment with single-dose metronidazole. Tinidazole is effective with no serious side effects but is more expensive (Livengood et al., 2007). The FDA has recently approved metronidazole, 750 mg daily for 7 days, and a single dose of intravaginal clindamycin for treatment of BV, but only limited data are available on efficacy (CDC, 2006). Hydrogen peroxide douching and triple-sulfonamide cream are considered ineffective (Oduyebo et al., 2009).

Recurrent BV can present a treatment challenge. If recurrence is suspected, the diagnosis should be confirmed, risk factors identified and controlled, and other causes considered while re-treating BV (Alfonsi et al., 2004). Metronidazole gel used twice weekly reduces recurrence of BV but is offset by increased vaginal candidiasis and pain complaints. (Sobel et al., 2006). If re-treatment fails, suppressive therapy with metronidazole 0.75% gel for 10 days, then twice weekly for 4 to 6 months, should be tried. There is no evidence that treatment of sexual partners (BASHH, 2006) or using oral or vaginal *Lactobacillus acidophilus* is effective to prevent recurrence (Alfonsi et al., 2004).

Candidal Vaginitis

Vulvovaginal candidiasis (VVC) is the second most common cause of vaginitis after BV, with a lifetime prevalence in women of 70% to 75% (Spence, 2007). *Candida albicans* is the most common etiology (80%-90%). Type 1 diabetes

KEY TREATMENT

All symptomatic women with BV should be treated (BAASH, 2006). Asymptomatic women undergoing abortion or hysterectomy should be treated to decrease the risk for infectious complications (BAASH, 2006). Oral or vaginal metronidazole (BAASH, 2006) and vaginal clindamycin are effective and equivalent in nonpregnant women (Kane, 2001). Treatment of male partners does not decrease relapse rates (BASHH, 2006). Tinidazole is effective with no serious side effects but is more expensive than metronidazole (Livengood et al., 2007) (SOR: A). In recurrent BV, suppressive therapy with metronidazole 0.75% gel for 10 days then twice weekly for 4 to 6 months may be successful (Alfonsi et al., 2004) (SOR: C).

is the strongest risk factor for VVC; other risk factors include recent antibiotic use, condom and diaphragm use, spermicide use, receptive oral sex, OC use, pregnancy, and immunosuppression. Patient self-diagnosis of VVC is incorrect 50% of the time and is therefore unreliable. Asymptomatic treatment of VVC is *not* recommended, even in women who have a positive swab for *Candida* (Spence, 2007). Because VVC is not sexually transmitted, routine partner treatment is also not recommended. Recurrent VVC is defined as four or more symptomatic episodes in a year. Rare complications of VVC include vulvar vestibulitis and chorioamnionitis (French et al., 2004).

The most common complaint associated with culture confirmed VVC is burning or pruritus. A thick, curdled-appearing discharge, signs of inflammation, and lack of odor all have high positive predictive value for diagnosing VVC (Anderson et al., 2004). In one study, however, a thin discharge was present in about half of women, later found to have VVC (French et al., 2004).

Although office microscopy is the first line for diagnosis of VVC, culture is the “gold standard” (Fig. 25-2) (ACOG, 2006). With *Candida albicans*, the vaginal pH is usually 5.0 or less but may be higher with non-*albicans* species. A wet mount should be performed to exclude trichomoniasis or BV. Potassium hydroxide (KOH) examination should also be performed, but it has a wide range of sensitivity. Thus, if candidiasis is suspected in a patient with persistent or recurrent symptoms and a wet mount and KOH are negative, a culture should be performed (French et al., 2004). The use of rapid antigen testing to detect vaginal yeast is more sensitive than a wet mount and is feasible for office practice. However, a negative result lacks sensitivity to rule out yeast, and a culture needs to be sent (Chatwani et al., 2007).

The imidazoles are the cornerstone of VVC treatment. Intravaginal OTC imidazoles (e.g., clotrimazole, miconazole, tioconazole) come in 1-, 3-, and 7-day therapy regimens and are equivalent to oral therapies for treatment, and single-dose therapy seems as efficacious as multidose therapy over days. The comparative efficacy of different azoles and of different durations of multidose regimens is unclear (Spence, 2007). *Lactobacillus*, administered vaginally, orally, or both, does not prevent postantibiotic-associated vaginal candidiasis (Priotta et al., 2004).

Recurrent VVC occurs in 5% to 8% of women. The Infectious Diseases Society of America recommends treating recurrent VVC for 10 to 14 days, followed by suppressive therapy using fluconazole, a single 150-mg dose weekly for

Figure 25-2 Candidal vaginitis (vulvovaginal candidiasis). Candidal organisms in a saline wet-mount preparation clearly demonstrate hyphae and conidia under high-power magnification.

(From Kaufman RH, Faro S: *Benign Disease of the Vulva and Vagina*, ed 4. St. Louis, Mosby, 1994.)

6 months (Pappas et al., 2009). It is unclear if oral regimens are better than intravaginal administration. In preventing recurrence, there is no evidence of benefit with intravaginal boric acid, tea tree oil, garlic, oral yogurt, douching, or treating a woman’s male sexual partner. Douching is associated with increased pelvic infections (Spence, 2007). For specific treatment regimens: see <http://www.cdc.gov/std/treatment/>.

KEY TREATMENT

Oral fluconazole and itraconazole are both effective for vulvovaginal candidiasis (Spence, 2007) (SOR: A). Oral and intravaginal regimens are equivalent, so cost and patient preference should guide choice (Nurbhai et al., 2009) (SOR: B). Intravaginal imidazoles are equivalent to oral therapies for VVC treatment, and single-dose seems as efficacious as multidose therapy (Spence, 2007) (SOR: B). Treat recurrent VVC for 10 to 14 days, followed by suppressive therapy using fluconazole, single 150-mg dose weekly for 6 months (Pappas et al., 2009) (SOR: A)

Trichomoniasis

Trichomoniasis is caused by a motile protozoan and affects 120 million women worldwide every year. It is usually sexually transmitted and is associated with transmission of other

STIs (Forna, 2009). Risk factors for acquisition include multiple sexual partners and possibly a decrease in the normal vaginal acidity. Men are usually asymptomatic carriers, but 10% of nongonococcal urethritis in men is caused by *Trichomonas* (French et al., 2004).

Up to 50% of women with trichomoniasis are asymptomatic. Symptomatic women may complain of a yellow-green, malodorous discharge, vaginal burning, and dysuria. On physical examination, hemorrhagic, punctate cervical lesions are pathognomonic but are only present in 2% of cases (French et al., 2004). More common signs are foul-smelling purulent discharge, vaginal tenderness, vulvar erythema and edema. The vaginal pH is usually basic. Office microscopy is first line for diagnosis of trichomoniasis (ACOG, 2006). The sample should be taken from the posterior vault, diluted in 2 drops of saline, and assessed quickly because motility of the protozoa diminishes rapidly (Fig. 25-3). Although microscopy has good specificity (99%), motile trichomonads are seen in only 50% to 80% of culture-proven cases. Thus, culture is the gold standard. Trichomonads can be reported on a Pap smear, but it is not recommended as a diagnostic test because of the low sensitivity (58%) (French et al., 2004). In men the wet prep has poor sensitivity, so culture of both a urethral sample and a first-voided urine sample is necessary to increase the diagnostic rate.

Metronidazole or tinidazole single-dose therapy is effective for treatment of trichomoniasis. An alternative effective regimen is metronidazole, 500 mg orally twice daily for 7 days. Metronidazole gel is less effective (<50% cure rate) as compared to oral metronidazole (CDC, 2006). Desensitization is recommended for patients allergic to metronidazole. Avoidance of alcohol is important with all nitroimidazoles. Metronidazole is not teratogenic in the first trimester (BASHH, 2007). Because most male sexual partners have asymptomatic trichomoniasis, simultaneous treatment is recommended.

If treatment fails with a 2-g single dose of metronidazole, a trial of metronidazole, 500 mg twice daily for 7 days, or a single 2-g dose of tinidazole is recommended (CDC, 2006). If this fails, a trial of tinidazole or metronidazole, 2 g orally once daily for 5 days, is recommended. Referral is advised for persistent failure. A test of cure is unnecessary if symptoms resolve (BASHH, 2007).

KEY TREATMENT

Women with trichomoniasis should abstain from intercourse until both she and her partner have been treated and are asymptomatic (ACOG, 2006) (SOR: A).

A single dose of a nitroimidazole can achieve parasitologic cure; tinidazole as a single 2-g dose may be most efficacious (CDC, 2006; Forna, 2009) (SOR: A).

If treatment fails with a single 2-g dose of metronidazole, a trial of metronidazole, 500 mg twice daily for 7 days, or a single 2-g dose of tinidazole is recommended (CDC, 2006) (SOR: B).

Other Forms of Vaginitis

Aerobic vaginitis is characterized by purulent vaginal discharge with a dominant abnormal aerobic flora. Patients experience a foul-smelling nonfishy discharge, and examination may reveal erythema, inflammation, and ulcers of the posterior fornix. Although culture is the gold standard, the diagnosis is usually one of exclusion, with pH greater than 6.0, white blood cells (WBCs) on microscopy, and absence

Figure 25-3 Trichomoniasis. Trichomonads are seen under high-power magnification in a wet mount prepared with physiologic saline. Usually, more immature epithelial cells are seen in the secretions of active trichomoniasis. (From Kaufman RH, Faro S. *Benign Disease of the Vulva and Vagina*, 4th ed. St Louis, Mosby, 1994.)

of hyphae or clue cells. Treatment with topical clindamycin has a good response (French et al., 2004). The addition of a topical estrogen may increase treatment success.

Irritant and allergic vaginitis should be considered in the differential diagnosis of vaginal complaints. Common etiologies include spermicidal products, douching solutions, diaphragms, latex condoms, and topical medications. The treatment is discontinuation of intravaginal products (French et al., 2004).

Cytolytic vaginitis is caused by an overgrowth of lactobacilli and cytolysis of squamous epithelial cells. Although it may be related to intravaginal products or other medication use, its etiology remains unclear. It can mimic VVC with a white, curdled-cheese discharge, and the pH range is typically 3.5 to 5.5. Treatment is discontinuation of intravaginal medications. Baking soda douches or sitz baths have been used, but minimal data exist to support this recommendation (French et al., 2004).

Desquamative inflammatory vaginitis (DIV) is characterized by copious purulent discharge with squamous epithelial cell exfoliation. The etiology is unclear but likely multifactorial. Some cases may be linked to lichen planus spectrum. Laboratory evaluation reveals a negative wet mount, KOH, and cultures. Treatment options include a trial of local or systemic corticosteroids (French et al., 2004) or clindamycin suppositories.

Vulvar Lesions

Key Points

- Visible condyloma should be treated.
- Biopsy is indicated for treatment-resistant warts, chronic symptomatic lesions, and nevus-like, pigmented lesions.
- Biopsy of lichen sclerosus is recommended to rule out vulvar squamous cell carcinoma.
- Topical corticosteroids are the cornerstone of management for nonneoplastic epithelial disorders of the vulva.

The differential diagnosis of vulvar lesions includes external genital warts (EGWs), *Candida*, herpes simplex, lichen sclerosus et atrophicus, lichen planus, psoriasis, and eczema.

EGWs are caused by HPV, which is primarily transmitted through sexual contact. Although exophytic warts are usually diagnosable with the naked eye, application of acetic acid can make flat warts visible. Biopsy is indicated for treatment-resistant warts, chronic symptomatic lesions, and nevus-like, pigmented lesions. For EGWs, cryotherapy is as effective as trichloroacetic acid and more effective than podophyllin. Podophyllotoxin and podophyllin are equally effective for clearance of EGWs and useful for small, solitary lesions. Imiquimod cream is also effective and should be applied to intact skin. Topical interferon is effective and preferable to systemic interferon. Electrosurgery is at least as effective as cryotherapy and more effective than podophyllin (Buck, 2006).

Nonneoplastic epithelial lesions of the vulva include lichen sclerosus, lichen planus, and lichen simplex chronicus. *Lichen sclerosus* is most common in postmenopausal women and presents with intense vulvar pruritus. Physical examination initially reveals thickened, white skin not involving the vagina, which progresses to a thin, wrinkled, "cigarette paper" appearance. High-potency topical steroids are effective in alleviating symptoms and preventing progressive architectural damage. *Lichen planus* is an autoimmune disorder that may involve the vagina as well as vulva. High-potency topical steroids or hydrocortisone suppositories are effective for treatment. *Lichen simplex chronicus* presents as lichenified, erythematous plaques resulting from chronic itching and scratching. Breaking the itch-scratch cycle is the cornerstone of treatment (O'Connell et al., 2008).

KEY TREATMENT

For external warts, cryotherapy is as effective as trichloroacetic acid and more effective than podophyllin; electrosurgery is at least as effective as cryotherapy and more effective than podophyllin (Buck, 2006) (SOR: B).

For lichen sclerosus, high-potency topical steroids are effective in alleviating symptoms and preventing progressive architectural damage (O'Connell et al., 2008) (SOR: B).

For lichen simplex chronicus, breaking the itch-scratch cycle is primary treatment (O'Connell et al., 2008) (SOR: C).

Acute Pelvic Pain

Key Points

- Acute pelvic pain can be related to multiple organ systems.
- Gynecologic pain typically includes pregnancy complications, infection, and ovarian cysts.
- Clinicians should have a low threshold for treating pelvic inflammatory disease because of the potential for long-term complications.

Acute lower abdominal pain can be caused by multiple organ systems. Urinary tract infections (UTIs) are often associated with pain over the bladder related to dysuria, frequency, and urgency of urination. Gastrointestinal causes of lower abdominal pain include acute appendicitis, diverticulitis, irritable bowel syndrome, and ischemic bowel.

Gynecologic causes of acute pelvic pain are usually related to complications of pregnancy, infections, or ovarian pathology. *Ectopic pregnancy* is a serious cause of acute pain in the context

of an early pregnancy. Ectopic pregnancy should be suspected when the quantitative human chorionic gonadotropin (hCG) level does not increase appropriately, or if hCG level is greater than 1500 mIU and transvaginal ultrasound does not show an intrauterine gestational sac. The dilation of the fallopian tube caused by the growing embryo is the etiology of the pain. Emergent treatment with either medication or surgery is necessary to prevent rupture of the tube. Ectopic pregnancy is usually diagnosed by ultrasound. Treatment of an ectopic pregnancy can be surgical or medical. Single-dose methotrexate is the most frequently used regimen, 50 mg/m² of body surface intramuscularly, but no studies have compared efficacy between single-dose and multidose therapies (Lozeau and Potter, 2005). Degenerating fibroid tumors may also cause pain as a result of ischemia during pregnancy, usually in the second trimester.

Pelvic infections such as acute cervicitis and *pelvic inflammatory disease* (PID) can cause pain associated commonly with abnormal vaginal discharge and systemic symptoms of infection. On examination, most women will have a purulent cervicitis, a tender uterus, and cervical motion tenderness. Both outpatient and inpatient treatment options are available from the CDC STI treatment guidelines, at www.cdc.gov (2006). Outpatient treatment of PID usually includes intramuscular (IM) ceftriaxone and doxycycline for 10 days to cover both *Neisseria gonorrhoeae* and *Chlamydia*. Untreated PID can lead to an abscess or scarring that can cause infertility. Clinical diagnosis of PID has a positive predictive value of 65% to 90% (BAASH, 2005). Therefore, clinicians should have a low threshold for treating women with suspected PID.

Ovarian cysts are common and often cause no pain. When cysts rupture, however, women will experience acute pelvic pain from peritoneal irritation. Large ovarian cysts are more likely to undergo torsion and can cause pain from ischemia.

KEY TREATMENT

Medical and surgical treatments for ectopic pregnancy are equivalent when patient selection is appropriate (Lozeau and Potter, 2005) (SOR: B).

Single-dose methotrexate is the most common regimen (50 mg/m² body surface IM) for ectopic pregnancy (Lozeau and Potter, 2005) (SOR: C).

Clinicians should have a low threshold for treating women with suspected PID because of potential long-term consequences (BAASH, 2005) (SOR: C).

Chronic Pelvic Pain

Key Points

- Chronic pelvic pain is an indication for 40% of the laparoscopies in the United States.
- The four most common causes of chronic pelvic pain are endometriosis, pelvic adhesions, interstitial cystitis, and irritable bowel syndrome.
- Up to 70% of women with chronic pelvic pain have more than one cause for their pain.

Chronic pelvic pain is defined as noncyclic pain that lasts longer than 6 months. It occurs frequently, affecting up to 15% of all women at some point in their reproductive years. Chronic pelvic pain is a diagnosis associated with up to 10%

of all outpatient gynecologic consultations, 40% of all laparoscopies, and 18% of all hysterectomies performed each year in the United States (Zondervan and Barlow, 2000). In 1990 the estimated cost of services related to chronic pelvic pain was \$2 billion (Reiter, 1990).

Almost half of all women with chronic pelvic pain have a history of past sexual abuse or depression (Latthe et al., 2006). Women with a history of trauma have more severe symptoms (Meltzer-Brody et al., 2007). A recent meta-analysis of women with a history of abuse found an increased prevalence of functional bowel disorders, nonspecific chronic pain, and chronic pelvic pain (Paras et al., 2009). Drug and alcohol abuse are associated with an increased likelihood of pain (Latthe et al., 2006). There is no difference in prevalence based on race, ethnicity, education, or socioeconomic status (ACOG, 2004).

The etiology of chronic pelvic pain is frequently multifactorial and comes from multiple organ systems. Up to 70% of women have more than one cause of pain (Butrick, 2007). The most common gynecologic causes of chronic pelvic pain are endometriosis and pelvic adhesions. The most common gastrointestinal cause is irritable bowel syndrome, and the most common urologic cause is interstitial cystitis (Bordman and Jackson, 2006). In addition, many women who have chronic pelvic pain also have some myofascial pain from the pelvic floor muscles (Box 25-6).

Initial evaluation of a woman with chronic pelvic pain includes a careful history to determine any pattern of the pain that would lead to a possible diagnosis. For example, history of abdominal surgery increases the risk of pelvic adhesions. A complete medical, surgical, family, sexual, and psychological history should also be completed. It is important to determine how the pain is affecting the woman's daily life. The physical examination should include a general exam in addition to a thorough pelvic assessment. Every effort should be made to replicate the pain through a bimanual or rectovaginal examination.

Laboratory evaluation is focused on the likely diagnosis. Many women have a pelvic ultrasound for further evaluation of the pelvic anatomy. Ultimately, many women undergo a diagnostic laparoscopy to evaluate the etiology of the pain. Laparoscopy is normal in 35% to 40% of these women. Endometriosis is diagnosed in about 30% of women at laparoscopy, and adhesions are diagnosed in about 25% (Howard, 2000).

Treatment of a woman with chronic pelvic pain should be multimodal to address the multifactorial nature of her pain (ACOG, 2004; Stones et al., 2009). A strong physician-patient relationship is imperative as a basis for successful treatment. First-line treatment includes pain control with nonnarcotic medication. Hormonal manipulation with medroxyprogesterone acetate, combined hormonal contraception, or gonadotropin-releasing hormone (GnRH) analogues can be effective treatments for endometriosis-related pain. GnRH analogues can only be used for up to 6 months because of side effects (e.g., menopausal symptoms, osteoporosis).

Laparoscopic treatment of endometriosis and lysis of dense adhesions are helpful in a subset of women. Lysis of adhesions that are not severe has not consistently decreased pain (ACOG, 2004). Hysterectomy is performed in women with untreatable pain and is most effective if accompanied by bilateral oophorectomy. Hysterectomy is major surgery with many potential complications but can cure some cases of pain related to endometriosis. Uterosacral nerve ablation

Box 25-6 Common Causes of Chronic Pelvic Pain

Gynecologic

- Endometriosis
- Pelvic adhesions
- Pelvic congestion
- Pelvic inflammatory disease
- Adenomyosis
- Vulvodynia
- Uterine myomas

Gastrointestinal

- Irritable bowel syndrome
- Inflammatory bowel disease
- Chronic constipation
- Colitis
- Diverticulitis

Urologic

- Interstitial cystitis
- Chronic urinary tract infections
- Urethral syndrome
- Radiation cystitis
- Urinary calculi

Musculoskeletal

- Myofascial pain (abdominal wall or pelvic floor muscles)
- Fibromyalgia
- Coccygeal or low back pain
- Nerve pain

Modified from Bordman R, Jackson B. Below the belt: approach to chronic pelvic pain. *Can Fam Physician* 2006;52:1556-1562; and Reiter RC. Chronic pelvic pain. *Clin Obstet Gynecol* 1990;33:117-118.

is not an effective method for treating idiopathic chronic pelvic pain (Daniels et al., 2009).

None of the above treatment modalities addresses the *physiology* of chronic pain. Several newer anticonvulsants (gabapentin, topiramate, valproic acid, pregabalin) and antidepressants, such as tricyclic antidepressants and selective serotonin reuptake inhibitors, have been successful in treating neuropathic pain from other sources. However, limited data are available in women with pelvic pain. Trigger point injections and botulinum toxin (Botox) injections in pelvic floor muscles show promise for treating myofascial pain (Gomel, 2007). Multidisciplinary treatment teams should include mental health professionals and physical therapists as well as physicians.

KEY TREATMENT

Treatment of chronic pelvic pain should be multidisciplinary and include a mental health professional (Stones et al., 2009) (SOR: A). Uterosacral nerve ablation is not an effective method for treating idiopathic chronic pelvic pain. (Daniels et al., 2009) (SOR: A). First-line treatment includes pain control with nonnarcotic medication (ACOG, 2004) (SOR: A). Hormonal manipulation with medroxyprogesterone acetate, combined hormonal contraception, or GnRH analogues can be effective treatments for endometriosis-related pain (ACOG, 2004) (SOR: A).

Menopause

Key Points

- The average age of menopause is 52.
- Vasomotor symptoms are the most common menopausal sign.
- The Women's Health Initiative showed that hormone replacement therapy did not prevent cardiovascular disease in postmenopausal women and in fact increased the risk of breast cancer.

Menopause is defined as the cessation of menstruation. It is a retrospective diagnosis that comes after a woman has not menstruated for 12 months. The menopausal transition occurs over several years as the number of ovarian follicles slowly decreases. This period in a woman's life can include menstrual cycles of variable lengths and durations, called the *perimenopause*. Because of the waxing number of follicles, the ovaries require higher levels of estrogen to stimulate a luteinizing hormone (LH) surge and subsequent ovulation. Consequently, serum levels of estrogen can vary substantially from one cycle to the next. The first physiologic change noted is a decrease in inhibin B levels (Burger et al., 1999). Subsequently, follicle-stimulating hormone (FSH) level will increase in response to lower estrogen levels. An FSH level greater than 40 U/L on two separate occasions at least 1 month apart is diagnostic of menopause. The main pathologic cause of abnormal vaginal bleeding during this period is anovulation in those cycles when estrogen did not reach target levels.

The average age of menopause in the United States is 52 years old. The majority of women will go through menopause between ages 40 and 58. Menopause before age 40 is defined as premature ovarian failure and may be related to other autoimmune disease. Factors associated with age at menopause include smoking and family history (Nelson, 2008).

Vasomotor symptoms, including hot flashes and night sweats, are the most common symptoms of menopause. Some women may begin to experience these symptoms years before their final menstrual period, during those months where their estrogen levels are lower. Many women will experience symptoms for several years. Up to 10% of women will continue to experience vasomotor symptoms into their 70s (Politi et al., 2008). Symptoms are worse in women who experience premature ovarian failure, have a premenopausal oophorectomy, are overweight or obese, or are depressed (Hendrix, 2005). Treatment of vasomotor symptoms begins with lifestyle changes and also can include pharmacologic treatment with hormonal or nonhormonal medications. Women may be able to manage their vasomotor symptoms by wearing natural-fiber clothing in layers, avoiding spicy foods, avoiding hot environments (e.g., saunas, hot tubs), avoiding alcohol, exercising, and maintaining a healthy weight.

Pharmacologic treatment of vasomotor symptoms includes hormone therapy (HT) at the lowest effective doses orally or transdermally (Bachmann et al., 2007). HT should

include both estrogen and progestin in women who have a uterus and estrogen alone in women who have had a hysterectomy. HT should be used in women at the lowest possible doses to treat symptoms for as short a time as possible (NAMS, 2004). In women for whom HT is contraindicated or who are worried about the risks, several nonhormonal options have been studied. Antidepressant medications such as fluoxetine, paroxetine, and venlafaxine have been shown to be better than placebo. Gabapentin, 900 mg daily, is also better than placebo in treating hot flashes (Grady, 2006).

Many women use complementary therapies to treat vasomotor symptoms. Various herbal preparations (e.g., black cohosh) have been used to treat vasomotor symptoms with varying success. Many women also obtain relief from soy products or other isoflavones. None of these treatments has consistently been more effective than placebo in randomized trials (Nelson et al., 2006). Stress management and meditation show promise in controlling these troublesome symptoms (Tremblay et al., 2008).

Atrophic vaginitis, or thinning of the vaginal epithelium caused by a lack of estrogen stimulation after menopause, is common, affecting 10% to 40% of all postmenopausal women. Women complain of vaginal dryness, irritation, and pain with intercourse. Unlike vasomotor symptoms, atrophic vaginitis does not develop immediately after menopause but causes symptoms months to years after the withdrawal of estrogen. Left untreated, atrophic vaginitis is progressive and is unlikely to improve spontaneously. Treatment of atrophic vaginitis begins with use of appropriate water based lubricants to make intercourse more comfortable. The mainstay of treatment is vaginal estrogen (Castelo-Branco et al., 2005). Several preparations of vaginal estrogen are available in the United States. Estrogen cream, tablets, and a slow-release silicone ring are all well tolerated and are equally effective in reducing symptoms of atrophic vaginitis. Because the vaginal estrogen has limited systemic absorption, a concomitant dosing with progestin is not necessary (Suckling et al., 2006).

Other common menopausal changes include memory difficulty (mostly with word finding), mood lability, and decreased libido (from decreased testosterone levels after menopause).

Before the Women's Health Initiative (WHI), HT was the most common treatment for menopausal symptoms. HT was also used for prevention of heart disease and osteoporosis. WHI was a large (>16,000 participants) population-based study of women between 50 and 79 years studying the effectiveness of estrogen plus progestin on congestive heart disease (CHD) prevention. The trial was stopped early because of excess cardiovascular and breast cancer events. There was an excess of 7 CHD events, 8 strokes, 8 breast cancers, and 14 venous thromboembolic events per 10,000 women. The estrogen-only arm of the study was stopped 2 years later due to excess strokes (12 per 10,000 women). There was no statistically significant increase in breast cancer incidence in the estrogen-only group (Anderson et al., 2004). The HT group in both arms of the study had fewer hip fractures. The estrogen-plus-progestin group also had fewer cases of colon cancer (Roussouw et al., 2002).

KEY TREATMENT

Hormone therapy can be used for treatment of menopausal symptoms but should be used at the lowest possible dose for the shortest time possible (NAMS, 2004) (SOR: C).

Atrophic vaginitis is treated most effectively by vaginal estrogen cream or tablets, usually three times a week initially and titrated down based on symptoms (Castelo-Branco et al., 2005) (SOR: A).

Antidepressant medications (fluoxetine, paroxetine, venlafaxine) are better than placebo in treating hot flashes (Grady, 2006) (SOR: A).

Gabapentin (900 mg daily) is also better than placebo in treating hot flashes (Grady, 2006) (SOR: A).

Stress management and meditation show promise in controlling troublesome menopausal symptoms (Tremblay et al., 2008) (SOR: B).

| | | Conclusion | 477 |

Among U.S. women, the prevalence of ever using a contraceptive method is almost 98% (Chandra et al., 2005). By addressing issues related to contraception at each visit, an informed family physician can help prevent complications stemming from interactions with prescribed and over-the-counter medications, as well as from the use of the contraceptive method itself.

Use of Contraception

History

Humans have tried to control fertility since ancient times. Egyptian papyruses describe methods to avoid pregnancy (Benagiano et al., 2006). The ancient Greeks sought to control the birth of animals using herbs, barrier methods, and other remedies (Riddle, 1999), and evidence of use of barrier methods to prevent pregnancy is found among prostitutes in France (Head, 1961). The approval of the oral contraceptive pill in the second half of the 20th century marked a great revolution in the development and widespread use of contraception methods (Winter, 1970).

Prevalence

The National Survey of Family Growth found the most frequent contraception method used during the first sexual intercourse for men and women was the male condom, which is openly available in pharmacies, supermarkets,

and medical offices (Chandra et al., 2005). When asked about use of current contraceptive methods, 62% of women report using a method, and in never-married cohabiting women, the most common method is the oral contraceptive pill (49%).

Impediments to Access

Lack of access is an important impediment to the use of contraception. With the exception of emergency contraception, all hormonal methods in the United States are available by prescription only. More than 47 million Americans (2010) do not have health insurance and have problems accessing primary care, and even with health insurance, access to contraception may be hampered by lack of coverage. For example, in a Washington state study comparing the 91 top-selling insurance plans, almost half did not cover any contraceptive method; 37% of women had no access to sterilization; and 53% had no access to pregnancy termination (Kurth et al., 2001). Another important impediment to the use of contraception can be physician difficulty in being reimbursed for contraception services. Therefore, Table 26-1 lists common *International Classification of Diseases* (ICD-9) codes for contraception counseling, prescriptions, and follow-up.

Counseling

When counseling patients about the use of contraception, nonjudgmental, impartial communication is best. Patients often bring experience, opinions, and some knowledge

Table 26-1 ICD-9 Codes Used for Contraception Reimbursement

| Code | Description |
|--------|--|
| V25.0 | General counseling and advice on contraceptive management |
| V25.01 | Oral contraceptive initiation or counseling |
| V25.02 | Initiation of other contraceptive method (diaphragm fitting, foam, etc) |
| V25.03 | Encounter for emergency contraceptive counseling and prescription |
| V25.04 | Counseling and instruction on natural family planning to avoid pregnancy |
| V25.09 | Other family planning advice |
| V25.1 | IUD, insertion |
| V25.2 | Sterilization |
| V25.3 | Menstrual extraction/regulation |
| V25.4 | Surveillance of previously prescribed contraceptive methods |
| V25.40 | Contraceptive surveillance, unspecified |
| V25.41 | Repeat prescription/surveillance of OCPs |
| V25.42 | IUD check, re-insertion or removal |
| V25.43 | Surveillance of implantable subdermal contraceptive |
| V25.49 | Surveillance of other prescribed contraceptive method |
| V25.5 | Insertion of implantable subdermal contraceptive |
| V25.8 | Post-vasectomy sperm count |
| V25.9 | Unspecified contraceptive management |
| V26.4 | General and counseling and advice on procreative management |
| V26.41 | Procreative counseling and advice using natural family planning |
| V26.42 | Other procreative management and advice |
| V26.5 | Sterilization status |
| V26.51 | Tubal ligation status |
| V26.52 | Vasectomy status |
| V26.9 | Unspecified procreative management |
| 57170 | Diaphragm/cervical cap fitting |
| 58300 | IUD insertion |
| 58301 | IUD removal |
| 99070 | Supply, diaphragm, IUD |
| J7300 | IUD, copper (supply) |
| J7302 | IUD, levonorgestrel (supply) |

IUD, Intrauterine device; OCPs, oral contraceptive pills.

about contraception that are easily elicited by open-ended questions. From this information, counseling can be customized to fit their specific needs. Use of their own words, frequent questions and answers, and feedback from patients play an important role in future compliance with medical advice.

An important consideration in contraceptive counseling is age because fertility among women varies with age. Barrier methods and some hormonal contraceptives can have low compliance in adolescents (ACOG, 2009). Older women can have more complications during pregnancy, making contraception an important component of health maintenance. Older women who are obese, smoke, or have comorbidities (e.g., hypertension, diabetes, migraines) are not good candidates to take combined hormonal contraceptives; progestin-only methods, intrauterine devices (IUDs) and sterilization may be good alternatives (Kaunitz, 2008). Women who use combined hormonal contraceptives after age 40 can be encouraged to stop in their early to mid-50s, when the likelihood of ovulation is low (ACOG, 2006).

Smoking is another important variable to consider when counseling patients. All patients should be encouraged to avoid smoking or to quit if they are smoking. The use of combined hormonal contraceptives in women over age 35 who smoked more than 15 cigarettes per day is contraindicated due to the increased risk of serious cardiovascular effects (Kroon, 2007). All women should be encouraged to use condoms consistently to reduce risk of sexually transmitted infections (STIs), especially in younger women with an increased risk of STI exposure.

Contraception Methods

Contraception is defined as the intentional prevention of conception or impregnation through the use of various devices, agents, drugs, sexual practices, or surgical procedures. The many methods available vary in efficacy, contraindications, and ease of use. Table 26-2 lists preferred contraceptive methods by patient type.

Failure Rates

Failure rates are typically described as percentage of women experiencing an unintended pregnancy within the first year of use (Zeiman et al., 2007). Two failure rates are measured, as follows (Table 26-3):

Perfect-use failure rate refers to the percentage of women who become pregnant during the first year of use when the method is used correctly and consistently according to instructions.

Typical-use failure rate refers to the percentage of women who become pregnant during the first year of use, which includes both those who use the method correctly and consistently and those who do not.

Medical Eligibility Criteria

The World Health Organization (WHO) periodically convenes an Expert Working Group to make evidence-based recommendations for who can safely use a

Table 26-2 Preferred Contraceptive Options for Select Patient Groups

| Patient type | Preferred options | Comments |
|--|--|---|
| Adolescent | DMPA, implant, COC, or IUC <i>plus</i> condoms | IUCs are excellent option currently underused in adolescents. |
| Potentially noncompliant | DMPA, implant, patch, ring, IUC | — |
| HIV and STD risk | Condom <i>plus</i> any other form of contraception | — |
| Postpartum and lactating | DMPA, implant, POP, IUC, LAM up to 6 months if specific criteria met | COCs can decrease quality and quantity of breast milk, but only if started before establishment of lactation. |
| Smoker >35 years old | DMPA, implant, POP, IUC, barrier methods | ECs contraindicated. |
| Diabetic | DMPA, implant, IUC, barrier methods | ECs appropriate in young normotensive well-controlled diabetic women. |
| Hypertensive | DMPA, implant, POP, IUC barrier methods | ECs appropriate in young well-controlled nonsmoking hypertensive women. |
| History of stroke/TIA | IUC, barrier methods | ECs contraindicated; may consider progestin-only methods. |
| History of thromboembolism | IUC, barrier methods | ECs contraindicated; may consider progestin-only methods. |
| Coronary artery disease | IUC, implant, barrier methods | ECs contraindicated, may consider progestin-only methods. |
| Mitral valve prolapse | DMPA, implant, IUC. COC; patch or ring if asymptomatic | — |
| Polycystic ovarian syndrome | COC, ring, patch, levonorgestrel IUC | COCs best shown to suppress androgen excess; levonorgestrel IUC provides excellent endometrial protection. |
| Sickle cell disease | DMPA, barrier methods | DMPA shown to decrease frequency of crises. |
| Gallbladder disease | DMPA, implant, IUC | COCs may accelerate progression. |
| Taking anticonvulsants or other hepatic inducers | DMPA, IUC | Efficacy of COCs, POPs, and implants may be reduced. |
| Desires long-term reversible contraception | DMPA, implants, IUC | — |
| Desires short-term reversible contraception | COC, POP, patch, ring, barrier methods | — |
| Desires convenience | DMPA, implant, IUC | — |
| Desires permanent contraception; no interest in future fertility | Vasectomy or tubal ligation | — |

Data from World Health Organization. Medical eligibility criteria for contraceptive use 2004, and 2008 Update of the Guide (WHO website).

COC, Combined (combination) oral contraceptive; DMPA, depot medroxyprogesterone acetate; IUC, intrauterine contraceptive; POP, progestin-only pill; LAM, lactational amenorrhea method; ECs, estrogen-containing contraceptives.

STD, Sexually transmitted disease; HIV, human immunodeficiency virus; TIA, transient ischemic attack.

contraceptive method. These criteria can be found on the WHO website.

Barrier Contraceptives and Spermicides

Key Points

- Barrier contraceptives and spermicides create a physical barrier to fertilization.
- Many of these methods are available over the counter, increasing access.
- Some barriers can provide protection against cervical infections; condoms also offer protection against HIV.

Mechanism of Action

Barrier contraceptives provide a physical barrier that prevents sperm from accessing the upper reproductive tract. They are often used in conjunction with spermicides, which act to destroy sperm and prevent fertilization.

Male Condom

Materials

Male condoms have been used since ancient times, with early condoms made from animal intestine. Mass production began in the 1840s with the advent of vulcanized

Table 26-3 Failure Rates for Contraceptive Methods: Percentage of Women who Become Pregnant during First Year of Use

| Contraceptive method | Women pregnant in first year | |
|---|------------------------------|-----------------|
| | Perfect Use (%) | Typical Use (%) |

| Sterilization | | |
| Tubal ligation | 0.5 | 0.5 |
| Essure | 0 | <1 |
| Vasectomy | 0.10 | 0.15 |

Data from Arevalo et al., 2002, 2004; Harrison-Woolrych and Hill, 2005; Palmer and Greenberg, 2009; Perez et al., 1992; Trussel, 2004; and van der Wijden et al., 2003.

rubber. Modern condoms are most often made of latex or polyurethane, but those made from animal intestine do still exist. Polyurethane condoms provide increased sensitivity for male partners, but the breakage and slippage rates are significantly higher (relative risk, 6.6 for breakage and 6.0 for slippage) compared with latex condoms (Frazier et al., 1998) (Level of evidence: A). This suggests that latex condoms should be encouraged except for those with latex allergy/sensitivity.

Advantages

Male condoms can decrease the transmission of STIs, including human immunodeficiency virus (HIV), when used correctly and consistently.

Disadvantages

To obtain maximum protection from pregnancy and STIs, condoms must be used correctly with every act of intercourse. Those individuals with an allergy or sensitivity to latex should avoid these condoms. Some men report decreased sensitivity with condom use. A new condom must be used for each act of intercourse.

Female Condom

The female condom is a thin polyurethane sheath with a ring on each end. It can be inserted into the vagina up to 8 hours before intercourse. It should not be used simultaneously with a male condom because of possible breakage or slippage of either device.

Advantages

Female condoms can decrease the transmission of STIs, including HIV, when used correctly and consistently. Many women prefer having direct control over a barrier device. The female condom can be placed in advance of intercourse, increasing spontaneity.

Disadvantages

To obtain maximum protection from pregnancy and STIs, condoms must be used correctly with every act of intercourse. Some women may experience vaginal irritation. A new condom must be used for each act of intercourse.

Cervical Cap and Diaphragm

Diaphragms are dome-shaped devices made from silicone or latex. Diaphragms come in a range of sizes and require a fitting and prescription from a health care provider. Diaphragms are used in conjunction with spermicide, can be placed in the vagina up to 6 hours before intercourse, and should be left in place for at least 6 hours after the last act of intercourse, but no longer than 24 hours. Subsequent acts of intercourse require insertion of additional spermicide without device removal.

A silicone cervical cap (FemCap) was approved by the U.S. Food and Drug Administration (FDA) in 2003. It is reusable, and the design includes a domed cap that completely covers the cervix and a brim that forms a seal against the vaginal wall, funneling the ejaculate into a groove between the dome and the brim that faces the vaginal opening, storing the spermicide and trapping sperm. It

comes in three sizes: for nulliparas, for women who have been pregnant but did not deliver vaginally, and for women who have delivered a full-term infant vaginally. It requires a fitting and prescription from a health care provider. The cervical cap is used in conjunction with spermicide and should be left in place for at least 6 hours after the last act of intercourse, but no longer than 48 hours. Subsequent acts of intercourse require insertion of additional spermicide without device removal.

Advantages

Many women prefer having direct control over a barrier device. Diaphragms and cervical caps can be placed in advance of intercourse, increasing spontaneity. These methods may offer some protection against cervical infections and pelvic inflammatory disease (PID) but offer no protection against HIV.

Disadvantages

Diaphragms and cervical caps should be used in conjunction with spermicide, which may cause irritation in some individuals. Those individuals with an allergy or sensitivity to latex should avoid those diaphragms. The incidence of urinary tract infections (UTIs) may increase.

Contraceptive Sponge

The Today sponge was reintroduced to the U.S. market in 2005. It is a polyurethane sponge that contains 1 g of nonoxynol-9 spermicide. There is a dimple on one side that fits over the cervix and a loop on the opposite side to aid in removal. It is available over the counter (OTC) and is effective for up to 24 hours, regardless of the number of times intercourse takes place. It should be left in place for at least 6 hours after intercourse, but no longer than 30 hours. Each sponge can be used only once.

Advantages

Many women prefer having direct control over a barrier device. The contraceptive sponge may offer some protection against cervical infections and PID but offer no protection against HIV.

Disadvantages

Some individuals may experience sensitivity to the spermicide. Some women may experience vaginal dryness or an increased incidence of yeast infections, particularly if the sponge is left in place for longer periods.

Spermicides

Mechanism of Action

Nonoxynol-9 is a nonionic detergent that disrupts the membranes of epithelial cells, bacteria, and viruses. It reduces sperm motility and reduces nourishment by disrupting fructolytic activity. It is available OTC in many forms, including gels, foams, and film. Although shown to inactivate many sexually transmitted pathogens *in vitro*, in actual use, nonoxynol-9 does not reduce rates of HIV, gonorrhea, or chlamydial infections when used with latex condoms (Roddy et al., 1998) (Level A).

Advantages

Many women prefer having direct control over contraception. Spermicides may be placed in advance of intercourse, increasing spontaneity, and can be used with barrier devices to increase efficacy.

Disadvantages

Some individuals may experience sensitivity to spermicide. Fresh spermicide should be placed with each act of intercourse.

Fertility Awareness Methods

Fertility awareness methods (FAMs) rely on a woman's awareness of when she is most likely to conceive, with abstinence or use of barrier contraceptives during that time.

Advantages

Women with religious or cultural reasons for not using contraception can use FAMs to avoid intercourse during fertile times. There are no medical contraindications to using these methods, and when used in reverse, FAMs can help a couple conceive a wanted pregnancy.

Disadvantages

A couple must be highly motivated to avoid intercourse during fertile times, which can also be a time of increased libido. The signs of ovulation/fertile periods can be subtle, so it may take time to master these methods. Even women with regular cycles experience cycle variability, and these methods are not reliable in women with irregular cycles.

Calendar Method

A woman records her cycles prospectively for 6 to 12 months to determine her cycle length. Using the longest and shortest cycle lengths during this time, and assuming that ovulation occurs 14 days before menses and that sperm can survive for 2 to 3 days, the fertile period is calculated. A simplified version of the calendar method, the Standard Days Method, eliminates the need for extended cycle evaluation before use. For women in whom most cycles are 28 to 32 days long, intercourse is avoided on cycle days 8 to 19 (Arevalo et al., 2002). CycleBeads are a set of color-coded beads that can be used to help a woman keep track of her cycles.

Ovulation Method

The ovulation method requires a woman to check her cervical mucus manually to detect the changes that occur during fertile periods, then avoid intercourse during these times. A simplified, TwoDay method requires that a woman ask herself two questions: "Did I notice secretions today?" and "Did I notice secretions yesterday?" If the answer is "no" for 2 consecutive days, it is safe to have intercourse (Arevalo et al., 2004).

Basal Body Temperature

Women must take their temperature each morning before arising and record it on a chart. This temperature can increase noticeably (by 0.4°-0.8° F) with ovulation and indicates times when intercourse should be avoided or barrier contraceptives used.

Symptomothermal Method

The symptomothermal method combines fertility awareness indicators (basal body temperature, changes in cervical mucus, libido, or cervical texture) to help a woman recognize her fertile days and avoid intercourse or use barrier methods during that time.

Postovulation Method

The postovulation method allows intercourse only after signs of ovulation have resolved.

Lactational Amenorrhea Method

The lactational amenorrhea method (LAM) refers to a specific set of circumstances under which a lactating woman does not ovulate and thus cannot conceive. This method is extremely effective, but only if all the following conditions exist (Kennedy and Visness, 1992; Level A):

1. The woman is exclusively breastfeeding an infant with both day and night feedings, so that 90% or more of the infant's nutrition is from breast milk.
2. The infant is less than 6 months old.
3. The woman is amenorrheic (except for spotting during first 8 weeks postpartum)

Once these specific conditions no longer exist, other contraceptive methods should be considered.

Mechanism of Action

Lactation causes a surge in prolactin, which inhibits ovulation.

Advantages

Breastfeeding provides excellent nutrition for infants and can aid in maternal weight loss, as well as decrease the risk for endometrial, ovarian, and possibly breast cancer.

Disadvantages

It is important to understand that ovulation will often precede the first menses in postpartum women, leaving them susceptible to pregnancy. This risk increases with time since delivery (Zieman et al., 2007). Some women may find long-term breastfeeding difficult or inconvenient.

Coitus Interruptus/Withdrawal

The male partner completely removes the penis from the vagina before ejaculation. Withdrawal reduces or eliminates sperm introduction into the vagina and thus the upper reproductive tract. Unless two acts of intercourse are close together, there is little concern for the presence of sperm in preejaculatory secretions (Zeiman et al, 2007).

The advantages are affordability and ready availability. The disadvantages are that coitus interruptus relies on the male partner to predict imminent ejaculation and quickly and completely remove the penis from the vagina and introitus. Withdrawal also may limit orgasmic pleasure and spontaneity.

Combined Hormonal Contraceptives

Key Points

- When used correctly and consistently, CHCs are very effective in preventing pregnancy.
- CHCs offer many noncontraceptive health benefits, such as increased cycle regularity, decreased risk of endometrial and ovarian cancers, and decreased PMS/PMDD.
- CHCs have not been shown to cause significant weight gain.
- The contraceptive patch and vaginal contraceptive ring can increase perfect-use compliance by decreasing dosing frequency.
- Ethinyl estradiol levels are higher in women using the contraceptive patch than in those using OCs or the ring, but there is no evidence of increased risk of venous thromboembolism.
- The patch may have decreased efficacy in women weighing more than 90 kg.

Mechanism of Action

Combined (or combination) hormonal contraceptives (CHCs) contain both an estrogen (ethinyl estradiol) and one of many progestins, which act in concert to suppress ovulation. This is achieved through negative feedback on the hypothalamic-pituitary system, leading to decreased gonadotropin-releasing hormone (GnRH) pulsatility, decreased pituitary responsiveness to GnRH stimulation, suppression of luteinizing hormone (LH) and follicle-stimulating hormone (FSH) production, and inhibition of the midcycle LH surge (Nelson et al., 2007). In addition, the progestin component causes thickening of the cervical mucus, which can inhibit sperm access to the upper genital tract.

Oral Contraceptives

Combined oral contraceptives (COCs, OCs), often referred to as "the pill," are the most common form of reversible contraception used in the United States (Chandra et al., 2005). Many formulations exist, with varying amounts of ethinyl estradiol and differing progestins. Newer formulations with 4-day pill-free intervals (vs. traditional 7 days), can offer increased relief from hormonal side effects (Sulak et al., 2000) and increased suppression of ovarian activity (Spona et al., 1996).

Advantages

The CHCs are very effective in preventing pregnancy when used correctly and consistently. OCs help to regulate menses, decrease menstrual flow and dysmenorrhea, and eliminate mittelschmerz. Certain formulations can be used to treat *premenstrual dysphoric disorder* (PMDD) (Lopez et al., 2009). Rapid return to fertility follows discontinuation of OCs. No

Box 26-1 Contraindications to Estrogen Use

- Smoker (≥ 15 cigarettes/day) ≥ 35 years old
- Active liver disease
- History of breast cancer
- Breast feeding (<6 weeks postpartum)
- Migraine with aura
- Uncontrolled hypertension
- History of clotting disorder
- Known thrombogenic mutations
- SLE with positive or unknown antiphospholipid antibodies
- Diabetes with vascular disease/retinopathy/neuropathy/nephropathy
- Major surgery with prolonged immobilization
- Multiple risk factors for CV disease/stroke
- DVT/PE (history of, acute, or established on anticoagulant therapy)
- Complicated valvular heart disease
- History of COC-related cholestasis or current gallbladder disease

evidence exists for significant weight gain in women taking CHCs. OCs may help reduce acne and may be used as emergency contraception with alternate dosing. Use of CHCs decreases benign breast disease, risk of ovarian and endometrial cancers, and risk of death from colorectal cancer (Zieman et al., 2007).

Disadvantages

Women must remember every day to follow the regimen for OCs to be effective. CHCs may cause spotting, breast tenderness, nausea, or headaches, especially in the first few months of use, as well as decreased libido. OCs offer no protection against STIs and cannot be used by women with contraindications to estrogen use (Box 26-1).

Contraceptive Patch

The contraceptive patch (OrthoEvra) is a 4.5-cm² adhesive patch placed on the upper arm, abdomen, back, or buttocks that provides 20 μg of ethinyl estradiol and 150 μg of norelgestromin daily. The patch is changed every 7 days for 3 weeks, with a patch-free week during which a woman is expected to menstruate. Steady-state hormone levels are achieved after 3 days, and there is enough hormone for up to 10 days' use (Abrams et al., 2002).

Advantages

Weekly dosing may offer increased compliance with correct use compared with COC use (Lopez et al., 2008). Sustained therapeutic hormone levels past the recommended 7 days for each patch give women leeway if they forget to change the patch on time. Other advantages are similar to those for COCs, although data on cancer and other noncontraceptive health benefits are not yet available.

Disadvantages

Overall, the contraceptive patch is similar to COCs, although the rate of side effects may be higher (Lopez et al., 2008). Localized skin reactions may occur. Decreased efficacy is noted in women weighing more than 90 kg (198 lb) (Nanda, 2007). Ethinyl estradiol concentrations are higher in women using the contraceptive patch than in those using either COCs

or the vaginal ring (van den Heuvel et al., 2005), raising concern for an increased risk of venous thromboembolism (VTE) or other cardiovascular events. However, the risk of nonfatal VTE for the contraceptive patch is actually similar to that for COCs with 35 μg of ethinyl estradiol (odds ratio 0.9; 95% CI 0.5-1.6) (Jick et al., 2006; Level A). Also, the risk of VTE with pregnancy remains much higher than with CHC use.

Vaginal Contraceptive Ring

NuvaRing is a flexible, colorless ring 4 mm thick and 5.4 cm in diameter. It is placed into the vagina and provides 15 μg of ethinyl estradiol and 120 μg of etonogestrel daily. Each ring is left in place for 3 weeks, followed by a ring-free week during which a woman is expected to menstruate. Ovulation suppression begins within 3 days of use and continues for up to 35 days while the ring is in place (Nanda, 2007).

Advantages

Monthly dosing with the vaginal ring may increase compliance with correct use compared with COCs (Nanda, 2007). Sustained therapeutic hormone levels past the 21-day recommendation for each ring give women leeway if they forget to change the ring on time. The ring may be removed for up to 3 hours for intercourse, although this is not recommended because most women and their partners are not bothered by its presence. Other advantages are similar to those for COCs, although again, data on cancer and other noncontraceptive health benefits are not yet available.

Disadvantages

Overall, drawbacks to vaginal ring use are similar to COC use. Although rates of breast discomfort, nausea, and vomiting may be decreased, rates of vaginitis and leukorrhea may increase compared with COCs (Lopez et al., 2008).

Progestin-Only Contraceptives**Key Points**

- Progestin-only contraceptives are very effective in preventing pregnancy when used correctly and consistently.
- Women with contraindications to estrogen use may safely use POPs.
- Overall, menstrual blood loss is decreased, but bleeding may be unscheduled or irregular.
- Longer-acting formulations may increase perfect-use compliance by decreasing dosing frequency.
- The effect of DMPA on weight gain is variable.
- Although prolonged DMPA use may decrease bone mineral density, this is reversible after discontinuation, and it is not associated with future fractures or osteoporosis.

Mechanism of Action

All progestin-only contraceptive methods act to thicken cervical mucus, thereby inhibiting sperm access to the upper genital tract. They also cause slowing of tubal motility and atrophy of the endometrium. Some methods act to suppress LH and FSH surges, inhibiting ovulation (Zieman et al., 2007).

Progestin-Only Pills

The sole progestin-only pill (POP, often called the “minipill”) currently available in the United States contains 35 mg of norethindrone. This pill is taken daily, without a pill-free interval. The main contraceptive effect is through thickening of cervical mucus; ovulation suppression occurs in only 50% of cycles.

Advantages

The POP is very effective in preventing pregnancy when used correctly and consistently. Benefits include decreased menstrual flow and dysmenorrhea, with rapid return to fertility. POPs may be used by women who desire an OC but have a contraindication to estrogen use.

Disadvantages

Main contraceptive effect begins to wane after 22 hours and is gone by 27 hours, so women who are more than 3 hours late with dosing need to use backup contraception. Although overall blood loss is decreased, bleeding or spotting may be irregular or unscheduled. POPs offer no protection against STIs, although infections of the ascending genital tract may be decreased because of thickened cervical mucus (Zieman et al., 2007).

Depot Medroxyprogesterone Acetate (DMPA)

A crystalline suspension, DMPA is injected every 3 months either intramuscularly (150 mg) or subcutaneously (104 mg). Its main contraceptive effect is through ovulation suppression.

Advantages

The convenient dosing schedule of DMPA can increase perfect-use compliance. Advantages include decreased menstrual flow, dysmenorrhea, and elimination of mittelschmerz. DMPA can improve pain from endometriosis and may be used by women with contraindications to estrogen use. It reduces the risk of endometrial and possibly ovarian cancer, as well as significantly decreasing sickle cell crises. DMPA can reduce the number of seizures in women with seizure disorders (Westhoff, 2003). No evidence indicates decreased efficacy in obese women (Goldberg and Grimes, 2007).

Disadvantages

Although overall blood loss is decreased, bleeding and spotting may be irregular or unscheduled. The high amenorrhea rate (>50%) may concern some women. Return to fertility may be delayed (average, 10 months from last injection). Patients often express concerns about weight gain, which is actually quite variable, with no studies showing a consistent impact on weight (Westhoff, 2003) (Level A). Although osteoporosis may develop with prolonged DMPA use because of decreased estradiol levels, bone mineral density (BMD) appears to recover completely after discontinuation, and BMD changes during DMPA therapy have not been linked to fractures or postmenopausal osteoporosis (Goldberg and Grimes, 2007).

Contraceptive Implant

The only contraceptive implant currently available in the United States is Implanon, a single rod 4 cm long and 2 mm wide made of ethylene vinylacetate (EVA) co-polymer and containing 68 mg of time-release etonogestrel. It is placed

subdermally by a health care provider and acts primarily by ovulation inhibition. Although FDA approved for 3 years' use, the implant has proven efficacy to at least 4 years (Isly and Edelman, 2007).

Advantages

The contraceptive implant is one of the most effective forms of available contraception, with rapid return to fertility; most women ovulate within 4 weeks of removal (Isly and Edelman, 2007). Benefits include decreased menstrual flow, dysmenorrhea, and elimination of mittelschmerz. The implant can improve pain from endometriosis and may be used by women with contraindication to estrogen use. No effect on BMD is seen.

Disadvantages

The woman must see a health care provider for implant initiation and discontinuation. Although overall blood loss is decreased, bleeding and spotting may be irregular or unscheduled. Amenorrhea may concern some women. The implant provides no protection against STIs and may be associated with headaches or increased acne.

Intrauterine Contraceptives

Key Points

- IUCs are among the most effective forms of contraception available.
- Although preventing fertilization, IUCs are not abortifacients.
- Adolescents can safely use IUCs but underuse this method.
- The levonorgestrel IUC is an effective treatment for menorrhagia and can decrease the risk of ascending genital tract infections.
- IUCs do not increase the risk of PID outside the first 20 days after insertion.
- The copper-T380A IUD can be used as emergency contraception.

Intrauterine contraceptives (IUCs) are small, T-shaped devices inserted into the uterine cavity by a medical provider. IUCs provide excellent long-term, reversible contraception. The two IUCs currently available in the United States are the copper-T380A intrauterine device (IUD) (TCu380A, Paragard) and the levonorgestrel intrauterine system (LNG-IUS, Mirena). In 2007 the American College of Obstetricians and Gynecologists (ACOG) concluded that modern IUCs are an excellent contraceptive choice for adolescents and are underused by this population. Contrary to popular belief, both IUCs act by inhibiting fertilization and are not abortifacients (Grimes, 2007; WHO, 1987) (Level A).

Copper-T380A Intrauterine Device

The TCu380A (Paragard in U.S.) is a polyethylene IUD with copper wire wound on the stem and copper sleeves on each of the arms, for a total of 380 mm² of exposed copper surface area. Although FDA approved for 10 years' use, it has proved efficacious for at least 12 years (UN/WHO, 1997) (Level A).

Mechanism of Action

Copper ions released from this IUD act as a spermicide to inhibit sperm motility and the acrosomal enzyme reaction. In addition, increased macrophages in tubal and uterine fluids act to phagocytize sperm.

Advantages

Among the most effective forms of contraception available, IUCs are long acting but easily reversible, with rapid return to fertility. Nonhormonal methods may be preferable to some women. IUCs may be used by those with a contraindication to estrogen use. IUDs decrease the risk of endometrial and possibly cervical cancer (Hubacher and Grimes, 2002). IUCs can be used as emergency contraception.

Disadvantages

The IUC must be placed and removed by a health care provider. IUCs may cause increased menstrual bleeding and dysmenorrhea. The IUD does not offer protection against STIs. There is increased risk of upper tract infection the first 20 days after insertion, but otherwise no increased risk of PID (Grimes and Schulz, 1999) (Level A).

Levonorgestrel Intrauterine System

The LNG-IUS (Mirena in U.S.) contains a steroid reservoir around the stem that releases 20 µg of levonorgestrel per day into the uterine cavity. Although FDA approved for 5 years' use, it has proven efficacy for at least 7 years (Sivin et al., 1991) (Level A).

Mechanism of Action

The main mechanism of action of the LNG-IUS is thickening of the cervical mucus, which blocks sperm access to the upper genital tract. In addition, changes in tubal fluid can impair both sperm and egg motility. There is occasional inhibition of ovulation (~20% of cycles).

Advantages

Among the most effective forms of contraception available, the LNG-IUS is long acting but easily reversible, with rapid return to fertility. Benefits include decreased menstrual flow and dysmenorrhea and effective treatment for menorrhagia. Thickened cervical mucus may contribute to decreased risk of ascending cervical infections (decreased rates of PID), especially in patients under 25 years old (Toivonen et al., 1991). The IUS may be used by women with contraindication to estrogen use. It decreases the risk of endometrial and possibly cervical cancer (Hubacher and Grimes, 2002).

Disadvantages

The LVG-IUS must be placed and removed by a health care provider. Amenorrhea may concern some women. It offers no protection against cervicitis or viral STIs. Risk of upper tract infection is increased in the first 20 days after insertion, but otherwise there is no increased risk of PID (Grimes and Schulz, 1999) (Level A). Some women may experience mild hormonal side effects, including headaches, breast discomfort, and acne.

Sterilization

Key Points

- Sterilization is one of the most effective forms of contraception but is permanent.

- Regret rates are higher for men and women who are young at sterilization, so counseling is key.
- Tubal ligation increases the risk of ectopic pregnancy if it fails; vasectomy does not.

Sterilization is the most common form of contraception in the United States, relied on by 23% of contraceptive-using women (Chandra et al., 2005).

Mechanism of Action

Sterilization creates a physical disruption in either the male (vas deferens) or female (fallopian tube) reproductive tract, thereby preventing fertilization.

Tubal Ligation

Traditional tubal occlusion can be accomplished by the laparoscopic placement of clips or Silastic bands or by tubal cautery. Alternatively, a mini-laparotomy may be performed for a partial salpingectomy. The Essure device was approved for use in the United States in 2002. This is a coil device made of stainless steel and nickel-titanium that is inserted transcervically into the tubal ostia, avoiding the need for general anesthesia. Placement causes an inflammatory response in the tubes, leading to dense fibrosis and tubal occlusion (Ogburn and Espey, 2007).

Advantages

Tubal ligation is a permanent, highly effective form of contraception that requires little to no follow-up.

Disadvantages

Tubal ligation requires a surgical procedure; some women may be poor surgical candidates. It does not protect against STIs and carries an increased risk of ectopic pregnancy if ligation fails. It is irreversible; achieving pregnancy after sterilization is costly and involves either additional surgery or in vitro fertilization. The Essure device requires use of another contraceptive for 3 months, or until tubal occlusion is confirmed by hysterosalpingogram. Regret rates are 20% for women 30 and younger at the time of sterilization, but only 6% for those over 30 (Pollack et al., 2007). Counseling is key.

Vasectomy

Vasectomy is a quick procedure, usually performed under local anesthesia in 5 to 10 minutes. The no-scalpel technique involves puncturing the scrotum to deliver the vas deferens, which is then ligated or cauterized.

Advantages

Vasectomy is a permanent, highly effective form of contraception that requires minimal follow-up. It is safer and more effective than female sterilization and does not increase risk of ectopic pregnancy if it fails. Vasectomy allows the male partner to have a role in contraception.

Disadvantages

A surgical procedure is required. Vasectomy does not protect against STIs and requires use of another contraceptive method for about 12 weeks, until azoospermia is confirmed. It is irreversible; achieving pregnancy after sterilization requires additional surgery and can be hampered by the development of antisperm antibodies. Regret rates are highest in men who, at sterilization, are less than 31 years old, are in an unstable marriage, have no or very young children, and are in a time of financial crisis (Pollack et al., 2007). Vasectomy rarely leads to chronic testicular pain.

Emergency Contraception

Emergency contraception refers to methods a woman can use after unprotected intercourse to decrease the chance of pregnancy. There are two categories: emergency contraceptive pills (ECPs) and the copper-T380A IUD. The only contraindication to emergency contraception is pregnancy. ECPs are ineffective once pregnancy is established, but will not harm an existing pregnancy. IUD placement may disrupt a pregnancy or increase the risk of serious infection and septic abortion.

Emergency Contraceptive Pills

Modern emergency contraception began with the Yuzpe regimen in the 1970s. This regimen consists of 100 µg ethinyl estradiol and 0.5 mg of levonorgestrel or 1 mg norgestrel taken within 72 hours of unprotected intercourse, followed by a repeat dose 12 hours later. This was initially accomplished by taking high doses of COCs, but began to be marketed as a specific product, Preven, in 1998 (Stewart et al., 2007). This method has a failure/pregnancy rate of 2-3%, with an average 74% reduction in the number of expected pregnancies when used (Trussel et al., 1996). Side effects are common, with about 50% of women experiencing nausea and 20% vomiting from the high doses of estrogen. Subsequent research has led to the preferred use of other EC methods, and Preven was pulled from the market in 2004.

A 1998 study by the WHO Task Force on Postovulatory Methods of Fertility Regulation compared two doses of 0.75 mg of levonorgestrel given 12 hours apart to the Yuzpe

regimen. The levonorgestrel-only method was both better tolerated and more effective than the Yuzpe regimen, with a failure/pregnancy rate of 1.1% and an 85% reduction in the number of expected pregnancies. In 1999 the FDA approved Plan B, which contains two 0.75-mg tablets of levonorgestrel. A single 1.5-mg dose of levonorgestrel taken up to 5 days after unprotected intercourse seems to be equally effective at pregnancy prevention (von Hertzen et al, 2002) (Level A). Plan B One-Step, a single pill containing 1.5 mg of levonorgestrel, is currently available.

Mechanism of Action

Treatment with levonorgestrel before ovulation inhibits the LH surge and therefore ovulation. If taken after ovulation, ECPs have little effect on hormone production and only a limited effect on the endometrium (Marions et al., 2002). Therefore, levonorgestrel for emergency contraception works by inhibiting ovulation; *it is not an abortifacient*.

Copper-T380A Intrauterine Device

The TCu380A IUD can be inserted up to 8 days after unprotected intercourse, and is the most effective form of emergency contraception, with a failure/pregnancy rate of about 0.1% (Zieman et al., 2007). Its mechanism of action likely involves the spermicidal activity seen in contraception, but the very high efficacy suggests that it may also interfere with implantation of a fertilized egg (Stewart et al., 2007). Insertion of the TCu380A IUD offers the additional benefit of providing continued contraception.

Conclusion

Many contraceptive methods are available to patients, and physicians should routinely counsel patients interested in contraception. Information and facts should be provided in an impartial, culturally sensitive, and customized manner, with the final decision made by the patient with support from the physician. Frequent follow-up and questioning about side effects and satisfaction with the chosen contraceptive method ensure an informed and involved patient.

Cardiovascular disease (CVD) is the leading cause of morbidity and mortality for both men and women in the United States. Enormous efforts are being made to stem the physical, emotional, and socioeconomic costs associated with the epidemic of cardiovascular diseases throughout the world. Almost 80,000,000 Americans have some form of CVD, and it was responsible for 34% of all mortality in 2006 (American Heart Association, 2010). Approximately 2300 people die from CVD daily in the United States (1 death every 38 seconds). The prevalence of various cardiovascular diseases in the U.S. is impressive, with 74 million people afflicted with *hypertension* (HTN); more than 16.8 million with *coronary artery disease* (CAD); 5.7 million with *congestive heart failure* (CHF); 6.5 million having a history of *stroke* (CVA); 1 million patients with a history of congenital heart disease; 8 to 12 million with *peripheral arterial*

disease (PAD); and 2.2 million with atrial fibrillation. Unfortunately, 20.8% of the American population (47.1 million people) still smokes. Two thirds of the American population is afflicted with being overweight or obese. It is estimated that in 2009 the direct and indirect costs associated with the management of CVD will exceed \$475 billion. In addition to the costs of pharmacologic intervention and lost productivity, some of this cost is also driven by a large number of cardiovascular procedures, including: 1,313,000 angioplasties; 1,115,000 diagnostic cardiac catheterizations; 448,000 coronary artery bypass graft (CABG) procedures; and the implantation of 199,000 pacemakers and 63,000 implantable defibrillators.

Detailed guidelines by professional societies and national commissions are being issued and continuously reevaluated and updated so as to optimize the management of risk factors

and established forms of disease. Despite these efforts, compliance with guidelines remains relatively low throughout the world. As populations age worldwide, as more patients survive acute cardiovascular and cerebrovascular events, and as the incidence of hypertension, dyslipidemia, metabolic syndrome, diabetes mellitus, obesity, and other risk factors continues to increase, the burden on family physicians to identify and effectively manage CVD will continue to escalate dramatically. This chapter addresses issues related to CVD prevention; diagnosing and managing the various manifestations of atherosclerotic disease, valvular dysfunction, congestive heart failure, and cardiomyopathy; pericardial disease; and arrhythmia identification and management.

Atherosclerosis

Atherosclerosis is a complex, multifactorial disease highly prevalent throughout the world. Atherosclerotic disease is etiologic for acute coronary syndromes such as myocardial infarction (MI) and unstable angina, ischemic stroke, renal arterial stenosis, and peripheral vascular disease (Libby, 2001). The development and progression of atherosclerosis is driven by a variety of risk factors, including dyslipidemia, hypertension, impairments in glycemic control, age, family history, cigarette smoking, obesity, and systemic inflammation. Novel risk factors are being recognized and their utility for identifying patients at risk for disease tested in epidemiologic and clinical trial settings. Evaluating patients for global cardiovascular risk burden and aggressively treating modifiable risk factors are a significant focus of any primary care setting.

Atherogenesis is no longer viewed as an inevitable consequence of passive, progressive lipid accumulation within the arterial wall, gradually resulting in symptomatic reductions in blood flow and oxygen delivery. Instead, *atherosclerosis* is a dynamic process encompassing a diverse array of biochemical and histologic changes that continuously modulate the establishment and evolution of atheromatous plaque (Libby et al., 2002; Hansson, 2005). Atheromatous plaque is modifiable, and therapeutic interventions can stabilize and even regress plaque, resulting in reductions in risk for cardiovascular morbidity and mortality.

Endothelial cell dysfunction is an early hallmark of atherogenesis (Toth, 2009). The endothelium is now viewed as an organ system. Endothelial cells line the luminal surface of blood vessels and mediate vascular tone and molecular trafficking into the vessel wall. When endothelium is stressed by rheologic disturbances, increased inflammatory or oxidative insult, glycemic injury, hyperlipidemia and hypertension, its functional characteristics change. Dysfunctional endothelium has less vasodilatory capacity, is more thrombogenic, and upregulates the expression of a variety of *cell adhesion molecules* (CAMs), such as vascular cell adhesion molecule-1 (VCAM-1) and intercellular adhesion molecule-1 (ICAM-1) (Lusis, 2000). CAMs promote the binding of monocytes, T cells, and mast cells to the endothelial surface. Bound inflammatory white blood cells (WBCs) then follow a gradient of monocyte chemoattractant protein-1 and other cytokines by intercalating between endothelial cells and ultimately transmigrate into the subendothelial space. Once in the subendothelial space, these WBCs take up residence, creating an inflammatory nidus. Monocytes can convert to macrophages in response to macrophage colony-stimulating

factor. Inflammatory WBCs are potent sources of oxygen free radicals such as superoxide anion, peroxide, and hydroxyl radicals. These reactive oxygen species can oxidize phospholipids within lipoproteins, rendering them more atherogenic. When exposed to oxidatively modified atherogenic lipoproteins, macrophages upregulate the expression of cell surface scavenger receptors (e.g., CD36, scavenger receptor A), which promote the internalization of cholesterol and cholesterol esters, resulting in the formation of foam cells. *Foam cells* coalesce to form fatty streaks, the histologic precursor to atheromatous plaques. Resident macrophages, T cells, and mast cells facilitate additional WBC recruitment and progression of atherosclerotic disease by producing a variety of cytokines, interleukins, and oxidative enzymes that adversely impact endothelial, smooth muscle cell, and fibroblast function and proliferation.

With disease progression, the molecular and histologic dynamics of *atheromatous plaque* remain in continuous flux. As foam cells die, cellular debris accumulates and further potentiates the inflammatory response (Tabas, 2005). Matrix metalloproteinases are expressed, which degrade the collagen, elastin, and proteoglycan extracellular matrix of plaque. When this occurs in the shoulder region of a plaque, acute rupture or plaque fissuring can result. Sudden plaque rupture exposes collagen, tissue factor, and the thrombogenic lipid core to platelets and coagulation factors, ultimately resulting in overlying thrombus formation, luminal obstruction, acute ischemia, and possible infarction if tissue blood flow is not rapidly reestablished. Atheromatous plaques that are highly inflamed and contain concentrated macrophage infiltrates or large lipid cores are particularly vulnerable to architectural destabilization and acute plaque rupture. Plaque can also suddenly distend and reduce coronary luminal diameter from sudden intraplaque hemorrhaging if the delicate vasa vasorum feeding the surrounding vascular tissue is injured.

In the majority of cases, culprit lesions giving rise to acute MI are not flow limiting. Any atheromatous plaque identified on coronary angiography should be viewed as a potential cause of an *acute coronary syndrome* (ACS). Patients with evidence of atherosclerotic disease in any portion of the vascular tree require rigorous evaluation of all risk factors and the appropriate institution of lifestyle and pharmacologic intervention to reduce risk for both disease progression and cardiovascular morbidity and mortality.

Dyslipidemia

Key Points

- Patients undergoing screening for dyslipidemia should have a complete fasting lipid profile.
- LDL and non-HDL (total cholesterol – HDL) are atherogenic and have defined targets for therapy based on global risk factor burden.
- LDL-C is currently the primary target of therapy in patients with dyslipidemia, although non-HDL-C or apoB100 may become the next primary target of therapy.
- HDL is antiatherogenic, and when less than 40 mg/dL in men and 50 mg/dL in women, therapeutic effort should be made to raise HDL.
- Therapeutic lifestyle changes are an important component of any regimen designed to treat dyslipidemia.

Figure 27-1 Molecular and histologic pathways for reverse cholesterol transport. To deliver peripheral cholesterol back to the liver or steroidogenic organs such as the adrenal glands, placenta, or ovaries, apoA-I and nascent discoidal HDL interact with cells such as macrophages and foam cells within blood vessel walls. The HDL undergoes a series of cell receptor–dependent and serum enzyme–dependent maturation and speciation reactions (HDL speciation). HDL can interact directly with a variety of hepatocyte surface receptors, including SR-BI. The cholesterol esters in HDL can also be transported back to the liver by an indirect pathway for reverse cholesterol transport that depends on CETP and the LDL and LDL-RRP receptors. *ABCA1*, ATP-binding membrane cassette transporter A1; *apoA-I*, apoprotein A-I; *ApoE*, apoprotein E; *CE*, cholesteryl ester; *CETP*, cholesteryl ester transfer protein; *GI*, gastrointestinal; *HDL*, high-density lipoprotein; *HL*, hepatic lipase; *IDL*, intermediate-density lipoprotein; *LCAT*, lecithin:cholesterol acyltransferase; *LDL*, low-density lipoprotein; *LDL-R*, low-density lipoprotein receptor; *LDL-RRP*, low-density lipoprotein receptor–related protein; *Lyso PC*, lysophosphatidylcholine; *PC*, phosphatidylcholine; *PGN*, proteoglycan; *PL*, phospholipid; *PLTP*, phospholipid transfer protein; *SR-BI*, scavenger receptor BI; *UC*, unesterified cholesterol; *VLDL*, very-low-density lipoprotein. (Reproduced with permission from Toth PP. High-density lipoprotein as a therapeutic target: clinical evidence and treatment strategies. *Am J Cardiol* 2005;96:50K-58K.)

Causes

Although it is pathogenic, *cholesterol* is also an important modulator of cell membrane fluidity and is a substrate for hormone biosynthesis by steroidogenic organs. There is an unequivocal relationship between dyslipidemia and risk for atherosclerosis within the coronary, peripheral, renal, and cerebral vasculature. *Dyslipoproteinemias* develop in response to genetic and environmental factors and are modifiable through lifestyle modification and pharmacologic intervention. As demonstrated in the Framingham Study, Multiple Risk Factor Intervention Trial, and the Seven Countries Study, as serum levels of cholesterol increase, the risk for developing CAD increases. The identification and treatment of dyslipidemia lowers the prevalence of atherosclerotic disease and its various clinical manifestations.

Serum very-low-density lipoprotein (VLDL) and low-density lipoprotein (LDL) particles deliver cholesterol to peripheral tissues and blood vessel walls. These lipoproteins can cross the endothelial barrier and induce atherosclerosis. Atherogenic lipoproteins not taken up by peripheral tissues are cleared from the circulation by hepatic LDL receptors.

Therapies targeted at the upregulation of hepatic LDL receptors are antiatherogenic by virtue of their ability to reduce circulating levels of atherogenic lipoproteins.

High-density lipoprotein (HDL) particles are antiatherogenic. With few exceptions, epidemiologic investigation has shown that high HDL levels reduce risk for the development of CAD (Toth, 2001, 2009). Consistent with this finding, patients with familial hypo- α -lipoproteinemia (low HDL) have increased risk for premature CAD, whereas patients with familial hyper- α -lipoproteinemia (high HDL) are relatively resistant to CAD (Toth, 2003, 2004). HDL extracts excess intracellular cholesterol from macrophages and delivers it back to the liver for elimination as bile salts through the gastrointestinal tract in a process referred to as “reverse cholesterol transport” (Fig. 27-1). HDL has also been shown to reduce endothelial CAM expression, augment endothelial nitric oxide and prostacyclin production, reduce oxidized LDL, decrease platelet aggregability, and inhibit endothelial cell apoptosis (programmed cell death). An HDL greater than 60 mg/dL is a “negative” risk factor. In general, the more

Table 27-1 Low-Density Lipoprotein (LDL) Cholesterol Goals and Thresholds for Initiating Therapeutic Lifestyle Change (TLC) and Pharmacologic Intervention

| Risk Category* | LDL Goal | LDL Level to Initiate TLC | LDL Level to Consider Drug Therapy |
|---|---|--|--|
| CHD or CHD risk equivalents (10-year risk >20%) | <100 mg/dL (optional goal <70) [†] | ≥100 mg/dL All patients regardless of LDL | ≥130 mg/dL (100-129 mg/dL: drug optional) ≥100 mg/dL [‡] (<100 mg/dL: drug optional) |
| 2+ risk factors (10-year risk: 10%-20%) | <130 mg/dL (optional goal <100) | ≥130 mg/dL All patients regardless of LDL | ≥130 mg/dL (>100 mg/dL: drug optional [‡]) |
| 2+ risk factors (10-year risk ≤10%) | <130 mg/dL | ≥130 mg/dL | ≥160 mg/dL |
| 0-1 risk factor [†] | <160 mg/dL | ≥160 mg/dL | ≥190 mg/dL (160-189 mg/dL: LDL-lowering drug optional) |

Based on Grundy SM, Cleeman JI, Merz CN, Brewer HB, et al. Implications of recent clinical trials for the National Cholesterol Education Program Adult Treatment Panel III guidelines. *Circulation* 2004;110: 227-239.

*Coronary heart (artery) disease (CHD, CAD) risk equivalents include diabetes mellitus, peripheral vascular disease, carotid artery disease, and abdominal aortic aneurysm. Risk factors included in Framingham risk evaluation are age, systolic blood pressure, total cholesterol, HDL-C, and smoking status.

[†]The optional goal of less than 70 mg/dL is particularly targeted at patients who are "very high" risk (e.g., recent acute coronary syndrome, poorly controlled diabetes with multiple risk factors).

[‡]When initiating statin therapy in these patients, the goal for LDL-C reduction should be 30% to 40% from baseline.

elevated the level of serum HDL, the lower is the risk for CAD. Therapeutic interventions should not be targeted at reducing serum HDL. Although emerging evidence suggests that some patients may harbor HDL species that appear to be proinflammatory and pro-oxidative because of alterations in their protein and enzyme cargo (Ansell, 2006), treatment with some types of lipid-modifying agents appears to restore normal functionality to these HDL particles (Heinecke, 2009).

Dyslipidemia can be the result of abnormalities in gastrointestinal nutrient absorption, serum and intracellular enzyme activities, and/or cell surface receptor expression. A complete fasting (12-14 hours) lipoprotein profile (including LDL, triglyceride, and HDL) should be obtained on anyone screened for dyslipidemia. Because of the relationship between specific lipoprotein fractions and risk for CAD, measuring total cholesterol levels has little clinical relevance.

Risk Factors

The National Cholesterol Education Program Adult Treatment Panel III (NCEP ATP-III, 2001) has defined risk-stratified, evidence-based target levels for atherogenic serum lipoproteins (Table 27-1). CAD risk is stratified by evaluating

Box 27-1 National Cholesterol Education Program Risk Factors

Negative

High-density lipoprotein cholesterol (HDL-C) >60 mg/dL

Positive

Cigarette smoking

HDL <40 mg/dL

Hypertension (BP >140/90 mm Hg, or use of antihypertensive agents)

Family history of premature coronary artery disease (CAD)

CAD in male first-degree relative <55 years

CAD in female first-degree relative <65 years

Age

Men ≥45 years

Women ≥55 years

a patient's cardiovascular risk factor burden (number of risk factors) and, if two or more risk factors are present, calculation of the Framingham risk score. In the setting of primary prevention, low risk is defined as 0-1 risk factor. Moderate and moderately high risk are defined as 2 or more risk factors with a 10-year Framingham risk of 5% to 10% and 10% to 20%, respectively. Patients who are in the high risk category either have CAD (previous history of MI, stable/unstable angina, revascularization with CABG or percutaneous coronary angioplasty) or a CAD *risk equivalent*, defined as diabetes mellitus, abdominal aortic aneurysm, peripheral vascular disease, significant carotid artery disease (transient ischemic attack or stroke from carotid origin, >50% obstructive atherosclerotic plaque in carotid artery), or a 10-year Framingham risk that exceeds 20%. The American Heart Association (AHA) also defines chronic kidney disease (glomerular filtration rate [GFR] <60 mL/min/1.73 m²) as a CAD risk equivalent. It is important to calculate the Framingham risk score so as to differentiate moderate, moderately high, and high risk among patients with multiple risk factors and no history of CAD or a CAD risk equivalent. An electronic Framingham risk calculator can be downloaded at www.nhlbi.nih.gov/guidelines/cholesterol. Box 27-1 summarizes established CAD risk factors.

Targets

In ATP-III the NCEP implemented these conceptual changes: (1) an optimal LDL-C is defined as less than 100 mg/dL for all patients independent of race or gender; (2) an HDL less than 40 mg/dL is now defined as a categorical risk factor for CAD; and (3) it defined target levels for non-HDL-C. *Non-HDL-C* is defined as total cholesterol minus HDL-C and is an estimate of atherogenic lipoproteins in serum (VLDL + LDL). The risk-stratified target for non-HDL-C is the LDL-C target plus 30 (see Table 27-1). LDL-C reduction is the primary goal of therapy in patients with dyslipidemia. However, in patients with fasting *triglyceride* (TG) levels greater than 200 mg/dL, non-HDL reduction is the secondary priority of therapy. There is currently no specified target for HDL-C elevation. However, in patients with low HDL-C, it is important to try to raise HDL-C as much as possible. According to a recent AHA Consensus Statement, an HDL-C less than 50 mg/dL in women is now considered low (Mosca et al., 2004). The American Diabetes Association (ADA) advocates

Table 27-2 Dietary Recommendations for Therapeutic Lifestyle Change

| Dietary Component | Recommended Allowance |
|---------------------|-----------------------------|
| Polyunsaturated fat | Up to 10% of total calories |
| Monounsaturated fat | Up to 20% of total calories |
| Total fat | 25%-35% of total calories |
| Carbohydrate | 50%-60% of total calories |
| Dietary fiber | 20-30 g/day |
| Protein | About 15% of total calories |
| Dietary cholesterol | <200 mg/day |

HDL-C goals of 40 mg/dL or higher for men and 50 mg/dL or higher for women with diabetes mellitus.

Based on such trials as the Heart Protection Study (Heart Protection Study Collaborative Group, 2002), Treating to New Targets study (LaRosa et al., 2005), and the Pravastatin or Atorvastatin Evaluation and Infection Therapy–Thrombolysis in Myocardial Infarction trial (Cannon et al., 2004), in regard to LDL-C reduction and reducing risk for CAD-related morbidity and mortality, “the lower the better” (Toth, 2004). The NCEP “white paper” recommended that physicians consider treating LDL-C to less than 70 mg/dL and non-HDL-C to less than 100 mg/dL in very-high-risk patients (e.g., recent ACS, diabetic patient with multiple, poorly controlled risk factors) (Grundy et al., 2004). Other therapeutic options include initiating antilipidemic medication with therapeutic lifestyle change if baseline LDL-C is greater than 100 mg/dL in patients with moderately high and high risk; in patients at high risk with baseline LDL-C less than 100 mg/dL, a further reduction of LDL-C by 30% to 40% with medication is a therapeutic option. AHA recommends LDL-C less than 70 mg/dL as a reasonable option for any patient with CAD (Smith et al., 2006).

Nonpharmacologic Interventions

Therapeutic lifestyle change (TLC) is first-line therapy for patients at risk for cardiovascular events. Patients who smoke should stop. The amount of daily consumed cholesterol should be less than 200 mg. Table 27-2 summarizes the distribution of calories from nutrients. Reduced saturated fat and increased consumption of mono- and polyunsaturated fats promote serum LDL-C reduction. The ingestion of viscous fiber and plant stanols decrease cholesterol absorption. Ideally, patients should exercise for 20 to 30 minutes five times per week. Regular exercise promotes weight loss and relieves visceral adiposity and insulin resistance.

Pharmacologic Interventions

Statins

The statins are reversible, competitive 3-hydroxy-3-methylglutaryl coenzyme A (HMG-CoA) reductase inhibitors. HMG-CoA reductase is the rate-limiting step for cholesterol biosynthesis in the liver and systemic tissues. Statins are the

most potent agents for reducing serum levels of LDL-C. The statins augment the elimination of atherogenic apoB100-containing lipoproteins (VLDL, VLDL remnants, and LDL) from plasma by upregulating the LDL receptor on the surface of hepatocytes. The statins also reduce VLDL secretion and stimulate apoprotein-AI expression and hepatic HDL secretion.

Many prospective, placebo-controlled clinical trials have shown that the statins significantly reduce rates of MI, stroke, and coronary and all-cause mortality in the primary prevention (Downs et al., 1998) and secondary prevention settings (Scandinavian Simvastatin Survival Study Group, 1994). Statins reduce the frequency of stable and unstable angina and decrease atheromatous plaque progression and, based on intravascular ultrasound measurement (Nissen et al., 2004), quantitative coronary angiography, and high-resolution magnetic resonance imaging (Corti et al., 2002), even stimulate some degree of plaque resorption. The statins reduce cardiovascular events in men and women, blacks and Hispanics, hypertensive and diabetic patients, smokers, and patients over age 70.

Seven statins are currently available. These drugs differ by potency and a number of pharmacokinetic properties. The choice of statin and its dosing depend on the magnitude of LDL-C and non-HDL-C reduction required (baseline vs. risk-stratified NCEP target). The LDL-C–lowering efficacy of the statins is as follows (e.g., Jones et al., 2003):

Rosuvastatin (Crestor): 45%-63% (5-40 mg daily)

Atorvastatin (Lipitor): 26%-60% (10-80 mg daily)

Simvastatin (Zocor): 26%-47% (10-80 mg daily)

Lovastatin (Mevacor): 21%-42% (10-80 mg daily)

Fluvastatin (Lescol): 22%-36% (10-20 mg daily)

Pitavastatin (Livalo): 32%-43% (1-4 mg daily)

Pravastatin (Pravachol): 22%-34% (10-80 mg daily)

Each doubling of a statin’s dose yields an additional 6% reduction, on average, in serum LDL-C (“rule of 6s”). Patients who are heterozygous or homozygous for familial hypercholesterolemia frequently require high potency statins at their highest doses coupled to stringent restriction in dietary lipid ingestion and the addition of one or more other lipid-lowering agents. The statins induce significant reductions in serum TG levels (typically 10%-25%) and modest elevations in serum HDL-C (2%-14%). Unlike the other statins, atorvastatin therapy is associated with decreasing capacity for raising HDL-C as a function of increasing doses. In patients with high baseline serum TG levels (>300 mg/dL), simvastatin and rosuvastatin raise HDL-C up to 18% and 22%, respectively.

The statins display significant differences in their pharmacokinetic profiles. Because of their relatively short half-life (1-4 hours), lovastatin, fluvastatin, pravastatin, and simvastatin should be taken after the evening meal in order to intercept the peak activity of HMG-CoA reductase, which occurs around midnight. Rosuvastatin and atorvastatin can be taken at any time during the day or night because of their long half-life (~19 and 14 hours, respectively). The coadministration of drugs or compounds that inhibit cytochrome P450 3A4 (macrolide antibiotics [erythromycin, clarithromycin], azole-type antifungals [ketoconazole, itraconazole], cyclosporine, HIV protease inhibitors, nefazodone, >1 qt grapefruit juice daily) with atorvastatin, simvastatin, and lovastatin is contraindicated because these statins depend on this P450 isozyme for oxidative modification and elimination (Neuvonen et al., 1998). CYP3A4 inhibition is associated with increased risk for myopathy and hepatotoxicity. The dose of

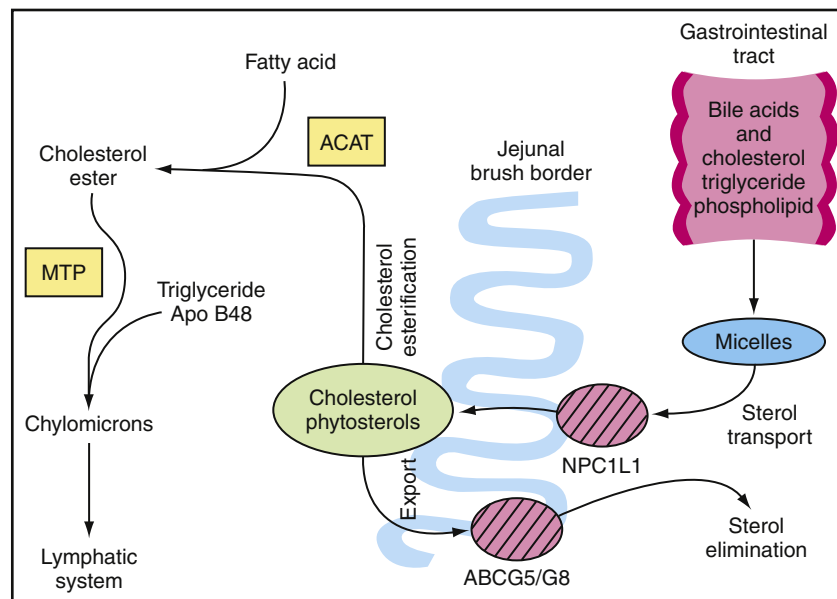

Figure 27-2 Gastrointestinal absorption of dietary and biliary lipid and cholesterol. In the gastrointestinal tract, cholesterol and triglycerides arising from biliary and dietary sources are assimilated with bile salts and phospholipids to form micelles. Micelles transport cholesterol and lipid to the jejunal brush border. Along the enterocyte surface, the sterol transporter known as Niemann Pick C1 Like 1 (*NPC1L1*) protein is responsible for importing cholesterol and phytosterols into the enterocyte. Once internalized, the cholesterol is esterified to cholesterol esters via the activity of acyl-CoA acyltransferase (*ACAT*). The esterified cholesterol is packaged with triglycerides, phospholipids, and apoprotein B48 (*ApoB48*) to form chylomicrons in an assimilation reaction catalyzed by microsomal transfer protein (*MTP*). The chylomicrons are released into gastrointestinal lacteals which conduct these lipoproteins into the central circulation. Excess intracellular sterols can be excreted back into the GI tract via the activity of the sterol exporter complex *ABCG5/G8* (ATP-binding cassette transporter *G5/G8*). (Reproduced with permission from Toth PP, Davidson MH. Cholesterol absorption blockade with ezetimibe. *Curr Drug Targets Cardiovasc Haematol Disord* 2005;5:455-462.)

simvastatin should be 20 mg or less daily in patients being treated with amiodarone or verapamil.

Although there is some concern about the potential toxicity of statins, their benefits significantly outweigh their risks. Liver toxicity can occur and is defined as an alanine transaminase (ALT) elevation of three times or more the upper limit of normal (ULN) on two occasions at least 1 month apart. The average risk of hepatotoxicity from statin therapy is approximately 1%, but risk increases as a function of increasing doses. Mild elevations in serum transaminase levels early during the course of therapy are relatively common and usually resolve spontaneously. If hepatotoxicity develops, statin therapy should be discontinued until transaminase levels normalize and therapy with a different statin can be initiated. There is no documented evidence that the statins increase risk for liver failure. The most important adverse event associated with statin therapy is rhabdomyolysis, myoglobinuria, and renal failure. The risk for rhabdomyolysis is less than 0.1%. Symptoms of rhabdomyolysis include worsening muscle pain, proximal weakness, nausea and vomiting, and brownish-red discoloration of urine. The statins can cause myalgia. If a patient develops myalgia or muscle weakness, a serum creatine kinase (CK) level can be obtained. The diagnosis of myopathy is made when CK levels exceed 10 times ULN. When assessing myalgia, it is important to evaluate patients for pain caused by arthritis, tendinopathy, fibromyalgia, and muscle strain induced by exertion.

Ezetimibe

Dietary and biliary sources contribute significantly to serum levels of cholesterol (Fig. 27-2). Although plant sterols and stanols block gastrointestinal (GI) cholesterol absorption,

ezetimibe (Zetia) is the first member of a class of lipid-lowering drugs known as cholesterol absorption inhibitors. Mechanistically, ezetimibe inhibits the Niemann-Pick C1 Like-1 protein, which mediates cholesterol and phytosterol transport along the brush border of the jejunal enterocyte (Altmann et al., 2004; Davis et al., 2004). After glucuronidation, ezetimibe undergoes enterohepatic recirculation with negligible systemic exposure. The half-life of ezetimibe is approximately 22 hours. When dosed at 10 mg once daily, ezetimibe reduces serum LDL-C on average by 20%, but up to 24% of patients experience a reduction of 25% or greater (Ballantyne et al., 2004; Davidson et al., 2002). Ezetimibe also decreases TGs by up to 8% and raises HDL-C by up to 4%. Ezetimibe does not decrease the absorption of bile acids, steroid hormones (ethinyl estradiol, progesterone), or such fat-soluble vitamins as vitamins A, D, E, or α - and β -carotenes.

The risk of hepatotoxicity with ezetimibe is almost identical to placebo (0.5% vs. 0.3%), and there is no documented evidence of increased risk for myopathy. Fixed-dose ezetimibe is also available in combination with increasing doses of simvastatin (Vytorin; 10/10, 10/20, 10/40, 10/80 mg daily). Ezetimibe can also be safely used in combination with other statins (Toth and Davidson, 2005). The ezetimibe provides additive changes in lipoprotein levels to that observed with statin therapy. The addition of ezetimibe to a statin regimen substantially reduces the likelihood of needing to titrate the statin.

Bile Acid-Binding Resins

The bile acid sequestration agents (BASAs) are orally administered anion-exchange resins that bind bile acids in the GI tract and prevent them from being reabsorbed into the

enterohepatic circulation. These drugs reduce serum LDL-C by two mechanisms: (1) increased catabolism of cholesterol secondary to the upregulation of 7- α -hydroxylase, the rate-limiting enzyme for the conversion of cholesterol into bile acids; and (2) increased expression of LDL receptors on the hepatocyte surface, which augments the clearance of apoB100-containing lipoproteins from plasma. At maximum doses, the BASA can reduce serum LDL-C by 15% to 30% and increase HDL-C by 3% to 5%. It is recommended that these drugs be used in conjunction with a statin whenever possible because BASA therapy increases HMG-CoA reductase activity in the liver, which leads to increased hepatic biosynthesis of cholesterol, thereby offsetting the effects of the BASA over time. The BASAs are contraindicated in patients with serum TG levels greater than 400 mg/dL because these agents can exacerbate hypertriglyceridemia.

There are currently three different BASAs available: cholestyramine (Questran; 4-24 g in 2-3 divided doses daily), colestipol (Colestid; 5-30 g in 2-3 divided doses daily), and colestevlam (Welchol; 1250 mg 2-3 times daily). The development of constipation, flatulence, and bloating is relatively frequent, although colestevlam has the most favorable side-effect profile of the three available BASAs. Increasing water and soluble-fiber ingestion ameliorates some of the difficulty with constipation. The BASA bind negatively charged molecules in a nonspecific manner. Consequently, they can decrease the absorption of warfarin, phenobarbital, thiazide diuretics, digitalis, β -blockers, thyroxine, statins, fibrates, and ezetimibe. These medications should be taken 1 hour before or 4 hours after the ingestion of BASA. The BASA can reduce the absorption of fat-soluble vitamins. Colestevlam also has an indication to reduce serum glycosylated hemoglobin levels in patients with diabetes mellitus.

Fibrates

The fibrates are fibric acid derivatives that exert a number of effects on lipoprotein metabolism. These agents reduce serum TG levels by 25% to 50% and raise HDL-C by 10% to 20%. Fibrates activate *lipoprotein lipase* (LPL) by reducing levels of apoprotein CIII (inhibitor of LPL) and increasing levels of apoprotein CII (activator of LPL) (Fruchart et al., 1999). This stimulates TG hydrolysis in chylomicrons and VLDL. Fibrates increase HDL-C by two mechanisms. First, the fibrates are PPAR- α agonists and stimulate increased hepatic expression of apoproteins AI and AII. Second, by activating LPL, surface coat mass derived from VLDL is ultimately used to assimilate HDL in serum. In some patients, fibrate therapy may be associated with an increase in serum LDL-C (" β " effect) secondary to increased enzymatic conversion of VLDL to LDL. This effect may diminish over time as the patient increases the expression of hepatic LDL receptors.

The fibrates are particularly valuable for treating dyslipidemia in patients with a combination of hypertriglyceridemia and low HDL-C. In this patient type, post hoc evaluations of data from two studies (Helsinki Heart Study and Bezafibrate Infarction Prevention Study) have demonstrated substantial cardiovascular event rate reductions using fibrate therapy (Bezafibrate Infarction Prevention Study Group, 2000; Manninen et al., 1988). In the Veterans Affairs High-Density Lipoprotein Intervention Trial (VA-HIT), men with CAD and low HDL (mean, 31 mg/dL) were treated with either gemfibrozil

(600 mg orally twice daily) or placebo over a 5-year follow-up period (Robins et al., 2001). With a 6% elevation in HDL, no change in LDL, and a 31% decrease in TGs, gemfibrozil therapy resulted in a 22% reduction in the composite end point of all-cause mortality and nonfatal MI versus placebo (Rubins et al., 1999). Gemfibrozil therapy also reduced the risk of stroke and transient ischemic attacks by 31% and 59%, respectively (Rubins et al., 2001). Diabetic patients in VA-HIT treated with gemfibrozil had a 32% reduction in the combined end point (41% in CHD death and 40% in stroke) (Rubins et al., 2002). Fibrates have been shown to exert many of the same pleiotropic effects as statins and to reduce atheromatous plaque progression in native coronary vessels and in coronary venous bypass grafts (Diabetes Atherosclerosis Intervention Study Investigators, 2001; Ericsson et al., 1996).

As with the statins, fibrates are associated with a low incidence of myopathy and mild elevations in serum transaminases. Fibrate therapy can increase the risk for cholelithiasis and elevate prothrombin time by displacing warfarin from albumin-binding sites. The periodic monitoring of serum transaminases (6-12 weeks after initiating therapy and twice annually thereafter) is recommended. The two most common fibrates are gemfibrozil (Lopid; 600 mg twice daily) and fenofibrate (Tricor; 54 or 160 mg daily). Bezafibrate is available in Europe and is dosed at 400 mg daily. The use of therapies combining a statin and fibrate is becoming more commonplace in clinical practice, especially as the incidence of complex dyslipidemias increases (Davidson and Toth, 2004). Gemfibrozil significantly reduces the glucuronidation of statins, which decreases their elimination (Backman et al., 2002; Prueksaritanont et al., 2002a, 2002b). This increases the risk for myopathy/rhabdomyolysis and hepatotoxicity. When used in combination with gemfibrozil, the doses for simvastatin and rosuvastatin should not exceed 10 mg daily. In general, when embarking on combination therapy, fenofibrate is a safer choice because it does not adversely impact the glucuronidation of the statins (Bergman et al., 2004). Fenofibric acid (Tri-lipix) is indicated for use in combination with statin therapy. Although there are no clinical trial data yet available to assess the effect of statin-fibrate combination therapy on cardiovascular morbidity and mortality, the efficacy of fenofibrate used in combination with simvastatin compared with simvastatin monotherapy is being tested in diabetic patients in the Action to Control Cardiovascular Risk in Diabetes Trial (<http://www.nhlbi.nih.gov/health/prof/heart/other/accord/>).

When serum TGs do not normalize in response to a low-fat diet and fibrate therapy, the physician should consider adding other agents. Patients with severe hypertriglyceridemia frequently possess mutations in LPL that reduce its lipolytic activity. The addition of orlistat (Xenical; 120 mg with meals) can reduce the absorption of dietary fat and thus the circulating levels of chylomicrons and TGs. The addition of fish oil should also be considered.

Fish Oils

Fish oil capsules enriched with omega-3 (eicosapentaenoic acid) and omega-6 (docosahexaenoic acid) fatty acids can reduce serum triglyceride and VLDL levels and raise HDL-C

in a dose-dependent manner. The omega-3 fatty acids inhibit the enzyme diacylglycerol acyltransferase-2, thereby reducing intrahepatic TG biosynthesis. They also stimulate mitochondrial beta-oxidation of fatty acids, decrease VLDL production and biosynthesis, and stimulate TG hydrolysis by LPL (Toth et al., 2009). Dietary supplementation with the *n*-3 polyunsaturated fatty acids (PUFAs) eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA) has also been shown to lower the risk of death, nonfatal coronary events, and stroke after MI (GISSI-Prevenzione Investigators, 1999). In several clinical trials, PUFAs have been shown to reduce TG levels by 20% to 30%, and up to 50% in patients with severe hypertriglyceridemia (TG >500 mg/dL) (O'Keefe and Harris, 2000).

The Japan EPA Lipid Intervention Study (JELIS) evaluated whether the addition of fish oils to patients already taking a statin would provide incremental risk reduction. Approximately 19,000 Japanese men and women with hypercholesterolemia were prospectively randomized to statin therapy with or without 1800 mg/day of EPA (Yokoyama et al., 2007). Combination therapy resulted in an additional 19% reduction in major coronary events at 4.6 years of follow-up compared to statin monotherapy.

Niacin

Niacin, or nicotinic acid, is a B vitamin that exerts multiple beneficial effects on lipoprotein metabolism. In contrast to statins and fibrates, niacin does not stimulate hepatic biosynthesis of HDL. Niacin appears to block HDL particle uptake and catabolism by hepatocytes without adversely impacting reverse cholesterol transport. This helps to increase circulating levels of HDL. Niacin reduces hepatic VLDL and TG secretion according to two mechanisms: (1) it decreases the flux of fatty acids from adipose tissue to the liver by inhibiting lipase activity; and (2) it inhibits TG formation within hepatocytes by inhibiting diacylglycerol acyltransferase. Niacin also reduces serum LDL-C concentrations by increasing the catabolism of apoB100. Consequently, niacin beneficially impacts all components of the lipoprotein profile.

When used as monotherapy at 3.0 g daily, crystalline niacin significantly reduced the incidence of MI and stroke in patients with established CAD in the Coronary Drug Project (1975). In the HDL-Atherosclerosis Treatment Study (HATS), combinations of high-dose niacin (2-4 g with simvastatin) reduced cardiovascular morbidity and mortality by up to 90% compared to placebo (Brown et al., 2001). This combination therapy also induced atheromatous plaque stabilization over a 3-year follow-up. Niacin should be started at a low dose and gradually titrated upward based on the results of follow-up lipid panels. When evaluated as a function of dose (500-2000 mg daily), Niaspan induces the following changes in serum lipid levels: LDL-C, 3% to 16% reduction; TGs, 5% to 32% reduction; HDL-C, 10% to 24% elevation (Capuzzi et al., 1998).

Niacin therapy is associated with a number of side-effects. The most common side-effect with niacin is cutaneous flushing; its incidence can be reduced by taking a 325-mg tablet of aspirin 1 hour before taking niacin. The flushing is prostaglandin mediated. Limiting fat intake for 2 to 3 hours before taking niacin also helps as fat is a source of

arachidonic acid, the substrate for cyclooxygenase. Niaspan is a sustained-release preparation of niacin associated with less flushing. Other side effects include bloating, pruritus, acanthosis nigricans, transient disturbances in glyce-mic control, and increased serum concentrations of uric acid. Niacin appears to increase rates of proximal tubular reuptake of urate from the glomerular ultrafiltrate. Niacin is available as a combination pill with lovastatin (Advicor; 500/20, 1000/20, and 2000/40 mg) or simvastatin (Simcor; 500/20, 750/20, and 1000/20 mg) with the two drugs in each combination pill providing additive changes in serum lipoprotein levels.

KEY TREATMENT

Statin, fibrates, niacin, omega-3 fish oils, and bile acid sequestration agents to treat dyslipidemia reduce cardiovascular morbidity significantly (SOR: A).

Statins are the most efficacious drugs currently available for reducing serum levels of LDL and significantly impact risk for both cardiovascular morbidity and mortality (SOR: A).

The omega-3 fish oils also appear to impact cardiovascular mortality, although the evidence is not as strong as with statins (SOR: A). Fibrates have the greatest capacity to reduce serum TGs and reduce cardiovascular morbidity (MI and stroke). The fibrates have not yet been shown to beneficially impact mortality as an independent end point in clinical trials. The fibrates have been shown to reduce rates of atherosclerotic disease progression in both diabetic and nondiabetic patients with CAD (SOR: A).

Niacin raises serum levels of HDL significantly better than other currently available antilipidemic medications, and it also reduces LDL, TGs, and lipoprotein(a) (SOR: A).

Therapy with combinations of drugs (statin-fibrate, statin-niacin, fibrate-niacin, statin-ezetimibe) is frequently required in patients with mixed forms of dyslipidemia and increases the likelihood of therapeutic success. The addition of niacin or omega-3 fish oils to statin therapy does provide incremental cardiovascular risk reduction over statin therapy alone (SOR: A).

The impact of fibrate and ezetimibe adjuvant therapy with a statin is currently being evaluated in prospective, randomized clinical trials.

POTENTIAL FOR HARM

Antilipidemic agents can induce hepatotoxicity and myopathy (SOR: A).

Statins and fibrates may induce transient elevations in serum transaminases and should be discontinued if levels exceed three times ULN. If levels are below this threshold, monitor liver function tests because transaminase levels usually decrease and trend toward normal spontaneously. Often, these drugs are discontinued prematurely to the detriment of patient care (SOR: A).

When combining a statin with a fibrate, use of gemfibrozil should be discouraged because it impairs the glucuronidation and elimination of the statins to varying degrees. This can result in increased risk for hepatotoxicity and rhabdomyolysis (SOR: A). Fenofibrate and fenofibric acid are safer choices in this context.

Patients complaining of myalgias or weakness, especially if escalating, should be monitored for myopathy. The statins and fibrates should be discontinued if serum CK levels exceed 10 times ULN (SOR: A). However, myalgias are common and not necessarily attributable to statin and fibrate use.

In patients presenting with rhabdomyolysis, antilipidemic medications should be discontinued immediately. Patients should be hospitalized, hydrated with intravenous fluids, and provided supportive care.

Table 27-3 JNC-7 Blood Pressure (BP) Classification

| Classification | Systolic (mm Hg) | Diastolic (mm Hg) | Lifestyle Modification | Drug Therapy |
|----------------------|------------------|-------------------|------------------------|---------------------------------------|
| Normal | <120 | and <8 | Yes | Usually no treatment |
| Prehypertension | 120-139 | and 80-89 | Yes | Yes, for compelling JNC-7 indications |
| Stage 1 hypertension | 140-159 | or 90-99 | Yes | Yes |
| Stage 1 hypertension | ≥160 | or ≥100 | Yes | Yes |

From Seventh Report of the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure (JNC-7).

Hypertension

Key Points

- Hypertension is highly prevalent in men and women and people of all ethnic and racial groups
- Hypertension tends to be undertreated in patients with both complicated and uncomplicated forms.
- In uncomplicated HTN the specific choice of drug is less important than the attainment of goal blood pressure.

Hypertension (HTN) is highly prevalent and is a significant risk factor for CAD, left ventricular hypertrophy (LVH), CHF, PVD, stroke, sudden death, nephropathy, and diabetes mellitus. The incidence of HTN increases as a function of age; patients who are normotensive at age 55 have a 90% risk of developing HTN at some point in their lives. Risk for hypertension is regulated by genetic background (e.g., mutations in cell membrane cation transporters in the renal proximal tubular epithelium and vasculature, cell surface receptors, endocrine influences, calcium handling in smooth muscle cells) and environmental factors. The Seventh Report of the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure (JNC-7) provides the current framework for defining and managing HTN in the U.S. population (Chobanian et al., 2003). [Table 27-3](#) summarizes the JNC-7 classification of blood pressure (BP), soon scheduled for revision. The reduction of BP to guideline-specified targets in patients with complicated and uncomplicated HTN substantially reduces risk for acute cardiovascular events, progression of atherosclerosis, and end-organ injury.

As demonstrated by the Framingham Study, BP is a continuous risk factor for CVD, with no threshold effect yet identified (Vasan et al., 2002). For every increase of 20/10 mm Hg in BP above 115/75 mm Hg, risk for CVD increases twofold. Contrary to a widely held misconception in medicine, among patients older than 50 years, the treatment of systolic blood pressure (SBP) reduces risk for CVD and renal disease significantly more than diastolic blood pressure (DBP). Despite the recognized dangers of HTN and the large number of medications available, only one third of patients are treated to target levels in the United States (Whelton et al., 2002). Hypertension is a defining feature of the metabolic syndrome and usually suggests that the patient has

some degree of underlying endothelial dysfunction, with an imbalance between vasodilatory and vasoconstrictive influences impacting the arterial wall.

Recommendations

In response to recent epidemiologic and clinical trial data, JNC-7 made a series of new recommendations for addressing the HTN epidemic, which now includes more than 73.6 million patients in the U.S. alone. Patients with SBP of 120 to 139 mm Hg and DBP of 80 to 89 mm Hg are defined as “prehypertensive” and warrant aggressive lifestyle modification to prevent progression to HTN. It must be assumed that even in this BP range, changes in vessel wall histology and physiology are inducing elevations in BP. Weight reduction, moderation of alcohol intake (2 drinks per day for men, 1 for women), reducing daily sodium intake to 2.4 g/day, increasing aerobic exercise, and the Dietary Approaches to Stop Hypertension (DASH) regimen are all associated with significant reductions in BP (Chobanian et al., 2003). Thiazide diuretics such as hydrochlorothiazide or chlorthalidone, alone or in combination with other antihypertensives, should be used to treat most patients with HTN.

If baseline BP is more than 20/10 mm Hg above target level, initial therapy should consist of two antihypertensive agents (one of which should be a thiazide diuretic unless there is a contraindication) started simultaneously. The majority of patients with HTN will need two or more drugs to achieve adequate control of BP. As demonstrated in the Hypertension Optimization Trial (Hansson et al., 1998), diabetic patients require, on average, 3.4 medications to achieve adequate control. In uncomplicated HTN the BP target is less than 140/90 mm Hg. In patients with diabetes or chronic kidney disease (GFR <60 mL/min/1.73m², baseline serum creatinine >1.5 mg/dL in men or >1.3 mg/dL in women, or albuminuria defined as >300 mg/day on 24-hr urine specimen or 200 mg albumin/g creatine on urine spot check), the BP target is less than 130/80 mm Hg.

A large number of antihypertensive medications are available ([Table 27-4](#)). Prevailing expert opinion now contends that, unless there are compelling indications for the use of a specific drug class because of background cardiovascular or renal disease, it makes little difference whether a calcium channel blocker (CCB), beta blocker, angiotensin converting enzyme inhibitor (ACEI), or angiotensin receptor

Table 27-4 Oral Antihypertensive Drugs (Usual Dose Range)

| Drug | Trade Name | Total mg/day (Freq/day) | Select Side Effects and Comments |
|--|------------------------------------|---------------------------|--|
| Diuretics* (partial list) | | | |
| Chlorthalidone (G) | Hygroton | 12.5-50 (1) | |
| Hydrochlorothiazide (G) | HydroDIURIL, Microzide, Esidrix | 12.5-50 (1) | |
| Indapamide | Lozol | 1.25-5 (1) | Less or no hypercholesterolemia |
| Metolazone | Mykrox Zaroxolyn | 0.5-1.0 (1) 2.5-10 (1) | |
| Loop Diuretics | | | |
| Bumetanide (G) | Bumex | 0.5-4 (2-3) | Short duration of action; no hypercalcemia |
| Ethacrynic acid | Edecrin | 25-100 (2-3) | Only nonsulfonamide diuretic; ototoxicity |
| Furosemide (G) | Lasix | 40-240 (2-3) | Short duration of action; no hypercalcemia |
| Torsemide | Demadex | 5-100 (1-2) | Hyperkalemia |
| Potassium-Sparing Agents | | | |
| Amiloride (G) | Midamor | 5-10 (1) | |
| Spironolactone (G) | Aldactone | 25-100 (1) | Gynecomastia |
| Triamterene (G) | Dyrenium | 25-100 (1) | |
| Adrenergic Inhibitors | | | |
| Peripheral Agents | | | |
| Guanadrel sulfate | Hylorel | 10-75 (2) | Postural hypotension, diarrhea |
| Fanethidine monosulfate | Ismelin | 10-150 (1) | Postural hypotension, diarrhea |
| Reserpine (G) | Serpasil | 0.05-0.25 (1) | Nasal congestion, sedation, depression, activation of peptic ulcer |
| Central Alpha-Agonist[†] | | | |
| Clonidine (G) | Catapres | 0.2-1.2 (2-3) | More withdrawal hypertension |
| Guanabenz acetate (G) | Wytensin | 8-32 (2) | Less withdrawal hypertension |
| Guanfacine (G) | Tenex | 1-3 (1) | |
| Methyldopa (G) | Aldomet | 500-3000 (2) | Hepatic and "autoimmune" disorders |
| Alpha Blockers | | | |
| Doxazosin mesylate | Cardura | 1-16 (1) | Can elevate high-density lipoprotein cholesterol (HDL) |
| Prazosin (G) | Minipress | 2-30 (2-3) | |
| Terazosin | Hytrin | 1-20 (1) | |
| Beta Blockers | | | |
| Acebutolol | Sectral | 200-800 (1) | Bronchospasm, bradycardia, heart failure; may mask insulin-induced hypoglycemia <i>Less serious:</i> impaired peripheral circulation, insomnia, fatigue, decreased exercise tolerance, hypertriglyceridemia (except agents with intrinsic sympathomimetic activity), reduced HDL, impaired glycemic control |
| Atenolol (G) | Tenormin | 25-100 (1-2) | |
| Betaxolol | Kerlone | 5-20 (1) | |

blocker (ARB) is used to initiate therapy in the setting of uncomplicated HTN (Blood Pressure Lowering Treatment Trialists wwwCollaboration, 2003; Julius et al., 2004; National Institute of Clinical Excellence Guideline 18, 2004; Pepine et al., 2003; Williams, 2005). Risk reduction is predominantly driven by the magnitude of BP reduction, rather than the specific mechanism by which it is achieved. Ideally, pharmacologic intervention will be coupled to lifestyle modification in order to achieve lasting and consistent reductions in BP reduction. If a patient's BP is greater than 20/10 mm Hg above goal, initiating therapy with a combination preparation increases the likelihood of therapeutic success and patient compliance. The use of combination therapy is also associated with reduced cost. Many ACEI, ARBs, CCBs, centrally acting drugs (e.g., reserpine, methyldopa), and β -blockers are available in combination with fixed doses of hydrochlorothiazide (12-25 mg) and, less often, chlorthalidone. **Box 27-2** summarizes combinations

of drugs that are efficacious and those associated with undesirable side effect profiles. **Box 27-3** summarizes recommendations for attaining BP targets in the more challenging patient.

Patients with BP poorly responsive to even aggressive intervention should be evaluated further for etiologies such as renal arterial stenosis, adrenal and pituitary tumors, poor compliance, thyroid "storm," and volume overload from acute or chronic renal disease. A broad range of clinical trials have demonstrated that the rate of progression of certain cardiovascular and renal disease states is slowed by the use of particular antihypertensive agents (Chobanian et al., 2003). These constitute "compelling indications" (**Table 27-5**). In patients requiring inhibition of the renin-angiotensin-aldosterone (RAAS) axis (CHF, CAD, post-MI, nephropathy, LVH), an elevation in serum creatinine of up to 35% is tolerable and is not an indication for discontinuing an ACEI or an ARB. In patients who develop

Box 27-2 Sample Antihypertensive Drug Combinations

Desirable

Thiazide diuretic *plus*:

- ACE inhibitor
- Aldosterone antagonist
- Angiotensin receptor blocker
- Beta blocker
- Calcium channel blocker

Calcium channel blocker *plus*:

- ACE inhibitor
- Angiotensin receptor blocker
- Beta blocker
- NDHPCCB (with refractory hypertension; preserved systolic heart function)

Not Desirable

Beta blocker *plus*:

- Central adrenergic inhibitor
- Rate-lowering CCB (NDHPCCB)

Alpha blocker *plus*:

- Central adrenergic inhibitor
- ACE, Angiotensin-converting enzyme; NDHPCCB, nondihydropyridine calcium channel blocker.

hyperkalemia in response to an ACEI or ARB therapy, consideration should be given to reducing their dosage, adding a thiazide diuretic to promote potassium excretion, reducing potassium intake, or, when necessary, discontinuing the drugs and arranging referral to a nephrologist. Acute hyperkalemia can be managed with oral or rectal Kayexalate, a resin that binds and promotes the excretion of GI potassium. Men with HTN and benign prostatic hypertrophy or low serum HDL can be treated with an alpha-adrenergic blocker. In contrast to α -blockade, which can raise HDL levels by up to 20%, β -blockade is associated with reductions in serum HDL. Beta blockers and thiazide diuretics are both associated with the antagonism of glycemic control. Potassium balance should be monitored regularly in patients receiving combinations of ACEI/ARB with aldosterone antagonists. Blood pressure management should be individualized, with providers paying close attention to potential unwanted side effects that may dampen the benefit of BP reduction.

Hypertensive emergencies increase risk for acute MI, hemorrhagic stroke, encephalopathy, and other adverse events. Table 27-6 summarizes intravenous (IV) medications that can be used to reduce BP rapidly in the acute, emergent setting.

The results of two prospective trials may impact JNC-8 recommendations. In the Anglo-Scandinavian Cardiac Outcomes Trial (ASCOT) an atenolol/hydrochlorothiazide (A/H) regimen was compared to amlodipine/perindopril (A/P) in 19,257 subjects with HTN and three other cardiovascular risk factors. Despite nearly identical BP control, the patients randomized to A/P experienced a 23% lower incidence of fatal/nonfatal stroke, 16% fewer cardiovascular events and procedures, 11% lower all-cause mortality, and 30% less new-onset type 2 diabetes mellitus compared to the

Box 27-3 Ten Tips for Attaining Goal Blood Pressure (BP)

1. Establish minimum goal BP; when >15/10 mm Hg above goal, BP monotherapy is unlikely to be effective.
2. In most situations, wait 4-6 weeks before titrating BP medications upward.
3. Realize that most hypertensive patients will ultimately require more than one (>1) drug to attain goal BP, especially those with diabetes, obesity, decreased kidney function, or proteinuria.
4. Initiate lifestyle modifications; diet should limit sodium (<2 g/day), saturated fat, cholesterol, and alcohol intake (<2 drinks/day); appropriate aerobic exercise; and weight loss (if indicated).
5. Remember that hypertension is *not* asymptomatic and that BP medications alleviate more side effects than they cause.
6. Minimize exposure to nonsteroidal anti-inflammatory drugs, including COX-2 inhibitors, when kidney function is reduced (<60 mL/min/1.73m²).
7. A diuretic appropriate to the level of kidney function is essential to the multidrug regimen when more than two (>2) antihypertensives are prescribed.
8. Consider using a dihydropyridine and a rate-lowering calcium antagonist in combination when BP is refractory to treatment.
9. Diuretic doses may need to be relatively high (e.g., furosemide, 160 mg/day in divided doses, or metolazone, 10-20 mg/day) when kidney function is <30 mL/min/1.73m².
10. If BP remains above goal on three or more (≥ 3) antihypertensives (one of which is a diuretic) at near-maximal doses, consider referral to a hypertension specialist or nephrologist.

Table 27-5 JNC-7–Defined Compelling Indications for Use of Specific Antihypertensive Agents in Complicated Hypertension

| Indications | Diuretic | BB | ACEI | ARB | CCB | AA |
|-----------------------------|----------|----|------|-----|-----|----|
| Heart failure | ✓ | ✓ | ✓ | ✓ | | ✓ |
| Post-MI | | ✓ | ✓ | | | ✓ |
| CAD risk | ✓ | ✓ | ✓ | | ✓ | |
| Diabetes mellitus | ✓ | ✓ | ✓ | ✓ | ✓ | |
| Renal disease | | | ✓ | ✓ | | |
| Recurrent stroke prevention | ✓ | | ✓ | | | |

From Seventh Report of the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure (JNC-7).

BB, Beta blocker; ACEI, angiotensin-converting enzyme inhibitor; ARB, angiotensin receptor blocker; CCB, calcium channel blocker; AA, aldosterone antagonist; MI, myocardial infarction; CAD, coronary artery disease.

A/H regimen over a median follow-up of 5.5 years (Dahlof et al., 2005). In the Avoiding Cardiovascular Events through Combination Therapy in Patients Living with Systolic Hypertension trial, 11,506 hypertensive patients were randomized to treatment with either benazepril/amlodipine (B/A) or

Table 27-6 Parenteral Drugs for Treatment of Hypertensive Emergencies

| Drug | Dose | Onset of Action | Duration of Action | Adverse Effects | Special Instructions |
|------------------------------|---|-----------------|--------------------|--|--|
| Vasodilators | | | | | |
| Sodium nitro-prusside | 0.25-10 $\mu\text{m}/\text{kg}/\text{min}$ as IV infusion (max dose, 10 min only) | Immediate | 1-2 min | Nausea, vomiting, muscle twitching, sweating, thiocyanate and cyanide intoxication | Most hypertensive emergencies; caution with high intracranial pressure or azotemia |
| Nicardipine | 5-15 mg/hr IV | 5-10 min | 1-4 hr | Tachycardia, headache, flushing, local phlebitis | Most hypertensive emergencies except acute heart failure; caution with coronary ischemia |
| Fenoldopam mesylate | 0.1-0.3 $\mu\text{m}/\text{kg}/\text{min}$ as IV infusion | <5 min | 30 min | Tachycardia, headache, nausea, flushing | Most hypertensive emergencies; caution with glaucoma |
| Nitro-glycerin | 5-100 $\mu\text{m}/\text{min}$ as IV infusion | 2-5 min | 3-5 min | Headache, vomiting, methemoglobinemia, tolerance with prolonged use | |
| Enalaprilat | 1.25-5 mg q6h IV | 15-30 min | 6 hr | Precipitous fall in pressure in high-renin states; response variable | Acute left ventricular failure; avoid in acute myocardial infarction |
| Hydralazine | 10-20 mg IV | 10-20 min | 3-8 hr | Tachycardia, flushing, headache, vomiting, aggravation of angina | Eclampsia |
| | 10-50 mg IM | 20-30 min | | | |
| Diazoxide | 50-100 mg as IV bolus, repeated, or 15-30 mg/min as infusion | 2-4 min | 6-12 hr | Nausea, flushing, tachycardia chest pain | Now obsolete; when no intensive monitoring available |
| Adrenergic Inhibitors | | | | | |
| Labetalol | 20-80 mg as IV bolus every 10 min 0.5-2.0 mg/min as IV infusion | 5-10 min | 3-6 hr | Vomiting, scalp tingling, burning in throat, dizziness, nausea, heart block, orthostatic hypotension | Most hypertensive emergencies except acute heart failure |
| Esmolol | 250-500 $\mu\text{m}/\text{kg}/\text{min}$ for 1 min, then 50-100 $\mu\text{m}/\text{kg}/\text{min}$ for 4 min; may repeat sequence | 1-2 min | 10-20 min | Hypotension, nausea | Aortic dissection; perioperative |
| Phentol-amine | 5-15 mg IV | 1-2 min | 3-10 min | Tachycardia, flushing, headache | Catecholamine excess |

benazepril/hydrochlorothiazide (B/H). The primary and secondary composite end points comprised (1) nonfatal MI and stroke, hospitalization for angina, resuscitation after sudden cardiac arrest, coronary revascularization, and cardiovascular mortality; and (2) nonfatal MI and stroke and cardiovascular mortality, respectively (Jamerson et al., 2008). The primary and secondary end points were both reduced more with B/A compared to B/H by 19.6% and 21%, respectively. These trials strongly support the use of ACE inhibition therapy combined with the dihydropyridine amlodipine when managing

hypertension. Among patients with established vascular disease or high-risk diabetes mellitus without heart failure, the ONTARGET trial demonstrated that the incidence of cardiovascular events was identical in groups treated with either telmisartan or ramipril (Yusuf et al., 2008). The incidence of angioedema in the telmisartan group was approximately one third of that observed in the ramipril group. Consequently, in patients such as those studied in ONTARGET, it is therapeutically legitimate to treat ACEI-intolerant patients with an ARB.

KEY TREATMENT

If BP is greater than 20/10 mm Hg above target level, two antihypertensives should be started simultaneously, usually including hydrochlorothiazide, although amlodipine is also used with an ACE inhibitor (SOR: A).

The use of combination therapy to treat HTN allows for the interception of multiple mechanisms etiologic for this disorder and increases the likelihood of therapeutic success (SOR: A).

JNC 7 encourages the use of specific antihypertensive agents in the setting of HTN complicated by CHF, CAD, MI, nephropathy, and other forms of CVD (SOR: A).

Lifestyle modification is an important component of HTN management (SOR: A).

Treatment with ACEI and ARBs is associated with decreased risk for new-onset diabetes mellitus in patients with HTN (SOR: A).

The majority of health care providers believe that diastolic BP impacts CVD more than systolic BP; the opposite is true (SOR: A).

POTENTIAL HARM

The CCBs (both dihydropyridines and nondihydropyridines) tend to be underused because of peripheral edema (SOR: A). Combining these drugs with a low dose of hydrochlorothiazide or an ACEI reduces the incidence of edema.

ACEI and ARBs tend to be withheld in patients with mild to moderate renal insufficiency. Such patients benefit significantly from these drugs. An increase in serum creatinine of up to 35% is acceptable, and patients should be monitored for hyperkalemia (SOR: A).

Beta blockers and thiazide diuretics can antagonize glycemic control in patients with insulin resistance and impaired glucose tolerance and are associated with increased risk for diabetes mellitus (SOR: A).

Metabolic Syndrome**Key Points**

- Metabolic syndrome is an insulin-resistant state associated with visceral adiposity, hypertension, hyperglycemia, dyslipidemia, and a proinflammatory and pro-oxidative state.
- Metabolic syndrome is not a CAD risk equivalent but is associated with heightened risk for CVD and diabetes mellitus.
- Metabolic syndrome should be treated with aggressive lifestyle modification, including weight loss, exercise, smoking cessation, and dietary modification.

Causes and Incidence

The incidence of obesity is rising worldwide. With increased mechanization and changes associated with increased food availability and lower average daily caloric expenditure, people are experiencing continuous weight gain with aging. Being overweight and the development of obesity now constitute the second most important preventable cause of mortality. In the United States, 30% of the population is obese, and 70% is overweight. The incidence of obesity is rising among both genders as well as all racial and ethnic groups. An important consequence of obesity is the development of insulin resistance and the metabolic syndrome (Haffner et al., 1990; Haffner and Taegtmeier, 2003). The metabolic syndrome (or "syndrome X") is defined by a constellation of cardiovascular risk factors and is associated with heightened risk for cardiovascular morbidity and mortality. A variety of definitions of the metabolic syndrome have been developed,

Table 27-7 NCEP ATP-III Criteria for Diagnosing Metabolic Syndrome

| Risk Factor | Defining Level |
|--|--|
| Abdominal obesity | Men: waist >40 inches Women: waist >35 inches |
| Triglycerides | ≥150 mg/dL |
| High-density lipoprotein cholesterol (HDL-C) | Men: <40 mg/dL Women: <50 mg/dL |
| Blood pressure | ≥130/ ≥85 mm Hg |
| Fasting glucose | ≥100 mg/dL |

From Third Report of the Expert Panel on Detection, Evaluation, and Treatment of High Blood Cholesterol in Adults (Adult Treatment Panel III) (NCEP ATP-III).

*Patients having any three of the above five risk factors meet criteria for the diagnosis of the metabolic syndrome.

but the one with the greatest clinical utility is that defined by the NCEP ATP-III (Grundy et al., 2004a, 2004b; Eckel et al., 2005). Waist circumference, blood pressure, fasting blood sugar, and serum TG and HDL levels are used to make the diagnosis (Table 27-7). Once three of the five criteria are met, the diagnosis of metabolic syndrome can be made.

Based on data from the Third National Health and Nutrition Examination Survey (NHANES-III), the incidence of metabolic syndrome increases linearly in both men and women as a function of age (Alexander et al., 2003; Ford et al., 2002). Hispanic and Native Americans are disproportionately affected. Current estimates suggest that 24% of the U.S. population have metabolic syndrome. In the Kuopio Ischaemic Heart Disease Risk Factor Study, patients with metabolic syndrome experienced a 3.77- and 2.43-fold increase in risk for coronary heart disease mortality and all-cause mortality, respectively, over 12-year follow-up compared to patients without the metabolic syndrome (Lakka et al., 2002).

Cardiovascular Risk Factors

As waist circumference increases, visceral adiposity increases. Visceral adipose tissue is metabolically highly active. An important conceptual shift has occurred in recent years with respect to how adipose tissue is viewed. It is no longer seen as a passive storage site for excess caloric ingestion. Instead, it is clear that visceral adipose tissue displays many features of an endocrine organ (Bradley et al., 2001; Toth, 2005a) (Fig. 27-3). Visceral adipose tissue produces a variety of inflammatory cytokines (tumor necrosis factor, transforming growth factor-β), interleukins (IL-1, IL-6), and effector molecules that regulate appetite (leptin) as well as insulin sensitivity and resistance (e.g., adiponectin, resistin). As the mass of visceral adipose tissue increases, adiponectin production decreases, which is associated with increased insulin resistance in adipose tissue, skeletal muscle, and the hepatic parenchyma (see Fig. 27-3). As adipose tissue becomes more insulin resistant, the capacity to regulate the catabolism of stored TGs becomes progressively more dysregulated and unresponsive to systemic tissue

Figure 27-3 Insulin sensitivity and degree of adiposity. (From Fujimoto WY, Abbate SL, Kahn SE, et al. *The visceral adiposity syndrome in Japanese-American men. Obes Res* 1994;2:364-371.)

Figure 27-5 Severity of hepatic fat deposition as visceral adiposity worsens. (From Banerji MA, Buckley MC, Chaiken RL, et al. *Liver fat, serum triglycerides and visceral adipose tissue in insulin-sensitive and insulin-resistant black men with NIDDM. Int J Obes* 1995;19:846-850.)

Figure 27-4 Risk of a major coronary heart disease (CHD)-related event associated with quintile of insulin levels in nondiabetic men enrolled in the Helsinki Policemen Study. (From Pyorala M, Miettinen H, Laakso M, Pyorala K. *Hyperinsulinemia predicts coronary heart disease risk in healthy middle-aged men: the 22-year follow-up results of the Helsinki Policemen Study. Circulation* 1998;98:398-404.)

needs. Serum levels of free fatty acids (FFAs) rise. The portal circulation becomes flooded with FFAs, resulting in both increased TG deposition within the liver (nonalcoholic steatohepatitis [NASH] or fatty liver) (Banerji et al., 1995) and increased VLDL secretion resulting in hypertriglyceridemia. A fatty liver in the absence of excessive alcohol intake is an important marker for insulin resistance and is highly correlated with the magnitude and severity of adiposity (Fig. 27-4). Elevation in FFAs induces progressive deterioration in glycemic control by (1) interfering with normal phosphorylation of the insulin receptor, resulting in less expression of a glucose transporter (GLUT 4) necessary for the internalization and oxidation of serum glucose (Dresner et al., 1999), and (2) the induction of "lipotoxicity," the process by which FFAs induce premature apoptosis and dropout of pancreatic β -islet cells. Patients experiencing concomitant worsening insulin resistance and progressive loss of insulin-producing capacity experience a continuum of glycemic disturbance, beginning with impaired fasting glucose, then impaired glucose tolerance, and ultimately diabetes mellitus. As serum levels of insulin rise, risk for CAD-related

events increases precipitously (Pyorala et al., 1996) (Fig. 27-5). Patients with metabolic syndrome have a threefold to fivefold increased risk for developing diabetes compared to patients without metabolic syndrome.

Insulin resistance and increased visceral adiposity in the setting of metabolic syndrome are associated with changes in multiple risk factors (Lamon-Fava et al., 1996) (Fig. 27-6). Insulin-resistant adipose tissue is a potent source of angiotensinogen, the precursor to vasoconstrictor angiotensin II. The BP in these patients also increases because (1) insulin stimulates increased sodium reabsorption at the level of the proximal tubular epithelium, which increases intravascular volume; (2) there is reduced endothelial nitric oxide production (Caballero, 2003); and (3) there is increased vascular sympathetic tone. In the face of insulin resistance, obesity can steadily worsen as a result of dysregulation of central centers transducing the signals for appetite and satiety. Serum HDL levels decrease for three principal reasons (Fig. 27-7). First, as the liver becomes insulin resistant, the capacity for insulin to stimulate the hepatic production of apo AI and AII is compromised, resulting in less HDL secretion. Second, in patients with insulin resistance, lipoprotein lipase is relatively inhibited. This reduces the hydrolysis of triglycerides in VLDL and chylomicrons. These large lipoproteins remain incompletely catabolized and form atherogenic remnant particles. Unless broken down further, they cannot release many of the surface-coat constituents used to assimilate HDL in serum. Third, as HDL particles become more enriched with TGs, they become a better substrate for *hepatic lipase*, an enzyme that catabolizes HDL and promotes its clearance from serum (Toth, 2005b). Patients with metabolic syndrome also tend to have smaller, denser LDL particles. These small LDL particles are believed to be more atherogenic than the larger, more buoyant variety because they are more easily oxidized, have reduced affinity for the hepatic LDL receptor resulting in less systemic clearance, and appear to more easily access the subendothelial space because of their smaller volume (St. Pierre et al., 2001). Visceral adipose tissue promotes increased systemic inflammation by secreting inflammatory mediators and by stimulating hepatic production of C-reactive protein (CRP) through IL-6. As serum levels of such acute-phase reactants as fibrinogen, CRP, and plasminogen activator inhibitor-1

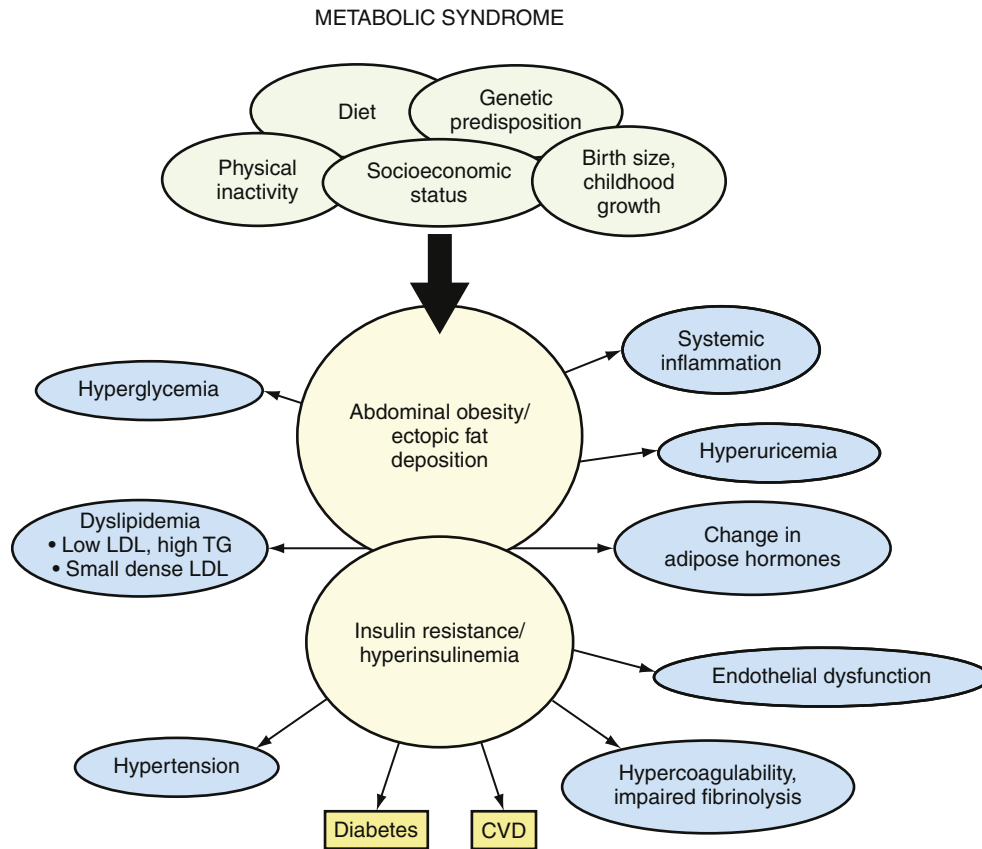

Figure 27-6 Complex interactions among genetic, environmental, and socioeconomic factors increase risk of developing visceral adiposity, insulin resistance with risk factor generation and clustering, and ultimately, diabetes mellitus with atherosclerotic disease. CVD, Cardiovascular disease; LDL, low-density lipoprotein; TG, triglyceride.

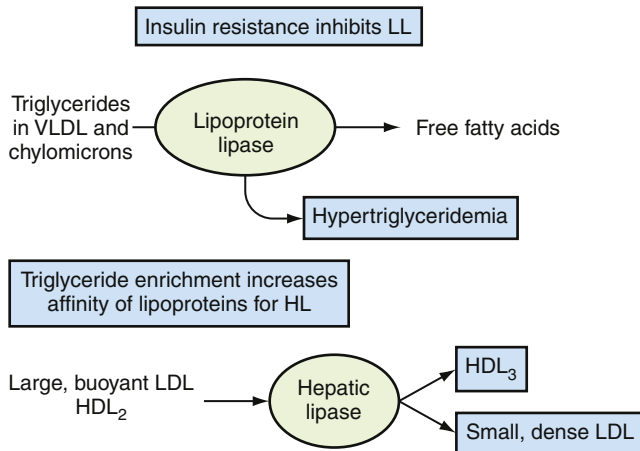

Figure 27-7 Molecular mechanisms that cause the atherogenic lipid triad in patients with insulin resistance. As a patient becomes insulin resistant, the activity of lipoprotein lipase (LL) decreases. This can occur secondary to reduced apolipoprotein CII and/or increased apolipoprotein CIII production. With reduced capacity to hydrolyze the triglycerides in such large lipoproteins as very-low-density lipoprotein (VLDL, derived from liver) and chylomicrons (derived from gut), triglycerides and large remnant particles accumulate in serum. In this scenario, low-density lipoprotein (LDL) levels in serum tend to be relatively low because less VLDL is being converted to LDL. As high-density lipoprotein (HDL) and LDL particles become progressively more enriched with triglycerides, these lipoproteins become better substrates for the enzyme hepatic lipase (HL). HL catabolizes these lipoproteins to form small, dense LDL and HDL. The small HDL particles can be further degraded to their phospholipid and apolipoprotein constituents, thereby reducing circulating levels of this beneficial lipoprotein. (Based on Toth PP, Davidson MH. Comparative effects of lipid-lowering therapies. *Prog Cardiovasc Dis* 2004;47:73-104.)

(PAI-1) rise, the risk for metabolic syndrome and diabetes increases (Dandona et al., 2005; Festa et al., 2002). As shown in the Women’s Health Study, as serum CRP levels increase in women with metabolic syndrome but no prior history of CAD, the risk for an acute cardiovascular event increases significantly (Ridker et al., 2003). As insulin resistance worsens, risk for nonalcoholic hepatic steatosis increases steadily (see Fig. 27-6).

Treatment

Metabolic syndrome is not defined by NCEP as a CAD risk equivalent. It is crucial that these patients undergo comprehensive evaluation of their global cardiovascular risk factor burden. Aggressive lifestyle modification with weight loss, increased exercise and physical activity, smoking cessation, and reductions in carbohydrate and saturated fat intake constitute front-line therapy for patients with the metabolic syndrome (Grundy et al., 2003b; Liu and Manson, 2001; Salmeron et al., 2002). Referral to a dietitian is frequently helpful. Weight loss and aerobic exercise are associated with improved insulin sensitivity and significant improvements in blood pressure and lipid levels (DeFronzo et al., 1987; Franssila-Kallunki et al., 1992). As shown in the Diabetes Prevention Project, aggressive lifestyle modification reduces risk for new-onset diabetes mellitus in obese middle-aged patients by 58% (Tuomilehto et al., 2001). In motivated patients unable to achieve adequate weight loss, pharmacologic intervention is an option. Orlistat (Xenical) is a GI

lipase inhibitor that reduces the absorption of dietary fat from the gut. It facilitates weight reduction and should be taken with meals; its major side-effect is fatty, oily stools that can precipitate diarrhea. Bariatric surgery for morbidly obese patients has been shown to relieve insulin resistance, promote substantial weight loss, reduce BP, and improve dyslipidemia. The Mediterranean diet (increased consumption of fish, legumes, whole grains, olive oil) is associated with weight loss and improvements in lipid, insulin sensitivity, and inflammatory indices.

Serum LDL-C and non-HDL-C should be treated to NCEP-defined targets. Therapeutic effort should be expended to raise HDL-C. The choice of whether a statin or fibrate should be used as initial therapy should be dictated by the specific features of a patient's lipid profile. In post hoc analyses of the Helsinki Heart Study (Manninen et al., 1992), VA-HIT (Robins et al., 2002) and Bezafibrate Infarction Prevention trials (BIP Study Group, 2000), fibrate therapy significantly improved lipid profiles and reduced cardiovascular morbidity and mortality in patients with insulin resistance and the metabolic syndrome. Many of these patients will require combinations of antilipidemic medications to normalize their lipid profiles. Since patients with the metabolic syndrome have activation of the RAAS axis, many authorities on hypertension believe it is reasonable to treat the hypertension of these patients with ACEI and ARBs as first-line therapy (Grundey et al., 2004a, 2004b). However, no clinical trials help to establish whether this is the optimal approach compared to other available classes of antihypertensive medication. On the other hand, a number of studies, including the HOPE (Heart Outcomes Prevention Evaluation Study Investigators, 2000), VALUE (Julius et al., 2004), Captopril Prevention Project (Hansson et al., 1999) and LIFE (Dahlof et al., 2003) trials, among others, have shown that ACEI and ARBs can reduce the onset of diabetes mellitus by 20% to 34% compared to non-RAAS-affecting comparative antihypertensives. Aspirin prophylaxis should be considered in patients with a 10-year Framingham risk that exceeds 10%.

KEY TREATMENT

In metabolic syndrome, comprehensive risk factor evaluation should be undertaken in all patients at risk for diabetes and CVD (SOR: A). Lifestyle modification can reduce risk of developing diabetes mellitus by 58% (Diabetes Prevention Project) (SOR: A). Weight loss can be achieved through caloric restriction, exercise, and when indicated, pharmacologic intervention or bariatric surgery (SOR: A).

Diabetes Mellitus

Key Points

- Diabetes mellitus is a CAD risk equivalent.
- Blood sugar should be regulated aggressively and patients initially treated with a combination of insulin sensitizers, including metformin and thiazolidinediones.
- More than three fourths of diabetic patients will die of complications of macrovascular disease.

Incidence

According to statistics compiled by the U.S. Centers for Disease Control (CDC, 2003), approximately 18.2 million people in the United States had diabetes mellitus (DM). Of these, 13 million are diagnosed, but approximately 5.2 million or more go undiagnosed. Almost all adult patients with DM (90%-95%) have type 2. Based on recent demographic trends, an estimated 1.3 million or more new cases of DM will be diagnosed annually. The World Health Organization (WHO) estimates that by 2025, more than 300 million people will have DM worldwide (King et al., 1998; see also Amos et al., 1997). Diabetes significantly magnifies the risk for MI, sudden death, stroke, CHF, adult-onset blindness and loss of lower extremities, and end-stage renal disease (ESRD). Given its burgeoning incidence, complications of DM will likely incur a level of human suffering unprecedented outside of wartime. This is an issue that must be addressed directly by family physicians worldwide.

Cardiovascular Effects

Diabetes induces diffuse atherosclerotic disease throughout the vascular tree. Almost 80% of diabetic patients will die of cardiovascular disease. The hyperglycemic, insulin-resistant milieu of type 2 DM initiates a broad-ranging cascade of pathophysiology that accelerates atherogenesis. Unfortunately, because of increasing obesity and metabolic syndrome in adolescents and young adults, type 2 DM is becoming relatively common in those younger than 21. Diffuse endothelial dysfunction, the accumulation of damaging advanced glycation end products in the vasculature, and a heavy risk factor burden typify the patient with DM. Diabetes induces a prooxidative and proinflammatory state. Diabetic patients also tend to have hypercoagulability (Meigs et al., 2000), likely from (1) increased hepatic production of coagulation factors; (2) increased platelet reactivity and aggregability; and (3) as endothelial dysfunction progresses, the endothelium produces less tissue plasminogen activator (tPA) and more PAI-1, rendering the surface of the vascular lumen more prothrombotic. This hypercoagulability and disordered fibrinolysis increases the likelihood that acute plaque rupture will result in greater and perhaps complete vascular luminal obstruction with acute ischemia and infarction.

Management

It is critical for diabetic patients to be diagnosed early and their risk factors evaluated and treated comprehensively. In addition to monitoring indices of glycemia, BP, serum lipids, smoking, and obesity status, baseline renal function should be evaluated. Hypertension, dyslipidemia, and albuminuria or proteinuria require aggressive management. Based on the East-West (Haffner et al., 1998) and OASIS (Malmberg et al., 2000) studies, the NCEP has defined DM as a CAD risk equivalent. As shown in the EPIC-Norfolk Study, as hemoglobin A_{1c} (HbA_{1c}) levels steadily rise above 5.0, risk for coronary events rises continuously (Khaw et al., 2004). The ADA recommends that HbA_{1c} be less than 7.0, although the American College of Endocrinology endorses a level less than 6.5. With more aggressive diabetes management, the risk for vascular disease development decreases,

but the risk for episodic hypoglycemia increases (Diabetes Control and Complications Trial Research Group, 1995). The United Kingdom Prospective Diabetes Study (UKPDS 35) demonstrated that for every 1% drop in HbA_{1c}, diabetic patients experience a 21% reduction in any diabetes-related end point, 14% drop in MI, 12% reduction in stroke, and a 37% reduction in risk of microvascular disease (Stratton et al., 2000). In the STENO-2 Study, intensive therapy of blood sugars, BP, and serum lipids resulted in a 50% lower incidence of the primary composite cardiovascular end point compared to “conventional” therapy, which was substantially less aggressive (Gaede et al., 2003). The UKPDS showed that metformin therapy reduces the risk for acute cardiovascular events by 38%. The thiazolidinediones (pioglitazone, rosiglitazone) exert multiple beneficial effects within the vasculature, improve glycemic control and reduce insulin resistance, and improve lipid profiles. In the Prospective Actos Clinical Trial in Macrovascular Events (PROACTIVE) (Dormandy et al., 2005), carotid intima-media thickness in atherosclerosis using pioglitazone (CHICAGO) (Mazzone et al., 2006) and the Pioglitazone Effect on Regression of Intravascular Sonographic Coronary Obstruction Prospective Evaluation (PERISCOPE) trials (Nissen et al., 2008), pioglitazone had demonstrable capacity to reduce risk for stroke and MI and stabilize carotid intima media thickness and coronary atheroma in patients with DM, respectively. Both rosiglitazone and pioglitazone have “durability of effect” relative to metformin and the sulfonylureas, helping to stabilize glycemic control for longer periods without the need for additional antiglycemic medication, possibly because they preserve islet cell insulin secretory capacity (Kahn et al., 2006). Unless there is a contraindication, diabetic patients should take prophylactic aspirin therapy. When initiating therapy for non-insulin-dependent DM (NIDDM), strong consideration should be given to using combination therapy with metformin and a thiazolidinedione to ensure insulin sensitization in the liver, skeletal muscle, and adipose tissue.

Hypertension typically accompanies diabetes. Diabetic patients require, on average, three or more antihypertensive medications to meet BP targets. Based on NHANES-III, 65% to 80% of diabetic men and women (Caucasian, Hispanic, or African-American) either have HTN or BP greater than 130/80 mm Hg. In diabetic hypertensive patients with and without nephropathy, the percentage reaching BP goals is 11% and less than 10%, respectively. Clinical trials have unequivocally demonstrated that BP control decreases risk for acute cardiovascular events and the development of nephropathy in patients with type 2 DM. The Hypertension Optimal Treatment trial evaluated the effect of BP reduction on cardiovascular event rates in 1501 diabetic patients (Hansson et al., 1999). There were increasing, statistically significant differences in the triple composite end point (MI, stroke, and mortality) as diastolic BP was reduced from 90 to 85 to 80 mm Hg. When comparing patients in the groups whose DBP was treated to 80 or less and 90 or less, the more intensively treated group had 51% fewer acute cardiovascular events and 43% less cardiovascular mortality. Importantly, this trial found no confirmation of the “J curve” hypothesis (i.e., the incidence of cardiovascular events increases as DBP decreases secondary to a reduction in coronary perfusion pressure during diastole). There was no increase in adverse

cardiovascular events; DBP was reduced to lower and lower levels. In the UKPDS (1998), 1148 type 2 diabetic patients were randomly assigned to one of two different BP target groups: less than 150/85 (“intensive” treatment) or less than 180/105 (“conventional” treatment). The average achieved BPs over 9 years of follow-up for the two groups were 144/82 and 154/87, respectively. The group that was more intensively treated experienced greater reductions in stroke (44%; $p = 0.01$), diabetes-related mortality (32%; $p = 0.02$), and microvascular complications (37%; $p = 0.009$), including nephropathy and retinopathy, compared to the group receiving conventional treatment. These studies endorse the need for aggressive pharmacologic intervention when treating HTN in diabetic patients.

In diabetic patients with nephropathy, ACEI and ARBs should be used as first-line therapy and titrated as tolerated so as to reduce BP and urinary albumin and protein excretion as much as possible (Brenner et al., 2001; Lewis et al., 1993 and 2001; Mogensen et al., 2000). It is recommended that 24-hour urine specimens be used to monitor the response to therapy and disease progression in patients with nephropathy (Cooper and Gilbert, 2000; Toth, 2003). In diabetic patients with albuminuria, both ACEI (HOPE Study Investigators, 2000) and ARBs (Parving et al., 2001) reduced the magnitude of albumin excretion and decreased the rates of progression to nephropathy. In the recent AMADEO trial, telmisartan was shown to be significantly more effective than losartan at reducing proteinuria in patients with diabetic nephropathy (Bakris et al., 2008). Nondihydropyridine CCBs (diltiazem, verapamil) have also been shown to reduce the magnitude of protein excretion in patients with diabetic nephropathy.

In diabetic patients, reductions in serum LDL and elevations in HDL are the first and the second priority of therapy, respectively, to reduce risk for acute cardiovascular events (Turner et al., 1998). Serum LDL and TG levels should be reduced to less than 100 mg/dL and less than 150 mg/dL, respectively. The ADA (2004) recommends that HDL be raised to 40 mg/dL or greater and 50 mg/dL or greater in men and women, respectively. The choice of antilipidemic medication should be dictated by the specific disturbances characterizing a lipid profile. In such studies as the Collaborative Atorvastatin Diabetes Study (Calhoun et al., 2004) and Scandinavian Simvastatin Survival Study (Pyorala et al., 1997), statin therapy was associated with a 37% and 42% reduction in the risk of cardiovascular events among diabetic patients in the primary and secondary prevention settings, respectively (Dunstan et al., 2002). Fibrate therapy has also been shown to reduce risk for cardiovascular events and rates of atheromatous plaque progression in patients with DM. The thiazolidinediones have also been shown to favorably impact lipoprotein levels (van Wijk et al., 2003).

KEY TREATMENT

Tight control of glycemia, dyslipidemia, and hypertension to nationally defined standards is tantamount to aggressive risk reduction for diabetes (SOR: A).
Treating diabetic patients with statins should be strongly considered regardless of lipid profile (SOR: A).
Nephropathy increases risk for CVD and should be screened for and treated with ACEI/ARB (SOR: A).

C-Reactive Protein

Key Points

- CRP can be measured in patients with a 10-year Framingham risk score of 10% to 20%.
- CRP helps further stratify patients into low-, moderate-, and high-risk groups.
- CRP should not be measured in low-risk or high-risk groups because it is unlikely to alter management.

Elevations in serum levels of C-reactive protein (CRP) have emerged as an important marker of systemic inflammation and increased risk for cardiovascular disease (Ridker, 2001; Ridker et al., 2002). CRP is a pentraxin molecule that, like other acute-phase reactants, is produced by the liver in response to increased levels of IL-6. Approximately one half of all strokes and acute MIs occur in people with normal cholesterol levels (Braunwald, 1997). Consequently, traditional risk factor evaluation does not always accurately identify patients at risk for acute cardiovascular events. Serum CRP levels measured with a high-sensitivity assay (hsCRP) add significant prognostic information when evaluating global cardiovascular risk factor burden at all levels of the calculated Framingham risk score and with all levels of severity of the metabolic syndrome.

Although not yet a therapeutic target, accumulating evidence suggests that CRP may play a direct role in atherogenesis (Ridker et al., 2003; Toth, 2005). CRP stimulates the expression of endothelial CAMs, monocyte chemoattractant protein-1, angiotensin type-1 receptors, endothelin-1 and promotes LDL oxidation. When bound to oxidized LDL, CRP can activate, complement, and promote formation of the cytotoxic membrane attack complex (Bhakdi et al., 1999; Torzewski et al., 1998). CRP induces endothelial cell dysfunction (Venugopal et al., 2002; Verma et al., 2002) and promotes the scavenging of LDL particles by macrophages. CRP is expressed by the cellular constituents of atheromatous plaque, further implicating its role in atherogenesis (Yasojima et al., 2001).

A number of studies have demonstrated a strong relationship between hsCRP and risk for cardiovascular disease. In the Physicians' Health Study, men in the highest quartile of CRP had a threefold higher risk for MI over 8 years of follow-up compared to men in the lowest quartile (Ridker et al., 1997). Similarly, the European Monitoring Trends and Determinants in Cardiovascular Disease (MONICA) study demonstrated a 2.6-fold increased risk for an acute cardiovascular event among men in the highest versus lowest quartiles of CRP over 8 years of follow-up (Koenig et al., 1999). CRP measurements also portend risk in women. Among women enrolled in the Women's Health Study, elevated CRP portends risk for cardiovascular disease and emerged as a better predictor of risk than serum LDL-C (Ridker et al., 2000, 2002). Elevated CRP levels are also associated with increased risk for stroke, metabolic syndrome, and new-onset DM (Pradhan et al., 2001; Ridker et al., 2003; Rost et al., 2001). Among patients with established CAD, a high CRP is associated with increased risk for recurrent ACS (Blake et al., 2003).

The AHA and CDC issued guidelines on the use of CRP for stratifying patients at risk for cardiovascular disease

(Pearson et al., 2003). High-sensitivity assays for this analyte are highly reproducible and accurate. Although other inflammatory markers have demonstrated predictive value (e.g., VCAM-1, lipoprotein associated phospholipase A2), at present, CRP is the only such marker recommended for risk-screening purposes. Patients at low (10-yr risk <5%) and high (CAD, CAD risk equivalent, or 10-yr risk >20%) risk should not be screened for CRP. In the primary prevention setting, the target population consists of patients at moderate risk (10-yr risk 5%-20%). CRP levels less than 1.0, 1.0 to 3.0, and greater than 3.0 mg/L portend low, intermediate, and high risk, respectively, for cardiovascular disease. CRP should be measured twice over 2 weeks and the results averaged; hsCRP values that exceed 10 mg/L suggest acute inflammation and should not be used. The test should be repeated when acute infection or inflammation has resolved. Patients in the high-risk group should institute lifestyle modification. Weight loss, exercise, and smoking cessation reduce CRP significantly. Pharmacologic intervention should be instituted for dyslipidemia, hypertension, and impaired glycemic control as indicated. AHA and CDC do not recommend CRP screening in patients with established cardiovascular disease. These patients should already be receiving aggressive lifestyle and pharmacologic intervention to reduce risk for secondary events.

The Justification for the Use of Statin in Prevention: an Intervention Trial Evaluating Rosuvastatin (JUPITER) trial was a primary prevention trial performed in 26 countries (Ridker et al., 2008). The primary objective was to determine if statin therapy would reduce risk for first-time events in men and women at risk for CVD secondary to elevated hsCRP (>2.0 ng/L) but did not meet criteria for lipid-lowering statin therapy because of a low to normal LDL-C of less than 130 mg/dL, as set by the National Cholesterol Education Program. Men older than 50 and women over 60 were enrolled, had no evidence of atherosclerotic disease, and could not be diabetic. The combined primary end point included stroke, MI, cardiovascular mortality, need for revascularization, and hospitalization for unstable angina. Analysis was by intention to treat. The median age of subjects was 66.0 years. The median baseline lipid profile included: LDL-C of 108 mg/dL, TGs of 118 mg/dL, and HDL-C of 49 mg/dL. The median attained lipid values after 4 years of rosuvastatin therapy included LDL-C of 55 mg/dL, triglyceride of 99 mg/dL, and HDL-C of 50 mg/dL. The median achieved serum CRP level after 1 and 4 years of rosuvastatin therapy was 2.2 and 1.8 mg/L, respectively. Rosuvastatin therapy reduced the relative risk for the primary composite end point by 44% compared to placebo. Significant relative risk reductions with rosuvastatin were also achieved in multiple secondary end points, including nonfatal MI (65%), nonfatal stroke (48%), arterial revascularization (46%), and all-cause mortality (20%). The composite end points of MI, stroke, or hospitalization for unstable angina and MI, stroke, or cardiovascular death were both reduced by 47%. All prespecified subgroups (male/female, age >65 or <65, with or without hypertension, \pm metabolic syndrome, smoking status, Framingham risk score >10% or <10%) derived significant benefit from rosuvastatin therapy. JUPITER is the first primary prevention trial with a statin to demonstrate statistically significant reductions in cardiovascular events for women (46%), elderly patients (>70 yr; 39%), and African American and Hispanic patients

(37%). Projected over 5 years, the number needed to treat (NNT) to prevent one vascular event is estimated at 25, a favorable figure for a primary prevention trial. In JUPITER, rosuvastatin therapy was also associated with reduced risk for thromboembolic phenomena.

Homocysteine

Although homocysteine is widely assumed to be an established risk factor for atherosclerotic disease, little prospective clinical trial or epidemiologic evidence supports this (Christen and Ridker, 2000). It has been known for decades that patients with homocystinuria have increased risk for CAD, stroke, PAD, and thromboembolic events (Handy and Loscalzo, 2003). Many documented enzyme mutations are etiologic for *hyperhomocysteinemia*, which is associated with increased endothelial dysfunction and hypercoagulability. Mutations in methylenetetrahydrofolate reductase, cystathionine- β -synthase, methionine synthase, and γ -cystathionase can lead to elevations in serum homocysteine levels. The supplementation of patients with folate and vitamins B₆ (pyridoxine) and B₁₂ (cyanocobalamin) frequently helps to normalize the levels of patients with hyperhomocysteinemia. These three vitamins are available in a single combination formulation (Folbee, Foltx).

Two clinical trials evaluating folate/B₆/B₁₂ supplementation in patients with CAD and undergoing percutaneous transluminal coronary angioplasty (PTCA) demonstrate the contradictory nature of some data in this field. In one study, triple-vitamin therapy resulted in reduced rates of atheromatous plaque progression, in-stent restenosis, and need for subsequent revascularization of the target lesion (Schnyder et al., 2001). In a subsequent study, triple-vitamin therapy showed increased rates of plaque progression as well as increased in-stent restenosis and need for target lesion revascularization (Lange et al., 2004). The AHA and American College of Cardiology (ACC) currently discourage widespread screening for hyperhomocysteinemia. Seven different randomized, placebo-controlled trials (RCTs) are prospectively evaluating whether treatment of homocystinemia reduces risk for cardiovascular morbidity and mortality.

Cigarette Smoking

Key Points

- Cigarette smoking is the single most preventable cause of mortality in the United States.
- Cigarette smoking cessation reduces risk for myocardial infarction and mortality by 36%.

On an annualized basis, cigarette smoking in the United States incurs over \$193 billion in lost productivity and direct health care costs. Approximately 23.5% of American men and 20.9% of American women are smokers. Unfortunately, the incidence of smoking among adolescents and teenagers continues to rise despite legislation limiting some forms of advertising and the sale of cigarettes to minors. Smoking is the single most *preventable* cause of mortality in the United

States. In addition to increasing risk for developing pulmonary, oral, laryngeal, and bladder neoplasms, cigarette smoking significantly raises risk for developing all forms of atherosclerotic disease and potentiates myocardial ischemia, adverse structural damage to the lung parenchyma, and arterial aneurysm formation. More than 440,000 Americans succumb annually from tobacco-related disease. Smoking also increases risk for erectile dysfunction, osteoporosis, insulin resistance, poor wound healing, pneumonia, and other complications.

Cigarette smoke contains more than 4000 exogenous chemicals. Cigarette smoking is associated with increased intravascular oxygen free-radical production and induces diffuse endothelial dysfunction, resulting in marked reductions in nitric oxide and tissue plasminogen activator (tPA) production (Chia and Newby, 2002). These changes result in increased oxidative injury to cells and lipoproteins, vasoconstriction, and reduced capacity for fibrinolysis in the setting of plaque rupture and overlying thrombus formation. In addition to accelerating rates of atherogenesis in native arteries, continued smoking reduces rates of arterial and venous graft patency in the heart and peripheral vasculature. Cigarette smoking is associated with increased serum levels of multiple emerging risk factors, including CRP, fibrinogen, and homocysteine (Bazzano et al., 2003).

Achieving lifelong smoking cessation in patients who have, or are at risk for, cardiovascular disease is a critical therapeutic goal. Smoking cessation results in a 36% reduction in risk for MI and mortality (van Berkel et al., 1999). Bupropion (Zyban, 150-300 mg orally daily) reduces the intensity of withdrawal symptoms in patients trying to quit smoking by inhibiting the neuronal reuptake of norepinephrine, serotonin, and dopamine. These neurotransmitters are associated with central centers modulating addiction and craving/appetitive behaviors. After taking bupropion for about 2 weeks, patients can begin to wean themselves from cigarette smoke according to a plan established with their provider. Sustained smoking cessation is facilitated by continuing bupropion for 3 to 6 months after patients smoke their last cigarette. Continued counseling and encouragement are important. Smoking cessation classes are also usually available as part of community health awareness programs. Another approach involves the use of nicotine replacement therapies, such as NicoDerm CQ or Habitrol (transdermal delivery systems) and Nicorette gum. These therapies also control withdrawal and craving by providing an alternative source of nicotine that can be progressively weaned over weeks to months. One recommended regimen for the nicotine patch is to wear each dose (21, 14, and 7 mg) for 1 month in a stepped-down fashion. Patients wearing the patch should be counseled not to smoke because this can induce headache, nausea, flushing, and even angina. If a patient cannot achieve smoking cessation on single-agent therapy, the combination of bupropion and a transdermal nicotine patch has been shown to increase success rates compared to the use of either agent alone.

Another smoking-cessation agent, varenicline (Chantix), is a nicotinic acetylcholine receptor agonist that controls withdrawal symptoms during abstinence from nicotine. Treatment with varenicline at 1 mg orally twice daily is associated with a 44% smoking-discontinuation rate after 3 months of continuous therapy (Gonzales et al., 2006). However, side effects have been a concern.

KEY TREATMENT

Smoking cessation is facilitated by patient education about the dangers of smoking and pharmacologic intervention with nicotine replacement products, bupropion, and varenicline (SOR: A). Relapse rates are high in the absence of education, encouragement, and individualized courses of therapy and follow-up (SOR: A).

Coronary Artery Disease**Stable Angina**

Angina pectoris can manifest as chest pain, chest pressure, or a heavy feeling or squeezing sensation. Angina is a symptom of myocardial ischemia. Stable angina is caused by a mismatch between coronary blood supply and myocardial oxygen demand. The latter is determined by several factors, including heart rate and left ventricular wall stress and contractility (Braunwald, 2000). Coronary supply is determined by oxygen transport capacity and delivery and conditions that regulate the coronary circulatory system (e.g., nitric oxide, endothelin), autonomic nervous system, metabolic activity, neural control, and perfusion pressure. Several pharmacologic interventions also affect the coronary circulation, including adrenergic receptor activation or blockade, adenosine, and acetylcholine. Most coronary flow occurs during systole, whereas only 25% of flow occurs in diastole (Feigl, 1998; Yada et al., 1999).

In stable angina, blood flow cannot meet myocardial oxygen demands because of an obstructive atherosclerotic plaque in one or more coronary arteries (Fig. 27-8). It typically occurs predictably with exertion and resolves within minutes of initiating rest. This stable angina pattern does not usually occur at rest. Nonatherosclerotic obstructive CAD can also cause angina. Although infrequent, it could be mediated by myocardial bridging, vasculitis, or congenital malformation of the coronary arteries. In addition, conditions without obstructive CAD (e.g., cardiomyopathies, valve disease) can trigger angina (Lee, 2000).

Symptoms of stable angina differ among patients. Angina can be perceived as a pressure, tightness, squeezing, or heaviness in the chest. This could radiate to the arm, jaw, shoulders, back, or abdomen. The pain can be associated with an increase in shortness of breath, a feeling of nausea, diaphoresis, or occasional vomiting. Lightheadedness and anxiety might accompany those symptoms. Patients might describe one or more of these symptoms, which can be very atypical in female and diabetic patients. Finally, as observed in patients with long-standing DM, myocardial ischemia can be silent with no angina reported. Dyspnea without chest pain can be an “anginal equivalent.” Ischemia can induce stiffness in the myocardium and reduces ventricular relaxility, which in return raises left ventricular end-diastolic pressure and leads to dyspnea. Angina or anginal-equivalent symptoms typically resolve with rest or nitroglycerin.

Noncardiac chest pain typically occurs with certain maneuvers, such as taking a deep breath (e.g., sharp pleuritic pain), palpation of the chest wall (as in musculoskeletal pain, costochondritis), or after certain types of food ingestion (e.g., esophageal pain from refluxed acid). If chest pain is noncardiac in origin or the cause of pain cannot be easily identified, it is important to rule out pulmonary embolism (Lee, 2002) or aortic dissection (Collins, 2004) because these etiologies

Figure 27-8 Glacov remodeling of the coronary lumen in response to early plaque formation.

can be fatal if missed. Pulmonary hypertension and pericarditis are also part of the differential diagnosis.

Several signs may be noted on examination in a patient with angina. Paradoxical splitting of the second heart sound (S₂), systolic murmurs, and S₃ or S₄ can be appreciated during an anginal episode. Findings of cardiomyopathy or valvular disorders may help establish the diagnosis of a noncoronary cause of chest pain. Patients can also be hypertensive, have signs of hyperlipidemia (arcus cornea or xanthelasmas), or findings of diabetes (neuropathy or diabetic retinopathy).

Noninvasive Testing**Electrocardiogram**

The electrocardiogram (ECG) often does not show ischemic changes in patients with stable angina who are at rest and have no symptoms. The resting ECG, however, might show nonspecific ST-segment and T-wave abnormalities in a patient with known severe CAD. False-positive results are common in patients with left ventricular hypertrophy (LVH), digoxin intake, electrolyte imbalances, or electrical conduction anomalies such as bundle branch blocks (BBBs) or preexcitation syndromes.

The ECGs need to be compared to previous readings. Frequently, new Q-wave abnormalities or the emergence of conduction disturbances might indicate an interval change in the patient's cardiac status. The ECG can be helpful during an episode of chest pain, when more than 50% of patients with normal resting ECG show new changes. Typically, these changes include the presence of ST-segment depression or elevation in two contiguous leads, new T-wave inversions or pseudonormalization of already-inverted T waves.

Exercise Treadmill Stress Testing

Exercise treadmill testing can be performed in patients who are able to exercise on a treadmill. Using different protocols (Bruce, Modified Bruce, Naughton), the patient exercises at

Figure 27-9 Myocardial perfusion scan shows reversible ischemia in the anterior wall, apex, and inferior wall.

different inclines and speeds until achieving 85% of peak predicted heart rate for age ($[220 - \text{age}] \times 85\%$). The test provides information about the presence of ischemic ST-segment changes, reproducibility of chest pain, arrhythmias, and changes in BP, heart rate, and functional capacity. Patients with good functional capacity generally have a good prognosis. An early positive stress test (in first two stages of exercise) can indicate a worse prognosis. The mean sensitivity of this test is 68% and specificity 77% (Gibbons et al., 2002). Some studies indicate that, when selection bias is removed, the sensitivity can be as low as 40% to 50%, but specificity as high as 85% to 90% (Detrano et al., 1989; Gianrossi et al., 1989).

The test specificity is reduced when baseline ECGs are abnormal with LVH, preexcitation syndrome, or BBB, or if the patient is taking digoxin (Sketch et al., 1981; Sundqvist et al., 1986) or has electrolyte abnormalities (Gibbons et al., 2002; Froelicher et al., 1999). Also, if a patient cannot reach target heart rate, the diagnostic accuracy of the test is diminished. If a patient experiences chest pain and 1 mm ST-segment depression during exercise, the test can be 90% predictive of the presence of CAD. A 2 mm ST depression accompanied by chest pain is almost pathognomonic of the presence of obstructive CAD. It should be noted that the presence of anti-ischemic agents (nitrates, β -blockers, calcium channel blockers) can reduce the sensitivity of the test and should be withheld for 2 to 3 days before the procedure for long-acting drugs and 24 hours for short-acting drugs, if the intent from the test is to diagnose the presence of obstructive disease (Gibbons et al., 2002).

A treadmill stress test can be a first choice test to diagnose CAD by the family physician, in both male and female patients, assuming the patient can exercise on a treadmill,

the baseline ECG has no indication of LVH or conduction abnormalities, and the patient has no electrolyte disturbances and is not taking digoxin (Melin et al., 1985). When adjusting for the pretest probability of disease, female patients have only a slightly reduced specificity on a regular stress than male patients. A baseline borderline ST-segment depression less than 1 mm is not an exclusionary criterion to perform a treadmill stress test.

The absolute contraindications to stress testing are decompensated CHF, symptomatic severe aortic valve stenosis, ongoing rest chest pain, a recent MI (in past week), severe hypertension, and intractable arrhythmias. When patients have conditions that reduce the specificity of a stress test, an imaging stress test (nuclear or echocardiographic) can more accurately evaluate for CAD.

Stress Myocardial Perfusion Imaging

Myocardial perfusion imaging (^{99m}Tc -sestamibi, ^{99m}Tc -tetrofosmin, or thallium-201) provides a more accurate modality to diagnose the presence of obstructive CAD than a treadmill ECG alone (Fig. 27-9). The sensitivity and specificity of this test have been reported to be 88% and 72%, respectively. When referral bias is accounted for, the specificity of this test is as high as 90%. In addition to myocardial perfusion, the test provides information about ejection fraction and wall motion abnormalities and is very valuable to predict a patient's prognosis (Klocke et al., 2003).

Nuclear stress testing is expensive, so regular treadmill testing is considered as the first diagnostic modality when possible. Nuclear stress testing is useful in patients with the likelihood of a low-specificity treadmill ECG. Nuclear imaging can provide information about prognosis and myocardial viability in regions of wall motion abnormalities, as well

as help localize the area of myocardium in jeopardy. As with most stress tests, these are best ordered in patients with an intermediate likelihood of obstructive CAD.

Myocardial perfusion imaging can be also performed with the induction of pharmacologic stress, usually with adenosine or dobutamine. Adenosine is a vasodilator and stresses the heart by a “steal phenomenon.” Adenosine and dipyridamole dilate normal coronaries, shunting blood from abnormal regions of the myocardium and creating a discrepancy in perfusion between normal and abnormal regions. Dobutamine increases heart rate and contractility and therefore increases myocardial oxygen demand.

Adenosine is typically infused over 4 or 6 minutes, depending on the protocol used. The infusion rate of 140 µg/kg/min starts with ECG monitoring. Usually halfway through the infusion, sestamibi (Myoview) or thallium is injected. Adenosine causes flushing, shortness of breath, nausea, chest pain, and a “strange” feeling in most patients that does not reflect the presence of CAD. Adenosine can also cause bradycardia and a high-degree atrioventricular (AV) block. Patients should not take any caffeinated beverages for at least 12 to 24 hours before the test. Also, adenosine can precipitate asthma and should not be used in patients with hyperreactive airway disease. Adenosine is an excellent choice for a test in patients who cannot exercise on a treadmill or those with a left BBB or a pacemaker rhythm. The sensitivity and specificity of adenosine stress imaging are 90% and 82%, respectively (Klocke et al., 2003).

Dobutamine is infrequently used and is reserved for patients who cannot exercise on a treadmill and have a contraindication to taking adenosine. Dobutamine is infused at 10 µg/kg/min for 3 minutes and then increased by increments of 10 µg/kg/min every 3 minutes to a maximum of 50 µg/kg/min, or if target heart rate has been achieved. If despite this high dose of dobutamine, target heart rate is not achieved, atropine is administered to a maximum of 1 to 2 mg. Cardiolite is injected typically at target heart rate, and the infusion is then terminated. Patients are generally observed for at least 10 minutes post-test or until the heart rate is below 100 beats/min. Dobutamine can cause a shaky feeling, nausea and arrhythmias. In general, it is well tolerated.

Although pharmacologic nuclear stress imaging provides similar diagnostic accuracy to treadmill nuclear stress testing, patients are best exercised on a treadmill. More information can be obtained from the treadmill test, including functional capacity, presence of arrhythmias with exercise, and hemodynamic response to physical exertion.

Stress Echocardiography

Stress echocardiography is an alternative imaging stress test to a nuclear stress test (Cheitlin et al., 2003). However, the sensitivity is slightly lower with an increase in specificity, making the overall accuracy of this test similar to stress nuclear imaging. Stress echocardiography is performed by obtaining an initial resting echocardiogram to assess a patient’s left ventricular ejection fraction, wall motion characteristics, and cavity size. In about 25% of patients, it may be difficult to obtain optimal echocardiographic images for adequate interpretation of the test, and therefore an alternative stress testing is needed. This is particularly true in patients with severe chronic obstructive pulmonary disease (COPD) and patients with severe obesity. Patients are then exercised on a treadmill

using a symptom-limited protocol. Patients need to achieve the minimum target heart rate for age (85% of maximum predicted) but preferably a higher rate to allow ample time for the sonographer to obtain immediate post-stress echocardiographic images while the heart rate is still over target. Typically, the sonographer needs about 20 to 30 seconds to obtain these images. In patients who cannot exercise, dobutamine can be used as previously described to achieve the target heart rate, and then the infusion is discontinued when all echocardiographic images are acquired.

Regardless of the modality of stress testing, a test should be terminated when a patient displays significant arrhythmias, lightheadedness, a symptomatic drop in BP, or significant ischemic changes on the ECG, particularly if associated with anginal symptoms. Also, a stress test should not be performed in patients with unstable rest symptoms, frequent arrhythmia, known severe left main disease, severe symptomatic valvular disease, or decompensated CHF. The test needs to be closely monitored at all times by the technician, and a physician must always be nearby and frequently checking ECG changes and assessing the patient’s symptoms and progress.

Computed Tomography of Heart

Multidetector computed tomography (MDCT) of the heart has recently emerged as an imaging modality for the diagnosis of coronary artery disease. As with the majority of noninvasive testing, MDCT is helpful in identifying CAD in patients with an intermediate pretest probability for CAD. Very-high-risk patients are not appropriate for this test and should undergo an invasive angiographic assessment. A negative MDCT result for CAD is helpful to exclude CAD, given the very high specificity of this test and thus low false-positive rate. Patients with equivocal noninvasive stress testing are ideal candidates, and if negative, MDCT can add to the reassurance of lack of significant obstructive CAD. CT angiography is not a screening tool in asymptomatic patients. Furthermore, MDCT is a reliable tool to evaluate bypass grafts and is an excellent test for identifying coronary anomalies (Cury et al., 2007). The test is not risk free, and the patient needs to be counseled on the risk of radiation exposure and contrast dye reactions.

Pharmacologic Management

Patients with stable angina have an imbalance between coronary blood supply and demand. Also, they are at increased risk of MI and arrhythmias. Medical therapies therefore should focus on alleviating angina, reducing plaque progression and rupture, and restoring a patient’s functional capacity. Some reversible causes of angina need to be evaluated, such as conditions that increase myocardial oxygen demand. These include fever, thyrotoxicosis, anemia, and cardiac stimulants such as cocaine or amphetamines. Severe valvular dysfunction and CHF might also be precipitating factors.

Nitrate Therapy

Nitrate therapy reduces myocardial oxygen demand by increasing venous capacitance and therefore reducing venous return and ventricular wall stress. Also, nitrates increase coronary blood supply by dilating the coronary arteries (Parker and Parker, 1998). Administering nitrates to patients with stable

angina increases their symptom-free walking distance and reduces the frequency and severity of their anginal episodes. Nitrates are not known to reduce risk for MI significantly or to prolong survival. On a chronic basis, nitrates can be administered orally or transdermally. Regardless of the mode of administration, it is important to have 8 to 10 hours of a nitrate-free period to avoid tolerance to this drug (Parker et al., 1995). Intravenous nitroglycerin is reserved for the unstable angina patient to reduce anginal pain and intracardiac filling pressures and to improve symptoms of heart failure.

Beta-Adrenergic Blockade

Beta-adrenergic blockers reduce myocardial oxygen demand primarily by reducing heart rate and contractility. Beta blockers are essential in patients with stable angina and a history of prior MI or reduced left ventricular function. In these conditions, β -blockers can prolong survival and should be administered to those patients unless absolutely contraindicated (Gottlieb et al., 1998).

It is unclear whether survival or serious arrhythmias are reduced in patients with stable angina and no prior MI or left ventricular dysfunction. Relative or absolute contraindications to beta-blocker therapy include patients with severe hyperreactive airway disease, heart block, severe bradycardia, or severe symptomatic peripheral vascular disease.

Calcium Channel Blockers

Long-acting CCBs are potent anti-ischemic drugs and also can be used to treat the patient with stable angina (Braunwald, 1982). Generally, short-acting CCBs need to be avoided because of the potential to increase adverse events. Dihydropyridines such as amlodipine (Norvasc) or nifedipine (Procardia XL) do not alter heart rate significantly and are primarily vasodilators. Diltiazem reduces heart rate but also increases coronary blood supply, whereas verapamil reduces oxygen demand primarily by reducing heart rate with less vasodilatory effects.

Ranolazine

Ranolazine (Ranexa) inhibits the cardiac late sodium current typically present in patients with ischemia. An increase in the late sodium current leads to excess entry of calcium into cardiomyocytes, which impairs cardiac relaxation. Ranolazine does not increase the rate pressure product, and its exact antianginal mechanism of action is unknown. In the Combination Assessment of Ranolazine in Stable Angina (CARISA) trial, patients were randomized to ranolazine and placebo added to standard antianginal therapy (Chaitman et al., 2004). Ranolazine increased exercise duration time and time to angina onset significantly, which was sustained at 12 weeks of therapy. Furthermore, in the Efficacy of Ranolazine in Chronic Angina (ERICA) RCT, ranolazine versus placebo was administered in patients with at least three anginal attacks per week despite high-dose amlodipine (10 mg/day). Over a 6-week period, ranolazine reduced anginal frequency by 23% and weekly nitroglycerin use by 25% compared to placebo (Stone et al., 2006).

Antiplatelet Agents

In high-risk patients, aspirin (81 mg) reduces vascular events by approximately 35% and is a prime therapy in patients with stable angina (Antiplatelet Trialists Collaboration, 1994). Aspirin is very effective in reducing MI in healthy subjects and elevated serum CRP levels (Ridker et al., 1997).

Aspirin resistance has been reported recently and can be present in approximately 25% of patients. Also, aspirin hypersensitivity is common and primarily related to GI side effects. Aspirin's side effects (e.g., bleeding, dyspepsia) can be reduced without compromising its effectiveness with the use of enteric-coated aspirin.

Clopidogrel (Plavix), an ADP-receptor antagonist, is a potent irreversible antiplatelet drug. In the Clopidogrel versus Aspirin in Patients at Risk of Ischaemic Events study (CAPRIE Steering Committee, 1996), Clopidogrel was slightly but statistically more effective than aspirin in reducing cardiovascular events in high-risk patients with a history of stroke, MI and peripheral vascular disease (8.7% relative risk [RR] reduction; $p = 0.043$). The combination of aspirin and clopidogrel in stable angina patients with no recent unstable coronary syndrome is unknown and currently being tested in the Clopidogrel for High Atherothrombotic Risk and Ischemic Stabilization, Management, and Avoidance (CHARISMA) trial (Bhatt and Topol, 2004). Clopidogrel is an effective alternative to patients who are unable to take aspirin.

In addition to the previous measures, aggressive management of dyslipidemia, hypertension, impaired glucose control, and smoking cessation are essential interventions to reduce future cardiovascular events in the stable angina patient. Cardiac rehabilitation is a critical therapeutic modality in patients with CAD, particularly after revascularization. The initiation of hormone replacement therapy in postmenopausal females is not indicated for cardiovascular risk reduction.

KEY TREATMENT

Beta blockers are recommended as initial therapy in the absence of contraindications in patients with or without prior myocardial infarction.

Aspirin is strongly recommended in patients with stable angina in the absence of contraindications.

ACC/AHA guidelines (Antman et al., 2008): SOR: A.

SECONDARY PREVENTION, CHRONIC STABLE ANGINA*

1. Comprehensive risk factor management and cardiac rehabilitation are essential in the management of the stable angina patients (SOR: A).
2. Recommended lipid management includes assessment of a fasting lipid profile. LDL-C should be less than 100 mg/dL (SOR: A).
3. Angiotensin-converting enzyme (ACE) inhibitors should be started and continued indefinitely in all patients with left ventricular ejection fraction (LVEF) of 40% or less and in those with hypertension, DM, or chronic kidney disease, unless contraindicated (SOR: A).
4. Angiotensin receptor blockers (ARBs) are recommended for patients who have hypertension, have indications for but are intolerant of ACE inhibitors, have heart failure, or have had an MI with LVEF of 40% or less (SOR: A).
5. Aldosterone blockade is recommended for use in post-MI patients without significant renal dysfunction or hyperkalemia who are already receiving therapeutic doses of an ACE inhibitor and a beta blocker, have LVEF of 40% or less, and have either diabetes or heart failure (SOR: A).
6. It is beneficial to start and continue beta-blocker therapy indefinitely in all patients who have had MI, acute coronary syndrome, or left ventricular dysfunction with or without heart failure symptoms, unless contraindicated (SOR: A).

*ACC/AHA quoted guidelines (Fraker, 2007).

Mechanical and Revascularization Strategies

Coronary Angioplasty and Bypass Surgery

Coronary angioplasty and stenting are currently reserved for patients who (1) are symptomatic and have failed optimal medical therapy with antianginal drugs or (2) have a moderate to large area of ischemia on nuclear scintigraphic imaging, severe proximal left anterior descending artery disease, single- or double-vessel CAD, or three-vessel CAD in nondiabetic patients with preserved left ventricular function.

Coronary artery bypass surgery is reserved for patients with (1) left main disease or severe three-vessel CAD, particularly diabetic patients or those with reduced left ventricular function, or (2) unsuitable anatomy for coronary angioplasty or those with disease in multiple CABGs, especially if the graft to the left anterior descending coronary artery is involved and can be considered for bypass surgery.

Enhanced External Counterpulsation (EECP)

Mechanical interventions such as EECP can be effective in the treatment of the patient with stable angina who is not a candidate for revascularization and has continued chest pain despite medical therapy (Michaels et al., 2005). This therapy requires about 32 sessions of 1-hour duration for 5 days a week. Although its functional mechanism is largely unknown, EECP improves exercise tolerance, reduces exercise-induced myocardial ischemia, and improves left ventricular diastolic filling in patients with CAD (Urano et al., 2001). Future therapies such as gene therapy to stimulate angiogenesis in the coronary arteries are being tested as an alternative to EECP in these patients.

Acute Coronary Syndromes

Key Point

- Patients with definite acute coronary syndrome should be evaluated for immediate reperfusion therapy (ACC/AHA guidelines; SOR: A).

Acute coronary syndromes (ACS) occur as a result of sudden atheromatous plaque rupture. Plaques with heightened inflammation, irrespective of severity, can rupture leading to overlying platelet and fibrin mesh formation, resulting in abrupt cessation of coronary blood flow. Patients might experience unstable angina or myocardial infarction (MI), depending on whether myocardial necrosis occurs. In the United States, 2.3 million people suffer an ACS annually.

Several crucial facts need to be considered by the practicing family physician. First, a large percentage of angiographically “normal” coronary arteries have significant plaque burden by intravascular ultrasound or magnetic resonance imaging (MRI), particularly in patients older than 40 years. Second, more than 60% of MIs are induced by culprit lesions that initially obstruct less than 50% of the arterial lumen. These lesions are generally not detected by stress testing. Third, when an ACS occurs, multiple vulnerable plaques generally coexist at the same time throughout the vascular tree. In an inadequately managed patient, any one of these lesions could suddenly rupture and precipitate an ACS. Therefore, a normal stress test does not necessarily exclude the possibility

of CAD and risk for MI. The prevention of MI should focus on reducing the chance of plaque rupture by controlling and normalizing, as much as possible, multiple cardiac risk factors, including hypertension, uncontrolled diabetes, dyslipidemia, obesity, lack of routine exercise, a heightened inflammatory state, and smoking.

Unstable Angina/Non-ST Segment Myocardial Infarction

Patients with unstable angina or a non-ST segment MI experience a partial occlusion to coronary flow as a result of plaque rupture and thrombus formation, microembolization, or the release of vasoactive substances leading to localized spasm. Patients typically have severe chest pain, with rest or minimal activity, which can be of sudden onset and with no preceding warnings and likely to last for more than 20 minutes unless treated with anti-ischemic agents. These patients are at high risk of ST-segment elevation MI and sudden death. Data from the Thrombolysis in Myocardial Infarction III (TIMI-III) registry indicated that death and MI could occur in these patients at a rate of 7.3% to 18.5%, depending on the severity of their symptoms, with postinfarction angina carrying the highest risk (Sharis et al., 2002). Patients might have electrocardiographic changes to indicate ischemia, mostly ST-segment depression in contiguous leads, T-wave inversion, or pseudonormalization of T waves. However, the electrocardiogram (ECG) could also be silent. Comparing the ECG to a previous one can be very helpful for detecting subtle but significant new changes.

Patients with suspected unstable angina should be referred to the emergency department (ED) or a specialized chest pain unit as soon as possible. They should be encouraged to call 9-1-1 and not drive themselves to the ED. A complete evaluation of their chest pain, including a comprehensive physical examination and history, obtaining an ECG within 10 minutes of arrival, chest radiograph and cardiac enzymes (e.g., troponin I, creatinine kinase MB), needs to be performed. Patients should be admitted to the hospital if they have ischemia on the ECG (ST-segment deviation or new T-wave abnormalities or new left BBB), ongoing chest pain, abnormal cardiac biomarkers, or develop CHF or hemodynamic instability.

Abnormal cardiac enzymes allow a definite diagnosis of MI. The most frequently used cardiac markers are myoglobin, creatinine kinase (CK) and CK-MB fractions, troponins T (TT) and I (TI). Myoglobin becomes abnormal in the first 1 to 2 hours following myocardial necrosis and remains abnormal for at least 7 to 12 hours. Its sensitivity is high for myocardial injury (83% within 6 hours of symptom onset), but it has a lower specificity. A positive myoglobin can result from muscle trauma, muscle disorders, rigorous exercise, and certain drugs such as statins. A more sensitive and specific marker than myoglobin is CK and its cardiac isoform CK-MB. This marker is 90% accurate for the diagnosis of MI at 6 hours from symptom onset. CK reaches its peak at about 24 hours of symptom onset and returns to normal or near normal by 72 hours. Troponin I is a very sensitive test for the diagnosis of MI at about 10 to 14 hours after onset of chest pain. Its sensitivity and specificity at 6 hours are approximately 58% and 94%, respectively, and 92% and 95% at 10 hours. TI levels remain abnormal for several days after myocardial injury.

Box 27-4 High-Risk Indicators in Patients with Unstable Angina*

1. New or presumably new ST-segment depression
2. Elevated troponin T or troponin I
3. Recurrent angina at rest or low level despite intense medical therapy
4. Reduced left ventricular function (ejection fraction <40%)
5. Recurrent angina or ischemia with congestive heart failure symptoms
6. Sustained ventricular arrhythmias
7. Hemodynamic instability
8. Recent history of coronary angioplasty or bypass surgery (past 6 months)
9. High risk based on noninvasive stress testing

*Level of evidence A, ACC/AHA guidelines (Braunwald, 2002).

Depending on the time of onset of chest pain, these markers have different levels of utility in the diagnosis of MI. For example, the diagnosis of MI in a patient who had chest pain more than 48 hours after presentation is best made with TI, whereas a recent onset MI of less than 6 hours' duration can best be made with myoglobin, CK and CK-MB. A negative TI after 12 hours of chest pain indicates a low risk for a cardiac event in the immediate future (<1 month). Therefore, patients who present with chest pain and have a negative TI at 12 hours after onset of chest pain can undergo a stress test either in the ED or as an outpatient, as long as the test has been scheduled within a few days of discharge.

Patients with suspected unstable angina/non-ST segment MI benefit significantly from an early aggressive therapy with angiography and revascularization, particularly when early high-risk indicators exist (Box 27-4).

The Treat Angina with Aggrastat and Determine Cost of Therapy with an Invasive or Conservative Strategy (TACTICS TIMI-18) study randomized unstable angina/non-ST elevation MI patients to an early aggressive therapy with revascularization (within 48 hours of presentation) versus an early conservative therapy in which patients were treated medically and then risk-stratified with exercise stress testing (Cannon et al., 2001). A significant reduction in the primary combined end point of death, MI, and rehospitalization for ACS was noted at 6 months (odds ratio [OR] 0.78, 95% CI [0.62, 0.97], $p = 0.025$). Other high-risk features include advanced age (>70), history of vascular disease, diabetes, and elevated hsCRP, WBC count, and B-type natriuretic peptide (BNP). Furthermore, based on data for the TIMI11B trial (1999), Antman and co-workers (2000) predicted that the risk of death, reinfarction, or recurrent severe ischemia requiring revascularization increased from 5% to 41% depending on the sum of the following individual prognostic variables: age greater than 65 years, more than three coronary risk factors, prior angiographic coronary obstruction, ST-segment deviation, more than two angina events within 24 hours, use of aspirin within 7 days, and elevated cardiac markers.

Although most unstable coronary syndromes are caused by plaque rupture, thrombosis, and superimposed spasm, rapidly progressive plaques can infrequently lead to an unstable syndrome. In addition, unstable angina can be precipitated by secondary causes such as thyrotoxicosis, severe

Box 27-5 Acute Pharmacologic Therapy of Unstable Angina/Non-ST Elevation Myocardial Infarction*

1. Aspirin (or clopidogrel in patients who cannot take aspirin) should be administered as soon as possible after onset of symptoms and continued indefinitely.
2. Clopidogrel should be added to aspirin in the hospitalized patient and continued for a least 1 month whether patient will be undergoing percutaneous intervention or treated conservatively. Continuing clopidogrel and aspirin for up to 9 months is based on Level B evidence.
3. Antithrombin therapy with unfractionated heparin or low-molecular-weight heparin (preferred over unfractionated heparin unless bypass surgery is planned within 24 hours) should be started with clopidogrel and aspirin.
4. GpIIb/IIIa inhibitors should be added to aspirin, clopidogrel, and antithrombin in patients with planned revascularization, or those with no planned revascularization but who are undergoing ischemia or having abnormal cardiac biomarkers. However, abciximab should be avoided in patients with no planned revascularization.
5. Fibrinolytics are contraindicated in patients with unstable angina or non-ST segment elevation myocardial infarction.

*Level of evidence A, ACC/AHA guidelines (Braunwald, 2002)

hypertension or valvular stenosis, tachycardia, anemia, hypotension, and hypoxia.

Pharmacologic Therapy

Pharmacologic management of the patient with unstable angina or non-ST segment MI can be divided into acute and chronic therapy. In the *acute* phase (Box 27-5), patients are typically treated with an antithrombin drug (unfractionated heparin or low-molecular-weight heparin), upstream use of intravenous (IV) GP2b/3a inhibitors such as tirofiban (Aggrastat) or eptifibatid (Integrilin) (upstream use of the monoclonal antibody abciximab should be discouraged unless patients are brought to the cardiac catheterization laboratory within few hours of starting this drug, because the resurfacing of GP2b/3a receptors occurs with prolonged infusion of abciximab leading to partial loss of its antiplatelet effect), aspirin, clopidogrel, beta blockers, statins, IV nitrate therapy, ACE inhibitors (in patients with left ventricular dysfunction and continued hypertension or in diabetic patients) and supplemental oxygen therapy (in patients with respiratory distress and hypoxemia).

Low-molecular-weight heparin (LMWH; e.g., enoxaparin or Lovenox) has been shown to have some advantages over unfractionated heparin (UFH). These include more reliable anticoagulation with predictable pharmacokinetics, resistance to inhibition by platelet factor 4, a lower risk of causing heparin-induced thrombocytopenia (HIT), greater anti-Xa activity, and possibly greater efficacy in reducing risk for ACS. In the Efficacy and Safety of Subcutaneous Enoxaparin in Non-Q-Wave Coronary Events (ESSENCE) trial, enoxaparin plus aspirin was more effective than UFH plus aspirin in reducing the incidence of the combined end points of death, myocardial infarction, and recurrent angina (19.8% vs. 23.3%, respectively; $p = 0.016$) in patients with unstable angina or non-Q-wave MI at 1 month of follow-up (Cohen et al., 1997). A recent meta-analysis of 22,000 patients also demonstrated that enoxaparin is more effective than UFH in

preventing the combined end point of death or MI (Petersen et al., 2004). Currently, enoxaparin, 1 mg/kg subcutaneously twice daily, is preferred over UFH (70 U/kg bolus IV, then 1000 U/hr adjusted every 6 hours with PTT checks) in patients who present with unstable angina or non-ST segment elevation MI.

Continued chest pain in patients with unstable angina despite optimal medical therapy indicates that the patient should be brought to the cardiac catheterization laboratory for immediate angiography and revascularization to minimize the chance of irreversible myocardial damage and loss of function. As previously noted, even in the pain-free patient with high-risk features, an aggressive approach to therapy is indicated and needs to be implemented within 48 hours of symptom onset. Morphine sulfate can be used to treat the acute pain unresponsive to anti-ischemic therapy.

Optimal antiplatelet treatment is needed with antithrombin drugs in the management of the patient with an ACS. Vascular injury leads to platelet activation and aggregation with subsequent fibrin deposition and thrombosis. Anti-thrombin therapy alone without optimal platelet inhibition leads to an inferior outcome during *percutaneous coronary intervention* (PCI). Early experience with PCI was performed with UFH in patients pretreated with aspirin. Aspirin is only partially effective as an antiplatelet drug by inhibiting cyclooxygenase and therefore partially blocking thromboxane A₂ and collagen-mediated platelet activation and aggregation (Shammas et al., 2005). Platelet inhibition with clopidogrel (Plavix) is dose and time dependent. After a single 400-mg dose of clopidogrel, maximum platelet inhibition is achieved in 2 to 5 hours. In contrast, clopidogrel at 75 mg daily requires 3 to 7 days to reach the same level of inhibition. Blocking the ADP receptor irreversibly with clopidogrel has become an important step before PCI to reduce intermediate and long-term cardiac events. In the Clopidogrel for the Reduction of Events during Observation (CREDO) study, pretreatment of patients with clopidogrel (300 mg) at least 15 hours preintervention reduced long-term adverse events (Steinhubl et al., 2002). In the ISAR-REACT trial, pretreatment with clopidogrel (600 mg) provided similar outcomes in low-risk to intermediate-risk patients, regardless of assignment to abciximab or placebo, with maximum antiplatelet effect seen within 2 to 3 hours of treatment before intervention (Kandzari et al., 2004). In the Antiplatelet Therapy for Reduction of Myocardial Damage during Angioplasty (ARMYDA-2) study, clopidogrel at 600 mg was more effective in reducing cardiac events than clopidogrel at 300 mg when given at a mean of 6 hours before PCI in both arms (Patti et al., 2005). ARMYDA-2 also did not exclude patients from receiving GPIIb/IIIa inhibitors, thereby also supporting the hypothesis that optimal ADP receptor antagonism before PCI might be essential even when intraprocedural inhibition of platelet aggregation is achieved with GpIIb/IIIa inhibitors.

Currently, clopidogrel is given to all patients with an ACS immediately on presentation at an oral loading dose of 300 mg, then 75 mg daily. If a patient is proceeding to the cardiac catheterization laboratory and has not been receiving clopidogrel, a total of 600 mg as a loading dose should be administered.

In the *chronic* phase, typically following a revascularization procedure, the mainstay of therapy is aspirin, clopidogrel for 9 to 12 months, statins, ACE inhibitors, and beta blockade.

The Heart Outcomes Prevention Evaluation (HOPE) trial showed that ramipril (10 mg daily) reduced cardiovascular events significantly, including cardiovascular and total mortality and strokes (Yusuf et al., 2000). Patients were 55 years or older, and the majority had a history of vascular disease (80% history of CAD and 42% with PAD). Similar data were seen in the European Trial on Reduction of Cardiac Events with Perindopril in Stable CAD (EUROPA), which included 13655 patients with previous MI (64%), angiographic evidence of CAD (61%), coronary revascularization (55%), or a positive stress test only (5%). The mean age was 60 years, and patients had no CHF and stable CAD (Fox, 2003). In this study, 10% of placebo and 8% of perindopril (8 mg once daily) patients experienced the combined primary end point of cardiovascular death, MI, or cardiac arrest (20% RR reduction; $p = 0.0003$; favoring perindopril therapy) at a mean follow-up of 4.2 years.

Patients will also need to quit smoking, exercise, adhere to a low-fat, low-carbohydrate diet, lose weight if obese, and if diabetic, achieve aggressive control of their blood sugar to keep their HbA_{1c} less than 7% and preferably less than 6.5%.

KEY TREATMENT

Aspirin (75-324 mg daily) or clopidogrel (75 mg daily, in patients with intolerance or hypersensitivity to aspirin), lipid-lowering drugs, and diet are recommended in patients with low-density lipoprotein greater than 130 mg/dL (or LDL >100 mg/dL) (ACC/AHA guidelines) (SOR: B).

ACE inhibitors in patients with left ventricular dysfunction (ejection fraction <40%), congestive heart failure, hypertension, or diabetes should be initiated in those with unstable coronary syndromes (ACC/AHA guidelines) (SOR: A).

ST Elevation Myocardial Infarction

ST-segment elevation MI (STEMI) occurs secondary to a sudden interruption of coronary blood supply to a part of the myocardium as a result of a complete thrombotic occlusion of a coronary artery (DeWood et al., 1980). Plaque rupture is the predominant mechanism of STEMI with subsequent platelet and fibrin deposition. It is estimated that half a million STEMIs occur in the United States every year (Fig. 27-10).

Emergent and complete revascularization is the most important goal in the acute STEMI therapy. Current guidelines indicate that a patient with symptoms and signs of STEMI should receive either thrombolytics within 30 minutes or angioplasty within 90 minutes of arrival to the ED (Antman et al., 2004). Based on a hospital multidisciplinary protocol preapproved by the cardiologists, ED physicians, primary care physicians, and allied health care professionals, the ED physician generally decides on the choice of therapy. Currently, angioplasty is considered the first choice because it leads to overall superior results (Magid et al., 2000), primarily reducing the rate of nonfatal MI, and fewer intracranial bleeds compared to thrombolysis. Stronger evidence exists for primary angioplasty in STEMI as the risk of fibrinolysis increases (Kent et al., 2002). Patients with cardiogenic shock or severe CHF benefit more from primary angioplasty (Hochman, 2001; Wu et al., 2002). To be effective, however, angioplasty should be performed in intermediate- and

Figure 27-10 Acute inferior myocardial infarction. **A**, Sudden occlusion of the right coronary artery with a filling thrombus at the occlusion site. **B**, The same vessel after initial angioplasty showing multiple filling defects, indicating thrombus.

high-volume centers with an experienced catheterization team and interventional cardiologists on call and an multi-disciplinary-approved hospital process (Canto et al., 2000). This MI “alert system” should be capable of effectively mobilizing all resources available to stay within the 90-minute period to first balloon inflation from arrival to the ED. Centers that do not have primary angioplasty capabilities should use fibrinolytic therapy as first-line therapy in STEMI. **Box 27-6** lists contraindications to fibrinolysis.

Thrombolytic therapy has been shown to reduce mortality in patients with STEMI. Thrombolytics are contraindicated in patients with non-ST elevation MI because no clinical benefit has been shown and unwarranted risks exist. Thrombolysis enhances the body’s fibrinolytic system by accelerating the formation of plasmin from plasminogen (Shammas, 1993). Plasmin degrades fibrin and several plasma proteins, including fibrinogen, prothrombin, and factors V and VIII, leading to a defective hemostasis. Thrombolytic agents are classified as clot-specific (alteplase [tPA], reteplase [recombinant-PA], and tenecteplase [TNK-tPA]) or non-clot-specific (streptokinase [SK], urokinase [UK], and anisoylated plasminogen activator complex [APSAC]). Clot-specific thrombolytics activate plasminogen at the site of the clot, whereas non-clot-specific ones act by generalized systemic lysis. In the United States, clot-specific thrombolytics are most often used (**Table 27-8**).

On arrival to the ED, patients with chest pain should have an ECG done within 10 minutes. If the ECG does not show ST-segment elevation, it is strongly advised that it be repeated within 5 to 10 minutes in patients with continued chest pain to rule out late appearance STEMI. It should be noted that ST-segment depression in the anterior leads with early precordial transition could indicate ST elevation posterior wall MI, particularly if associated with ST elevation in the inferior leads (inferoposterior MI). Right-sided precordial leads can be helpful in patients with acute inferior wall MI to

Box 27-6 Contraindication to Fibrinolytic Therapy*

Absolute

1. History of intracranial hemorrhage
2. Known intracranial neoplasm or vascular lesions
3. Active bleeding or known bleeding disorder (exclude menses)
4. Embolic stroke within 3 months (exception: embolic stroke within 3 hours)
5. Suspected aortic dissection
6. Significant facial or head trauma within 3 months

Relative

1. Uncontrolled severe hypertension (> 180 systolic, > 110 diastolic)
2. Prolonged CPR (> 10 minutes) or recent surgery (<3 weeks) or noncompressible vascular puncture
3. Recent internal bleeding or active peptic ulcer disease
4. Pregnancy
5. Currently anticoagulated with high INR
6. For streptokinase; prior exposure to the drug or history of allergic reaction

*ACC/AHA guidelines (Antman, 2004).

CPR, Cardiopulmonary resuscitation; INR, international normalized ratio.

determine right ventricular involvement (ST elevation will be seen in the right precordial leads) (**Fig. 27-11**).

Patients with STEMI should receive supplemental oxygen therapy, morphine sulfate for pain control, IV nitrate therapy if they are not hypotensive and have not ingested a phosphodiesterase inhibitor for erectile dysfunction, 162 mg of chewable aspirin, statins, ACE inhibitors (particularly in patients with CHF, reduced left ventricular function, hypertension, or diabetes), and clopidogrel (**Box 27-7**).

Hemodynamic instability should be aggressively treated with pressor agents, typically dopamine started at 5 $\mu\text{g}/\text{kg}/\text{min}$ and titrated every 5 minutes to keep the systolic pressure above 90 mm Hg. Normal saline fluid boluses can be helpful, particularly in the inferoposterior MI patient with right-sided involvement. In these patients, bradycardia also needs to be aggressively treated if associated with hypotension,

using either atropine (1 mg IV, can repeat twice) or a temporary pacemaker if there is inadequate response to atropine. Patients with right ventricular involvement usually respond well to a fluid challenge, correcting the bradycardia, administering dopamine, and maintaining sinus rhythm as they rely on a normal atrial kick for increasing their end-diastolic volume and cardiac output. If hypotension does not respond well to these conservative measures, patients need to have an intra-aortic balloon pump inserted. Typically, these patients should be brought emergently to the cardiac catheterization laboratory for more definitive management because their mortality is excessively high without immediate revascularization (Hochman et al., 2001).

The long-term management of these patients is similar to the unstable angina/non-ST elevation MI, with aggressive preventive measures and continued long-term aspirin, beta blockers, ACE inhibitors, statins, exercise, and low-fat diet. Smoking cessation, control of hypertension and diabetes, and achieving ideal body weight are paramount to prevent further progression of disease and MI. Preferably, clopidogrel needs to be continued for 12 months irrespective of whether the patient received a revascularization procedure with drug-eluting stents or was conservatively managed.

Prasugrel (Effient) is a new ADP-receptor antagonist, recently approved by the U.S. Food and Drug Administration (FDA) to treat ACS patients after coronary angioplasty. In the landmark Trial to Assess Improvement in Therapeutic Outcomes by Optimizing Platelet Inhibition with Prasugrel (TRITON-TIMI-38), in patients with acute coronary syndrome (unstable angina, non-ST elevation MI, and STEMI), prasugrel reduced the combined end point of death from cardiovascular causes, nonfatal MI, or nonfatal stroke at 450 days by 19% compared to clopidogrel (12.1% vs. 9.9%, $p < 0.001$). Acute stent thrombosis was also reduced by 52% using prasugrel compared to clopidogrel ($p < 0.001$) during the same time frame. Major bleeding, however, was increased with prasugrel (2.4% vs. 1.8%, $p = 0.03$) compared to clopidogrel, including life-threatening bleed (1.4% vs. 0.9%, $p = 0.01$) and fatal bleed (0.4% vs. 0.1%, $p = 0.002$). The net clinical benefit, however, favored prasugrel over clopidogrel for the combined end point of all-cause death, nonfatal MI,

Table 27-8 Common Thrombolytics in Treatment of Acute Myocardial Infarction

| Drug | Dose | Cautions |
|---------------|--|--|
| Streptokinase | 1.5 million IU intravenously (IV) Give infusion over 60 minutes. | Watch for hypotension, anaphylaxis, severe bleeding, and stroke. |
| Retavase | 10 U IV over 2 minutes Give second dose of 10 U IV 30 minutes after first dose if no complications. | Watch for intracranial hemorrhage, arrhythmia, and hemorrhage. |
| Activase | 15-mg bolus IV, then 0.75 mg/Kg (max 50 mg) over 30 minutes, then 0.5 mg/Kg (max 35 mg) over 60 minutes; give with heparin. | Watch for intracranial hemorrhage, arrhythmia, severe bleeding, and anaphylaxis. |
| Tenecteplase | Weight <60 kg: 30 mg IV, max 50 mg Wt 60-69 kg: 35 mg IV, max 50 mg Wt 70-79 kg: 40 mg IV, max 50 mg Wt 80-89 kg: 45 mg IV, max 50 mg Wt >90 kg: 50 mg IV, max 50 mg | Watch for intracranial bleeding, anaphylaxis, and reperfusion arrhythmias. |

Figure 27-11 Acute inferior myocardial infarction with ST elevation in the inferior leads.

Box 27-7 Acute and Secondary Pharmacologic Therapy of ST Elevation Myocardial Infarction (STEMI)***Acute Pharmacologic Therapy**

1. Chewable aspirin (162 mg) in patients not previously taking aspirin.
2. Intravenous (IV) beta blockers should not be administered to STEMI patients who have (a) signs of heart failure, (b) evidence of a low-output state, (c) increased risk for cardiogenic shock, or (d) other relative contraindications to beta blockade (P-R interval >0.24 second; second-degree or third-degree heart block; active asthma; or reactive airway disease).
3. STEMI patients presenting to a hospital with percutaneous coronary intervention (PCI) capability should be treated with primary PCI within 90 minutes of first medical contact as a systems goal.
4. STEMI patients presenting to a hospital without PCI capability and who cannot be transferred to a PCI center and undergo PCI within 90 minutes of first medical contact should be treated with fibrinolytic therapy within 30 minutes of hospital presentation as a systems goal unless fibrinolytic therapy is contraindicated (Level B).
5. In the absence of arrhythmias, IV magnesium should not be administered.

Secondary Pharmacologic Therapy

6. For patients with BP of 140/90 mm Hg or greater (or $\geq 130/80$ mm Hg for patients with diabetes or chronic kidney disease), it is useful as tolerated, to add BP medication, treating initially with beta blockers and/or ACE inhibitors, with the addition of other drugs such as thiazides as needed to achieve goal BP.
7. A fasting lipid profile should be assessed in all patients and within 24 hours of hospitalization for those with an acute cardiovascular or coronary event. For hospitalized patients, initiation of lipid-lowering medication is indicated as recommended before discharge. LDL-C should be less than 100 mg/dL.
8. If baseline LDL-C is 100 mg/dL or greater, LDL-lowering drug therapy should be initiated.
9. If on-treatment LDL-C is 100 mg/dL or greater, intensifying LDL-lowering drug therapy (may require LDL-lowering drug combination) is recommended.
10. Managing warfarin to INR of 2.0 to 3.0 for paroxysmal or chronic atrial fibrillation or flutter is recommended, and in post-MI patients when clinically indicated (e.g., atrial fibrillation, left ventricular thrombus).
11. ACE inhibitors should be started and continued indefinitely in all patients recovering from STEMI with left ventricular ejection fraction (LVEF) of 40% or less and for those with hypertension, diabetes, or chronic kidney disease, unless contraindicated.
12. Use of angiotensin receptor blockers (ARBs) is recommended in patients who are intolerant of ACE inhibitors and have heart failure (HF) or have had an MI (LVEF $\leq 40\%$).
13. It is beneficial to start and continue beta-blocker therapy indefinitely in all patients who have had MI, acute coronary syndrome (ACS), or LV dysfunction with or without HF symptoms, unless contraindicated.

*Level of evidence A. From Antman EM, Anbe DT, Armstrong PW, et al. ACC/AHA guidelines for the management of patients with ST-elevation myocardial infarction—executive summary: a report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines (Writing Committee to revise the 1999 guidelines for the management of patients with acute myocardial infarction). *J Am Coll Cardiol* 2004;44:671-719. nonfatal stroke, and non-CABG TIMI major bleed (12.2% vs. 13.9%, $p = 0.004$). Physicians using prasugrel need to weigh its risks and benefits as they decide which drug to use when treating patients (Wiviott et al., 2007).

Congestive Heart Failure

Congestive heart failure (CHF) is a clinical syndrome resulting from the inability of the heart to meet the metabolic requirements of the body at normal filling pressures. Although heart failure can be precipitated by left ventricular systolic dysfunction, it can also be secondary to diastolic dysfunction. Occasionally, CHF can occur without impairment of myocardial function (Braunwald et al., 1976). CHF is highly prevalent in the United States, with more than 500,000 new cases diagnosed annually. Also, mortality remains very high, with over 300,000 people dying every year from this syndrome (Hunt et al., 2001). Hospitalization for CHF in the United States is rising in both men and women at a prohibitively high cost to the health care system (O'Connell and Bristow, 1993). It is important for family physicians to understand the pathophysiology of CHF and apply known effective therapies.

Pathophysiology

The hemodynamic model of CHF has been largely abandoned and replaced by the concept of left ventricular remodeling (Francis, 2001). Remodeling of the left ventricle indicates stretching and dilation with subsequent reduction in left ventricular function. The remodeling process can be triggered by a multitude of potential injuries (Levy et al., 1996; Kannel et al., 1994), including CAD, MI, hypertension, valvular heart disease, diabetes, congenital heart defects, anemia, and alcoholism. Regardless of the precipitating injury, neurohormonal mechanisms are activated and promote the remodeling process. These include the renin-angiotensin-aldosterone system (RAAS) and the sympathetic nervous system (SNS). A rise in endothelin-1 production, a product of dysfunctional endothelium, also occurs and contributes to vasoconstriction. In addition, inflammatory markers and cytokines are increased, further exacerbating endothelial dysfunction (Blum and Miller, 2001; Francis, 1998).

Pharmacologic interventions that block neurohormonal activation can reduce mortality and morbidity in patients with CHF (Fig. 27-12). A rise in angiotensin II (AII) promotes programmed cell death (apoptosis), hypertrophy, and fibrosis. AII also causes an increase in aldosterone secretion (Fig. 27-13), which in return augments the harmful effects of AII on myocardium and promotes adverse remodeling. Aldosterone, however, "escapes" angiotensin suppression (McKelvie et al., 1999) and, therefore, selective aldosterone blockade is needed in addition to therapy with ACEIs or ARBs (Pitt et al., 1999, 2001). A rise in circulating levels of catecholamines in response to SNS activation can lead to suppression of adrenergic receptors and has direct toxic effects on myocardium (Bristow et al., 1993). Catecholamines mediate toxicity as a result of beta-adrenoceptor-mediated cyclic adenosine monophosphate (cAMP)-dependent calcium overload of cardiac myocytes (Mann, 1998; Mann et al., 1992). Also, catecholamines increase myocardial oxygen consumption and coronary blood flow requirements and decrease myocardial

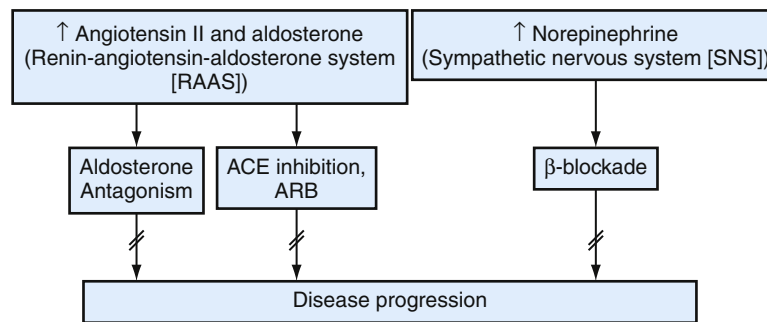

Figure 27-12 The renin-angiotensin-aldosterone system and the sympathetic nervous system are currently the target for treating patients with congestive heart failure. *ACE*, Angiotensin-converting enzyme; *ARB*, angiotensin receptor blocker.

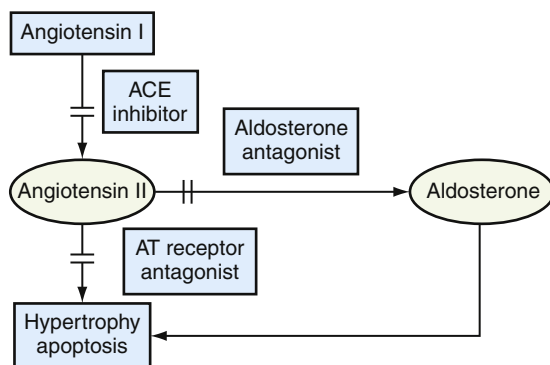

Figure 27-13 Various pharmacologic interventions to block the renin-angiotensin-aldosterone system; *ACE*, angiotensin-converting enzyme; *AT*, angiotensin.

mechanical efficiency (Nikolaidis et al., 2004). Catecholamines also induce left ventricular hypertrophy (LVH) and can precipitate potentially debilitating and fatal arrhythmias.

American College of Cardiology/American Heart Association Classification

The newer ACC/AHA classification for CHF takes into account risk factors in addition to the presence of left ventricular dysfunction and symptoms (Hunt et al., 2001). This classification complements the New York Heart Classification (NYHC) and considers recent advances in pharmacologic and nonpharmacologic approaches to evaluate and treat the heart failure patient (Ahmed, 2003). The following four stages are proposed:

Stage A describes patients who are at risk of CHF but are asymptomatic and have no left ventricular dysfunction.

More than 60 million people fall in this category and include those with CAD, hypertension, diabetes mellitus, and a family history of cardiomyopathy. Stage A is an additional classification that was not present in the prior NYHC.

Stage B describes patients with left ventricular dysfunction but no symptoms. This is equivalent to Class I of the NYHC. This includes about 10 million people in the United States.

Stage C describes patients with left ventricular dysfunction who are symptomatic with exertion. This is equivalent to the NYHC Class II and Class III. This includes about 5 million people in the United States.

Stage D describes patients with symptoms at rest. This is equivalent to Class IV of the NYHC. This includes about 200,000 people in the United States.

This classification reliably allows the physician to follow patients as their heart failure progresses from one stage to the next and offers a unique set of treatment appropriate to each stage.

Evaluation of the Patient

Patients with CHF need to have a complete history and physical examination with a focus on cardiovascular risk factors that lead to progression of failure. A careful documentation of their volume status, weight, and NYHC for symptoms needs to be done. Diagnostic tests should include a complete blood count (CBC), serum electrolytes, kidney and liver functions, urinalysis, blood glucose, thyroid function test, iron saturation test and ferritin, erythrocyte sedimentation rate (ESR), antinuclear antibodies to rule out connective tissue disease, 12-lead ECG, echocardiogram, and coronary angiogram, particularly in those with significant reduction in left ventricular function, to rule out underlying severe CAD. Brain natriuretic peptides (BNP and NT-proBNP) can be useful when a patient presents with symptoms of dyspnea of unclear etiology and the diagnosis of CHF is uncertain (de Lemos et al., 2003; Siebert et al., 2006).

Routine myocardial biopsy or Holter monitoring is not recommended. Levels of catecholamines might be obtained if clinically indicated in patients with severe episodic hypertension and tachycardia. The rapid development of CHF with reduced left ventricular function in the absence of a clear etiology should raise suspicion of a viral cardiomyopathy, especially in younger patients. This can be suspected if the patient had a recent viral syndrome over the past several weeks, followed by a progression of dyspnea and CHF. Findings on cardiac biopsy show mostly an acute inflammatory reaction, and since therapy is generally supportive, an endomyocardial biopsy will not alter treatment or prognosis. Therapy for viral cardiomyopathy and CHF consists of supportive therapy and the use of beta blockers, diuretics, ACE inhibitors, and if failure is advanced (class III and IV), spironolactone.

Risk Factor Modification

Patients with CHF should have their cardiovascular risk factors modified aggressively. Hypertension is strongly linked to the development of CHF and should be aggressively treated (Vasan and Levy, 1996). The target BP should be 130/85 mm

Hg or less, except in diabetic patients, in whom the target is lowered to 125/85 mm Hg or less.

Control of dyslipidemia and diabetes is also very important in the management of patients with CHF. Screening for sleep apnea and thyroid disease and aggressively treating these conditions need to be done. The avoidance of alcohol, illicit drug use, and smoking is strongly advised. Losing weight and establishing a routine exercise program are also important preventive measures in the CHF patient. Patients with a history of heart palpitations need to be evaluated for tachycardia because this is a well-established risk factor for cardiomyopathy and CHF. If patients have daily palpitations, a 24-hour Holter monitor is sufficient to help establish the type of arrhythmia. On the other hand, if palpitations occur infrequently (a few times per month), an “event care” monitor is more useful because patients can keep this type of monitor with them at home for a month and record the arrhythmia as it occurs. If palpitations are very infrequent, it is unlikely that they will be contributing to tachycardia-induced cardiomyopathy, but their diagnosis can be made with an implantable loop recorder, typically done by the electrophysiologist.

KEY TREATMENT

Control of systolic and diastolic hypertension in accordance with established guidelines is strongly indicated in the CHF patient (ACC/AHA guidelines; SOR: A).

Pharmacologic Therapy

Diastolic Dysfunction

Diastolic dysfunction is typically diagnosed by echocardiography. It is characterized by dyspnea and CHF with normal left ventricular systolic function but impaired relaxation. Conditions that increase left ventricular (LV) stiffness include CAD, hypertension, diabetes, valvular heart disease, and age (Ewy, 2004). Patients with LV diastolic dysfunction need to be treated with aggressive BP control and diuretics, beta blockade, or nondihydropyridine CCBs (diltiazem or verapamil). ACE inhibitors or ARBs can have long-term value in reducing LVH and theoretically may improve LV compliance (Mandinov et al., 2000).

Left Ventricular Systolic Dysfunction

Patients with *asymptomatic* LV dysfunction (Stage B, ACC/AHA classification) benefit significantly from ACE inhibitors and beta blockade. The correction of anatomic abnormalities that are linked to LV systolic dysfunction is also important, including severe mitral or aortic insufficiency and aortic stenosis. Periodic follow-up of these patients is indicated, with serial assessment of LV function using echocardiography or isotope ventriculography (IVG). Patients with familial LV systolic dysfunction need to have their immediate family members screened for asymptomatic cardiomyopathy.

Symptomatic LV systolic dysfunction (Stage C, ACC/AHA classification) requires intensive pharmacologic treatment and close follow-up. Echocardiography or IVG is typically done to monitor LVEF over time, generally every 6 months or less frequently if a patient is clinically stable. An IVG provides a more accurate assessment of ejection fraction (within \pm 3%

variability in reading) than an echocardiogram but is more expensive. Whether an echocardiogram or an IVG is ordered depends on the patient's clinical presentation, history, and the management approach of the treating physician. Diuretics are important in the hypervolemic patient, and digoxin improves symptoms in patients with clinical evidence of CHF or symptomatic, severely reduced LV function. No data, however, support that a diuretic or digoxin alters a patient's long-term survival. Current therapies known to impact a person's mortality are summarized next (Cohn, 1996; Hunt et al., 2001; Packer et al., 1999). Table 27-9 lists drugs and dosages in treating patients with congestive heart failure.

Although there is no one way to start pharmacologic therapy for CHF patients, it is advisable that patients be started on a small dose of beta blockers, ACEI, or both. Diuretics are generally reserved for patients who are fluid overloaded. Caution needs to be exerted when a diuretic and an ace inhibitor are started simultaneously as hypotension could occur and serum creatinine levels can rise markedly. Beta blockers (Hori, 2004) and ACE inhibitors (Majumdar, 2004) need to be titrated to the maximum tolerated dose in order to achieve maximal therapeutic efficacy.

Angiotensin-Converting Enzyme Inhibitors

Angiotensin-converting enzyme inhibitors (ACEIs) reduce mortality by an absolute 4% and relative 15% to 20% in patients with LV systolic dysfunction (LVEF <40%). In addition, ACEIs reduce the combined end point of morbidity (heart failure hospitalizations) and mortality by 30% to 35%. Despite the benefits of ACE inhibitors (Wong et al., 2004), mortality from CHF remains at 50% within 5 years of the diagnosis and 30% of patients are rehospitalized within 3 months.

Several trials have noted a mortality reduction with ACEIs in patients with clinical evidence of CHF after sustaining an MI (Kober et al., 1995). The Acute Infarction Ramipril Efficacy Study (AIRE) showed a 27% ($p = 0.002$) reduction in the 30-month cumulative mortality with ramipril over placebo in post-MI CHF patients. Furthermore, trandolapril reduced mortality by 22% ($p = 0.01$) in patients with reduced left ventricular function after an MI (Kober, 1995). Guidelines also emphasize the use of ACEIs in patients with asymptomatic LV dysfunction and history of MI. These patients are at high risk of developing LV remodeling and CHF several months after the initial insult (Jessup, 2003).

KEY TREATMENT

ACE inhibitors are recommended in all patients with CHF and left ventricular dysfunction unless a contraindication exists. ACEIs should be used in all patients with history of MI and asymptomatic reduced LV function regardless of ejection fraction. ACC/AHA guidelines (SOR: A).

Angiotensin Receptor Blockers

Key Point

- Angiotensin receptor blockade can be used in patients being treated with digitalis, diuretics, and a beta blocker and who cannot be given an ACE inhibitor because of cough or angioedema (ACC/AHA guidelines; SOR: A).

Table 27-9 Selected Drugs and Dosages in Treatment of Congestive Heart Failure

| Drug | Dosage |
|--|--|
| Angiotensin-Converting Enzyme Inhibitors | |
| Enalapril | 2.5 to 20 mg PO bid, max 40 mg/day, start at 2.5 mg qd |
| Captopril | 12.5 to 50 mg PO tid, max 150 mg/day, start 6.25 to 12.5 mg PO tid |
| Ramipril | 5 mg PO bid, max 10 mg/day, start at 2.5 mg PO bid |
| Lisinopril | 5-20 mg PO qd, max 40 mg/day, start 2.5 to 5 mg PO qd |
| Perindopril | 4-16 mg PO qd, max 16 mg/day, start 2 mg PO qd |
| Monopril | 10-40 mg PO qd/bid, max 80 mg/day, start 10 mg PO qd |
| Angiotensin Receptor Blockers (for ACE Inhibitor-Intolerant Patients) | |
| Losartan | 25-100 mg PO qd, max 100 mg/day, start 25-50 mg PO qd* |
| Candesartan | 8-32 mg PO qd, max 32 mg/day, start 16 mg PO qd* |
| Valsartan | 40-160 mg PO bid, max 320 mg/day, start 40 mg PO bid |
| Irbesartan | 75-300 mg PO qd, max 300 mg/day, start 75 mg PO qd* |
| Beta Blockers | |
| Carvedilol | 3.125-25 mg PO bid, max 50 mg PO qd, start 3.125 mg PO bid |
| Metoprolol succinate | 12.5 to 200 mg PO QD, max 200 mg/day, start 12.5 mg PO qd |
| Metoprolol | 12.5-100 mg PO bid, max 100 mg PO BID, start 12.5 mg PO bid* |
| Aldosterone Antagonists | |
| Spironolactone | 12.5-25 mg PO bid, max 50 mg/day, start 12.5 mg PO bid |
| Eplerenone | 50 mg PO qd, max 50 mg/day, start 25 mg PO qd† |
| *Off-label use. | |
| †For CHF patients post-myocardial infarction. | |

Early studies comparing ARBs and ACEIs in the management of CHF patients suggested that an ARB was as safe, effective, and tolerable as an ACEI. In the Randomized Evaluation of Strategies for Left Ventricular Dysfunction (RESOLVD) pilot study, 768 patients (NYHC II-IV, LVEF <40%) received candesartan, candesartan plus enalapril, or enalapril alone for 43 weeks (McKelvie et al., 1999). Left ventricular cavity size increased less and BNP levels decreased more with combination therapy compared to ARB or ACEI alone. In

the Losartan Heart Failure Survival Study (ELITE II), 3152 patients (≥ 60 years old; NYHC II-IV; LVEF <40%) were randomly assigned to losartan (1578 patients) titrated to 50 mg once daily or captopril (1574) titrated to 50 mg three times daily (Pitt et al., 2000). There were no differences in all-cause mortality or sudden death between the two groups. In a subset of the Val-HeFT (Valsartan in Heart Failure Trial) trial of patients intolerant to ACEI, valsartan (titrated to 160 mg twice daily) reduced both all-cause mortality and combined mortality and morbidity compared with placebo (17.3% vs. 27.1%, $p = 0.017$; and 24.9% vs. 42.5%, $p < 0.001$, respectively) (Maggioni et al., 2002). In this trial, adding an ARB (valsartan) to an ACEI in CHF patients (LVEF <40%) did not reduce mortality further, whereas the combined end point of mortality and morbidity was reduced by about 27.5%, mostly from a reduction in CHF hospitalizations (Cohn et al., 2001).

In the Candesartan in Heart Failure Assessment of Reduction in Mortality and Morbidity (CHARM) trial, candesartan (titrated to 32 mg once daily) significantly reduced cardiovascular deaths and hospital admissions for CHF (Pfeffer et al., 2003). In the "overall programme" of this study, which included both preserved and reduced LV function, total mortality was not reduced compared to placebo. However, in a subset analysis, patients with symptomatic heart failure and reduced LV function (<40%), candesartan significantly reduced all-cause mortality, cardiovascular death, and CHF hospitalizations when added to standard therapies, including ACEIs, beta blockers, and aldosterone antagonists (Young et al., 2004). These patients should have their BP, creatinine, and serum potassium carefully monitored. The Valsartan in Acute Myocardial Infarction Trial (VALIANT) randomized patients 0.5 to 10 days after an acute MI with reduced LV function to valsartan (4909 patients) titrated to 160 mg twice daily, valsartan (80 mg twice daily) plus captopril (50 mg three times daily) (4885 patients), or captopril (4909 patients) titrated to 50 mg three times a day in addition to standard therapy (Pfeffer et al., 2003). Valsartan was equally effective as captopril in reducing all cause mortality. For reasons that remain unclear, combining valsartan with captopril did not improve survival compared to either captopril or valsartan alone but did increase adverse events.

Currently the recommendation is to use an ACEI as first line therapy to treat CHF patients. However, a growing body of evidence suggests that an ARB could be as effective as an ACEI in the treatment of heart failure patients with reduced left ventricular function.

Aldosterone Blockers

Aldosterone is secreted by the zona glomerulosa of the adrenal gland and is induced by AII, adrenocorticotropic hormone, and potassium. Aldosterone leads to sodium and water absorption and the excretion of potassium. Although AII is a dominant stimulus of aldosterone secretion (Weber, 2001), ACEI are not sufficient to block aldosterone secretion (McKelvie, 1999; Schjoedt, 2004). Until recently the role of aldosterone blockade in the management of patients with CHF has been unclear.

Two large trials investigated the role of aldosterone antagonists in CHF management. The Randomized Aldactone Evaluation Study (RALES) randomized patients with advanced CHF

(LVEF <35%) to spironolactone (25 mg daily) or placebo in addition to standard therapy (Pitt et al., 1999). After a mean follow-up of 24 months, spironolactone reduced mortality by 30% through reducing progression of CHF and sudden cardiac death. In addition, patients who received spironolactone had a significant improvement in the symptoms of heart failure as assessed by NYHA functional class ($p < 0.001$). Recurrent hospitalization from worsening CHF was also reduced by 35% ($p < 0.001$). The Eplerenone Post-AMI Heart Failure Efficacy and Survival Study (EPHESUS) randomized patients with CHF (LVEF <40%), 3 to 14 days post-MI, to eplerenone (25-50 mg daily) or placebo (Pitt et al., 2001). At a mean follow-up of 27 months, eplerenone, a competitive, relatively selective mineralocorticoid receptor antagonist, reduced total mortality by 15% ($p = 0.008$), cardiovascular mortality or cardiovascular hospitalizations by 13% ($p = 0.002$), and sudden cardiac death by 21% ($p = 0.03$). Based on these trials, aldosterone antagonists are now considered to be a primary therapy in patients with LV dysfunction and CHF.

Beta-Adrenergic Blockade in Heart Failure

The activation of the sympathetic nervous system in patients with CHF leads to excess catecholamine secretion, which adversely affects myocardium and contributes to left ventricular remodeling and CHF.

Multiple beta blockers have been tested in CHF. Beta blockers have been shown to reduce mortality by approximately 35% when added to an ACEI in mild to moderate CHF (MERIT-HF with metoprolol succinate, U.S. trials with carvedilol, and CIBIS-II trial with bisoprolol) or in very advanced CHF (Copernicus trial with carvedilol) (Packer et al., 2001). Beta blockers also reduce hospitalizations by 33% to 38% and work in synergy with ACEIs to reduce cardiac remodeling, reduce cavity size, and improve ejection fraction (CIBIS-II, 1999; Fowler et al., 2001; MERIT-HF, 1999; Packer et al., 1996; Remme et al., 2004).

There are differences in the antiadrenergic actions of β -adrenergic blocking drugs. The ratio of β_2 - and α_1 -adrenergic receptors in the damaged heart changes compared to the normal myocardium (Bristow, 1993). β_1 receptors are reduced and α_1 receptors increased with little change in the β_2 receptors. Almost 50% of the adrenergic receptors on the failing myocardium are β_2 and α_1 , which are typically not affected by selective β_1 blockade. Norepinephrine is known to exert negative effects through β_1 , β_2 , and α_1 receptors. To test whether a nonselective β_1 , β_2 , or α_1 blocker yields better mortality reduction than a β_1 blocker alone, the Carvedilol or Metoprolol European Trial (COMET trial) recruited 3029 patients with NYHC II-IV heart failure at 317 centers in 15 European countries (Torp-Pedersen et al., 2005; Poole-Wilson et al., 2003). At 58 months, there was a 17% reduction in mortality with carvedilol compared to metoprolol tartrate ($p = 0.0017$). Despite the controversy about the adequacy of β -blockade and the use of the shorter-acting metoprolol tartrate instead of the long-acting metoprolol succinate in this study, the data seem to favor the theory that the nonselective adrenergic blockade is superior to the selective short-acting β_1 -receptor blockade in reducing mortality in the CHF patient.

Carvedilol (6.25-25 mg twice daily) was shown in the Glycemic Effects in Diabetes Mellitus: Carvedilol-Metoprolol

Comparison in Hypertensives (GEMINI) study not to alter glycemic control in diabetic patients compared with metoprolol tartrate (50-200 mg twice daily). Also, carvedilol did improve some components of the metabolic syndrome such as improving insulin sensitivity (Bakris et al., 2004). Carvedilol appears to be a favorable drug in diabetic patients, in contrast to other selective beta blockers.

Aggressive titration of beta blockers is needed in patients with CHF. Higher levels of β -blockade are associated with better improvement of ejection fraction and greater reductions in cardiovascular hospitalizations (Hori et al., 2004; Bristow et al., 1996). A stepwise approach in titration of beta-blockade is generally followed with an increase in the dose every 2 weeks as tolerated until achieving the maximum tolerable dose.

KEY TREATMENT

Beta blockers (bisoprolol, carvedilol, and sustained-release metoprolol succinate) should be used in asymptomatic patients with a recent MI regardless of ejection fraction (SOR: A).
Beta blockade should be used in all stable stage C patients unless contraindicated (ACC/AHA guidelines; SOR: A).

Miscellaneous Pharmacologic Therapy

Patients receiving ACE inhibitors might benefit from the addition of the combination of hydralazine and nitrates. ACC recommendations indicate that this treatment is likely to benefit African American patients with advanced CHF symptoms.

In addition to pharmacologic therapy, CHF patients should be instructed on dietary salt restriction (2 g sodium/day), daily weight monitoring (with reporting of 3-lb/wk weight increase to their physician), free water restriction to 1 L daily, smoking cessation, regular exercise, avoidance of alcohol intake, and aggressive treatment of hypertension and lipid disorders. Supplemental oxygen is needed in patients with oxygen saturation less than 92% on room air after ambulation. Finally, sleep apnea has been associated with CHF, and these patients need to be screened and aggressively treated for moderate to severe apnea. Patients with symptomatic CHF are best treated at a heart failure clinic to ensure appropriate therapy is administered by a specialized provider, to increase patient compliance, and to reduce recurrent hospitalization. A heart failure clinic will also ensure that national benchmarks in management of CHF patients are met. These include the optimal utilization of ACEIs and beta blockers, documentation of LV function, and smoking cessation.

KEY TREATMENT

The combination of a fixed-dose of isosorbide dinitrate and hydralazine to a standard medical regimen for heart failure (HF), including ACE inhibitors and beta blockers, is recommended to improve outcomes for patients self-described as African Americans, with NYHA functional class III or IV HF. Others may benefit similarly, but this has not yet been tested (ACC recommendations; Jessup, 2009) (SOR: A).
Referral of patients with refractory end-stage HF to a HF program with expertise in the management of refractory HF is useful (ACC/AHA guidelines; Jessup, 2009) (SOR: A).

Figure 27-15 Bicuspid aortic valve.

Valvular Heart Disease

Aortic Stenosis

Aortic stenosis is defined as an obstruction that impedes blood flow from the left ventricle to the aorta and is mostly secondary to aortic valvular disease. Other, less common etiologies of aortic stenosis include supralvalvular and membranous subvalvular stenosis, which are generally congenital.

Aortic valvular stenosis is the most common valvular abnormality in the United States. It can be congenital, rheumatic, or calcific and degenerative. *Calcific* aortic valve stenosis is most prevalent in patients over 70 years of age (Fig. 27-14), whereas *congenital*, mostly bicuspid valve disease is more common in younger patients (Fig. 27-15). A bicuspid aortic valve leads to flow turbulence and valve trauma, which in return precipitates fibrosis, stiffness, and calcification. A third of bicuspid valves will become stenotic between the fourth and sixth decades of life and account for half of all surgical cases. Age-related calcific valves are affected by the same risk factors as in atherosclerosis, with inflammatory

cells (macrophages, T lymphocytes), lipid and calcium deposits, and development of fibrosis. *Rheumatic* aortic valve stenosis is now uncommon in developed countries and is mediated by adhesion and the fusion of cusps.

The aortic valve surface area is normally 3.0 to 4.0 cm². Symptoms typically do not appear unless the valve is narrowed to at least a fourth of its normal surface area. Stenosis is graded as *mild* (valve area >1.5 cm²), *moderate* (>1.0 to 1.5 cm²), or *severe* (≤1 cm²) (Rahimtoola, 1989). The valve area narrows at an average rate of 0.12 cm² per year (Otto et al., 1997). As the valve narrows, cardiac output remains stable at rest but diminishes with exercise. As disease progresses, LV mass increases and diastolic dysfunction becomes evident with an increase in LV filling pressure. Myocardial oxygen demand typically increases, and even in the absence of CAD, patients may experience angina. Patients with aortic stenosis have a good prognosis if they do not have symptoms of angina, CHF, or syncope/near-syncope, particularly with activity. Surgical management of the valve becomes necessary in symptomatic patients because of the increased incidence of sudden cardiac death.

Patients with severe aortic valve stenosis describe progressive dyspnea, chest pain and syncope with exertion, and symptoms of CHF, including orthopnea, paroxysmal nocturnal dyspnea, and edema. Syncope at rest is typically induced by arrhythmia. Patients with severe aortic valve stenosis have a 5% history of sudden cardiac death. In addition, these patients may give a history of rheumatic fever or rheumatic heart disease, transient ischemic attacks from calcium deposit systemic embolization, and intermittent GI bleeding from an increased incidence of arteriovenous malformations.

The typical physical signs of severe aortic valve stenosis are diminished carotid pulses (delayed and weak), a sustained apical impulse, a single second heart sound, an S4 gallop, and midsystolic crescendo-decrescendo murmur with late peaking best heard at the base of the heart, although in elderly patients it might be heard only at the apex.

Diagnostic tests include a chest radiograph, which could show a calcified valve, pulmonary venous congestion, or an increase in ascending aortic root size secondary to post-stenotic dilation. Also, a 12-lead ECG may show LVH and conduction abnormalities. An echocardiogram typically confirms the diagnosis. Valve structure can be assessed, including the presence of calcification, reduction in cusp motion, and congenital abnormalities such as a bicuspid or abnormal tricuspid valve. A gradient can be measured across the valve (Fig. 27-16), and valve area can be determined using Doppler flow with reasonable accuracy (Currie et al., 1986). The presence of concomitant aortic valve insufficiency can also be visualized using color Doppler flow characteristics. Other important findings on echocardiography include the presence or absence of LVH and assessment of LV compliance, atrial size, and associated other valvular abnormalities. If noninvasive findings support the diagnosis of severe aortic stenosis and the patient is symptomatic, then diagnostic angiography is indicated to confirm the presence of severe aortic valve stenosis and assess the coronary arteries. Combined valve surgery and CABG can then be considered as indicated. Stress testing is absolutely contraindicated in the setting of symptomatic, severe aortic valve stenosis.

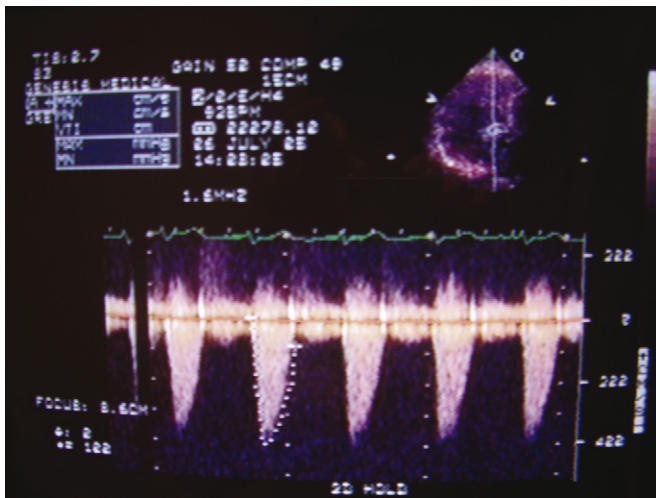

Figure 27-16 Velocity gradient across a calcified stenotic aortic valve, as seen with Doppler echocardiography.

The treatment of aortic valve stenosis depends on the presence or absence of symptoms. Symptomatic, severe aortic valve stenosis carries a poor prognosis, with the average life expectancy of patients being 2 to 3 years (Ross and Braunwald, 1968). The 5- and 10-year mortality is approximately 52% to 80% and 80% to 90%, respectively (Horstkotte and Loogen, 1988; Turina et al., 1987). Aortic valve surgery with or without CABG is the treatment of choice (Lund, 1990; Schwarz et al., 1982). Aortic valvuloplasty carries a poor outcome and is reserved as a palliative therapy for inoperable patients. Typically, the improvement in the aortic valve gradient is mild with valvuloplasty, and a recurrence of severe stenosis can be expected within 6 months (Block and Palacios, 1988; Davidson et al., 1990). Surgery is typically not advised for asymptomatic severe valvular stenosis. Patients with dyspnea and indication of progressive LV dysfunction need to be considered for valve replacement. However, most patients with asymptomatic, severe aortic valve stenosis will develop symptoms within 5 years of follow-up. The 1-, 2-, and 5-year event-free probabilities were 80%, 63%, and 25%, respectively. Independent predictors of all-cause mortality include age, chronic renal failure, inactivity, and aortic valve velocity (Pellikka et al., 2005). A low threshold to intervene in patients with asymptomatic severe aortic stenosis needs to be considered, particularly when peak systolic velocity is 4.5 m/sec or greater on Doppler echocardiography, if associated with moderate or severe valvular calcification (Rosenheck et al., 2000).

Patients need to be advised on antibiotic prophylaxis to prevent endocarditis, especially with rheumatic valve disease (Dajani et al., 1997) (Table 27-10). Patients with moderate to severe aortic valve stenosis need to avoid moderate to severe physical exertion (Cheitlin et al., 1994). Arrhythmias need to be corrected promptly in patients with severe aortic stenosis. Follow-up echocardiography is indicated every year in patients with asymptomatic, severe aortic stenosis and every other year in those with moderate stenosis (Bonow et al., 1998).

Aortic valve replacement can be performed with a mechanical valve or a tissue valve depending on the clinical situation. For example, patients who have a contraindication to

Table 27-10 Prophylaxis for Bacterial Endocarditis*

| Drug | Adult Dose | Pediatric Dose* | Time before Procedure |
|-------------------------------------|------------------------|-------------------------------------|-----------------------|
| General Prophylaxis | | | |
| Amoxicillin | 2 g PO 2 g IV or IM | 50 mg/kg PO 50 mg/kg IM or IV | 1 hour 30 minutes |
| Penicillin-Allergic Patients | | | |
| Clindamycin | 600 mg PO | 20 mg/kg PO | 1 hour |
| Clarithromycin | 500 mg PO | 15 mg/kg PO | 1 hour |
| Azithromycin | 500 mg PO | 15 mg/kg PO | 1 hour |
| Clindamycin | 600 mg IV | 20 mg/kg IV | 30 minutes |
| Cefazolin | 1 g IV or IM | 25 mg/kg IM or IV | 30 minutes |

*Should not exceed adult dose

Figure 27-17 Aortic valve regurgitation, as seen with color Doppler echocardiography. Note the blue turbulent jet into the left ventricle in diastole.

anticoagulation with warfarin should receive a bioprosthetic valve. These valves typically do not require anticoagulation with warfarin, and patients generally receive only an aspirin subsequent to the procedure. Patients in their 60s or 70s with no contraindication to warfarin (Coumadin) are best served with mechanical valves because these last longer and may obviate the need for another valve surgery. Very elderly patients (80s) are typically given a tissue valve to obviate the need for anticoagulation. Antibiotic prophylaxis to prevent endocarditis is strongly recommended in patients with prosthetic valves.

Aortic Valve Regurgitation

Aortic valve regurgitation (AR) is defined as blood flow from the aorta to the left ventricle in diastole because of an incompetent aortic valve (Fig. 27-17). Aortic valve insufficiency is

Figure 27-18 Mechanical prosthetic valve. Note the acoustic shadowing generated by the mechanical prosthesis.

Figure 27-19 Rheumatic mitral valve stenosis. Note the doming of the stenotic mitral valve with thickening of the anterior leaflet.

generally acquired through valve infection, dilation and dissection of the aortic root, trauma, or long-term degenerative change of the valve, particularly in the setting of hypertension. Patients with a history of prosthetic valves can also have aortic valve insufficiency (Fig. 27-18). Aortic insufficiency can also be caused by a congenital bicuspid aortic valve.

Aortic regurgitation leads to volume overload of the left ventricle and an increase in left ventricular end-diastolic pressure (LVEDP). In chronic AR, symptoms might not appear before LV cavity dilation and reduced LV function develop. In acute AR, a sudden rise of LVEDP occurs because of the inability of the left ventricle to dilate acutely in response to a sudden volume overload. Patients are generally acutely symptomatic with CHF. Patients with severe AR will eventually become symptomatic, displaying symptoms of dyspnea and CHF. Angina is less common but can result from a reduction in coronary perfusion pressure. Physical signs of severe AR include a rapid, quick arterial pulse (Corrigan's pulse), a wide pulse pressure, an early high-pitched, blowing diastolic murmur heard best over the left sternal border, an S3 gallop, and a low-pitched diastolic murmur at the apex (Austin-Flint murmur).

The ECG shows LVH and possibly conduction abnormalities. Echocardiography can help make the diagnosis accurately and also provides information about LV function and cavity size. Other associated valvular abnormalities can also be assessed by the echocardiogram. Aortic root and left atrial sizes can be measured (Zoghbi et al., 2003). Stress testing can provide information about functional capacity and hemodynamic response to exercise. Diagnostic angiography allows the verification of the severity of the AR and helps in the assessment of the aortic root size, cavity size, and the presence or absence of CAD.

The surgical treatment of AR is indicated in symptomatic patients with dyspnea, angina, or CHF (Bonow, 2000). Asymptomatic patients should undergo surgery if LVEF is 55% or less, or left ventricular end-systolic dimension approaches 5.5 cm. Patients with moderate to severe AR should avoid competitive sports, heavy workloads, and weightlifting. Patients with severe AR may benefit from long-acting vasodilators such as nifedipine XL. This treatment

before aortic valve replacement may improve postoperative ejection fractions and improve long-term outcomes (Scognamiglio et al., 2005). Following valve replacement for AR, the use of beta blockers may improve cardiac performance (Matsuyama et al., 2000).

Mitral Stenosis

Mitral stenosis is defined as the reduced ability of the blood to move from the left atrium to the left ventricle in diastole. It is mostly caused by dysfunction in the mitral valve, which lacks the ability to open its leaflets in diastole (Fig. 27-19). Mitral valve stenosis (MS) is predominantly caused by rheumatic carditis and is more prevalent in female patients (Bonow et al., 1998). Acute rheumatic carditis leads to valvular disease in approximately 50% of affected patients. The mitral valve is the most often affected by rheumatic heart disease, followed by the aortic valve, then combined aortic/mitral valves. MS is considered severe if the valve area is less than 1 cm²; normal mitral valve area is 4 to 6 cm². A valve area of 1.5 cm² or less associated with severe dyspnea (NYHC III or IV) or severe pulmonary hypertension (pulmonary pressure >50 mm Hg at rest and ≥60 mm Hg with exercise) is also considered clinically significant and warrants therapy.

The main symptom of MS is slowly progressive dyspnea and fatigue. In advanced MS, left atrial pressure develops with a redistribution of blood to the chest. Patients might complain of orthopnea and paroxysmal nocturnal dyspnea. Pulmonary hypertension can become severe, and right-sided ventricular failure can then lead to dependent edema, hepatomegaly, and right upper quadrant pain. An increase in left atrial size can lead to palpitations secondary to atrial fibrillation, as well as subsequent cardioembolic strokes if not recognized in a timely manner.

Most auscultatory signs of MS are missed if not performed in the left lateral decubitus position. Typically, the first heart sound (S1) is accentuated. A low-pitched diastolic rumble, heard with the bell of the stethoscope over the apex, is also present. The high-pitched *opening snap* (OS), caused by the abrupt stopping of the domed mitral valve into the left ventricle, is also appreciated in most patients midway between

the left sternal border and apex. A shorter A2-OS distance indicates a more severe MS. Signs of pulmonary hypertension such as a loud P2 and right ventricular hypertrophy can also be present as MS becomes more severe.

The ECG findings in MS might show a biphasic P wave in V1, a large P wave in lead II, and possibly atrial fibrillation. A chest radiograph may show evidence of an enlarged left atrium and an increase in pulmonary congestion with interstitial edema. An echocardiogram can accurately diagnose MS and assess valvular and subvalvular structure and valve area (Rahimtoola et al., 2002). In addition, an echocardiogram can help distinguish the cause of MS, whether valvular or from different etiologies such as tumors, vegetations, extreme calcification of the annulus, left atrial myxoma, cor triatriatum, or presence of a large thrombus. An echocardiogram can also help estimate pulmonary pressures and assess for right-sided enlargement. Typically, LV function is preserved in MS. In addition, echocardiography can help in calculating a mitral valve score that takes into account leaflet mobility, thickening, valve calcification, and distortion of the subvalvular apparatus. The interventional cardiologist typically uses the valve score to determine the feasibility of balloon valvuloplasty. A score less than 8 generally indicates a good prognosis from mitral valvuloplasty. Furthermore, a transthoracic echocardiogram is not well suited to see the left atrial appendage, so transesophageal echocardiography (TEE) becomes necessary to rule out the presence of an atrial thrombus prior to valvuloplasty, because this can be a significant risk for an embolic stroke. Finally, a left- and right-sided heart catheterization remains the best modality to assess mitral valve severity and full hemodynamics and determine coronary anatomy before contemplated corrective surgery.

Treatment

All patients with rheumatic mitral valve disease require bacterial endocarditis prophylaxis before dental, genitourinary, or GI procedures. Increasing diastolic filling time is important in the treatment of moderate to severe MS. Therefore, drugs such as β -blockers or verapamil might be used. Maintaining sinus rhythm can also reduce symptoms because loss of atrial contraction reduces ventricular emptying. Patients with atrial fibrillation need to be aggressively treated with rate control and anticoagulation with warfarin to reduce embolic strokes. *Chemoversion* (with amiodarone or other antiarrhythmics) or cardioversion can be performed after the patient has been anticoagulated for at least 3 weeks. Anticoagulation should be maintained for a minimum of 1 month after the procedure. Generally, anticoagulation is maintained long term because the recurrence of atrial fibrillation can be unpredictable. TEE can be performed before cardioversion to rule out the presence of a left atrial thrombus (Fig. 27-20). Even when a thrombus is excluded, patients need to be heparinized for at least 48 to 72 hours before cardioversion, then maintained on warfarin. The target international normalized ratio (INR) in patients with atrial fibrillation needs to be 2.0 to 3.0.

Patients with moderate to severe symptoms (NYHC II-IV) or asymptomatic patients with severe MS (valve area <1.5 cm²) and pulmonary hypertension (pulmonary pressure >50 mm Hg at rest and ≥ 60 mm Hg with exercise) will require percutaneous valvuloplasty, mitral valve repair, or mitral valve replacement. Balloon valvuloplasty leads to

Figure 27-20 Left atrial appendage thrombus seen on transesophageal echocardiography.

Box 27-8 Common Contraindications for Mitral Balloon Valvuloplasty

1. Presence of left atrial thrombus seen on transesophageal echocardiography
2. Associated severe mitral regurgitation
3. Associated coronary artery disease that requires bypass surgery
4. A high valve score as determined by echocardiography (unfavorable valve morphology)
5. Associated other valvular pathology or aortic pathology that will require surgical interventions
6. Difficulty in obtaining access

commissural separation as the main mechanism that leads to an improvement in valvular function. Mitral valvuloplasty is currently the preferred method of treating severe MS when no contraindications exist (Box 27-8). The procedure carries an exceedingly low risk of mortality, with an acute success rate over 95% and very good long-term results similar to surgical commissurotomy (Rahimtoola et al., 2002). Patients who are qualified for valvuloplasty (favorable valve score) can undergo valve repair if balloon valvuloplasty is not available or left atrial thrombus persists despite anticoagulation. Mitral valve surgery is reserved for patients with a calcified valve and a high valve score on echocardiography who are essentially excluded from balloon valvuloplasty.

Mitral Regurgitation

Mitral regurgitation (MR) is defined as an abnormal blood flow into the left atrium in systole as a result of an abnormal closing of the mitral valve. In chronic mitral insufficiency, the LVEF and cavity size may remain preserved for several years. However, LV remodeling eventually occurs, cavity size begins to dilate, ejection fraction becomes reduced, and patients enter a decompensated state. In acute MR, the left atrium and left ventricle have no chance for gradual dilation, and therefore a sudden rise in LV and pulmonary venous pressure occurs, leading to pulmonary edema.

Chronic MR is generally asymptomatic or associated with minimal symptoms of dyspnea or generalized fatigue. When

Figure 27-21 Left ventriculogram in the right anterior oblique (RAO) projection showing severe mitral insufficiency.

LV function declines severely, patients can become symptomatic with symptoms and signs of CHF. Patients might provide a history of rheumatic fever, endocarditis, CAD, or CHF. Acute MR needs to be in the differential diagnosis of a patient with sudden-onset pulmonary edema.

On examination, patients will display a systolic murmur, most often holosystolic, high-pitched and present at the apex with radiation to the axilla, left scapula, middle back, or left sternal border, depending on the direction of the regurgitant jet. A midsystolic click is often heard if associated mitral valve prolapse is seen. Occasionally a low-pitched diastolic rumble and an S3 sound can be heard.

The ECG often displays an enlarged left atrium (biphasic P wave in V1), large QRS complex secondary to LV enlargement, possible atrial fibrillation, and in ischemic MR, evidence of old or acute inferior infarcts can be seen. The chest radiograph may show an enlarged cardiac silhouette, calcified mitral valve, or increased pulmonary vascular congestion. Echocardiography provides the diagnosis by assessing the presence of the MR, its severity, and its etiology, such as severe prolapse, endocarditis, calcification, papillary muscle or chordae rupture, or a degenerative valve. Left- and right-sided heart catheterization is indicated before corrective surgery to determine the presence of CAD and confirm the diagnosis of MR with the use of left ventriculography. MR is graded based on the amount of contrast seen in the left atrium in systole: *grade I*, contrast does not opacify entire left atrium; *grade II*, contrast opacifies all left atrium but less dense than the contrast in the left ventricle; *grade III*, contrast equally opacifies left atrium and left ventricle; and *grade IV*, contrast in the left atrium is darker than the left ventricle with opacification of pulmonary veins (Fig. 27-21). Also, the angiogram can quantitatively determine the regurgitant fraction (RF). An RF greater than 50% generally indicates severe MR that requires corrective surgery.

Treatment

Patients with a history of mitral insufficiency need to have bacterial endocarditis prophylaxis. Chronic MR benefits from long-term afterload reduction, although this remains controversial. Aggressive treatment of atrial fibrillation with rate control and warfarin anticoagulation is needed. Patients with moderate to severe MR need to be closely monitored for LVEF and LV cavity size. A lower threshold for surgical intervention is generally agreed on when compared to AR. Symptomatic patients (NYHC II-IV) or asymptomatic patients with LV end-systolic dimension approaching 4.5 cm or LVEF of 60% or less should be treated. Patients with lower ejection fraction and a larger cavity size carry a poorer outcome after surgery. However, those with LVEF of 30% to 50% and LV cavity size in systole of 50 to 55 mm also benefit from surgery. Asymptomatic patients with preserved LV function and cavity size but with atrial fibrillation might benefit from surgery.

Acute MR should be treated aggressively with afterload reduction (e.g., sodium nitroprusside). These patients generally require immediate surgery but will do best if they can be initially treated medically and enter a compensated state before surgery. Most regurgitant mitral valves can now be repaired instead of replaced. Techniques for percutaneous repair of the mitral valve are now being tested and hold significant promise.

Mitral Valve Prolapse

Mitral valve prolapse (MVP) is described as bulging of one or more of the mitral leaflets into the left atrium in systole (see Fig. 27-21). Although the most common cause of significant MR (Cheng and Barlow., 1989), it can be isolated without valvular insufficiency. MVP with MR is a strong indication for prophylaxis against bacterial endocarditis during dental, GI, and genitourinary procedures. MVP carries a benign course (Freed et al., 2002). On rare occasions it may be associated with significant arrhythmias and sudden cardiac death. When associated with MR, patients need to be carefully monitored for progressive left atrial and left ventricular cavity dilation and atrial fibrillation.

Primary MVP might be familial and is inherited as an autosomal dominant trait with different rate of penetrance and typically found in patients with connective tissue disease, cardiomyopathies, and Marfan's syndrome (Pyeritz and Wappel, 1983). Secondary MVP is generally seen in patients with CAD and rheumatic heart disease.

Patients with MVP are often asymptomatic. However, some patients describe palpitations, chest pain, dyspnea, and fatigue with or without MR. Although previously thought that strokes occur more frequently in patients with MVP, recent data do not support this conclusion (Gilon et al., 1999). Panic attacks have been frequently described. A high-pitched midsystolic click is often heard that occurs shortly after S1 and can be associated with a systolic murmur. Baseline electrocardiography is often unrevealing, and routine stress testing carries a high false-positive rate. Stress imaging is more accurate in evaluating these patients for myocardial ischemia. An echocardiogram is the most helpful methodology for making the diagnosis of MVP. A displacement of the leaflets beyond the mitral annulus on a parasternal short axis is strongly suggestive of MVP. Cardiac catheterization is generally not needed for diagnosis.

Asymptomatic patients with MVP generally do not require treatment unless they have severe associated MR (Devereux et al., 1989). Symptomatic patients with MVP can be treated with beta blockers. Flail mitral leaflets caused by chordae rupture or severe MR associated with MVP needs to be followed and mitral valve repair becomes indicated if patients develop symptoms of dyspnea (NYHC III or IV), the ejection fraction and cavity size become adversely affected, or atrial fibrillation appears.

Tricuspid Valve Disease

Tricuspid regurgitation (TR) is commonly present on echocardiography in the majority of patients and therefore, when mild, is considered a normal variant. Severe TR can occur, however, and can create significant symptoms of right-sided CHF (cor pulmonale) and dyspnea. Isolated TR is most often seen in drug addicts secondary to tricuspid valve endocarditis but can also be caused by carcinoid syndrome, trauma, right ventricular (RV) infarction, and certain congenital anomalies. The most common etiology of TR, however, is annular dilation from RV cavity dilation.

Patients with TR present with various symptoms depending on the etiology of the valvular abnormalities. Typically, dyspnea, right- and left-sided failure, and in the case of endocarditis, fever and night sweats may be present. The right ventricle is generally dilated, and a precordial lift is present. The jugular veins are pulsatile and increased. A systolic murmur is generally heard along the left sternal border that increases with respiration.

Patients with severe TR are treated with diuretics and digitalis to treat the associated right-sided failure. ACE inhibitors are indicated if left ventricular dysfunction is present. Treatment of associated valvular abnormalities is typically indicated, such as severe MR or MS. Tricuspid valve annuloplasty is generally done, particularly when the symptoms are severe and long-standing and secondary to mitral valve disease. Tricuspid valve replacement is reserved for those patients with abnormal tricuspid valves not amenable to annuloplasty or tricuspid valve repair.

Tricuspid valve stenosis (TS) is mostly caused by rheumatic heart disease and is typically associated with other valvular involvement. TS can also be caused by the carcinoid syndrome (most frequently causes TR) and certain connective tissue diseases. Secondary causes of TS (e.g., tumors, thrombi) can also precipitate secondary TS. Patients can be dyspneic with activity. Typically, there is an increase in the jugular vein with a large *a* wave, indicating atrial contraction against a stiff tricuspid valve. TS is usually treated with percutaneous valvular commissurotomy, unless unfeasible. Open commissurotomy is then performed, or valve replacement if the leaflets and subvalvular structures are not reparable. Bioprosthetic valves are typically used, and patients generally start warfarin therapy after tricuspid valve replacement.

Pulmonic Valve Disease

Pulmonic valve regurgitation (PR) is typically acquired from increased pulmonic pressures (pulmonary hypertension). PR can also result from primary valve abnormalities caused by endocarditis. PR causes a diastolic murmur along the left sternal border. Surgery for patients with acquired PR is rarely performed.

Pulmonic valve stenosis (PS) is mostly congenital, although secondary causes include tumors, endocarditis, and carcinoid. PS is best treated with percutaneous valvuloplasty, with good long-term results.

Prevention of Endocarditis

To prevent adverse complications from infective endocarditis, recent guidelines indicate that only high-risk cardiac patients should receive bacterial endocarditis prophylaxis when undergoing dental procedures that involve manipulation of gingival tissue or periapical teeth or perforation of oral mucosa. The routine use of infective endocarditis prophylaxis before GI or genitourinary (GU) tract infections is not recommended, except in patients with GI or GU infections. Cardiac patients at high risk for complications of infective endocarditis include those with prosthetic cardiac valves or prosthetic material used for cardiac valve repair, prior history of infective endocarditis, unrepaired congenital heart disease, or repaired congenital heart defect with a prosthesis during the first 6 months after the procedure. Residual defects at the repair site and valvular regurgitation secondary to structural valvular disease in a cardiac transplant patient are also considered high risks (Nishimura et al., 2008).

Peripheral Arterial Disease

Key Points

- Patients must be encouraged and supported to stop smoking and to avoid secondhand smoke (Smith et al., 2001) (SOR: A).
- Nicotine replacement therapies to prevent withdrawal symptoms (bupropion, varenicline) are useful aids for tobacco cessation (SOR: A).
- Patients should participate in regular aerobic exercise for at least 30 minutes a day three or four times weekly. Walking improves claudication (SOR: A).
- Patients should receive dietary counseling and be encouraged to achieve an ideal body weight (SOR: A).
- Pedal pulses should be palpated as part of the routine physical examination in all patients at risk for atherosclerosis (SOR: A).
- Diabetic patients should undergo yearly foot examinations that consist of vascular, neurologic, musculoskeletal, and skin evaluation (SOR: A).
- Patients with absent pulses or symptoms suggestive of intermittent claudication should undergo a noninvasive vascular study. For patients with calcified, noncompressible vessels, the toe-brachial index can be used instead of the ankle-brachial index (ABI).
- Patients with an abnormal resting ABI, or postexercise ABI less than 0.9, should have CTA or MRA

Epidemiology

Atherosclerotic peripheral vascular disease (PVD) is an underdiagnosed, undertreated, age-dependent disease that profoundly impacts patient quality of life, and is an independent predictor of mortality (Criqui et al., 1992; Nikolsky et al., 2004; Vogt et al., 1993). On average the mortality rate of claudicant patients is 2.5 times higher than nonclaudicant patients (Fig. 27-22).

Figure 27-22 Survival of patients with intermittent claudication and matched controls. (Reprinted with permission from the Society of Vascular Surgery. Dormandy JA, Rutherford RB. Management of peripheral arterial disease (PAD). TransAtlantic Inter-Society Consensus (TASC). *J Vasc Surg* 2000;31:S1-S296, Figure 12.)

Atherosclerosis is a ubiquitous process of chronic low-grade inflammation with superimposed acute thrombotic events (Libby, 2001) that affects the entire arterial tree in the coronary, cerebral, visceral, and upper and lower extremity circulation. Patients with PVD are at increased risk of cardiovascular and cerebrovascular events, including death, MI, and stroke. The clinical continuum of PVD ranges from asymptomatic stenosis to limb-threatening ischemia. *Intermittent claudication* (IC) is defined as ischemic limb pain in one or both legs that occurs with exertion and is alleviated with rest. IC is associated with marked limitations in walking ability, which translates into a considerable negative impact on occupational, social, and leisure activities (Regensteiner et al., 1990; Olsen et al., 1988; Vogt et al., 1994).

Atherosclerosis begins in childhood and evolves over decades (Freedman et al., 1988), affecting more than 85% of adults over age 50 (Tuzcu et al., 2001). However, many patients remain entirely asymptomatic; thus estimating the true prevalence of PVD is difficult and highly dependent on the definition of disease. Most epidemiologic studies only report symptomatic disease; therefore the true incidence of PVD is not accurately known and underestimated. In addition, published reports on the incidence and prevalence of PVD vary greatly because the true occurrence of disease is directly related to the risk group of the population studied, and the sensitivity and specificity of the diagnostic testing methodology (Criqui et al., 1985).

Intermittent Claudication

Intermittent claudication is only a symptom of PVD and can be misleading in measuring the prevalence of PVD. For example, a patient with advanced PVD may not have significant IC due to functional decline and inactivity, whereas those who are very active may have significant IC even if they only have mild disease. Several questionnaires, such as the World Health Organization (WHO)/Rose, Edinburgh Claudication, and Walking Impairment questionnaires, have been developed to identify patients with IC. The prevalence of IC based on the Rose criteria ranged from 0.4% to 14% of the adult population (Dormandy and Rutherford, 2000). Although these questionnaires are typically highly specific in excluding healthy patients, as assessed by

a physician, they are only moderately sensitive in detecting disease. Only about one third of patients with PVD have typical symptoms of IC (Schroll and Munck, 1981; Zheng et al., 1997). Furthermore, asymptomatic patients are not at all detected by questionnaire screening. These individuals can only be diagnosed with noninvasive or invasive imaging. Therefore, epidemiologic studies based solely on the use of questionnaires significantly underestimate the true prevalence of disease.

Asymptomatic Disease

More than 50% of patients with PVD are asymptomatic and only identified by noninvasive testing, such as the ankle-brachial index (ABI). Most epidemiologic studies have used a resting ABI less than 0.9 as the criterion for the diagnosis of PVD. However, this definition has several limitations and also leads to an underestimation of the true prevalence of disease. For example, this definition will miss mild to moderate disease in patients with normal resting ABIs, but who may have a considerable ischemic drop in the ABI with exercise. Furthermore, heavily calcified vessels, particularly in diabetic patients, will have falsely elevated ABIs from inability to compress the vessel. Nonetheless, the Systolic Hypertension in the Elderly Program (SHEP) found a prevalence of asymptomatic PVD in 25.5% of 1537 patients (Newman et al., 1993), using a resting ABI <0.9 as the diagnostic criteria. The Peripheral Arterial Disease Detection, Awareness, and Treatment in Primary Care (PARTNERS) program evaluated 6979 patients age 70 years and older, or age 50 to 69 with a history of either diabetes or cigarette smoking, by history and ABI. The diagnosis of PVD was made based on a resting ABI <0.9, a documented medical history of PVD, or a prior lower extremity revascularization. The PARTNERS program found a prevalence of PVD in 29% of patients. More concerning, however, is that 83% of patients with a known prior history of PVD were aware of their diagnosis, whereas only 49% of their physicians were aware of this diagnosis (Hirsch et al., 2001).

Critical Limb Ischemia

Critical limb ischemia (CLI) is defined by the presence of ischemic resting pain in the distal foot, ischemic nonhealing ulcerations, or gangrene, and represents less than 10% of patients with PVD (Hiatt, 2001). Although this subset represents the smallest percentage of patients with PVD, these patients have tremendous disease burden and are clearly the highest risk subset for morbidity and mortality, with up to 73% to 95% progressing to limb loss or death at one year if left untreated (Wolfe and Wyatt, 1997). Each year 150,000 to 200,000 nontraumatic lower extremity amputations are performed in the United States, 85% to 90% of which could be avoided through early revascularization and aggressive risk factor management. Amputation carries a high rate of long-term morbidity and mortality. The fate of the amputee is poor, particularly in the elderly. The level of amputation also dictates the overall prognosis; two to three times as many below-the-knee (BK) amputees achieve full mobility compared to above-the-knee (AK) amputees, but the initial rehabilitation may take up to 9 months. In addition, 5 years after a BK amputation, 30% of patients will have had a major

contralateral amputation, 50% will be dead, and only 20% will be alive with one leg intact (Dormandy and Rutherford, 2000).

Pathophysiology

Peripheral arterial insufficiency is caused by hemodynamically significant narrowing of the arterial circulation, usually from atherosclerosis, which clinically reduces blood flow to the affected limb. Longitudinal epidemiologic studies such as the Framingham Heart Study (Murabito et al., 1997), and INTERHEART study (Yusuf et al., 2004) have defined the risk factors for PVD.

Traditional Risk Factors

Age

The prevalence of PVD increases with age. The incidence of IC in five large population-based studies is four times higher and prevalence eight times higher comparing the 35-39 to the 70-74 age group (Dormandy and Rutherford, 2000).

Smoking

Smoking is a very strong independent cause of atherosclerotic PVD. The severity of PVD increases with the number of cigarettes smoked (Cronenwett et al., 1984; Powell et al., 1997) and the amount of exposure to second-hand smoke (Barnoya and Glantz, 2005). In a series of epidemiologic studies, the incidence of developing IC among smokers is twofold to threefold higher than in nonsmokers (Dormandy and Rutherford, 2000). Smokers develop IC approximately a decade before nonsmokers (Kannel and Shurtleff, 1973), and the association between smoking and PVD may be stronger than the association between smoking and CAD (Fowkes et al., 1992; Kannel, 1994). Moreover, smokers are much more likely to progress to CLI than nonsmokers. Smokers with IC have an 11-fold greater amputation rate than nonsmokers (Dormandy et al., 1999a).

Smoking cessation slows the progression of disease, improves the symptoms of IC, decreases the likelihood of amputation, improves the patency of revascularization procedures (Krupski, 1991), and improves overall longevity (Taylor et al., 2002). Finally, all-cause mortality is significantly reduced by smoking cessation, but not by smoking reduction (Godtfredsen et al., 2002). It is imperative that patients entirely cease smoking and not just reduce their consumption of tobacco products.

Diabetes Mellitus

Diabetes/glucose intolerance is one of the most powerful independent modifiable risk factors that contributes to the development of PVD, IC, and CLI (Murabito et al., 1997; Fowkes et al., 1992; Kannel and McGee, 1979). The incidence of IC in diabetic patients is approximately two times higher than in nondiabetic patients (Dormandy and Rutherford, 2000). Diabetes not only has a significant effect on the larger-vessel arterial circulation, but also directly causes microangiopathy as well. Therefore, in conjunction with diabetic peripheral neuropathy, these patients are particularly vulnerable to amputation.

Approximately 60% of all nontraumatic amputations performed in the United States each year are in diabetic

patients (ADA Fact Sheet, 2005). The diabetic patient with PVD has approximately a 10-fold higher amputation rate than a nondiabetic patient (Da Silva et al., 1979). There does not appear to be any significant difference in microvascular or macrovascular comorbidity between type 1 and type 2 diabetics (Zander et al., 2002). However, there is a dose-response relationship between the HbA_{1c} level and the risk of amputation (Lehto et al., 1996). Therefore, patients with diabetes should be aggressively treated to normalize glycemic control. In addition, diabetic patients should be instructed on good foot hygiene, such as proper-fitting shoes and foot hygiene, to avoid skin breakdown and ulcer formation.

Hyperlipidemia

As in CAD, low-density lipoprotein cholesterol (LDL-C) and triglyceride (TG) levels are directly related, while high-density lipoprotein cholesterol (HDL-C) levels are indirectly related, to the progression of PVD, and the observed risk seems to demonstrate a linear relationship (Fowkes et al., 1992; Murabito et al., 2002). Most data on lipid-lowering therapy are from patients with CAD. However, several studies specifically demonstrate an improvement in the relative risk of an abnormal ABI, walking distance on a treadmill, frequency and severity of claudication, and limb loss (Blankenborn et al., 1991; Buchwald et al., 1996; Mohler et al., 2003; Pedersen et al., 1998), suggesting that all patients with PVD should be treated with lipid-lowering therapy regardless of baseline LDL-C.

Hypertension

Hypertension is a major risk factor for PVD and carries a 2.5-fold age-adjusted risk for men and a 3.9-fold age-adjusted risk for women (Kannel and McGee, 1985; Murabito et al., 1997). There have been concerns, based on early case reports, that beta-blockade therapy may worsen the symptoms of IC. A meta-analysis on this subject and critical review of these studies concluded that beta blockers are safe and do not worsen IC (Radack and Deck, 1991). ACE inhibitors (ACEIs) may offer significant benefits for the prevention of atherosclerotic vascular disease beyond that expected from a reduction in blood pressure alone. However, there remains considerable debate as to whether or not the data from the HOPE (Heart Outcomes, 2000) and EUROPA (Fox et al., 2003) studies can be generalized to all ACEIs.

Gender

The initial data from Framingham suggested that men develop IC approximately 10 years before women (Kannel et al., 1970). More recent data do not support this observation (Hirsch et al., 2001; Murabito et al., 2003; Reunanen et al., 1982). In light of these data, patients should be screened for PVD regardless of gender.

Obesity

Obesity, as measured by an increased body mass index (BMI) greater than 30, has long been recognized as a risk factor for atherosclerotic disease. It is now recognized that adipocytes, particularly visceral adipocytes, contribute to a proinflammatory state by generating a variety of cytokines (e.g., IL-6, TNF- α , CRP), which play a direct role in the development of

atherosclerosis (Hansson, 2005). As further support, liposuction does not seem to lower risk for CAD, because it reduces subcutaneous fat mass but has no effect on lowering visceral fat mass (Klein et al., 2004).

Nontraditional Risk Factors

High-Sensitivity C-Reactive Protein

Atherosclerosis is a disease of chronic low-grade inflammation. High-sensitivity CRP is a nonspecific marker of inflammation emerging as a simple but powerful marker of atherosclerotic risk. Prospective data from the Physicians' Health Study demonstrate that baseline levels of hsCRP independently predict future risk of developing symptomatic PVD (Ridker et al., 1998).

Lipoprotein(a)

Lipoprotein(a) [Lp(a)] is an atherogenic subspecies of LDL that is covalently linked to apoprotein(a). Apo(a) is homologous to plasminogen. Lp(a) may exacerbate risk for ACS by inhibiting endogenous fibrinolysis (Hajjar et al., 1989). Furthermore, Lp(a) may augment the release of endothelial plasminogen activator inhibitor-1 (PAI-1), which further impairs fibrinolysis (Etingin et al., 1991). The net result is that Lp(a) contributes to atherogenesis and a prothrombotic or hypercoagulable state.

Lipoprotein(a) has been implicated as an independent predictor of PVD (Cheng et al., 1997; Prior et al., 1995). However, many of these studies are cross-sectional or retrospective and cannot establish causal relationships between risk factors and disease. Prospective data from the Physicians' Health Study did not show a significant relationship in baseline Lp(a) levels and the future development of PVD (Ridker et al., 2001). Widespread screening of Lp(a) levels in the general population is not recommended. However, this should be considered in patients who present with premature vascular disease and few traditional risk factors. Niacin can modestly reduce Lp(a) levels. There is no clinical trial evidence to prove that reducing serum levels of Lp(a) reduces risk for the development or progression of PVD.

Fibrinogen

Fibrinogen has been implicated in atherogenesis by early epidemiologic studies (Kannel et al., 1987). However, fibrinogen is an acute-phase reactant, with considerable inpatient variability in its expression over time. Other markers of inflammation, such as hsCRP, have a more powerful association in predicting PVD. Furthermore, fibrinogen levels are directly related to age, obesity, cigarette smoking, diabetes, and LDL-C, and inversely related to HDL-C, physical activity, alcohol use, and estrogen levels. Controversy surrounds the independent predictive value of hyperfibrinogenemia. Therefore, routine fibrinogen level screening is not recommended, unless there is suspicion of a hypercoagulable state.

Natural History

Atherosclerosis is an age-dependent disease that begins in childhood and progresses throughout adulthood, particularly if the risk factors are left unchecked. However, early studies suggested that PVD led a contrary, benign course

Figure 27-23 Overlap of atherosclerotic disease. Patients often manifest symptoms in more than one vascular bed. (Modified from Ness J, Aronow WS. Prevalence of coexistence of coronary artery disease, ischemic stroke, and peripheral arterial disease in older persons, mean age 80 years, in an academic hospital-based geriatrics practice. *J Am Geriatr Soc* 1999;47:1255-1258.)

that was not progressive (Imparato et al., 1975; McAllister, 1976). However, in most of these studies, IC was used as an end point, not ABI or even a patient functional assessment. Intermittent claudication is a relatively insensitive marker of PVD presence. Those studies typically reported a stabilization or improvement in IC over time, which does not necessarily indicate stabilization or improvement in the disease process, ability to ambulate, or functional status. Early authors suggested that relief of IC over time was a sign of improved collateral flow, but to experience IC, a patient must be physically active. Stabilization or improvement of IC was strongly related to functional decline (i.e., patients walked at a slower pace and for shorter distances to avoid experiencing IC) (McDermott et al., 2004). Thus, PVD is a progressive disorder that leads to a significant decline in quality of life.

Coexisting Vascular Disease

The most important fact regarding the diagnosis and management of PVD is that PVD is a powerful, independent predictor of mortality (Criqui et al., 1992). Intermittent claudication and/or CLI can have a significant impact on quality of life. Many patients may accept their physical limitations as a consequence of aging and tolerate this morbidity. Less than 5% of patients with IC will ever progress to amputation. Much more significant, however, is that PVD is a systemic disorder, and it has considerable overlap with CAD and cerebrovascular disease, ultimately leading to an increase in mortality. Approximately 40% of patients with atherosclerotic vascular disease manifest symptoms in more than one vascular bed (Fig. 27-23) (Ness and Aronow, 1999). Compared to people without PVD, patients with PVD are about four times more likely to have an MI (Criqui et al., 1992) and two to three times more likely to have a stroke (Wilterdink and Easton, 1992). The all-cause mortality rate in patients with PVD is about equal between men and women and is elevated even in asymptomatic patients (Hiatt, 2001). The lower the ABI, the greater is the risk for cardiovascular events. Patients with CLI, who typically have the lowest ABI, have an annual mortality rate of 25% (Dormandy et al., 1999b; McKenna et al., 1991; Vogt et al., 1993b).

Diagnosis

A thorough history and physical examination can accurately suggest a diagnosis of PVD 80% to 90% of the time.

History

The vast majority of disorders related to the peripheral vascular system are (1) atherosclerosis involving the arterial tree or (2) thrombophlebitis involving the venous circulation—both predominantly affecting the lower extremities more so than the upper extremities or viscera. Patients with suspected vascular disease typically present for evaluation with varying types of limb pain or discomfort, ulcerations or gangrene of the extremities, or swelling of the affected limb.

Most limb pain or discomfort typically falls into three etiologies: vascular, musculoskeletal, or neuropathic. Most limb swelling is caused by venous obstruction or insufficiency, increased venous pressure (e.g., CHF), decreased oncotic pressure (e.g., hypoproteinemia, hypoalbuminemia), lymphedema, or lipedema. Many patients, particularly the elderly, have multifactorial etiologies of pain or swelling that can usually be distinguished by a thorough history and physical examination. Using a systematic approach with key pointed questions, a presumptive diagnosis can often be deduced on clinical grounds and subsequently confirmed with noninvasive testing. The history should focus on identifying risk factors for atherosclerosis. The past medical history should concentrate on prior vascular events such as MI, stroke, amputation, DVT and revascularizations in any vascular bed either percutaneously or surgically, as well as, but not limited to, a history of CHF, back problems, osteoarthritis, inflammatory conditions (e.g., rheumatoid arthritis, plantar fasciitis, polymyalgia rheumatic), gout, varicose veins, and lymphatic obstruction (e.g., after surgery or radiation therapy).

The etiology of leg pain can be determined by the characteristics, severity, location, duration, frequency, and precipitating or alleviating factors of the discomfort. *Claudication* is typically described as a cramping or aching discomfort in the muscle associated with exertion and alleviated with rest. Most often this occurs in the calf, but it can occur in the hip and buttocks if there is occlusive disease in the aortoiliac segment. Nocturnal cramping of the calf and foot is not typically vascular in etiology and is most likely caused by an exaggerated neuromuscular response to stretch that occurs while sleeping.

Critical limb ischemia can cause resting pain that is constant throughout the day and night. A classic description of nocturnal pain from CLI is a moderate to severe aching paresthesia/dysesthesia while lying horizontal that is alleviated by dangling the leg over the side of the bed. Pain from CLI can be so severe that it may not be relieved by narcotic analgesia. On the other hand, diabetic patients with severe peripheral neuropathy may be completely insensate despite significant tissue loss. Distinguishing the etiology of constant resting limb pain between a vascular and nonvascular etiology can be done by physical examination and noninvasive testing. Pain that occurs at rest may be caused by CLI if other findings in the history and examination support the diagnosis of advanced atherosclerosis. Otherwise, pain that occurs at rest, with change in position, or simply standing without

exertion, is more typically musculoskeletal or neuropathic in nature. Tables 27-11 and 27-12 list the distinguishing features and differential diagnosis of the most common types of leg pain and swelling, respectively.

For example, acute loss of motor and sensory function in the distal extremities, particularly with associated acute severe pain, pallor, and coolness of the limb, is a sign of acute arterial occlusion. However, chronic motor and sensory loss may be vascular in etiology but more likely is neuropathic. Several standardized classification schemes exist for categorizing the severity of both acute and chronic limb ischemia. Table 27-13 is the revised Rutherford-Baker classification for acute limb ischemia, and Table 27-14 is the combined Fontaine classification (more popular in Europe) and the Rutherford-Baker scheme for CLI (Dormandy and Rutherford, 2000; Rutherford et al., 1997).

Physical Examination

The physical examination in patients with PVD should consist of inspection, palpation, auscultation, and even percussion. Observations should note any asymmetry between the limbs, joint deformities, varicose veins, skin discoloration, absence of hair, swelling, ulcerations, tissue loss, and gangrene. Acute CLI from embolism or thrombosis typically causes pallor with decreased capillary refill that eventually leads to mottling unless adequate collateral flow can be recruited. Chronic ischemia may have a normal skin color with relatively normal or slightly delayed capillary refill, particularly if collateral flow has developed. Chronic advanced CLI can lead to dependent rubor due to chronic dilation of the postcapillary venules. The toes of the dependent limbs can become red with brisk capillary refill. This is often mistaken for hyperemia rather than a sign of severe ischemia. A cadaveric pallor on elevating the limb to greater than 45 degrees above the horizontal for 1 to 2 minutes, followed by slow venous filling with rubor after returning to a dependent position (Buerger's sign), also signals advanced CLI.

Ulcerations may be caused by chronic venous insufficiency or edema and arterial insufficiency. Chronic venous disease typically causes pigmentation of the lower legs from extravasation of red blood cells with superficial ulcers in the calves, more often medially than laterally. Arterial ulcerations are characteristically distal, involving the toes and even forefoot in advanced disease.

Palpation of the pedal pulses should be a mandatory part of the routine physical examination. Notably, even in healthy individuals, the dorsalis pedis (DP) pulse, the posterior tibial (PT) pulse, or both are unable to be palpated 8.1%, 2.9%, and 0.7% of the time, respectively (McGee and Boyko, 1998). This results from normal anatomic variation. Wide and prominent femoral or popliteal pulses may be a sign of an aneurysm. A significant temperature gradient from proximal to distal and between ipsilateral and contralateral limbs often is a sign of advanced disease. The abdomen should be palpated to assess for the presence of an abdominal aortic aneurysm. Reproduction of pain with palpation over joints is not caused by vascular disease and seems to be a sign of such orthopedic conditions as degenerative joint disease, sacroiliitis, gout, trauma, or plantar fasciitis. Reproduction of pain with palpation of muscle groups may be vascular in etiology if there is severe ischemia, but the clinician should also

Table 27-11 Differential Diagnosis of Claudication

| Diagnosis | Location of Discomfort | Features of Discomfort | Onset Relative to Exertion | Onset Relative to Standing | Effect of Rest | Effect of Body Position | Other Features |
|---|--|--|--|-----------------------------------|--|---|---|
| Arterial claudication | Depends on level of stenosis (occlusion): aortoiliac disease affects hip/thigh/buttock, can affect entire limb Infringuinal disease affects calf and foot | Aching, cramping, weakness | Consistently reproduced with same degree of activity | Unrelated to standing | Relieved promptly | None | Gradual onset of discomfort with exercise Very reproducible |
| Venous claudication | Entire limb, usually worse in thigh and groin | Tight, tense sensation | After exercise | Unrelated to standing | Relieved slowly | Relieved more quickly with elevation | History of DVT, edema, or venous congestion |
| Chronic critical limb ischemia | Always involves foot; symptoms may be more proximal with more proximal disease | Severe burning, aching, but may be asymptomatic in patients with profound neuropathy | Worse with minimal activity | Unrelated to standing | Improved, but incompletely | Symptoms may be improved with dangling foot over side of bed while sleeping | Gradual or subacute onset Dependent rubor Elevation pallor Gangrene |
| Acute critical limb ischemia | Always involves foot; symptoms may be more proximal with more proximal disease | Severe aching, cramping, painful | Worse with minimal activity | Unrelated to standing | Improved, but incompletely | Symptoms may be improved with dangling foot over side of bed while sleeping | Acute onset Pale, cold Loss of motor/sensory functions is an emergency |
| Arthritis | Joints | Aching, may be sharp with position change | Variable | Weight bearing reproduces pain | Variable, may be present with rest | Less pain in non-weight bearing position | Variable, may be related to weather May have effusion |
| Lumbar back pain (e.g., herniated disc, nerve root compression) | Lumbar region; may radiate down dermatomes if there is nerve root compression | Sharp, stabbing, shooting | Immediate | Weight bearing reproduces pain | Variable, may be present at rest | Certain positions exacerbate or alleviate pain | History of back problems Worse with lifting May have motor/sensory deficits Reproducible with percussion |
| Sacroiliitis | Sacroiliac region | Sharp, stabbing, shooting | Immediate | Weight bearing reproduces pain | Variable, may be present at rest | Certain positions exacerbate or alleviate pain | Inflammatory disorder Reproducible with palpation |
| Plantar fasciitis | Plantar region | sharp, stabbing, searing | Immediate | Weight bearing reproduces pain | Immediate relief with non-weight bearing | Less pain in non-weight-bearing position | Reproducible with palpation |

consider other causes of myopathy, such as fibromyalgia, polymyalgia rheumatica, drug-induced myalgia, and trauma.

The carotid arteries, abdomen, and femoral arteries should be auscultated for *bruits*. Only gentle pressure should be applied with the stethoscope over the carotid and femoral arteries because pseudobruits can be created by compression of the underlying vessel. Finally, percussion over the lumbar spine may be useful in eliciting pain from sacroiliitis, lumbar disk disease, or nerve root compression.

Noninvasive Testing

Noninvasive vascular testing is useful to confirm clinical suspicion of PVD in patients with leg discomfort and to screen asymptomatic patients at risk for vascular disease, particularly diabetics. Noninvasive testing is also very helpful for the surveillance of vessel patency after percutaneous or surgical intervention.

Noninvasive Vascular Study

A complete noninvasive vascular study (NIVS) consists of the ABI, segmental BPs, and pulse-volume recordings (PVR) obtained at rest. When physically possible, the ABIs should also be ordered with exercise to assess for an ischemic response (Fig. 27-24).

The ABI is defined as the highest systolic blood pressure (SBP) of either the DP artery or PT artery divided by the higher of the SBP from either the right or left brachial artery (Table 27-15). Segmental BPs provide more specific information as to the location of the stenosis/obstruction. BP readings are obtained at the high-thigh, low-thigh, calf, ankle, metatarsal, and toe level, specifically looking for pressure gradients proximally to distally. Pulse-volume recordings

are plethysmographic measurements that detect changes in the blood volume flowing through the limb. A normal PVR tracing resembles a normal arterial pulse wave tracing with a rapid upstroke, prominent dicrotic notch, and rapid downstroke. As the severity of the disease increases, the waveforms become more blunted, the dicrotic notch disappears, and ultimately the waveforms become flat.

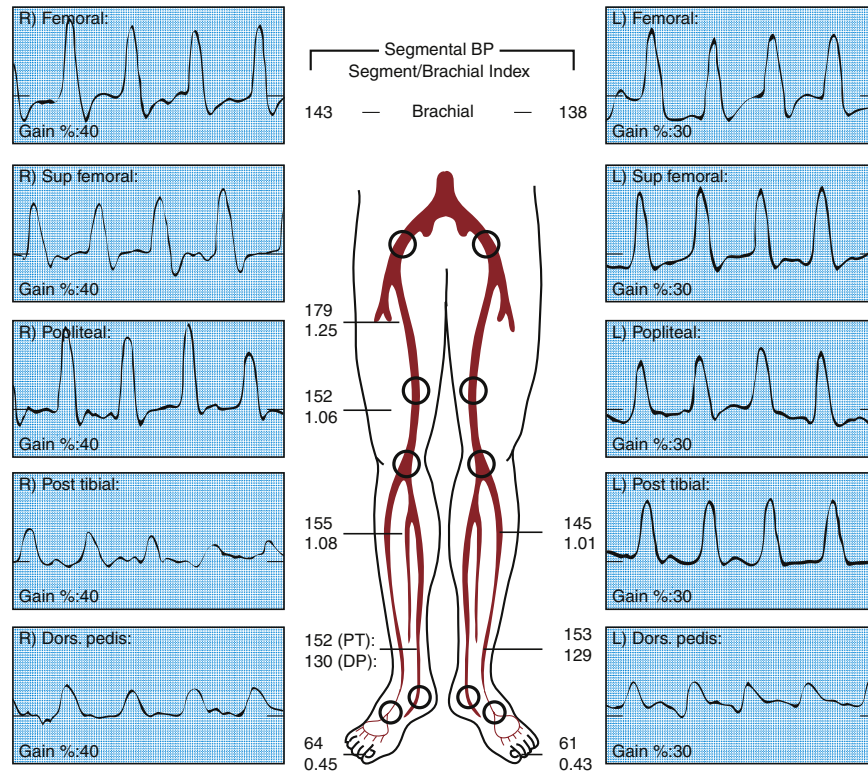

The standard exercise protocol of walking on a treadmill for 5 minutes at 2 mph at a 12% grade (Rutherford et al., 1997) is quite modest in comparison to the workload involved in a routine Bruce protocol that is typically employed for cardiac stress testing. The purpose of the Rutherford protocol is not to induce coronary ischemia and thus is typically well tolerated from a cardiopulmonary standpoint. Relative contraindications to walking on a treadmill include severe symptomatic CAD (Canadian Cardiovascular Society Class 3 or 4), severe decompensated CHF (NYHA Class III or IV), severe symptomatic COPD, orthopedic or balance disorders that preclude safe ambulation on a treadmill, or severely depressed resting ABI (<0.5). If patients are unable to walk on a treadmill, other means of exercise may suffice, such as stationary bicycling, walking in the hallway, or toe lifts. However, these alternative forms of exercise are not standardized and may impact the diagnostic sensitivity and specificity of the study.

Some patients with mild PVD may have an ABI that is normal at rest but significantly decreased with exercise (Fig. 27-25). In fact, comparing angiography, which is the "gold standard" for diagnosing PVD, to ABIs, there actually needs to be a rather severe single stenosis, or moderate diffuse multilevel disease, to have a depression in the resting ABI. Even a mildly depressed resting ABI implies there is a considerable burden of disease. Therefore, ABIs done at rest only and not with exercise will have a relatively high false-negative rate, and many patients with a normal resting ABI will be misdiagnosed as having nonvascular limb pain when the true etiology of their discomfort is PVD. A corollary to this is that many epidemiologic studies use only resting ABI as a diagnostic criterion for PVD, which leads to underestimation of the true incidence of PVD. In fact, obtaining ABIs at rest only without exercise is similar to performing a nuclear myocardial perfusion imaging study at rest only and trying to establish a diagnosis of coronary artery disease—this is impossible. The myocardial perfusion may be normal at rest, but it is the stress images that allow one to determine whether there is reversible ischemia.

Another potential pitfall of ABIs is vascular calcification. Severe calcification of the arterial wall eventually leads to an inability to compress the blood vessels despite cuffs inflated to suprasystolic pressures. Consequently, ABIs can be falsely elevated, and caution should be used in interpreting an ABI greater than 1.3. This is particularly common in patients with diabetes and patients on chronic hemodialysis. In this case the toe-brachial index has been established as an adequate surrogate to the ankle-brachial index (Sahli et al., 2004).

An NIVS can provide a general region (e.g., femoropopliteal segment) that is diseased. However, the NIVS is not precise enough to determine the exact location of the stenosis or occlusion. In other words, NIVS provides physiologic information with limited anatomic localization of disease. Arterial duplex Doppler ultrasound, computed tomography

B Pt walked for 5 min at 1.3 mph. He had no claudication at this time.

Figure 27-24 A, Normal pulse volume recording demonstrates triphasic waveforms with normal segmental pressures. No pressures were obtained in the left thigh because of previously placed stent. **B**, Normal ankle-brachial indexes at rest, with a normal response to exercise. The red lines and green lines are essentially flat throughout exercise.

angiography (CTA), or magnetic resonance angiography (MRA) are more suited to provide detailed anatomic information and complement the NIVS data.

Doppler Ultrasound

Arterial duplex Doppler sonography utilizes high-frequency sound waves (typically 5.0-7.5 MHz) to provide real-time vascular images that can accurately localize atherosclerotic disease. Color-flow encoding is useful to localize vessels quickly and determine the presence or absence of blood flow. Doppler technology uses the physical principles of the reflected sound wave frequency in relation to the transmitted frequency to determine the velocity of blood flow. As the severity of stenosis increases, the peak systolic velocity (PSV) of flow increases. By using established criteria of the absolute

PSV and the ratio of PSV in the normal reference segment compared to the PSV in the diseased segment, the overall range of stenosis can be determined.

Ultrasound is particularly useful for assessing stent or graft patency after a revascularization procedure. Potential pitfalls of ultrasound include visualizing the tibial vessels, which are relatively small and deep in the calf, and visualizing highly calcified vessels, which are acoustically shadowed by the calcium.

Computed Tomography and Magnetic Resonance Angiography

The noninvasive imaging modalities CTA and MRA have essentially replaced traditional invasive diagnostic angiography. Both CTA and MRA produce similarly accurate anatomic information and provide highly detailed images that can be used to plan revascularization procedures, assess the size and location of aneurysms, and occasionally find incidental pathology such as occult malignancy. These two technologies are fundamentally very different.

Traditional CT has evolved by the addition of multiple detectors, now up to 64 per machine. MDCT allows much shorter acquisition times and submillimeter resolution; thus an entire body scan can be performed in seconds to minutes with excellent spatial resolution. By adding three-dimensional reconstruction software, the bone, soft tissue, and organs can be virtually removed, and the vasculature reconstructed and viewed from multiple projections. [Figure 27-26](#) provides examples of normal and abnormal CT angiograms. CTA utilizes ionizing radiation and iodinated contrast. Therefore, multiple scans (cumulative radiation dose)

Table 27-15 Ankle-Brachial Index (ABI) and Severity of Disease

| ABI | Disease Classification |
|-----------|------------------------|
| >1.30 | Noncompressible |
| 0.90-1.30 | Normal |
| 0.80-0.89 | Mild |
| 0.60-0.79 | Moderate |
| 0.40-0.59 | Severe |
| <0.40 | Critical ischemia |

Figure 27-25 Normal noninvasive vascular study at rest. The right ankle-brachial index (ABI) is 0.93, and the left ABI is 1.09. However, there is a marked ischemic response to exercise. Note the pronounced drop of the red and blue lines with exercise and the severe drop of the right ABI to 0.14 and the left ABI to 0.49. This patient had bilateral, focal, 95% to 99% stenoses in the superficial femoral arteries, which were successfully stented. This example clearly demonstrates the importance of obtaining ABIs at rest and with exercise. Failure to obtain ABIs with exercise, particularly when the resting values are normal, often fails to diagnose the disease. BP, Blood pressure.

and renal insufficiency are relative contraindications to CTA. Other limitations include severe vascular calcifications and prosthetic joints, which cause scatter artifact. The lumen of a stented vessel can be visualized with CTA, although a mild to moderate degree of scatter artifact makes accurate assessment of in-stent restenosis difficult.

Traditional MRI has also evolved through the development of more powerful magnets and improved scanning algorithms. MRA can also produce submillimeter spatial resolution. In contrast to CTA, however, the scanning time for MRA can be up to an hour per patient. In a busy practice or hospital, this can lead to problems with patient throughput. Software can also reconstruct MRA images into three dimensions. MRA utilizes magnetic fields and variable-frequency

radio waves to detect changes in alignment and distribution of protons in a given tissue. The obvious advantage over CTA is that MRA does not use ionizing radiation or iodinated contrast. Thus, there is practically no risk of stochastic injury or contrast nephropathy. Patients with pacemakers or defibrillators cannot undergo MRA because the magnet can interfere with device function. Severely calcified vessels can be adequately imaged with MRA, but stents appear as voids and thus falsely give the impression of a totally occluded artery even if the stent is widely patent.

The false-positive rate for detecting a hemodynamically significant stenosis is considerably higher with MRA than CTA. With CTA the lumen of the vessel visualized is essentially a column of contrast; thus a precise assessment of the

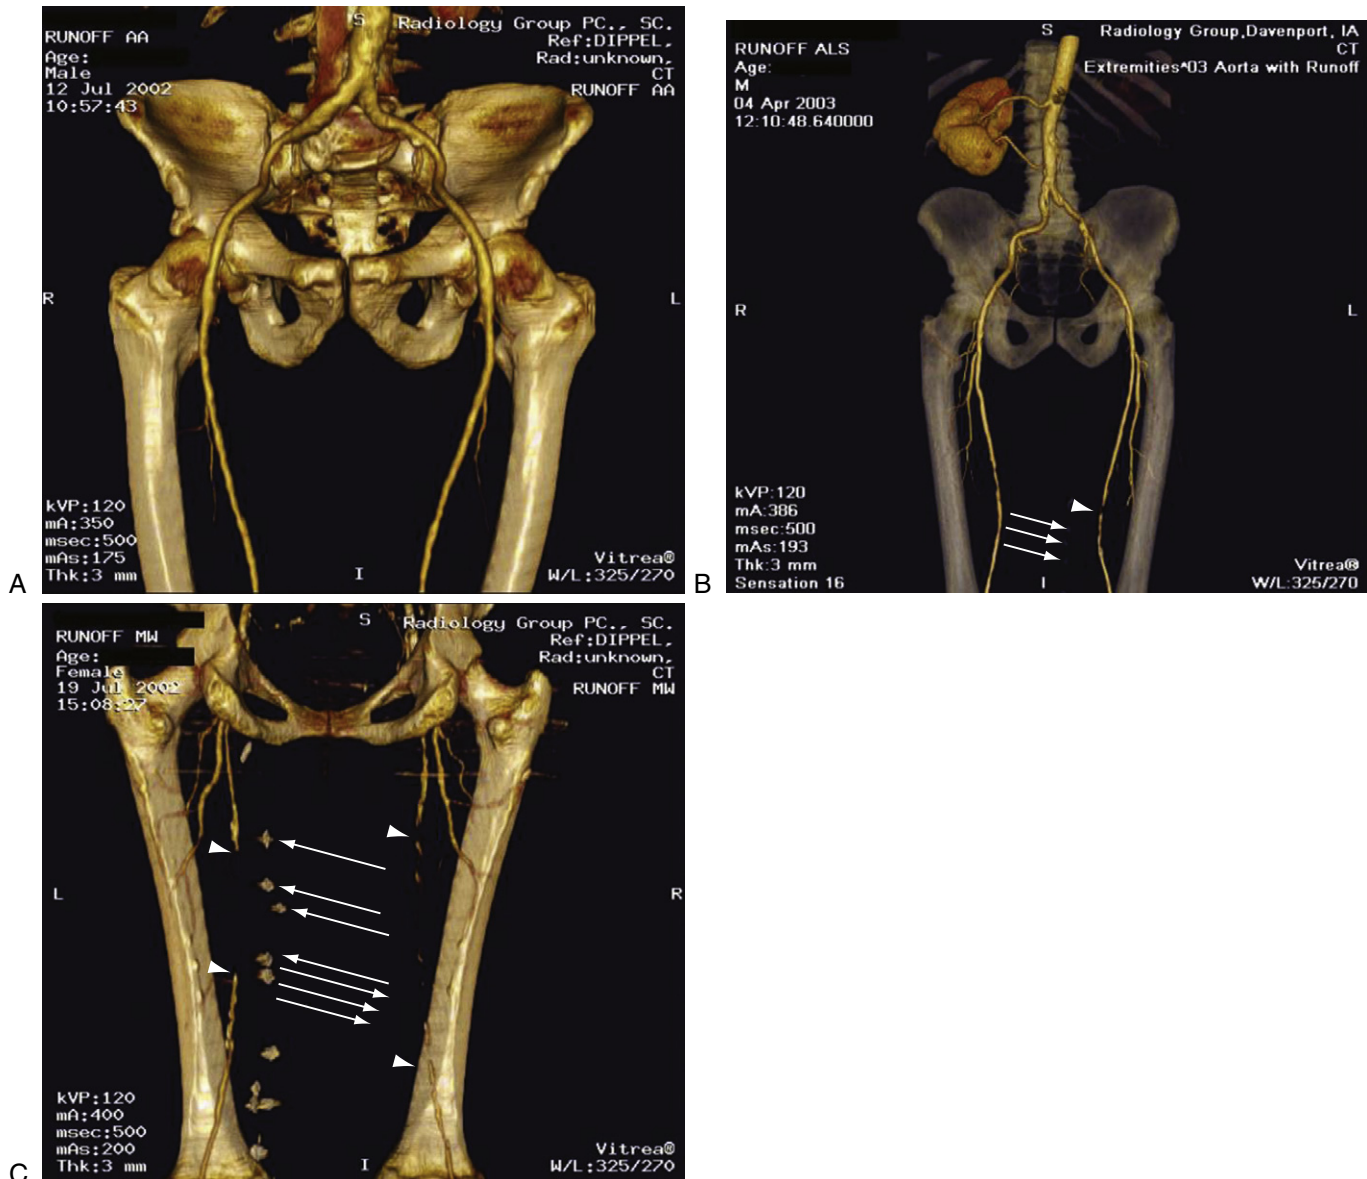

Figure 27-26 **A**, Anteroposterior (AP) view of a multidetector computed tomography angiogram (CTA) reconstructed with three-dimensional imaging software. This image shows the distal aorta, iliac arteries, common femoral arteries, and proximal superficial femoral arteries. There are minimal plaques in the distal aorta, common iliac arteries, and superficial femoral arteries. **B**, AP view of a multidetector CTA demonstrating a short total occlusion of the distal left superficial femoral artery (*arrowhead*). Note surgical clips from prior saphenous vein harvest (*thin arrows*). Note absence of the left kidney. **C**, Posterior view of a multidetector CTA demonstrating a long total occlusion of superficial femoral arteries (between *arrowheads*). These were successfully stented. Again, note vascular clips from prior saphenous vein harvest (*thin arrows*).

degree of stenosis is usually possible. However, MRA technology requires flow through the vessel to determine where the lumen exists. The pitfall occurs when the vessel runs through the same plane as the frequency of the radio wave. This leads to flow voids, which appear as gaps in the vessel and are frequently overdiagnosed as stenoses. This phenomenon is particularly common at the origin of the renal arteries and throughout the tortuosity of the carotid arteries.

Invasive Imaging

Traditional invasive diagnostic angiography has been the gold standard for diagnosing PVD since the 1950s. This technique involves the percutaneous placement of catheters within the vessel, injecting iodinated contrast through the catheters, and recording fluoroscopic and cineographic images. As with CTA, conventional angiography uses ionizing radiation, and the same relative risks apply. The potential complications include vascular access site injury, pseudoaneurysm or arteriovenous fistula formation, bleeding, dissection, and atheroembolization. For these reasons, and with the advances in noninvasive CTA/MRA imaging, routine diagnostic stand-alone invasive angiography is not routinely recommended. The only remaining indications for a conventional diagnostic angiogram are an inconclusive or indeterminate CTA/MRA and at a planned endovascular intervention.

Therapy

Therapy for PVD should involve a patient care plan consisting of (1) patient education on pathophysiology of atherosclerosis, risk factors that contribute to disease, and prognosis; (2) encouragement of lifestyle changes that emphasize risk factor modification and routine exercise; (3) pharmacologic therapy to relieve symptoms and treat risk factors; and (4) revascularization procedures to relieve IC and limb salvage in CLI. The goals of therapy are to improve the patient's functional status by relieving symptoms, improving the quality of life, and improving exercise capacity; preserve the limb via revascularization and decrease or limit the extent of amputation; prevent the progression of atherosclerosis by aggressive risk factor modification; and reduce cardiovascular and cerebrovascular mortality and nonfatal events such as MI and stroke.

Risk Factor Management

By far the most important therapy for both primary and secondary prevention of PVD is aggressive management of the risk factors for atherosclerosis. Both the American Heart Association (AHA) and the National Cholesterol Education Program (NCEP) recommend the same level of risk factor modification in patients with PVD as in patients with known CAD (Grundy et al., 2004; Smith et al., 2001). Despite the growing recognition that PVD is associated with a higher mortality rate, the risk factors in patients with PVD have historically been grossly undertreated. This is exemplified by data on a cohort of 1733 patients with known PVD and no overt CAD. Of these patients, only 33.1% were receiving beta-blockade therapy, 28.9% were receiving ACEIs, and 31.3% were treated with a statin. Furthermore, 92% had a recent BP measurement, but 56% had SBP greater than 130 mm Hg, 45.5% had DBP >80 mm Hg, and 13.6% had DBP

>90 mm Hg. In addition, only 62.6% had a screening lipid profile, yet 56% had an LDL-C >100 mg/dL, and 21% had an LDL-C >130 mg/dL. Finally, in patients with diabetes, HbA_{1c} was >7.0% in 54.2% of patients (Rehring et al., 2005). Unfortunately, such data are representative of current practice patterns. The risk factors of atherosclerosis must be aggressively identified and treated to reduce risk for disease progression.

Exercise

Routine aerobic exercise is recommended for all patients with PVD. The benefit of walking programs has been clearly established to increase time-to-claudication and maximal walking distance (Hiatt and Regensteiner, 1990; Hiatt et al., 1994). Regular exercise will have a strong impact on improving functional capacity and quality of life. A minimum of 30 to 60 minutes of exercise is recommended preferably daily, but at least three or four times a week. This should be supplemented by an increase in daily lifestyle activities, such as walking breaks at lunch, gardening, or household chores (Smith et al., 2001).

Weight Management

Obesity is at epidemic levels, which ultimately contributes to the progression of atherosclerosis. Patients should be counseled on weight loss strategies with a target body mass index (BMI) of 18.5 to 24.9 kg/m² (Smith et al., 2001).

Pharmacologic Therapy

Pharmacologic treatment can be divided into two separate but equally important components: therapy for the control of risk factors and therapy for the relief of symptoms of ischemia or claudication.

Pharmacologic therapy for risk factor modification is the same as for any other forms of atherosclerotic vascular disease, such as coronary or cerebrovascular disease. The most important consideration is that the mortality of patients with PVD is high, and thus they should be treated aggressively. Current national guidelines should be adhered to for the primary and secondary prevention of atherosclerotic vascular disease (ADA, 2005; Grundy et al., 2004; Seventh Report, 2004; Smith et al., 2001). The four primary categories of pharmacologic therapy include antiplatelet therapy, lipid-lowering therapy, antihypertensive therapy, and glycemic-lowering therapy, as discussed earlier. These therapies are complementary and confer additive benefit. From a practical standpoint, patients with several comorbidities may be taking multiple medications daily, so to ensure compliance, they should be repeatedly educated as to the importance of risk factor control.

The only FDA-approved pharmacologic therapy that has a consensus of benefit for the relief of claudication is cilostazol (Pletal). Cilostazol is a phosphodiesterase III inhibitor, which increases the intracellular concentration of cAMP, leading to significant antiplatelet and vasodilatory properties and possibly antiproliferative properties (Tsuchikane et al., 1999). Cilostazol undergoes extensive metabolism by the hepatic cytochrome P4503A4 (CYP3A4) isoform enzyme, and to a lesser extent the 2C19 and 1A2 isoforms. Although cilostazol does not inhibit the CYP450 system, drugs that inhibit CYP3A4, 2C19, and 1A2 can lead to increased levels of cilostazol in serum.

Pentoxifylline (Trental) is another drug FDA approved for claudication. However, no randomized data demonstrate

Figure 27-27 Mean percentage change from baseline maximum walking distance on a treadmill for patients with intermittent claudication randomly assigned to cilostazol, pentoxifylline, or placebo. * $p < 0.05$ at each 4-week time point for cilostazol versus placebo and pentoxifylline. (Reprinted with permission from *Excerpta Medica*. Dawson DL, Cutler BS, Hiatt WR, et al. A Comparison of cilostazol and pentoxifylline for treating intermittent claudication. *Am J Med* 2000;109:523-530, Figure 2.)

that it is better than placebo, so there is no recommendation to use this agent for the treatment of claudication. Eight RCTs compared cilostazol to placebo and pentoxifylline (Smith, 2002). In all studies, cilostazol demonstrated a statistically significant improvement in objective and subjective end points compared to placebo. In one study, comparing cilostazol (100 mg twice daily) with pentoxifylline (400 mg three times daily) or placebo, the maximal walking distance on a treadmill increased by 54% from baseline in the cilostazol group, versus 30% increase in the pentoxifylline group ($p < 0.001$), and 34% increase in the placebo group (Fig. 27-27) (Dawson et al., 2000).

Revascularization

Peripheral arterial revascularization is indicated for relief of ischemic symptoms, including intermittent claudication and resting ischemic pain, and limb preservation in the setting of critical limb ischemia. Historically, revascularization has been performed surgically; however, with advances in endovascular technology, a percutaneous approach is now considered first-line therapy. From 1995 to 2000, the number of percutaneous revascularizations performed in the United States increased by almost 1000%, compared to a 30% to 35% decrease in the number of surgical revascularizations (Fig. 27-28) (Anderson et al., 2004).

An endovascular approach confers a similar acute procedural success rate and similar long-term results, with considerably less periprocedural morbidity, shorter recovery time, shorter hospitalization time, and less pain than a surgical procedure. In addition, failure of the two therapies is completely different. With surgical therapy, graft closure is often sudden without sufficient time to develop collateral flow, leaving the limb in an acutely ischemic situation that frequently results in major amputation. Furthermore, surgical therapy can only be repeated a limited number of times, as dissection planes, surgical targets, and anastomosis sites become obliterated by repetitive surgery and conduit becomes exhausted. On the other hand, restenosis by neointimal hyperplasia of an endovascular procedure is a well documented, slow process that occurs over weeks to months, and thus gives the limb ample

Figure 27-28 Volume trends for percutaneous revascularization and surgical revascularization for the lower extremities from 1980 through 2000. Data obtained by reviewing ICD-9 codes for all vascular procedures using the National Hospital Discharge Survey of nonfederal U.S. hospitals. (Modified from Anderson PL, Gelijns A, Moskowitz A, et al. Understanding trends in inpatient surgical volume: vascular interventions, 1980-2000. *J Vasc Surg* 2004;39:1200-1208.)

time to develop collateral flow. Patients returning with failure of an endovascular procedure rarely do so in a limb-threatening situation. Moreover, an endovascular procedure can be repeated as often as necessary to maintain vessel patency.

The appeal of a minimally invasive approach for revascularization is that it significantly lowers the threshold of when to treat patients. Traditional surgical dogma has reserved revascularization until there is a limb-threatening situation. However, this leaves many patients left to face debilitating IC inadequately treated. Endovascular therapy offers a paradigm shift in this philosophy. Because it is safer, effective, and reproducible, patients can be treated earlier in the disease process during the claudication stage, with marked improvement in quality of life (Dippel et al., 2004). Figure 27-29 shows an artery before and after an endovascular revascularization.

From 150,000 to 200,000 nontraumatic amputations are done annually (ADA Fact Sheet, 2005). The alarming statistic is that 40% to 50% of limbs are amputated without a presurgical angiogram. It is estimated that more than 90% of these limbs could be salvaged, or converted to a lesser amputation, with revascularization. Another advantage of an endovascular approach over a surgical approach is that totally occluded arteries can be revascularized endovascularly with a high acute procedural success rate, even when no distal targets are available to bypass and surgery is not technically feasible. Therefore, it is recommended that patients with CLI or claudication not adequately alleviated with medical therapy be referred for endovascular revascularization. If an endovascular approach is not viable, surgical therapy should be considered as a second-line alternative.

Conclusions

Peripheral vascular disease is an underdiagnosed, under-treated, highly prevalent, age-dependent condition associated with a high mortality rate because of cardiac and cerebrovascular events. Furthermore, PVD has a very strong negative impact on quality of life, and patients have a functional status similar to NYHA Class III symptoms of CHF.

Clinicians must be more diligent in diagnosing and treating PVD. The diagnosis consists of a goal-directed history and physical examination, non-invasive vascular studies, and CTA or MRA. Therapy consists of routine exercise, smoking cessation, treating the appropriate risk factors to their target goals, and relief of ischemic symptoms either pharmacologically or through a revascularization procedure. Patients with CLI, with or without tissue loss, should be referred urgently for revascularization. [Figure 27-30](#) provides an algorithm for management.

KEY TREATMENT

Risk factors for atherosclerosis should be identified and treated to their target goals (SOR: A).
 Patients should take aspirin (81-325 mg/day) unless there is a contraindication to aspirin therapy, such as active GI bleeding or a history of allergy to aspirin (SOR: A).
 Clopidogrel (75 mg/day) can be used as an alternative to aspirin. Patients at high risk for vascular events may take both clopidogrel (75 mg/day) and aspirin (81 mg/day). Avoid aspirin (325 mg) when used in combination with clopidogrel because of a higher incidence of GI bleeding (SOR: A).
 Ticlopidine (250 mg twice daily) may be used as an alternative to clopidogrel for patients with intolerance or allergy to clopidogrel, but routine blood counts must be performed to assess for bone marrow suppression (SOR: A). The safety of long-term combination ticlopidine-aspirin therapy has not been assessed (SOR: C).
 LDL-C should be lowered to less than 100 mg/dL, or less than 70 mg/dL if the patient has concomitant CAD. A statin should be considered first-line pharmacologic therapy, in addition to diet and exercise. Ezetimibe and/or colesvelam may be added to statin therapy to achieve the target goal (SOR: A).
 Blood pressure should be lowered to less than 130/80 mm Hg. For patients with vascular disease, ACEIs or ARBs have a vasculoprotective effect and should be considered first-line agents (SOR: A).
 Diabetic patients should have HbA_{1c} lowered to less than 7%, preferably closer to 6.5%.
 Cilostazol (50-100 mg twice daily) is recommended for symptomatic relief of claudication (SOR: A).
 Pentoxifylline is not recommended for the treatment of PVD because of a lack of benefit versus placebo (SOR: A).
 Because of its minimally invasive nature, an endovascular procedure should be considered first-line therapy for revascularization. Surgery is now second-line therapy, when an endovascular approach is not technically feasible (SOR: A).
 Patients should be referred for a revascularization procedure when an exercise program and cilostazol therapy fail to alleviate ischemic symptoms.
 All patients with critical limb-threatening ischemia with or without tissue loss should be urgently referred for a revascularization procedure (SOR: A).

Cardiac Electrophysiology and Arrhythmias

Key Points

- Treatment of patients with symptoms referable to an arrhythmia is possible for many physicians.
- Accurate diagnosis of the arrhythmic event may prove difficult, and additional diagnostic tests not readily available to the family physician may be needed.

- More conscientious use of antiarrhythmic drugs is necessary as their proarrhythmic effects become known.
- Implantable devices continue to evolve and promise to alter the natural history of many malignant cardiac disease states.

The accurate understanding and interpretation of electrocardiograms (ECGs), rhythm strips, and unusual cardiac beats is a rewarding practice. Understanding is based not only on recognition of patterns but also on knowledge of electrical activation and repolarization of individual cells alone and in the aggregate. Anticipation of what *should* be happening will aid in determining what *is* happening during any particular beat. Appreciation of the history of electrophysiology and arrhythmology further aids in rhythm management.

Normal cardiac cellular actions may include automaticity, rhythmicity, conductivity, and contractility. Specialized cardiac cells may perform one of these functions better than a prototypical myocyte, thus facilitating organ function. Clinical arrhythmias result from disorders of impulse formation, abnormal impulse conduction, or a combination of these events (Akhtar et al., 1988; Zipes and Jalife, 1990).

The correct action of all cardiac cells depends on a normally functioning cell membrane or sarcolemma. As with central and peripheral neurons, cardiac cells have bilayer cell membranes composed of phospholipid molecules with specialized channels or pores that function as a semipermeable membrane to a variety of molecules. Sodium (Na⁺), potassium (K⁺), calcium (Ca⁺⁺), chloride (Cl⁻), and other ions move across the cell membrane in an organized fashion, resulting in depolarization of the cell from a resting electro-negative state. Specialized structures along both the long axis and the short axis of cardiac cells facilitate in the coupling of mechanical and electrical action (Hoyt et al., 1989).

Two specialized electrical cell types with different permeability characteristics for Na⁺ and Ca⁺⁺ give rise to specialized action. Slowly depolarizing and conducting calcium-dependent cells are more abundant in the sinus node and the atrioventricular junctional area. Rapidly depolarizing, fast-conducting sodium-dependent cells are more widespread and include atrial and ventricular myocytes and specialized His-Purkinje fibers, as well as abnormal cardiac structures such as bypass tracts, as discussed later. Medications, ischemia, injury, fibrosis, and external stimulation affect these cells differently, allowing for treatment and diagnosis of a variety of arrhythmias.

Cardiac Conduction System

The normal heartbeat results from a series of electrical and mechanical actions that result in forward output of blood. Alterations in cardiac performance occur from changes in heart rate and contractility in response to variation in autonomic tone and metabolic stress. To carry this out, the heart has developed a specialized conduction system.

Sinus Node Complex

Arising in the right atrium in the superior septal aspect at the junction of the lateral margin of the superior vena cava with the right atrium and the atrial appendage, the sinoatrial (SA) node extends laterally into the crista terminalis

Figure 27-29 **A**, Baseline angiogram of the right superficial femoral artery demonstrates a short, chronic total occlusion. **B**, Angiogram of the same artery 2 weeks after stent placement.

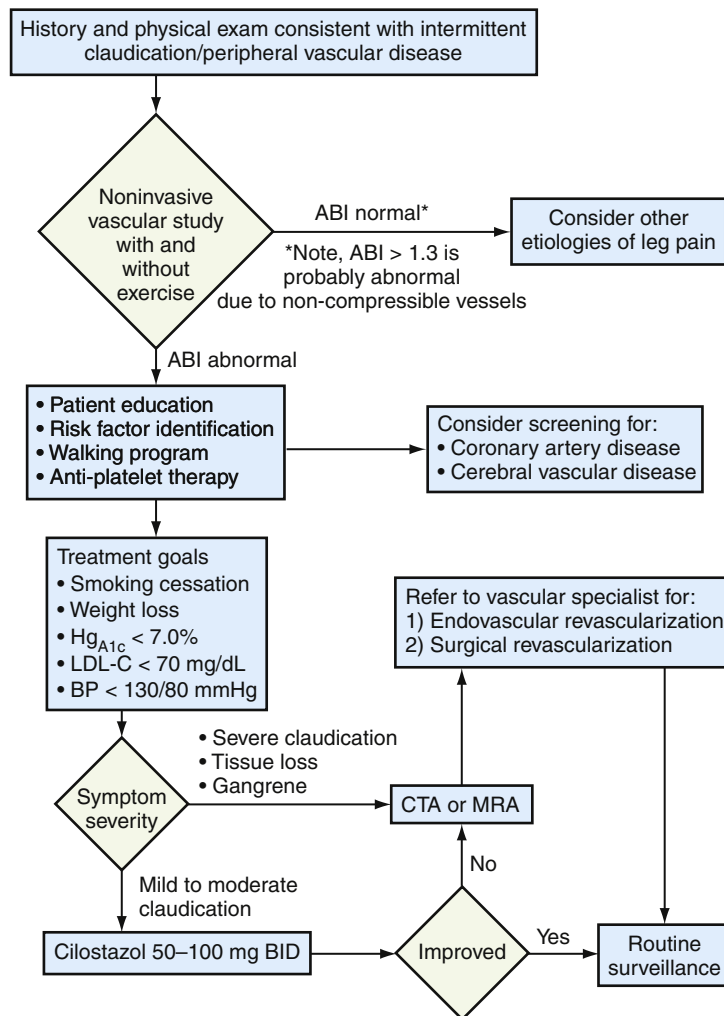

Figure 27-30 Management algorithm for patients with peripheral vascular disease. *ABI*, Ankle-brachial index; *BP*, blood pressure; *CTA*, computed tomographic angiography; *HbA_{1c}*, hemoglobin A_{1c}; *LDL*, low-density lipoprotein cholesterol; *MRA*, magnetic resonance angiography.

(Schlant et al., 1994). The sinus node includes three types of cells: nodal cells, transitional cells, and atrial muscle cells. Impulse formation and rhythmicity in primates are influenced by rich innervation with postganglionic adrenergic and cholinergic nerve terminals (Billman et al., 1989). Impulses leaving the sinus node complex travel through the right and left atria and converge on the atrioventricular node. Controversy still exists as to whether conduction spreads preferentially through specialized internodal and interatrial conduction pathways of the anterior, middle and posterior internodal pathways or simply through atrial myocytes (Racker, 1989). Regardless, right and left atrial depolarization occurs over 55 to 100 milliseconds (ms), resulting in the surface P wave. Cells residing in the SA node complex are predominantly Ca^{++} dependent, slow conducting, and have a higher resting membrane potential than atrial or ventricular myocytes and Purkinje tissue (Sperelakis, 1979).

Atrioventricular Node Complex

The atrioventricular (AV) node lies at the apex of the triangle of Koch. This is formed by the septal leaflet of the tricuspid valve and the tendon of Todaro (Anderson et al., 1988). The AV node is subendocardial and is not visible on gross inspection. The node extends through the AV groove into the ventricle as the His bundle, before branching into the right and left bundle branches of the His-Purkinje system. The AV node contains cells similar to the sinus node P cells. These cells and the associated transitional cells comprise a slow-conducting structure richly innervated with cholinergic and adrenergic fibers. Automaticity and conduction speed are influenced by this innervation. Slow, calcium-dependent cells predominate in the AV node. Conduction time through the AV node is approximated from the end of the P wave to the onset of the QRS complex.

Bundle Branch Network/His-Purkinje Tissue

The distal portion of the AV node becomes the His bundle. These cells have fast-conducting, sodium channel-dependent cells with more negative resting potentials. Branching off into the right and left bundle branches and finally the endocardial Purkinje network, these fibers transmit impulses 10 times faster than atrial or ventricular myocytes and 50 to 60 times faster than sinus or AV nodal cells (Sperelakis, 1979). Rapid activation of the His-Purkinje network results in global, nearly simultaneous activation of the right and

left ventricular myocytes. Purkinje activation results in a narrow QRS complex (<120 msec) noted on the surface ECG. Abnormalities of the right or left bundle branches result in slower activation of myocardium through cell-cell activation and thus the typical wide bundle branch block QRS on the surface ECG (>120 msec).

Atrial and Ventricular Myocytes

Myocardial cells are specialized cells designed to shorten when activated by a threshold electrical stimulus, thus providing mechanical force to produce contraction. The cell membrane is characterized by fast, sodium channel activation. Depolarization of the cell results in release of sarcoplasmic calcium and cardiac cell contraction. Conduction velocities are intermediate between SA and AV nodal cells and the Purkinje cells. Cell death, injury resulting in scarring or functional conduction slowing, or changes in cellular automaticity may result in clinical arrhythmias (Zipes, 1992).

The Action Potential

Diagrams of action potentials of cardiac tissue cause considerable consternation in student and physician alike. However, understanding a few simple concepts on the microscopic or cellular level facilitates arrhythmia evaluation and treatment.

Figure 27-31 is a schematic representation of the transmembrane action potentials of the fast, Na^+ inward current cell and the slow, Ca^{++} inward current cell. In the left panel, Phase 4 represents the resting transmembrane potential and is -90 mV, with the intracellular area being negative. This membrane potential difference is maintained by a sodium/potassium pump utilizing energy to maintain the difference. The membrane is permeable to potassium (K^+) and impermeable to Na^+ at rest. By expending energy, 3 Na^+ ions are pumped out of the cell in exchange for 2 K^+ ions into the cell. Positive K^+ ions flow across their chemical gradients out of the cell, thus leaving the intracellular space electronegative.

Phase 0 is characterized by the rapid influx of Na^+ ions into the cell, thus depolarizing the cell. Sodium influx is gated. When a sufficiently large depolarization occurs, ion channels are recruited and open, allowing for more influx of ions. Conductance declines as the channel is open and the equilibrium potential for the ion is reached. The channel closes, and Na^+ is again impermeable to influx. Phase 1 represents a

Figure 27-31 Currents and channels involved in generating the resting and action potential: *left*, time course of a stylized action potential of atrial and ventricular cells; *right*, time course of sinoatrial node cells. Above are the various channels and pumps that contribute the currents underlying the electrical events.

rapid repolarization of the cell through transient K^+ outward currents and beta-adrenergic, adenosine monophosphate (AMP), and histamine activated chloride (Cl^-) inward current restoring the membrane potential toward 0 mV.

Phase 2 or the plateau phase is a long phase that may last several hundred milliseconds. Conductance to all ions falls dramatically. Continued Na^+/K^+ pump activity reduces the membrane potential slightly. An *inward* rectifying K^+ current further depolarizes the cell along with continued Ca^{++} influx through the slow inward calcium channels. *Phase 3* represents the final rapid repolarization of the cell membrane. This occurs from inactivation of the slow inward calcium current and from activation of an *outward* K^+ current. The intracellular space becomes more negative, and potassium conductance increases in a regenerative manner.

Phase 4 resumes at the end of phase 3. In portions of the heart, however, a small depolarization current occurs and may result in threshold being reached and depolarization of the cell. This inward depolarizing current is noted in the SA node, distal AV node, and His-Purkinje fibers. This results in automaticity. The rate of depolarization is greater in the SA node than in other structures and thus results in the SA node as the dominant pacemaker. Adrenergic and cholinergic modulation further results in the SA node as the faster pacemaker, subordinating the automaticity of other pacemaker-like tissues. More frequent stimulation results in shortening of phases 2 and 3 of the action potential, resulting in unchanged or slightly increased conduction velocity.

In the right panel of [Figure 27-31](#), the action potential of the slow inward current type of cells is shown. In these cells, Ca^{++} and K^+ play a greater role in setting the resting membrane potential slightly less negative than in Purkinje or myocytes (phase 4). Phase 0 occurs through activation of slow Ca^{++} current. No phase 1 is noted, and the plateau phase is not as prolonged because of the relative importance

of the Ca^{++} and K^+ currents dominated by the slow activating and inactivating Ca^{++} current. More frequent stimulation leads to a decrease in the resting membrane potential, lower peak phase 0 velocity, slower phase 3 repolarization, and ultimately slower overall conduction velocity (Rosen and Schwartz, 1991).

Antiarrhythmic drugs have differential effects on the Na^+ , K^+ , and Ca^{++} channels or on receptors that mediated the channels. By slowing or enhancing cellular membrane pore activity, one observes changes in either conduction or repolarization characteristics. This may be reflected in changes in the surface ECG as well.

Surface Action Potential (Electrocardiogram)

The surface action potential can be thought of as a series of discrete electrical events occurring over time. [Figure 27-32](#) schematically demonstrates cardiac events with the surface ECG. The P wave begins with spontaneous depolarization of the SA node with propagation throughout the right and left atrium. This is upright in the inferior leads as depolarization occurs from the topmost portion of the atrium and converges on the atrial septum at the AV node. The depolarization of and conduction through the AV node results in no surface activity, causing an isoelectric portion beginning at the end of the P wave and continuing to the onset of the QRS complex. The PR interval is the total time from SA node activation through the AV node until the beginning of ventricular depolarization. The His-Purkinje network is activated, rapidly depolarizing the large mass of ventricular myocardium. This results in the large QRS complex. The Q-T interval represents myocardial repolarization and may be prolonged in the setting of bundle branch block, drug effect, and genetic disorders causing abnormal ion channel function.

Figure 27-32 Schematic diagram of the cardiac chambers and the associated surface electrocardiogram findings.

Mechanisms of Arrhythmias

Two main mechanisms for the initiation and perpetuation of arrhythmias have been proposed. Putative mechanisms include disorders of *impulse formation* and disorders of *impulse conduction*. These may occur alone or in combination and result in isolated electrical events and sustained arrhythmias. Alterations in automaticity or triggered activity are two main areas of disordered impulse formation. Clinical examples of *abnormal automaticity* include inappropriate sinus tachycardia, multifocal atrial tachycardia, sinus pauses, idioventricular rhythm post-MI, and ectopy in heart failure. *Triggered activity*, or spontaneous depolarization dependent on prior stimulation, is characterized as early or late after depolarizations. This mechanism may be responsible for arrhythmic events during hypoxia, use of sotalol or the metabolite of procainamide, or in patients with idiopathic and acquired long QT syndrome and digoxin toxicity.

Changes in impulse conduction can be clinically divided into *block* with or without *reentry*. Simple block occurs when the propagation of the impulse results in an inadequate depolarization stimulus to the adjacent tissue and the impulse terminates. Clinical examples include SA or AV block or simple bundle branch block. In SA block, normal depolarization of the SA node is inadequate to excite adjacent tissue, resulting in absence of a P wave. In AV block, block may occur within the AV node or as it attempts to depolarize His tissue, resulting in a P wave followed by a delayed or absent QRS complex. On the surface ECG, differentiation between block in the AV node or His bundle is only a guess. Bundle branch block or hemiblock is a result of block in a specific branch of the specialized conduction tissue. Activation of tissue beyond the bundle branches must then occur through slower myocyte-to-myocyte activation.

In *block with reentry*, unidirectional block within a tissue results in activation of adjacent tissue (Fig. 27-33). Tissue not initially activated then becomes excited by the conducting tissue. Tissue that has had time to recover excitability may then be activated again in a single or perpetual event. Clinical examples may occur within the SA node, AV node, within the atrium such as atrial flutter, and in Purkinje and myocardial tissue as ventricular tachycardia. Additional macroreentrant rhythms include atrial reentry and pre-excitation with orthodromic and antidromic reciprocating tachycardias.

Electrocardiographic Evaluation of Arrhythmias

The basic single-lead rhythm strip is still used in many offices as a quick verification of ongoing abnormal rhythms. New or used, inexpensive equipment can be found through many equipment vendors. This allows for rapid evaluation of symptoms reported during an office visit. Slightly more expensive, 12-lead ECG machines provide not only useful information on the ongoing rhythm but may demonstrate ischemic changes or prior or ongoing injury pattern. Multiple lead analyses help discern difficult-to-see P waves during arrhythmia evaluation as well.

The single-lead and 12-lead ECGs are helpful only for ongoing arrhythmia analysis. Obviously, short-lived events

or events that occur unpredictably are rarely identified by these simple techniques. Ambulatory 24-hour recording of a single or multiple leads is performed through Holter monitoring. Small patches or electrodes are placed on the skin and are attached to a digital or analog recording device, usually worn on the belt. Off-line data analysis is performed and relayed to the interpreting provider. Monitoring over 24 to 48 hours allows for increased sensitivity in ambulatory screening. Longer periods of monitoring can be performed using small, 30-day recorders. By recording and repeatedly overwriting the last several minutes of a rhythm, individuals with very infrequent events can lock in a symptomatic event and then transmit the information over the phone. This method may also be helpful in monitoring response to pharmacologic therapy such as rate control in atrial fibrillation. However, prolonged electrode contact can result in skin irritation and poor patient acceptance.

Newer, implantable loop monitors became available in the early 1990s. Devices smaller than a disposable lighter are implanted under the skin overlying the chest wall. Lasting 18 to 30 months, these loop recorders have automatic and activated memory. Evaluation of the recorded events is performed in the clinician's office, remote from the clinical event. Implantation is usually performed by a cardiologist or an electrophysiologist when other recording efforts have failed.

Exercise testing may also be useful for clinical events that occur during activity or stress. Elevations in adrenergic state facilitate conduction and repolarization. Sinus node, AV node, or His-Purkinje disease resulting in block may be revealed. Initiation of various supraventricular or even ven-

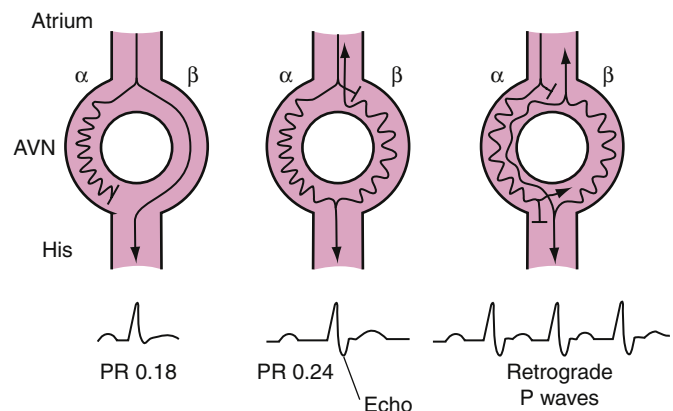

Figure 27-33 Mechanism of typical atrioventricular (AV) nodal reentry. The AV node (AVN) is drawn schematically with fast and slow pathways. Differential conduction and refractoriness is noted between the two pathways; the β pathway (fast pathway) has fast conduction and long refractoriness; the α pathway has slower conduction and shorter refractoriness. *Left*, The depolarization wave front from the atrium penetrates both pathways. The β pathway conducts the wave front faster than the slow pathway, and the P-R interval is normal. *Center*, Block occurs in the fast pathway. The slow pathway conducts the wave and depolarizes the ventricle. The β pathway (fast pathway) has time to recover, and conduction proceeds retrograde up the fast pathway and depolarizes the atrial tissue once again, resulting in an AV node echo beat. *Right*, Continuation of the reentry can occur. As the fast pathway is activated in the retrograde fashion during an echo beat, the slow pathway, with a shorter refractory period, is able to recover. The excitable tissue can then be activated, and conduction again proceeds back down the slow pathway (α pathway), and the cycle continues.

tricular tachycardias may also occur. Ischemia as a trigger for arrhythmias may be detected. Exercise testing should be considered in patients with reproducible, activity-associated arrhythmias and in those suspected of long QT syndrome or who manifest preexcitation.

Inpatient evaluation of arrhythmias is seldom needed. However, patients with clinical syncope or transient loss of postural control thought to be arrhythmic, patients in whom ischemia-induced arrhythmias is a concern, and those with a clinical history concerning for a life-threatening ventricular arrhythmia should be considered for inpatient evaluation. In this setting, an organized testing regimen may be employed during continuous ECG monitoring.

A comprehensive discussion of rhythm and 12-lead ECG findings is beyond the scope of this chapter. However, using a standard, stepwise approach to all rhythm strips can be easily learned. Keeping in mind the changes in impulse formation and impulse propagation, the correct ECG diagnosis can usually be made. Clinical information such as drug therapy or prior myocardial injury can be equally useful. Each rhythm analysis should address the following questions:

- What is the origin of the impulse? In essence, determine the P-QRS relationship. Determine if the P wave is the initial event or the secondary event and if it is associated with neighboring depolarizations. If P waves exist, examine the morphology and determine if it is appropriate for the lead reviewed. If the rhythm is irregular, do the irregular beats look the same? These steps will help decide if the rhythm comes from the atrium, AV junction, or the ventricle. Further differentiation into irregular atrial events such as atrial fibrillation (AF) or multifocal atrial tachycardia can be made. Wide QRS beats may arise from premature ventricular contractions (PVCs), bundle branch block, or preexcitation.
- What is the basic heart rate? Is the rate appropriate for the origin of the impulse? This will distinguish tachycardias from bradycardias or normal rates for the rhythm (e.g., sinus arrhythmia).
- Is the rhythm regular? Is this appropriate? A fixed, regular ventricular response in the setting of AF suggests third-degree AV block and may be caused by digitalis toxicity if the rate is greater than expected for a junctional escape.
- *Are intervals appropriate and constant?* Changes occur in setting of altered origin of impulse, basic heart rate, and with varying degrees of block (e.g., type I second-degree SA or AV block).
- Are QT, ST segments, or T waves helpful? Are Q waves present? This may give clues to ongoing metabolic, ischemic or drug effects that cause common arrhythmias.

With these few questions in mind, most rhythm strips can be interpreted correctly.

Basic interpretation begins with a rhythm strip of good quality, typically representing lead I, II, or V1. Multiple leads aid in the diagnosis but are not always necessary. Evaluation of heart rate, intervals, and axis is necessary. Regularity of the rhythm, consistency of the P waves, QRS complexes, and T waves and abnormalities of the ST segment should be characterized.

Pattern Recognition of Arrhythmias

Atrial Rhythms

Key Points

- Treatment of asymptomatic or minimally symptomatic, non-life-threatening atrial rhythms should be less risky than no treatment at all.
- The proarrhythmic side effects of drug therapy, including ventricular fibrillation, should be carefully weighed before initiation of drug therapy.

Sinus rhythm is a regular, organized atrial rhythm between 60 and 100 beats/min at rest in healthy individuals. Slower rates as low as 40 to 50 beats/min may be normal in some individuals. Originating high in the right atrium, sinus P waves should be positive in limb leads I and II. *Sinus bradycardia* originates in the sinus node with a P wave indistinguishable from the normal sinus beat, but at a rate slower than the established lower limit of 60 beats/min. This is physiologically normal in patients during sleep, in athletic individuals, and as a consequence of many adrenergic blocking drugs (e.g., β -blockers). Excessive bradycardia may come as a consequence of changes in vagal tone in sleep apnea, during painful stimuli, or mesenteric stretch. There are typically no significant changes in the P-QRS-T intervals with resting sinus bradycardias. During vagal-mediated sinus slowing, associated prolongation in the P-R interval may give a clue as to the etiology. Typically, no treatment is necessary in this benign condition. If the heart rate slowing is excessive or symptomatic, acute atropine administration, epinephrine and dopamine may be used acutely. Over the long term, pacemaker implantation may be necessary.

Sinus arrhythmia is the normal variation of heart rate, likely caused by changes in volume and vagal tone as a consequence of respiration. Occasional slowing below 60 beats/min at rest is considered acceptable. Patients with high adrenergic tone such as heart failure often lose normal variations in heart rate and a reduction in the degree of sinus arrhythmia. A *wandering atrial pacemaker* occurs if, at normal heart rates, there is significant variation in the P wave morphology and regularity. Associated P-R and R-R intervals are variable because of the different atrial origin and variations in the prematurity of the atrial beat. It is more frequent in young persons and as a result of changes in vagal tone. The origin of the impulse may arise from within the sinus node complex but at distant sites within the right atrium, giving rise to the changes in P-wave morphology.

A *sinus pause* and the more extreme case of *sinus arrest* are demonstrated as a sudden change in the heart rate, often preceded by mild slowing in the general sinus rate. A sinus pause is typically caused by changes in vagal tone such as gagging, carotid sinus stimulation, pain, and as a consequence of neurocardiogenic activation (Fig. 27-34). Very long episodes of no surface atrial activity are considered to have *sinus arrest*. This may result from atrial tissue disease, drug therapy, metabolic derangements, and significant vagal activation. Figure 27-35 demonstrates a long pause noted during neurocardiogenic reflex activation during a tilt-table test in the evaluation of syncope. The pause was approximately 50 seconds and resulted in loss of consciousness. Typically, withdrawal of the offending agent, improvement in cardiac

Figure 27-34 Sinus rhythm is followed by sinus arrest and motion artifact during a seizure. Sinus rhythm then resumes.

Figure 27-35 Sinus rhythm slows slightly before sinus arrest occurs for 50 seconds. Return of sinus rhythm is not shown.

Figure 27-36 Sinus rhythm with type I Wenckebach sinoatrial block. Note shortening of the P-P interval before the dropped P wave and the pause of less than twice the shortest P-P interval. The return cycle length is longer than the cycle length before the pause.

function, and elimination of stimuli causing reflex vagal activation help ameliorate symptoms. In difficult symptomatic cases and in patients without a reversible cause, pacemakers may be necessary. Demonstration of sinus pauses and sinus arrest as a cause of dizziness or syncope may be difficult and requires prolonged ambulatory monitoring.

A pause may also result from sinus node disease. In patients with atrial disease, myofibrosis, and atrial pressure overload, changes in the automaticity and rhythmic depolarization of the SA node may be affected. Regular impulses may fail to exit the sinus node complex and depolarize the atrium, resulting in no P wave on the surface ECG and no atrial mechanical contraction. This may occur in regular patterns, such as in *type I SA block*, characterized by sequential shortening of the P-P interval and then absence of a P wave. The return cycle length is less than twice the shortest cycle length, and the next cycle is longer than the cycle length just before the dropped P wave (Fig. 27-36). *Type II SA block* is characterized by constant P-P intervals followed by a missing P wave. The pause is twice the cycle length of the P-P interval, and the return cycle length is the same as the sinus rate (Fig. 27-37).

Premature atrial contractions (PACs) or depolarizations may occur frequently in normal patients. The ECG finding is that of an abrupt early P wave that may or may not be followed by a QRS complex. PACs may occur as isolated events, couplets, or as sequential events. Most individuals are minimally symptomatic if at all. Benign causes include exogenous stimulants such as tobacco, caffeine, alcohol excess, and sympathomimetic drugs. Digitalis toxicity should be considered in patients receiving digitalis treatment. Patients with underlying heart or lung disease or ectopy from extrinsic compression on the atrium and adjacent abnormal structures may become symptomatic. Reducing automaticity or triggered activity through antiarrhythmic therapy and treating hypoxia and ischemic heart disease may reduce patient symptoms. In asymptomatic patients, no specific therapy is necessary. Beta blockers and calcium channel blockers may reduce ectopy rates and slow or block the ventricular response to the PACs, thus reducing symptoms. Potent antiarrhythmic medications (class Ia, Ic, or III) may occasionally be necessary.

An *ectopic atrial rhythm* is said to occur when the P wave does not have the normal upright morphology in limb leads

Figure 27-37 Sinus rhythm with type II second-degree sinoatrial block. Note the almost constant P-P interval before loss of P-wave activity. The pause is twice the cycle length of sinus rhythm. The return cycle length is the same as before the pause.

Figure 27-38 An ectopic atrial rhythm at 85 beats/min with negative P waves in lead II is replaced by slower sinus rhythm with upright P waves and then returns at the end of the rhythm strip. A dual-chamber pacemaker senses and tracks both types of P waves and paces the ventricle accordingly.

Figure 27-39 Ectopic atrial tachycardia is initiated by a premature atrial complex. Note the P-wave morphology change of the faster ectopic atrial rhythm.

I, II, and III. Heart rate during the rhythm can be slower than, equal to, or greater than normal sinus rhythm. Ectopic rates greater than 100 beats/min are termed *ectopic atrial tachycardia* (Figs. 27-38 and 27-39). The morphology of the ectopic P wave should be consistent and the P-P intervals approximately equal. This helps to distinguish this from sequential PACs. Asymptomatic ectopic atrial rhythms are usually benign and do not require therapy. Patients with incessant, rapid tachycardias may eventually develop rate-related cardiomyopathy. Treatment for or prophylaxis against this type of cardiomyopathy is warranted.

Several additional atrial tachyarrhythmias deserve attention. *Sinus tachycardia*, or sinus rhythm at a rate greater than expected for the physiologic state, may be seen. Atrial wave morphology is normal. However, sustained increased rates may be related to failure of autonomic regulation, metabolic stress, drug use (prescribed or illicit), or idiopathic causes. Inappropriate sinus tachycardia syndrome is usually a self-limited problem of young people and may be caused by a variety of factors. *Positional orthostatic tachycardia syndrome* (POTS) is a condition of marked increases in heart rate with upright posture, not always associated with a fall in blood pressure. Volume status is usually normal and differentiates this from simple orthostatic hypotension with reflexive tachycardia. Treatment of these disorders using beta blockers and serotonin antagonists has been helpful in some individuals. Expansion of plasma volume may also be helpful (<http://home.att.net/~potsweb/POTS.html>).

Multifocal atrial tachycardia is characterized as irregular atrial activity at rates greater than 100 beats/min. Three or more P waves are present as the driving force of the tachycardia. Patients in metabolic stress and with hypoxia are prone to this arrhythmia. Treatment is usually supportive, but verapamil helps some patients. Treatment with digoxin is rarely helpful, and upward titration may result in toxicity

indistinguishable from the original rhythm disorder (Hazard and Burnett, 1987).

The ECG findings of *atrial fibrillation* (AF) are the absence of organized atrial activity with an irregular, usually rapid ventricular response (Fig. 27-40). Atria are depolarized from widespread regions of both the left and right atrium and result in chaotic activation at rates exceeding several hundred beats per minute. AF may be asymptomatic or highly symptomatic, ranging from simple palpitations to MI and heart failure. Recognition of the arrhythmia is the first step in good care. Treatment using an appropriate anticoagulation strategy, ventricular rate control, and consideration of sinus rhythm restoration is necessary even in asymptomatic patients (see later discussion).

Atrial flutter (AFL) is also a rapid rhythm of the atrium, usually at a rate near 300 beats/min. The ventricular response may be fixed or variable. Sawtooth flutter waves are usually noted in the inferior limb leads (Fig. 27-41). Misidentification of atrial flutter with 2:1 conduction as sinus tachycardia is common and should be considered in all regular tachycardic rhythms. Similar to AF, treatment strategies should include anticoagulation with warfarin (Coumadin). In contrast to AF, atrial activation in flutter is organized and frequently caused by macroreentry. The wave front ascends the right atrial septum, crosses the roof of the right atrium, and extends down the lateral wall along the crista. The wave front then extends between the inferior vena cava and the tricuspid annulus along the isthmus and proceeds to the atrial septum. Targeting the isthmus is often done with linear radiofrequency (RF) lesions to effect cure (Fig. 27-42).

Junctional Rhythms

Similar to PACs, earlier-than-expected depolarization arising from the AV node complex results in a QRS without a preceding P wave, termed a *premature junctional complex* (PJC).

Figure 27-40 The rapid, irregular nature of atrial fibrillation and its chaotic activation of atrial tissue results in no discrete P waves. Conduction through the atrioventricular node is variable, resulting in the irregular ventricular response.

Figure 27-41 Atrial flutter is more organized, resulting in a sawtooth appearance in the limb leads and precordial leads. Atrial rates of almost 300 beats/min are noted, with variations in the ventricular response.

Figure 27-42 Atrial flutter waves noted in leads II, III, and aVF terminate abruptly, and sinus rhythm is restored. An intracardiac ventricular recording and output from a radiofrequency (RF) generator are shown in the lower portion of the diagram. RF application was made at the tricuspid–inferior vena cava isthmus. (From Feld GK, Fleck P, Chen PS, et al. Radiofrequency catheter ablation for the treatment of human type I atrial flutter: identification of a critical zone in the reentrant circuit by endocardial mapping techniques. *Circulation* 1992;86:1233-1240.)

Figure 27-43 Junctional rhythm at a rate greater than the sinus node dominates the rhythm. Conduction through the atrioventricular node occurs with the fifth QRS complex and resets the junctional rhythm. Excessive bradycardia and the associated junctional rhythm may be associated with digoxin toxicity.

Retrograde, inverted P waves may be seen within the early portion of the QRS or following the QRS complex. These are usually benign but may be an early sign of occult cardiac disease. Drugs, adrenergic stimulants, and metabolic stress may be associated with PJCs. In the absence of heart disease or underlying medical condition, these usually asymptomatic beats do not require treatment.

When the AV junction has rhythmic spontaneous depolarization, a *junctional* or *nodal rhythm* occurs (Fig. 27-43). The normal pacemaker function of the AV node cells occurs at a rate of 35 to 50 beats/min. In sinus node failure, the

junctional pacemaker rate may be higher than the sinus rate, resulting in junctional bradycardia. Abnormal reentry within the AV node results in *junctional tachycardia*, usually at a rate between 120 and 190 beats/min, and is considered a form of supraventricular tachycardia. Differentiation of accelerated junctional tachycardia from more typical supraventricular tachycardias is not possible by surface ECG. Because of simultaneous activation of the ventricle and retrograde activation of the atrium, junctional rhythms may be more symptomatic than their rate would predict.

Disorders of Atrioventricular Node Conduction

Key Points

- Atropine may worsen AV block if block occurs at the level of the Purkinje system. Increased sinus rates conducting through the AV node will be blocked from the refractory His-Purkinje tissue.
- In contrast, epinephrine may enhance both AV conduction and shorten Purkinje refractoriness, resulting in decreased block. Atropine delivery thus may help distinguish the level of AV block and determine the urgency of permanent pacing.
- The atrial rate must be faster than the escape rate to confirm complete heart block.
- Digoxin toxicity and ischemia may cause accelerated junctional rhythm and should be considered when this rhythm is seen.

First-degree AV block is demonstrated as a P-R interval of greater than 200 milliseconds (Fig. 27-44). Persistent AV delay is usually noted, but variations may be seen depending on heart rate. Adrenergic tone shortens the AV delay, whereas drugs such as beta blockers and calcium channel blockers may worsen AV conduction, leading to more progressive types of AV block. First-degree AV block is almost always at the level of the AV node. Except for very long AV intervals resulting in atrial contraction while the prior ventricular beat is maintaining AV valve closure, first-degree AV block typically does not require treatment. Advanced age is often associated with this conduction disorder.

Second-degree AV block is separated into type I (Wenckebach), type II, 2:1, and high-grade AV block. *Type I* second-degree AV block is characterized by a progressive prolongation of the P-R interval followed by failure to conduct and depolarize the ventricle. The P-R interval on the return beat will be shorter than the P-R just before the block

Figure 27-44 Sinus rhythm with first-degree atrioventricular block and bundle branch block.

Figure 27-45 Sinus rhythm with type I (Wenckebach) second-degree atrioventricular block. There is prolongation of the P-R interval, then a dropped QRS.

Figure 27-46 Sinus rhythm with third-degree (complete) atrioventricular block. There is complete dissociation of atrial and ventricular activity. The escape rate is less than 30 beats/min, and QRS complex is wide, suggesting a ventricular escape.

(Fig. 27-45). Similar to first-degree AV block, this typically does not require treatment with a pacemaker and does not predict life-threatening complete heart block. In patients with concomitant BBB, the clinician should question if block is actually occurring at the level of the His-Purkinje system. Withdrawal of drugs indicated in AV block is indicated. Dual-chamber pacing in symptomatic patients may be necessary.

Type II second-degree AV block is the abrupt failure of conduction through the AV node and absence of a QRS complex. The P-R intervals should be similar before and after block. Atrioventricular block may occur both at the level of the AV node and His-bundle complex and is indistinguishable without invasive electrophysiology study. Pacing is usually indicated to avoid unpredictable progression to complete heart block. Withdrawal of AV conduction blocking drugs is indicated. *Two-to-one* (2:1) AV block can result in very low heart rates and considerable symptoms, including syncope and low-output heart failure. Loss of ventricular activation every other beat typifies this rhythm. Block at the level of the AV node is suggested by preexistent PR prolongation, but block at the level of the His-Purkinje system cannot be excluded by surface ECG.

High-grade AV block or *intermittent complete AV block* is similar to type II second-degree AV block. However, more than one consecutive QRS complex is absent with the block. This degree of AV block strongly suggests significant AV nodal disease or distal Purkinje disease, and the physician should strongly consider permanent pacemaker implantation. The one exception may be high-grade AV block occurring at night in the setting of sleep apnea.

Third-degree AV block results from failure of atrial impulses from the sinus node to conduct down to the ventricle (Fig. 27-46). The finding on a rhythm strip or ECG indicates serious cardiac disease and may be related to significant valvular or coronary disease. An escape rhythm that is narrow suggests that the level of block is above the His-bundle complex and may be more stable. Adrenergic stimulation or atropine may result in an accelerated junctional escape. A slow, wide QRS escape suggests the level is below the His-bundle system, and atropine is unlikely to help. Adrenergic stimulation may help increase the escape rate. Urgent temporary or permanent pacing is indicated. Transcutaneous pacing may be used temporarily but is unreliable and poorly tolerated by the patient.

Ventricular Rhythms

Key Points

- Determination of the site of pacing is important.
- A bundle branch block pattern on surface ECG contralateral to the site of pacing should occur.
- Inappropriate left ventricular endocardial lead placement delivered across a patent foramen ovale can be detected before serious consequences of embolic stroke.
- Appropriate left ventricle epicardial pacing can be confirmed through paced right BBB morphology. Right ventricular endocardial pacing results in a left BBB pattern on surface ECG.

The presence of a wide QRS is usually caused by (1) normal AV conduction with bundle branch block (BBB) aberrancy, (2) presence of preexcitation, or (3) origin of the beat within the ventricle as a *premature ventricular contraction* (PVC) or consecutive ventricular activation, as seen in *ventricular tachycardia* (VT). A PVC is noted as an early beat, arising before normal atrial activation through the AV node can activate the His-bundle system and depolarize the ventricle. PVCs occur as single beats and couplets but may consecutively appear much like VT. Unifocal PVCs are typically seen as more benign than multifocal PVCs. The origin of the abnormal beats is usually enhanced automaticity or triggered activity. Cardiac literature has demonstrated higher mortality rates in patients with ischemic heart disease with decreased ejection fraction and increased rates of ventricular ectopy. Suppression of these ectopic beats with Class I or Class III antiarrhythmic medicines, however, has not significantly improved mortality (Cardiac Arrhythmia Suppression Trial, 1992; Echt et al., 1991).

Ventricular ectopy in patients with a normal heart is not correlated with significant increases in mortality. Patients are usually asymptomatic, although even low-frequency ectopy may bother some individuals. Beta-blocker therapy for these patients often results in symptomatic improvement. In highly symptomatic patients, membrane-active drugs (Class I or III) may occasionally be required. Electrophysiologist referral should be made if antiarrhythmics are used. Some

symptomatic patients may also be treated with RF ablation of the arrhythmic focus.

Ventricular tachycardia is clinically divided into two main categories: In *monomorphic* VT, QRS complexes are nearly identical, and the R-R interval is typically regular. Slight variations at the beginning and end of a run of VT tend to show greater fluctuations in rate. This tends to occur more frequently in scar-related reentry in patients with prior MI and in patients with “normal heart” VT, such as right ventricular outflow tract tachycardia and idiopathic left ventricular tachycardia (Fig. 27-47). In *polymorphic* VT (PMVT), QRS morphology is constantly changing, and the R-R intervals are often inconsistent. Torsades de pointes is a specific clinical PMVT and is characterized by a long QT interval in the first beat of the tachycardia and a twisting about the axis on a rhythm strip (Fig. 27-48). In almost all cases, referral to a cardiologist or electrophysiologist is indicated. Frequently, inpatient evaluation is necessary.

Ventricular fibrillation (VF) is a disorganized electrical rhythm of the ventricle and leads to no meaningful ventricular contraction. Without cardiac resuscitation and electrical cardioversion, the individual will die. Figure 27-49 demonstrates a patient hospitalized with a myocardial infarction. Immediate hospitalization is recommended in patients who have had prior episodes of near syncope or syncope in which VT is suspected due to known underlying ischemic or nonischemic heart disease. Patients suspected of long QT syndrome or VT associated with clinically significant *hypertrophic obstructive cardiomyopathy* (HOCM) should be considered for inpatient or invasive evaluation. Patients who are resuscitated from an out-of-hospital VF arrest must be referred to a cardiac specialist for further evaluation and treatment because of the high rate of recurrence (Huikuri et al., 2001). Inpatient evaluation may include invasive coronary angiography or electrophysiology testing.

Paced Rhythms

Temporary or permanent pacemaker implantation is now performed at almost all hospitals in which a cardiologist practices. Activation of myocardium results in a nearly

Figure 27-47 Nonsustained monomorphic tachycardia is seen in the setting of underlying atrial fibrillation with increased ventricular response. This terminates spontaneously.

Figure 27-48 Torsades de pointes polymorphic ventricular tachycardia is initiated by sequential premature ventricular contractions (PVCs) that prolong the Q-T interval in a rate-dependent manner. An early PVC landing in the long Q-T interval results in the characteristic twisting about the axis. Spontaneous termination is seen.

normal P wave but with a notable BBB pattern of ventricular capture on the surface ECG. The ECG recorder may amplify the energy from the pacemaker pulse, resulting in a pacing artifact on the surface 12-lead or rhythm strip to aid in interpretation. Knowledge of the type of pacemaker and the current programming may be necessary for complete analysis. The pacing morphology can be reviewed to confirm consistent and appropriate lead placement. Sensed cardiac events may result in pacemaker inhibition and masking of its presence. Evaluation of unexpected events on the ECG may identify abnormal pacemaker operation (Fig. 27-50). Detailed pacemaker ECG interpretation is beyond the scope of this chapter.

Special Clinical ECG Syndromes

Sick sinus syndrome (SSS) is a group of electrocardiographic and clinical findings. Patients often have symptoms of fatigue, palpitations, and heart racing and may suffer from dizzy spells or even syncope. The findings of paroxysmal atrial tachycardia, atrial fibrillation (AF), or atrial flutter result in tachypalpitations and heart racing. Excessive SA

node suppression often occurs with drugs used to slow AV conduction or reduce atrial arrhythmias. Figure 27-51 demonstrates typical ECG findings seen in SSS. Pharmacologic treatment to reduce symptoms is often problematic, and permanent pacing is often required. Anticoagulation with warfarin in patients with documented AF should be considered. Patients without documented AF should be considered for aspirin anticoagulation because of the high frequency of asymptomatic AF in this patient population (Myerbaug, 1994).

There are at least two types of *supraventricular tachycardia* (SVT) that should be routinely considered for referral. Patients with *preexcitation syndrome* (Wolfe-Parkinson-White, WPW) or *atrioventricular reciprocating tachycardia* (AVRT) and paroxysmal, symptomatic *atrioventricular node reentrant tachycardia* (AVNRT) may benefit from drug therapy or RF ablation therapy. The ECG signature of WPW is the delta wave. Atrial activation of the ventricle is through the AV node–Purkinje system and is activated through a bundle or bypass tract of muscle inserting along one of the AV valves. The combined activation pattern results in the delta wave. Figures 27-52 and 27-53 demonstrate presence and absence of the delta

Figure 27-49 Sinus rhythm is noted to degrade initially to a polymorphic ventricular tachycardia and then organizes for about minutes (not shown in entirety). A premature ventricular contraction during ventricular tachycardia results in ventricular fibrillation, to which the patient ultimately succumbed.

Figure 27-50 Dual-chamber pacing with loss of ventricular output.

Figure 27-51 Sick sinus syndrome is characterized by rapidly conducted atrial fibrillation, pauses during restoration of sinus rhythm, and excessive bradycardia in normal rhythm.

wave before and after RF therapy for SVT associated with the bypass tract. SVT results from a macroreentrant circuit where conduction proceeds down the AV node into the ventricular myocardium and retrograde up the bypass tract to activate the atrium. The circuit is completed as the AV node is again activated. Tachycardias moving in the opposite direction are identified as wide QRS tachycardias and may be indistinguishable from VT by surface ECG. Adenosine administration during tachycardia may terminate WPW tachycardia but is unlikely to terminate VT. Caution to avoid hypotension or ventricular fibrillation during diagnostic atropine administration in nonhypotensive wide-complex tachycardia is recommended. Advanced cardiac life support equipment should be available during administration.

Sudden, rapid onset and offset of narrow-complex tachycardia occurs in AVNRT. Either an inverted P wave immediately follows the QRS complex, or it may not be visible

at all. Termination of the arrhythmia using vagal maneuvers (e.g., carotid sinus massage, Valsalva, stimulation with ice-cold water) may be used clinically. Treatment with AV node–blocking agents can be successful in most patients. Safe, highly effective treatment with invasive electrophysiology study and RF therapy is common at most larger centers. Figures 27-53 and 27-54 illustrate the mechanism and ECG findings.

Long QT syndrome, a disorder of myocardial repolarization, results from abnormalities in membrane ion channels. Syncope and life-threatening polymorphous VT and VF may result. Autosomal dominant inheritance patterns and variable phenotypic penetrance may be seen. Diagnosis in affected individuals is difficult because the QT interval may occasionally be normal. Provocative maneuvers by a trained specialist may be necessary. Genetic testing for some but not all of the genetic abnormalities is available for confirmation.

Figure 27-52 Sinus rhythm with obvious delta waves consistent with a right-sided septal or posteroseptal origin. Twelve-lead electrocardiography is performed before radiofrequency ablation.

Figure 27-53 Normal electrocardiogram following radiofrequency ablation of the manifest right posteroseptal bypass tract.

Families with a history of sudden cardiac death or syncope should be evaluated carefully to determine the need for treatment, including beta blockers and implantable defibrillators (Priori et al., 2003).

Atrial fibrillation is the most frequent arrhythmia requiring treatment. In America, 2.2 million people have persistent or permanent AF (Feinberg et al., 1997). A basic understanding to the approach of AF can render most patients asymptomatic and dramatically reduce their risk of stroke. The AFFIRM trial represents a landmark study treating all AF patients with warfarin (Coumadin). Patients were then randomized to either (1) *control of heart rate* utilizing AV nodal blocking agents, or if necessary, AV junction ablation and pacemaker therapy, or (2) *maintenance of sinus rhythm* utilizing antiarrhythmic drug therapy and repeated direct-current (DC) cardioversion. Patients were followed for up to 5 years and had similar mortality. Patients randomized to rhythm control had more hospitalizations and adverse drug effects, mostly related to antiarrhythmic therapy. Stroke events were similar but were higher in patients who discontinued warfarin, regardless of treatment arm (AFFIRM Investigators, 2002). Based on this study, patients who are candidates for either heart rate control or rhythm control can pursue either treatment strategy with similar efficacy. In patients undergoing restoration of sinus rhythm, the use of DC cardioversion is safe and effective. Anticoagulation with an INR goal of 2 to 3 in nonvalvular AF is recommended for a minimum of 3 weeks before a cardioversion.

Conscious sedation with short-acting narcotics and intravenous benzodiazepines allows for synchronized shock delivery in ASA class I and II patients by experienced physicians. In patients adequately anticoagulated with warfarin, DC cardioversion can restore sinus rhythm at least transiently in 70% to 90% of patients (Lundstrom and Ryden, 1988; Sodermark et al., 1975; Van Gelder et al., 1991). Maintenance of sinus rhythm at 12 months on antiarrhythmic medications may be as low as 40% depending on drug selection and the patient population (Van Gelder et al., 1996). Despite this, the practicing physician may elect to gain expertise in conscious sedation and cardioversion when referral electrophysiologists are not readily available and in patients not requiring or intolerant to drug therapy. Prior recommendations for discontinuation of warfarin after 6 weeks in sinus rhythm (SR) are being scrutinized because of the high stroke rate in patients in the AFFIRM trial that discontinued warfarin despite being in SR. Caregivers may treat patients long

term, even after SR is restored, or in patients with asymptomatic AF. Because of the high 6-month recurrence rate after cardioversion, many maintain patients on anticoagulation for 6 or more months before considering stopping it. Recommendations for anticoagulation are certain to change as new drugs become available.

Syncope is the sudden loss of postural tone and may be caused by both cardiac and noncardiac causes; up to 30% of patients may ultimately have no explanation. A detailed history that includes dietary and fluid intake, personal and family history, medication use and timing, and precipitating factors will aid in the diagnosis. The best single determinant of an etiology is likely the history. Additional testing depends on the presence or absence of structural heart disease. Invasive electrophysiology study in the setting of structural heart disease may identify the cause of syncope in up to one half of patients (Linzer et al., 1997). In the absence of structural heart disease, tilt-table testing may identify the cause in 11% to 87% of patients (Kapoor, 1990, 1992). Referral to an electrophysiologist should be considered in the setting of structural heart disease.

Treatment of Cardiac Arrhythmias

An organized approach to the treatment of cardiac arrhythmias is paramount. Initial steps include identification and verification of the arrhythmia type and an assessment of potential harm to the patient. **Box 27-9** outlines various rhythms categorized by their cardiac chamber of origin. As previously described, inpatient evaluation is recommended in some patients. When pharmacologic therapy is recommended, the side-effects and proarrhythmia potential must be known. **Table 27-16** outlines antiarrhythmic agents according to the Vaughan-Williams classification system. A newer classification based on channel effects and mechanisms of arrhythmogenesis, the Sicilian Gambit system, although helpful, is too complex for most individuals to use and has not gained favor in the current era of invasive arrhythmia therapy (Rosen and Schwartz, 1991).

Evaluation and treatment of patients with arrhythmias is a rewarding practice. Many arrhythmias can be symptomatically improved through use of medications, lifestyle changes, and reassurance. However, meta-analysis of antiarrhythmic drug trials and the Cardiac Arrhythmia Suppression Trial (CAST) demonstrated the potential dangers of drug therapy in the treatment of cardiac arrhythmias (Echt et al., 1991; Sodermark et al., 1975). In addition, invasive evaluation and treatment of common bothersome or malignant arrhythmias is carried out by cardiac specialists trained in electrophysiology. In addition to drug therapy, an electrophysiologist may offer invasive techniques to treat arrhythmias. Arrhythmia ablation, implantation of pacemakers and defibrillators, and cardiac resynchronization therapy are all techniques to help reduce morbidity and mortality.

Electrophysiology Study and Ablation

Patients recommended for invasive arrhythmia therapy are evaluated in special catheterization suites. During an electrophysiology study (EPS), several electrodes or wires are inserted through the femoral vein or jugular vein and advanced to the right atrium, right ventricle, coronary sinus,

Figure 27-54 Sinus rhythm is noted in the upper strip. In the lower panel, supraventricular tachycardia consistent with atrioventricular nodal reentrant tachycardia is seen. Retrograde (inverted) P waves immediately following the QRS complex during tachycardia are evident. During the tachycardia at almost 150 beats/min, the normal P-R interval is no longer seen.

Box 27-9 Classification of Rhythms**Atrial**

Sinus rhythm
 Sinus bradycardia
 Sinus pause
 Sinus node exit block (type I and type II)
 Sinus arrest
 Sinus tachycardia
 Premature atrial contraction
 Wandering atrial pacemaker
 Ectopic atrial rhythm
 Ectopic atrial tachycardia
 Multifocal atrial tachycardia
 Atrial fibrillation
 Atrial flutter

Junctional Rhythms

Premature junctional beat
 Junctional rhythm
 Accelerated junctional tachycardia
 Atrioventricular nodal reentrant tachycardia

Atrioventricular (AV) Conduction Block

First-degree AV block
 Second-degree AV block (types I and II; 2:1; high grade)
 Third-degree AV block (complete AV block)

Ventricular Rhythms

Premature ventricular contractions
 Accelerated idioventricular rhythm
 Ventricular tachycardia (monomorphic and polymorphic)
 Ventricular fibrillation

Special Rhythms

Preexcitation
 AV reciprocating tachycardia
 Long QT interval
 Paced rhythms

and in the region of the AV node/His-bundle complex. Special pacing sequences and premature beat delivery are used to initiate arrhythmias. The wires may then be moved to different sites within the heart. Application of radiofrequency current through the tip of the catheter electrode results in elimination of the arrhythmia focus. Variations in duration and power of the current are used to alter lesion size. Studies may last less than an hour to several hours depending on the nature of the arrhythmias treated. This essentially painless method replaced the traditional technique of direct-current lesion application, which was poorly controlled and quite painful and required general anesthesia. Radiofrequency ablation is now used as the standard technique in treatment of AV node-dependent arrhythmias, including AVNRT, AV reciprocating tachycardia, and junctional tachycardia. Atrial flutter is successfully cured in most cases (see Fig. 27-42), and even paroxysmal atrial fibrillation may be suppressed or cured by RF ablation. Future refinements of this technique may be used to cure many more patients with bothersome atrial fibrillation.

Alternate energy sources, including microwave, ultrasound, and cryotherapy, are being investigated and used. Radiofrequency, however, remains the energy source in almost all cases for the routine treatment of supraventricular arrhythmias treated with ablation. Treatment of arrhythmias through open-chest procedures was once the only method to cure arrhythmias. Considered high risk in most patients and too invasive for nonlethal arrhythmias in the era of RF ablation, surgical ablation for AF has enjoyed a resurgence as adjunct therapy during valvular heart surgery with cryotherapy and RF therapy of pulmonary veins (Todd et al., 2003).

Pacemakers and Defibrillators

Significant development in the area of pacing has occurred since transvenous pacemakers were first produced and implanted. Once able to pace only in a single chamber at a preset rate and without the ability to detect underlying rhythms, current pacemakers are more sophisticated. A pacemaker in its simplest form is a battery, pulse generator, and a lead to deliver an impulse. The use of sensing and

Table 27-16 Common Antiarrhythmic Drugs

| Type of Drug | Typical Indications | Route | Considerations, Contraindications, and Complications | Frequency of General Use |
|----------------------------------|---------------------|--------|---|---|
| Class I | | | | |
| Class Ia | | | | |
| Disopyramide (Norpace) | PACs, AF, SVT, PVCs | PO | Useful in normal hearts without ischemia; prolongs QT; atropine effect | Atrial arrhythmias only |
| Procainamide (Procan, Procanbid) | AF, PAC, PVC, VT | PO, IV | Wider range of use in mild LV dysfunction; lupus side effect; prolongs QT and QRS; best used in normal hearts only Renal excreted with active metabolite (class III) | Atrial arrhythmias Acute suppression of VT post-CABG |
| Quinidine (Quinidex, Quinaglute) | AF, PACs, PVC, VT | PO, IV | Marked QT prolongation, myasthenia, idiosyncratic blood defects; may enhance AV conduction | Limited use; mostly AF, AFL |

Continued

Table 27-16 Common Antiarrhythmic Drugs—Cont'd

| Type of Drug | Typical Indications | Route | Considerations, Contraindications, and Complications | Frequency of General Use |
|--------------------------------|----------------------------|--------|---|---|
| Class Ib | | | | |
| Lidocaine | VT, torsade | IV | Rapid onset; may cause CNS changes and seizures | Acute VT termination and suppression Being replaced by IV amiodarone |
| Mexiletine (Mexitil) | PVCs, VT | PO | Significant GI upset, mild proarrhythmia, mild effect Can be used carefully in setting of LV dysfunction | PVC suppression when other agents fail |
| Phenytoin (Dilantin) | VPB, VT | PO, IV | CNS effects, rash, blood dyscrasias | Rarely used; minimal effect |
| Tocainide (Tonocard) | VT | PO | CNS, blood dyscrasias, GI upset, pneumonitis | Rarely used |
| Class Ic | | | | |
| Flecainide (Tambacor) | AF, AFL, PACs, EAT, WPW | PO | Well tolerated; may increase conduction of slowed atrial flutter; contraindicated in CHF | Frequently used for AF, AFL |
| Propafenone (Rhythmol) | PACs, EAT, AF, AFL, PVC | PO | Contraindicated in CHF | Frequently used for AF, AFL |
| Class II | | | | |
| Beta Nonselective | | | | |
| Propranolol | ST, AT, IST, PVCs, VT, AF* | PO, IV | Excess bradycardia, hypotension, CNS effects Negative inotrope Pulmonary bronchospasm | Short acting, rapid onset; increased replacement by longer-acting cardiac selective agents |
| Beta Selective | | | | |
| Atenolol | ST, AT, IST, PVCs, VT, AF* | PO, IV | Excess bradycardia, hypotension, CNS effects Negative inotrope | Inexpensive, resulting in frequent use |
| Metoprolol (Lopressor, Toprol) | ST, AT, IST, PVCs, VT, AF* | PO, IV | Excess bradycardia, hypotension, CNS effects Negative inotrope | Frequently used, long-acting preparation with infrequent side effects |
| Pindolol | ST, AT, IST, PVCs, AF* | PO | Excess bradycardia, hypotension, CNS effects Negative inotrope | Intermediate-frequency use |
| Timolol | ST, AT, IST, PVCs, AF* | PO | Excess bradycardia, hypotension and CNS effects Negative inotrope | Low-frequency use |
| Esmolol (Brevibloc) | ST, AT, IST, PVCs, AF* | IV | Short acting Excess bradycardia and nonselective at high doses | Low-frequency use caused by IV form only |
| Mixed Alpha/Beta | | | | |
| Carvedilol (Coreg) | CHF, PVCs, AF* | PO | Excess bradycardia, hypotension, exacerbation of CHF, fatigue | Infrequent as first choice for arrhythmias but primarily indicated for systolic heart failure |
| Class III | | | | |
| Ibutilide (Corvert) | AF, AFL | IV | Proarrhythmia frequent including PVCs, VT, and torsades; prolongs QT and slows heart rate; requires acute monitoring | Intermediate use; high efficacy in acute AF/AFL but with potential serious acute side effects |
| Dofetilide (Tikosyn) | PACs, AF, AFL | PO | High efficacy; prolongs QT and QRS; proarrhythmic including torsades; requires training to prescribe (Is mortality neutral in CHF and MI patients?) | Low-frequency use caused by inpatient initiation and potentially dangerous proarrhythmia |

Table 27-16 Common Antiarrhythmic Drugs—Cont'd

| Type of Drug | Typical Indications | Route | Considerations, Contraindications, and Complications | Frequency of General Use |
|----------------------------------|----------------------------------|--------|---|--|
| Sotalol (Betapace) | ST, AT, IST, PVCs, VT, AF* | PO | Excess bradycardia; prolongs QT with potential torsades | Moderate-frequency use; reasonably safe in setting of mild LV dysfunction in absence of ischemia |
| Amiodarone (Pacerone, Cordarone) | ST, AT, AF, AFL, PVCs, VT, AF* | PO, IV | Class I, II, III, and IV effects Very well tolerated but may produce serious thyroid dysfunction and lethal pulmonary and liver dysfunction Close monitoring for side effects mandatory | High-frequency use caused by very low acute side effect profile and very high efficacy in variety of arrhythmias Indiscriminate use discouraged |
| Class IV | | | | |
| Diltiazem (Cardizem, Cartia) | AF*, PVCs, calcium dependent VT, | PO, IV | Bradycardia, hypotension, exacerbation of systolic heart failure Continuous infusion available | Used frequently for AVN slowing in setting of AF with or without LV dysfunction |
| Verapamil (Calan, Isoptin) | AF*, PVCs, calcium dependent VT | PO, IV | Bradycardia, hypotension, exacerbation of systolic heart failure | Used frequently for AVN slowing in setting of AF |
| Class V (Other) | | | | |
| Adenosine (Adenocard) | SVT | IV | Acute onset with very powerful AV node block and to less extent SA block, producing marked bradycardia and transient asystole; temporary pulmonary symptoms | Agent of choice for abrupt termination of most AV node-dependent arrhythmias |
| Digoxin | AF* | PO, IV | Proarrhythmic, including heart block and enhancing bypass tract conduction, GI side effects | Frequent adjuvant drug for slowing ventricular response in AF |
| Atropine | SB | IV | Avoid in patients with acute-angle glaucoma | Acute treatment for sinus bradycardia and heart block not caused by Purkinje failure |
| Magnesium sulfate | Torsades, PVC and VT suppression | PO, IV | Caution in renal failure | Frequent adjuvant drug for VT suppression |

Drugs organized according to the Vaughan-Williams classification scheme. Indications represent both approved and nonapproved indications.

PO, Oral (per os); IV, intravenous; SA, sinoatrial; ST, sinus tachycardia; AT, atrial tachycardia; IST, inappropriate sinus tachycardia; AF, atrial fibrillation; AFL, atrial flutter; AF*, AV node blockade in atrial fibrillation; PACs, premature atrial contractions; PVCs, premature ventricular contractions; SB, sinus bradycardia; VT, ventricular tachycardia; torsades, torsades de pointes; LV, left ventricular; GI, gastrointestinal; CNS, central nervous system; CHF, systolic congestive heart failure; CABG, coronary artery bypass graft.

Figure 27-55 Dual-chamber pacemaker with endocardial passive and active fixation leads. (Courtesy Medtronic, Minneapolis).

timing circuits coupled with motion detectors within the pacemaker allows inhibition of pacing when sensed events occur and an increase in paced rate with motion or activity. As technology advanced, pacemakers were able to pace effectively in the atrium and ventricle and AV node, or P-R intervals could be adjusted. Telemetry through the skin using proprietary programming devices allow adjustment in the physician's office. Miniaturization has now resulted in sophisticated pacemakers able to pace the heart when necessary, detect rapid rhythms, and attempt to pace terminate the arrhythmia in a package about the size of a half-dollar coin (Fig. 27-55) (Furman et al., 1993). Implantable defibrillators with endocardial leads were developed in the early 1990s, allowing for a safer and less invasive procedure. These devices are now able to identify and attempt to terminate ventricular arrhythmias through painless overdrive pacing or using an endocardial shock that can be uncomfortable if the patient is not syncopal (Figs. 27-56 and 27-57).

Figure 27-56 Ventricular tachycardia is pace terminated by three rapid ventricular pulses from the implanted pacemaker-defibrillator. Atrioventricular sequential pacing resumes following termination of the ventricular tachycardia.

Figure 27-57 Attempt at pace termination of ventricular tachycardia with acceleration of the ventricular tachycardia into ventricular fibrillation. The transient of the endocardial shock is noted, and pacing resumes with organized cardiac activity.

Figure 27-58 Radiographs from a dual-chamber biventricular defibrillator. Right and left anterior oblique views are shown in a patient treated for left ventricular systolic dysfunction and NYHA Class III heart failure. Standard leads terminate in the right atrium and the right ventricular septum. A third lead enters the coronary sinus from the right atrium and extends into a branching vein to provide synchronous left and right ventricular activation.

Figure 27-59 Left bundle branch block and right BBB are produced from contralateral ventricular pacing. Right ventricular pacing with left BBB morphology is noted on the left. Pacing activates one side of the ventricle earlier and therefore results in a BBB pattern of the opposite side of the chamber paced. On the right, inappropriate left ventricular endocardial lead placement delivered across a patent foramen ovale was detected before serious consequences of embolic stroke. Epicardial pacing of the left ventricle is also accomplished through lead placement through the coronary sinus.

Cardiac Resynchronization and Defibrillator Therapy

Patients with refractory clinical congestive heart failure have a sixfold to ninefold increase in sudden cardiac death compared to the general population (AHA, 2002). Despite therapy with beta blockers, ACE inhibitors, angiotensin II receptor blockers, diuretics, spironolactone, digoxin, and invasive revascularization strategies, patients continue to have significant morbidity and mortality from systolic CHF.

Electrophysiologists have been impacting mortality and morbidity for over a decade through cardiac pacing resynchronization therapy and defibrillator placement.

The slowing of conduction through the left ventricle in the setting of BBB or significant scarring leads to asynchronous lateral and septal contraction. This dyssynchrony (asynchrony) results in excess energy expenditure and decreases cardiac performance. Placement of a pacing device capable of pacing in the right ventricle as well as at the lateral left ventricle has significantly reduced morbidity and mortality. The addition of a defibrillator further decreases mortality (Bristow et al., 2004; Cleland et al., 2005; Young et al., 2003). **Figure 27-58** shows the radiographic appearance of a biventricular system. Pacing in both ventricles demonstrates a shortening of the QRS complex and is associated with improvements in cardiac contractility and over time, reduction in LV chamber size, reduction in mitral valve regurgitation, and improvements in 6-minute walk test, quality of life, and NYHA classification (Abraham et al., 2002). Changes in the QRS morphology depend on the site of electrical stimulation (**Fig. 27-59**). During right and left ventricular activation, the QRS morphology in lead V1 is shown.

Patients suffering from lethal tachycardia events such as ventricular tachycardia and ventricular fibrillation have been extensively studied. For much of modern electrophysiologic history, the EPS was used to induce VT in patients with syncope and structural heart disease, in patients with symptomatic stable VT, and in patients resuscitated from arrhythmic sudden cardiac death. Drugs were then initiated and repeat testing performed to test the success of the antiarrhythmic drug. More recent studies have challenged this approach. Drug versus implantable defibrillator therapy trials have demonstrated mortality benefit as secondary prevention of syncope VT or resuscitated sudden cardiac death with

structural heart disease (AVID Investigators, 1997; Connolly et al., 2000; Kuck et al., 2000). Further studies have demonstrated mortality benefit from implantable defibrillators compared to drug therapy in primary prevention trials. Specific groups demonstrating superiority of device therapy over drugs include patients with asymptomatic ventricular ectopy with inducible VT, those with prior MI and ejection fraction less than 30%, and those with LVEF less than 35% with NYHA II or III heart failure for longer than 3 months (Bardy et al., 2005; Buxton et al. 2000; Moss et al., 1996, 2002). Patients fulfilling these criteria should be referred to an electrophysiologist.

Safe approaches to common surgical procedures can be performed by primary care providers in an outpatient setting without significant sedation. This chapter provides the foundation to build skills of competency in common procedures, including adequate preparation, appropriate setup, informed consent, good technical skills, and knowledge of how to handle potential complications. Discussions of the basic surgical skills and setup required, patient consent, and local anesthesia are followed by a review of common office procedures in family medicine, with tips to perform these successfully and methods to prevent complications.

As the U.S. health care system grapples with medical home concepts, family medicine providers must develop proficient skills to carry out common procedures in primary care clinics. The health care system may continue to provide high remuneration for procedural medicine but may change to a system driven by outcomes, competency, and ability to provide competent procedural services in the medical home. Comprehensive patient care will return to the primary care realm, where it is more cost-effective.

For a brief history of surgery, see the online discussion at www.expertconsult.com.

Basic Skills

The Patient History

Before undertaking any procedure, the physician must begin with a pertinent comprehensive health history and thorough understanding of the patient and their current health condition. Preexisting diagnoses, such as diabetes or hemophilia, may affect wound healing or bleeding.

Allergies to medication, tape, or preparation agents should be elicited along with any personal or family history of bleeding or thrombosis. Anticoagulant use, including aspirin, clopidogrel, warfarin, nonsteroidal anti-inflammatory drugs (NSAIDs), ticlopidine, dipyridamole, and fish oil may affect bleeding and hemostasis during any procedure. Short-acting NSAIDs should be held for 1 or 2 days before surgery based on their antiplatelet effect and drug half-life. Aspirin, dipyridamole, ticlopidine, and long-acting NSAIDs should be stopped 7 to 10 days before surgery if the benefit of improved hemostasis during the procedure outweighs the risk of complications from the underlying medical condition for which the medication is prescribed. Warfarin (Coumadin) should be stopped based on risk profiles. Low-risk patients with no thrombotic history who are taking anticoagulants for atrial fibrillation may have their warfarin stopped 3 to 4 days before surgery and may have no “bridging” heparin. If a patient has a high risk for thromboembolism, such as past pulmonary embolism, mechanical valve, or current treatment for deep vein thrombosis, a “bridge” with low-molecular-weight heparin or regular heparin should be given. Warfarin may be resumed immediately after surgery, and then the heparin may be discontinued once the international normalized ratio (INR) is therapeutic (Singer et al., 2008b).

Aspirin and other antiplatelet medications may be resumed 24 hours after surgery. If the patient is high risk and receiving a superficial procedure, the physician should continue the blood-thinning agent and consider using local anesthesia with epinephrine. Local cautery, direct ligation of bleeding vessels, and direct pressure are used as needed for hemostasis. Fish oil taken with aspirin or warfarin may potentiate the antiplatelet effects (Ramsay et al., 2005).

A history of delayed healing or keloid (thick scar) formation should be elicited. A prior vasovagal event or fainting episode warrants preventive measures to reduce the potential risk of complications should a patient faint during or after a procedure.

KEY TREATMENT

Anticoagulant agents should be stopped 7 to 10 days before surgery if there is no contraindication (SOR: A).
Warfarin should be stopped based on risk profiles (SOR: A).
(Singer et al., 2008b).

Skin Preparation

Prepare the skin with an appropriate antiseptic solution starting in the middle of the surgical site and going outward in concentric circles in aseptic fashion. Alcohol, chlorhexidine, povidone-iodine (Betadine), or a combination may be used as an antiseptic cleansing agent (Mangram et al., 1999).

The U.S. Centers for Disease Control and Prevention (CDC) and Healthcare Infection Control Practices Advisory Committee (HICPAC) updated guidelines in 2002 on skin preparation related to reducing central line infections. The CDC issued additional guidelines for the prevention of surgical site infection in 1999. The U.K. National Institute for Health and Clinical Excellence–Surgical Site Infection guidelines from 2008 agreed with each of these groups as well. Skin aseptic preparation with chlorhexidine 2% plus 70% isopropyl alcohol was the best at preventing surgical site infections as it achieves greater reductions in skin microflora and has greater residual activity after a single application (Mangram et al., 1999).

Chlorhexidine gluconate is effective even in the presence of blood or serum proteins, whereas blood and serum proteins may inactivate povidone-iodine. However, conflicting data show that a combination of iodine povacrylex in isopropyl alcohol may reduce infection rates greatest in general surgery patients (Swenson et al., 2009). Isopropyl alcohol 70% is effective immediately, but the antiseptic effect is not sustained. Combinations are superior to isopropyl alcohol or chlorhexidine alone (Adams et al., 2005; Hibbard, 2005).

Many surgical site infections are from endogenous staphylococcal skin flora. An increasing number are also resistant to antibiotics, such as methicillin-resistant *Staphylococcus aureus* (MRSA). No clear guidelines exist on how best to reduce MRSA infections, but good handwashing and aseptic technique are a part of the prevention of MRSA-related surgical site infections (Siegel et al., 2006).

KEY TREATMENT

Chlorhexidine plus alcohol-containing skin preparations provide the best reduction in skin flora in the perioperative period (Murkin, 2009) (SOR: A).
Do not remove hair preoperatively unless the hair is at or around the incision site and would interfere with the procedure. If hair removal is required, clip immediately before surgery, and do not shave it (Mangram et al., 1999) (SOR: A).

Bites

Bites represent special risks for laceration repair. Cat bites often involve deep puncture wounds and should be cleaned and irrigated thoroughly and not closed but allowed to heal by secondary intention. Untreated cat bite infection rates are 18% to 33% (Dire, 1991). Treating cat bites with prophylactic antibiotics significantly reduces infection rates. Dog bites may be more lacerated and after high-pressure flushing at greater than 7 psi (obtained using 50-cc syringes and saline or iodine in water in 1:10 ratio) may be closed primarily in the first 6 hours after the injury. Infection rates for dogs are less than 20% (Dire, 1992).

Primary closure by suturing is not generally recommended for nonfacial bite wounds, especially deep punctures, bites to the hand, and clinically infected wounds. Anecdotal data suggest an increased risk of infection after closure of these wounds. Sterile skin closure strips or delayed closure may be appropriate (Singer et al., 2008a).

Human bites on the hands and specifically overlying the metacarpophalangeal joints are problematic because of potential damage to underlying tissue, tendons, and joint

spaces. Hand injuries may therefore lead to aggressive secondary infections of these structures. Profuse flushing of human hand bites or lacerations, prophylactic antibiotics, and consultation are advised. These wounds may need to be surgically opened under anesthesia to flush adequately.

Wounds to both the hands and face need immediate care because infection rates almost double to 29% if not treated within 12 hours. Prophylactic antibiotics should be used with hand and facial bite wounds. Facial wounds may be flushed and closed primarily because of the good blood supply and a risk for poor cosmesis if left open (Henry et al., 2007).

KEY TREATMENT

A review of Cochrane data suggests that antibiotics should be used prophylactically in human bites to the hand (NNT = 4) (Medeiros and Saconato, 2008) (SOR: A).

Immunizations

With any laceration or open skin injury, tetanus immunizations should be updated if indicated. If patients have received 3 or more primary tetanus immunizations, they should receive an update if their last immunization was more than 10 years ago for a clean wound and if more than 5 years ago with a dirty wound. Patients should receive tetanus immune globulin (TIG) and begin their tetanus immunization series if they have had less than 3 immunizations in the past. Diphtheria toxoid and pertussis antigens with tetanus toxoid (Tdap) should replace a single dose of Td for adults age 19 through 64 years who have not received a dose of Tdap previously and require a booster. Tdap may be given as close as 2 years after a Td. Td can be given every 10 years when needed after one Tdap is received (CDC, 2009; see Web Resources).

Patients should begin the hepatitis B immunization series for any human bite wounds or for mucus membrane blood exposure. Patients should be offered and consented for baseline testing for hepatitis B virus (HBV) and C virus (HCV) and human immunodeficiency virus (HIV). Appropriate follow-up based on test results must be arranged. HBIG is indicated if the patient has injuries from a person known to be positive for hepatitis B surface antigen (HBsAg); however, needle stick guidelines suggest that the injured patient receive only a hepatitis B immunization series and not HBIG if the contact person has an unknown or negative carrier status. In the case of a needle stick, HIV prophylaxis with three drugs is recommended if the contact person is a known HIV positive. If the source patient has an unknown HIV status, postexposure prophylaxis (PEP) generally is not indicated, unless there is concern that the source is higher risk, in which case two-drug PEP is offered.

Procedure Room

A clean procedure room with a table that elevates and an overhead surgical light that can be adjusted and focused gives the provider the best environment to carry out procedures. An adjustable and mobile mayo stand allows the most comfortable access to sterile trays and instruments during a procedure. Surgical instruments should be stored in sterile packs, ideally set up for specific procedures. Extra

equipment may be in individual sterile packs and should be readily available. Check sterility date expiration for all packaged equipment.

Patients should be made comfortable for the procedure with use of an adjustable bed and pillows as needed. Open, supportive conversation with an empathetic approach encourages relaxation and reassurance before, during, and after the procedure. An assistant is helpful in setup and during the procedure and provides support for the patient during care. In children undergoing general surgery, a family-focused dialog and ongoing conversation were similar to using midazolam in reducing anxiety and speeding recovery (Kain et al., 2007).

Equipment

The most basic sterile pack for skin procedures contains a needle driver, Adson tissue forceps with teeth, iris or suture scissors, and a scalpel handle with blade. The instruments should comfortably fit the physician's hands.

There are three primary scalpel blade styles used in the outpatient setting. A #10 blade has a large, rounded cutting surface and may be used for longer, straight incisions on larger areas with thicker skin, such as the trunk or limbs. A #15 blade has a smaller, rounded cutting surface to allow more mobility and may be used on most skin procedures, particularly those with nonlinear incisions. A #11 blade has a pointed blade without a curve and is better used for paring superficial lesions, such as warts or calluses, or puncturing skin abscesses. The Adson forceps with teeth has one side with one tooth and the other side with two teeth. Less tissue trauma occurs using the single tooth on the external tissue while everting the skin edges or using a skin hook (Fig. 28-1).

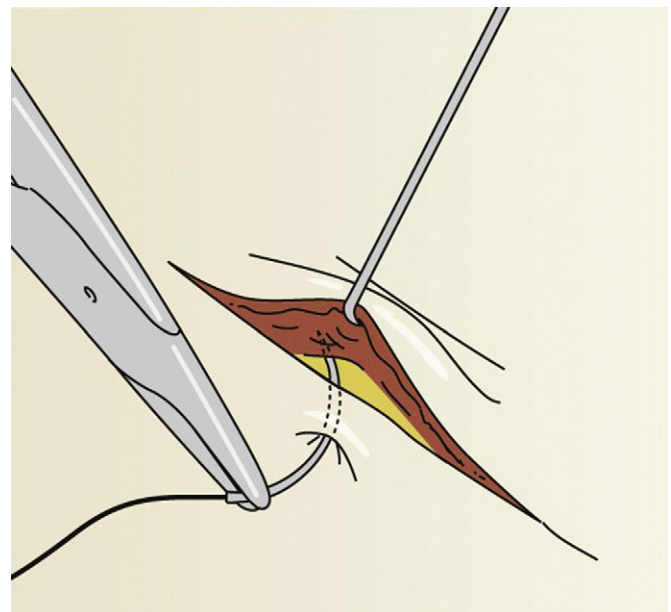

Figure 28-1 Use of a skin hook to evert wound edge. This technique allows the operator to see the needle path, ensuring that the proper depth has been reached, and promotes eversion of the skin edges.

(From Lammers RL. *Methods of wound closure*. In Roberts JR, Hedges JR [eds]. *Clinical Procedures in Emergency Medicine*, 5th ed. Elsevier, Philadelphia, 2010.)

Needle drivers should fit the physician's hand; the ring finger fits in the lower circle of the handle, and the thumb may fit in the top circle of the handle with the index finger extended along the shaft to stabilize the needle driver. Load the needle by locking the needle driver about three-quarters the way up the shank of the needle, with the needle held perpendicular to the needle driver. Sharps are kept in the same area of the sterile field to develop a system for reducing needle stick injuries.

Suture

Three basic types of suture exist: natural absorbable, synthetic absorbable, and nonabsorbable. Sutures are sized according to the 1937 *U.S. Pharmacopeia* classification system. Smaller suture has a higher number of zeroes (2-0 is 00 and 4-0 is 0000). The physician should use the smallest size that provides adequate tensile strength initially to close the wound and not to fail during the healing process. The clinician should use deep sutures to reduce surface tension if the wound is deep and there is high skin surface tension. Ideally, skin sutures gently approximate the skin edges with minimal tension.

Absorbable types of suture include plain gut, chromic gut, and synthetic sutures made of polyglycolic acid, polylactic acid, polydioxanone, and caprolactone. Plain gut suture used externally has a tensile strength lasting 5 to 7 days, whereas chromic gut used internally has a tensile strength lasting 10 to 14 days. The synthetic absorbable types of suture vary in length of tensile strength and rate of absorption. Nonabsorbable suture is made of nylon, special silk, polypropylene, or polyester. These sutures are made in different colors and are inert. Most have long-lasting tensile strength. Non-absorbable sutures are used externally but can be used internally for prolonged tissue reinforcement. Nonabsorbable sutures cause less immune response and therefore less scarring. Frequently, they are used superficially when cosmetic outcome is critical.

Traditionally, it was advised that absorbable suture be used only if it is placed below the skin's surface because of its porous structure and a possible wick for bacteria on the skin surface. However, this recommendation is not evidence based. A meta-analysis of two randomized, controlled trials (RCTs, Jadad scores 3) comparing absorbable versus nonabsorbable sutures in the management of traumatic lacerations and surgical wounds showed no changes in infection rates, scar appearance, patient satisfaction, or dehiscence. In children, the benefit is not requiring suture removal (Al-Abdullah et al., 2007).

Plain gut sutures last intact for 5 to 7 days and may be used to close small mucosal lacerations or excisions. Plain gut sutures do not survive long enough for use on deep tissue reapproximation. Use 5.0 to 6.0 nylon suture on the face, and remove in 3 to 5 days. If the wound is elsewhere on the trunk, extremities, or other areas with tension, use 3.0 to 4.0 nylon sutures and remove in 10 to 14 days.

Needles

Suture needles are classified by the geometry of their points. Taper needles have a round body that tapers smoothly to a point. Cutting needles are triangular with a sharp cutting

edge on the inside curve of the needle; reverse cutting needles have the cutting edge on the outside of the curve. A taper-cut needle is round but ends in a short, triangular cutting point. Some needles are attached permanently to suture and others, called "pop offs" separate from the suture with a sharp pull. With a wide range of needle types, the physician should be familiar with supplies and examine the outside of the package closely before opening. Reverse cutting needles are stronger than conventional cutting needles; both minimize trauma to the skin and so are appropriate for most skin closure.

Anesthesia

Topical Anesthesia

An equal mixture of prilocaine 2.5% and lidocaine 2.5%, EMLA cream may be used as a topical anesthetic. EMLA works best if applied to the dermal site at least 1 hour before the procedure and covered with an occlusive dressing. It is not used more often because of the time needed for onset of anesthesia, increased expense, and risk of methemoglobinemia in susceptible individuals such as those with congenital disease, pyruvate kinase-deficient and glucose-6-phosphate dehydrogenase (G6PD)-deficient patients, and those with rare, acquired forms resulting from medications (e.g., prilocaine, antimalarials, sulfonamides). Patients under 3 months of age are vulnerable to developing methemoglobin because the breakdown product ortho-toluidine can produce methemoglobinemia following systemic doses of prilocaine approximating 8 mg/kg. A rectangle measuring 1.5 × 0.2 inches is about 1 g of EMLA or 25 mg of prilocaine. The maximal area of application is age and weight dependent (Table 28-1).

Other topical anesthetics are used in some circumstances. Ethyl chloride cools the skin superficially and works well for needle punctures. Unfortunately, it is flammable and has a brief action, limiting its usefulness. A 30% lidocaine cream

Table 28-1 EMLA Dosing

| Age/Weight requirements | EMLA cream (max total dose) | Maximum application area | Maximum application time |
|-------------------------|-----------------------------|--------------------------|--------------------------|
| 0-3 months or <5 kg | 1 g | 10 cm ² | 1 hour |
| 3-12 months and >5 kg | 2 g | 20 cm ² | 4 hours |
| 1-6 years and >10 kg | 10 g | 100 cm ² | 4 hours |
| 7-12 years and >20 kg | 20 g | 200 cm ² | 4 hours |

EMLA, Eutectic mixture of local anesthetics.

must be applied with an occlusive patch at least 45 minutes before any procedure. Liposomal encapsulation forms of topical tetracaine and lidocaine are as efficacious as EMLA (Eidelman et al., 2005). Lidoderm patches are a 5% concentration and are not potent enough for surgical skin anesthesia. (See **Tuggy Video: Topical Anesthesia.**)

Local Anesthesia

For most office procedures, a local injection is a quick and easy way to provide anesthesia, by blocking the fast sodium channels and stopping pain fiber neurotransmission. However, an injection of local anesthetic may distort skin edges and adversely affect skin anatomy and alignment. Consider marking incisions and vital alignment before infiltrating with a local anesthetic. Anesthetize before flushing the wound in repair of contaminated lacerations. Infiltration of 1% lidocaine does not damage local defenses, promote infection, or exhibit antimicrobial activity that would obscure a culture from a wound (Edlich et al., 2010).

There are two groups of local anesthetics: amides and esters. Allergies are more common to the esters. Allergy to an amide is usually caused by the preservative methylparaben. If a patient has an ester allergy, use an amide; no cross-reactivity occurs between classes (Archar and Kundar, 2002) (**Box 28-1**).

The most common locally injected anesthetic is lidocaine, with or without epinephrine; 1% lidocaine contains 10 mg/mL of lidocaine. Lidocaine dosing should not exceed 4.5 mg/kg without epinephrine (maximum 300 mg in adults, or 30 mL of 1% lidocaine) or 7 mg/kg of lidocaine with epinephrine (maximum 500 mg in adults, or 50 mL of 1% lidocaine with epinephrine) (Tetzlaff, 2000). Others list the recommended safe dose of infiltrated lidocaine as 200 mg or less in an adult, which is 20 mL of 1% lidocaine (Rosenberg et al., 2004). If doing a paracervical or pudendal block, the maximum total dose over 90 minutes is 200 mg of lidocaine, or 20 mL of 1% lidocaine

Box 28-1 Local Anesthetic Classifications

Amides

Lidocaine (Xylocaine)
Bupivacaine (Marcaine)
Prilocaine (Citanest)
Etidocaine (Duranest)
Mepivacaine (Carbocaine)
Articaine (Septocaine, Zorcaline)
Ropivacaine (Naropin)

total (10 mL per side). Lidocaine has an elimination half-life of 1.5 to 2.5 hours in most patients, and average infiltrative anesthesia lasts 2 to 6 hours. Bupivacaine has a longer onset and length of action and an elimination half-life of 2.7 hours in adults and 8 hours in neonates. Data on mixing lidocaine and bupivacaine are limited.

Some local anesthetics have epinephrine as an additive to help with hemostasis in very vascular locations. Buffering any local anesthetic containing epinephrine with a 1:10 ratio of sodium bicarbonate to anesthetic before injection helps reduce discomfort during the injection by neutralizing the acidic properties of the fluid. The current dogma is to avoid the use of epinephrine on end-artery areas, including fingers, ears, nose, lips, penis, and toes. However, a recent review on the use of local anesthesia with epinephrine in a digital block challenges this dogma (Mohan and Cherian, 2007). To be safe, epinephrine should not be used in distal-end vascular beds until the data are more conclusive. (See **Tuggy Video: Local Anesthesia.**)

Local Ring Anesthesia Block

For anesthesia around a superficial skin lesion, a ring block can be placed with good results. Use a larger needle to draw up the anesthetic and a 25- to 30-gauge needle to infiltrate the tissues. Insert the needle into the subcutaneous skin a few millimeters outside the planned incision line, and advance along that circular line around the lesion. Aspirate intermittently to ensure no flashback of blood, to avoid direct instillation of anesthetic into a vein or artery. Infiltrate the local anesthetic as the needle is advanced. Use anesthetized areas to puncture the skin, and inject more distal areas as needed around the planned surgical field until the lesion is fully circumscribed. Slow instillation with the anesthetic solution and warming the syringe by holding in the hand can make the infiltration more comfortable for the patient. Local anesthesia may be instilled through the subcutaneous tissue through a laceration side wall and may be less painful than going through intact skin.

Digital Block

A digital block can be an effective method for providing anesthesia for fingers and toes. A dorsal or interdigital approach is used to provide anesthesia to the digit. The digital nerves are 3 to 5 mm under the skin at the 2, 4, 8, and 10 o'clock positions around the digit. Each location can be infiltrated with 1 to 2 cc (mL) of 1% lidocaine without epinephrine. It may take 5 to 30 minutes for distal anesthesia to develop after injection. Occasionally, local anesthesia is needed at the base of the digit circumferentially if achieving complete anesthesia becomes difficult (**Fig. 28-2**). Patients may continue to feel pressure and motion but should not feel sharp pain when the anesthesia is effective. (See **Tuggy Video: Digital Block.**)

Complications with Local Anesthesia

Recognizing the various side effects and reactions to local anesthesia is critical to prevent serious complications. The most common complication with the use of local infiltrative anesthesia is a vasovagal episode. The patient may look pale, begin to sweat, and then feel faint or even fall unconscious.

Although accompanied by one or two tonic-clonic beats in some cases, this is not considered a seizure. Lying the patient down in reverse Trendelenburg positioning with both legs elevated can increase blood return to the heart and improve vagally depressed cardiac output. Atropine can reverse vagal bradycardia but is rarely needed. Recovery occurs spontaneously within minutes, but the queasiness may persist for 30 to 60 minutes.

Inadvertent instillation of an anesthetic into a blood vessel may cause seizures, jitteriness, or palpitations and may be avoided by always aspirating before infiltrating the local anesthetic. If a flash of blood is obtained on aspiration, pull the needle back partially, aspirate again, and instill only if no blood return occurs. Other reactions to local anesthesia are discomfort, bruising, and edema of the injection site. True anaphylaxis to lidocaine is estimated to occur in less than 1% of injections (Haugen and Brown, 2007). Administer diphenhydramine (Benadryl), 25 to 50 mg orally, intravenously, or intramuscularly in adults and 1 mg/kg in children, and epinephrine 1:1000 subcutaneously every 5 minutes as needed. The adult dose of epinephrine 1:1000 is 0.3 to 0.5 mL/kg and the pediatric dose 0.01 mL/kg at the same intervals. Emergency response personnel should be notified, and prolonged observation may be warranted.

Sedation

Some patients may require minimal to mild conscious sedation during a procedure in the outpatient clinic setting. Use of a low-dose benzodiazepine, such as 1 to 2 mg of lorazepam or 0.5 to 1 mg of alprazolam, may be appropriate for light conscious sedation. Sedation may also be accomplished with a dose of an oral opioid, such as hydrocodone or oxycodone. These patients should not operate a car or heavy machinery, and another person should provide their transportation. Use of an opioid in combination with a benzodiazepine may cause significant respiratory depression.

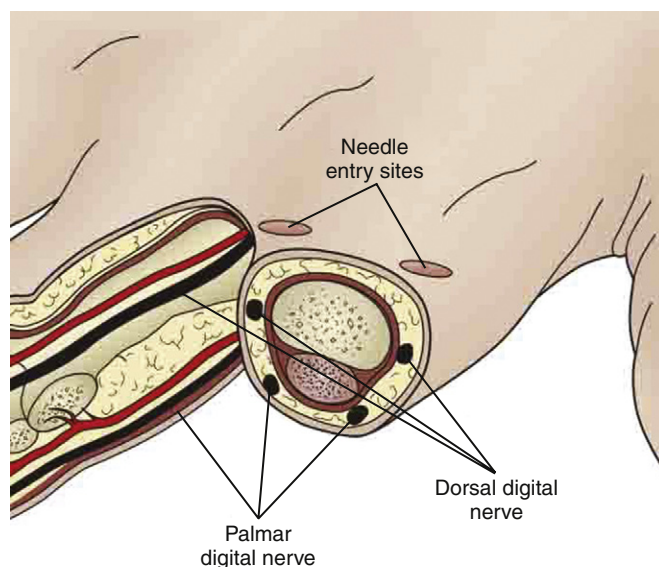

Figure 28-2 Digital nerve anatomy.

(From Frank BL. *Principles of pain management*. In Auerbach PS. *Wilderness Medicine*, 5th ed, Mosby-Elsevier, Philadelphia, 2007.)

This mixture is usually considered moderate to heavy sedation and requires additional constant monitoring of cardiac and oxygenation status, which may not be available in some ambulatory clinical practices.

Wound Irrigation

Wound healing is affected by infection, tension, perfusion, and alignment. Cleaning a wound with tap water or isotonic saline removes debris and bacteria mechanically from the wound and reduces infection rates. One study found no clinically important differences in infection rates between wounds irrigated with tap water or a normal saline solution (Valente et al., 2003).

Many studies recommend 7 psi (lb/in²) or greater for adequate irrigation of dirty wounds and 0.5 psi for clean wounds. Irrigation of the wound with a 35-mL syringe and a 19-gauge needle produces 7 psi, whereas using a bulb syringe only produces 0.5 psi, which is inadequate to flush and decontaminate a dirty wound. The potential for lateral subcutaneous dissemination with use of high-pressure irrigation can make a clean wound more susceptible to infection, so it should be reserved for contaminated wounds where benefits are greater than the risk of dissemination. The low-pressure bulb syringe is used for clean lacerations. The pressure is more important in dislodging adherent bacterial and small particles than the amount of solution used. Splash protection should be used by all health care personnel (Edlich et al., 2010).

There is debate on using povidone-iodine (Betadine) to cleanse dirty wounds. In general, avoid Betadine surgical scrubs within the laceration because it can be toxic to tissue. If used, dilute Betadine 1:10 with water. Chlorhexidine and hydrogen peroxide may also be toxic to tissue inside a laceration and should be used with care. Poloxamer-188 solutions are safe to use within wounds and are even used on ophthalmologic skin surgeries to cleanse the conjunctiva and by dentists to cleanse oral mucosa.

KEY TREATMENT

Studies recommend 7 psi or greater for adequate irrigation of dirty wounds (Edlich et al., 2010) (SOR: A).

Debridement

A dirty, uneven wound may benefit from direct sharp debridement back to clean viable tissue. Obtaining clean, even skin edges may improve healing, facilitate repair, and reduce scarring. If road grit is present, it must be removed to avoid infection and tattooing and may also need to be scrubbed. Generally, unless high-pressure irrigation is not removing grit, scrubbing is avoided because it may disrupt clotting along the skin edges. High-velocity trauma, soiled deep wounds, and fecal contamination represent wounds best cleaned in the operating room and allowed to heal open by secondary intention, as primary closure is contraindicated (Edlich et al., 2010).

Good anesthesia is critical to appropriate irrigation and debridement. If significant debridement is planned, the physician should document neurologic function in the injured area and distally before infiltration of the anesthetic.

Principles of Healing

Wound healing begins immediately after the initial trauma or cut. Traditional descriptions of wound healing use three distinct but overlapping phases (inflammatory, proliferative, remodeling), whereas others use four phases to better describe the healing process. Surgical technique and smoking are modifiable risk factors for poor wound healing. Other factors affecting wound healing include anemia, diabetes, malnutrition, HIV infection, and cancer.

Trauma to surrounding tissue by the injury and surgical techniques (e.g., too much tension on sutures) may affect healing. Adequate oxygenation and blood flow are critical to good healing. Medications that affect healing include steroids, NSAIDs, and immunosuppressive medications.

Stages of Healing

Exudative or Inflammatory Phase

Immediately after a laceration, fibrin deposits with an influx of platelets, forming a visible clot. The platelets secrete various wound-healing growth factors that activate macrophages and fibroblasts. These growth factors and more than 30 cytokines cause an influx of cellular structures. This phase occurs from 0 to 72 hours (Fig. 28-3).

Resorptive Phase

After 24 to 72 hours, the degradation products of fibrin lead to activation of chemotaxis in the resorptive phase. Leukocytes and macrophages migrate into the wound, causing inflammation. The cellular components then begin autolysis and remove injured tissue by a fermentative process. This process creates an effective phagocytosis, a sterilizing defense, and an activation of the immune system.

Proliferative Phase

Between 72 hours and day 7, fibroblasts migrate into the wound, and vascular proliferation occurs. Granulation tissue formation marks the proliferative phase. Epidermal cells begin to grow at the edges of the wound. A delicate balance of cytokine systems leads to new capillary formation to feed and oxygenate the budding granulation tissue. Extracellular matrices form and act as struts to support the new tissue. The primary clots are broken down by naturally developing fibrinolytic compounds (Fig. 28-4).

Regenerative or Remodeling Phase

The remodeling stage is a continuation of the proliferative phase, with ongoing maturation of collagen. The thickening collagen leads to an increased resistance to shearing and tearing forces. The regenerative phase is characterized by epithelialization and scar formation. This last phase may take up to 1 year. Collagen type III is converted into the mature type I collagen (Fig. 28-5). The extracellular matrix and cells within the wound are regulated by cytokines and integrins (transmembrane cell receptors) (Fig. 28-6).

Keloids

Keloids are fibrous elevated scars that extend outside wound margins. Keloids are unlikely to regress, are likely to recur if excised, and are most likely to occur in patients with darker skin (relative risk [RR] 15-20). Keloids are frequently located over the midline chest, cheeks, and earlobes, and peak incidence is age 10 to 20 years. Wounds that heal by secondary intention and burn wounds are high risks for developing keloids. Keloids may be painful as well as cosmetically unacceptable (Juckett and Hartman-Adams, 2009) (Fig. 28-7).

Figure 28-3 Cutaneous wound 3 days after injury. The cells and growth factors necessary to facilitate cell migration into the wound are shown. FGF, Fibroblast growth factor; IGF, insulin-like growth factor; KGF, keratinocyte growth factor; PDGF, platelet-derived growth factor; TGF, transforming growth factor; VEGF, vascular endothelial growth factor.

Hypertrophic Scars

Hypertrophic scars are limited to the wound edges and tend to regress over the first year. The treatment of both keloid and hypertrophic scars is similar, except hypertrophic scars have better outcomes. Genetic expression of various cytokines and inflammatory pathways may affect the myofibrocytes in granulation tissue to continue producing scar; the exact causes are being investigated. Pressure dressings and colloidal silicone placed on scars after suture removal or on burn scars may reduce the incidence of both keloids and hypertrophic scars, whereas onion-skin extract (Mederma) alone is not effective (Karagoz et al., 2009).

Hypertrophic scar fibroblasts exhibit resistance to a specific form of apoptosis, or cell death, elicited by contraction of collagen matrix gels. This phenomenon depends on excess activity of cell surface tissue transglutaminases (Linge et al., 2005).

KEY TREATMENT

Cryotherapy is useful for smaller lesions such as acne and keloids (SOR: B).
Pressure dressings in burns help prevent hypertrophic scars (SOR: B).
Intralesional corticosteroid injections are first-line primary care therapies for keloids; surgery is a second-line option (SOR: B).

Juckett and Hartman-Adams, 2009.

Wound Dressings

Covering the wound with an occlusive dressing prevents drying and allows the wound to be moist, promoting healing with collagen synthesis and angiogenesis (Field, 1994). Using a topical antibiotic reduces infection only in wound laceration repairs (Dire et al., 1995), not in elective hospital or office surgical procedures (Smack et al., 1996). Studies show no dressing preference for burn wound care (American Burn Association, 2001), although it should be based on wound origin, depth, size, location, exudate, and degree of contamination (Singer et al., 2008a). Wounds closed with tissue adhesives provide their own protection and require no additional dressing. Review warning signs of infection with the patient, and advise on standard postoperative wound care and timing of suture removal.

Figure 28-7 Skin keloid.

(From Habif TP. *Clinical Dermatology*, 5th ed. Elsevier, Philadelphia, 2010.)

Nonhealing Wounds

Patients underlying healing status may be affected by nutritional status and underlying medical conditions such as diabetes, cancer, and anemia. Healing may be slowed by smoking as well as age. Surgical repairs with too much tension on skin closure increase the chance of dehiscence and nonhealing. In the United States, chronic wounds affect 6.5 million patients. More than \$25 billion is spent annually on treatment of chronic wounds, and the burden is rapidly growing because of increasing health care costs, an aging population, and a sharp rise in the incidence of diabetes and obesity worldwide (Sen et al., 2009).

Principles of Skin Closure

Closure techniques should minimize skin trauma, result in good skin-edge approximation without undue tension, and result in a cosmetically pleasing appearance (Fig. 28-8). The best cosmetic results can be achieved by using the finest suture possible, depending on skin thickness and tension. Generally a 3-0 (000) or 4-0 (0000) suture is appropriate on the trunk, 4-0 or 5-0 on the extremities and scalp, and 5-0 or 6-0 on the face. Forceps with teeth and skin hooks should be used to reduce crush injury to wound edges. Use the least amount of sutures to close the skin with good approximation and without deep, open space. Sutures on the face should be removed about day 3 to day 5, wounds not under tension on day 7 to 10, and wounds under tension, on the hands, or over joints on day 10 to 14. If you remove a suture and the wound opens up, cease removing the other sutures and place a sterile strip while asking the patient to return in 2 days.

Sutures are an option along with staples, tissue adhesives, and use of hair to tie edges together on some scalp wounds. Avoid staples in the scalp if computed tomography (CT) or magnetic resonance imaging (MRI) is planned. Expedient cleaning, debridement, and closure with the least trauma to the wound and patient should be the goal.

Figure 28-8 Wound repair: skin closure. **A**, Too few stitches used. Note gaping between sutures. **B**, Too many stitches used. **C**, Correct number of stitches used for a wound under an average amount of tension. (From Lammers RL. *Methods of wound closure*. In Roberts JR, Hedges JR [eds]. *Clinical Procedures in Emergency Medicine*, 5th ed. Elsevier, Philadelphia, 2010.)

Skin Tension Orientation

Surgeons searching for an ideal guide for elective incisions have developed 36 named guidelines. Karl Langer (1819–1887) studied and drew skin lines of cleavage after noting that round punctures in cadaveric skin produced ellipses. The topographic orientation of these lines coincides with the dominant axis of mechanical tension in the skin. Langer lines were developed by studying skin tension in cadavers with rigor mortis and therefore may not be representative of a living human's skin tension lines. Kraissl noted tension lines in living tissue and developed lines oriented perpendicular to the contraction of the underlying muscles. Later, Borges described *relaxed skin tension lines* (RSTLs), which follow furrows formed when the skin is relaxed and are produced by pinching the skin. These are only guidelines, however, and many factors contribute to the camouflaging of scars, including wrinkles and contour lines. RSTLs are formed by the natural tension on the skin from underlying soft tissue and rigid bony or cartilaginous substructure.

Superior results in scar revision arise from making incisions parallel or nearly parallel to RSTLs. The Borges RSTLs and Kraissl lines may be the best guides for elective incisions of the face and body and are often mislabeled “Langer lines.” Cosmetic appearance is best if RSTLs are used on the face. The face can be divided into parallel variations of the four main facial lines: the facial median, nasolabial, facial marginal, and palpebral lines. When doing punch biopsies, stretch the skin 90 degrees perpendicular to follow the RSTLs so that the resulting ellipse-shaped wound and closure are parallel. This also improves cosmesis (Fig. 28-9).

Skin Tension on Closure

Ideally, any wound, excision, or repair should be designed so that the skin edges approximate under minimal tension. If not, and it is a clean laceration or elective excision, the surgeon may undermine tissue and trim to make edges approximate. Debridement or excision of the edges of dirty wounds may improve alignment and allow closure. Placement of

tension-relieving sutures or deep sutures should always be considered to facilitate direct closure of noninfected wounds under tension. If a suture is less than ideal, it is best to remove and replace it.

Tips and beveled lacerations are challenges because too much tension on the narrowest edges may contribute to necrosis or wound breakdown. Ideally, the skin sutures are used to approximate slightly everted edges and not to pull primary deep tissue under high tension. If the wound or excision has a clean approximation under minimal tension, a single-layer repair is preferred. If not, consider deep interrupted sutures to close the potential space (Fig. 28-10). The goal is also to avoid deep pockets where hematomas, infection, or abscesses could develop. (See Tuggy Video: *Inverted Subcuticular Stitches*.)

Tissue Adhesive

On clean lacerations under low tension in dry areas, skin adhesives are an appropriate substitute for standard suturing materials and methods. Adhesives may also work on shallow, irregular, beveled lacerations and are useful on pediatric scalp lacerations. Since 1998, the long-chain medical tissue adhesive, 8-carbon 2-octylcyanoacrylate (OCA), has been available in the United States for tissue adhesive closure of wounds. OCA is more durable and flexible than the short-chain butylcyanoacrylates. The long-chain cyanoacrylates create less dehiscence in wounds longer than 8 cm. Avoid adhesive use in moist or hairy areas, on mucous membranes, if hemostasis is required, over joints or highly mobile tissue, and in bite wounds or dirty lacerations. Consider the adhesives to have about the same strength as 5.0 sutures. If OCAs are used, the patient may shower immediately, but if the butylcyanoacrylates are used, the repaired wound should be kept dry for at least 48 hours. Moisture exposure increases dehiscence risk (Singer and Dagum, 2008). If the area to repair is under higher tension, deep sutures to approximate the skin edges before closing with a superficial adhesive results in better outcomes (Singer and Thode, 2004).

Tissue adhesive agents form their own bandage, and no additional care is needed. Full tensile strength is achieved after 2½ minutes. Because antibiotic and white petrolatum ointments can remove tissue adhesive, patients must be instructed to avoid using these on the repaired wound (Forsch, 2008).

Dehiscence occurred on 2.5% of wounds closed with tissue adhesives in an animal study comparing 2-cm and 10-cm laceration repairs with adhesive versus various suture types and different stitches. In the 2-cm wounds, results were identical. The 10-cm wounds favored deep suturing even if tissue adhesive was used. The final decision on the method and materials used for wound closure depends on the length and location of the wound as well as the time for closure and efficiency of closure (Zeplin et al., 2007). (See Tuggy Video: *Tissue Glue*.)

KEY TREATMENT

Wound closure of superficial lacerations by tissue adhesives is quicker and less painful compared with conventional suturing, with similar outcome on appropriate wounds (Aukerman et al., 2005) (SOR: A).

Suture Placement

Interrupted Sutures

Individually placed single sutures are the most common form of closure. Although slower than using a running suture, single sutures usually appear better cosmetically and have a reduced risk for dehiscence. Slightly everting skin edges will result in the best wound appearance. Enter the skin 2 to 3 mm from the skin edge with the needle perpendicular to the skin plane, and rotate the wrist smoothly. Go an equal distance in depth as the horizontal distance from the wound edge. If unable to obtain an equidistant bite on the opposite side in one step, use an additional step. Bring the needle out through the laceration, then enter at the same level within the laceration, and come out through the skin at a symmetric distance from the wound's edge (Fig. 28-11). (See **Tuggy Video: Instrument Tie**.)

One may reduce the risk for dog-ears by placing a suture in the middle of a laceration and then another in the middle of the remaining gaps until equal tension and alignment approximate the skin edges in a cosmetic and hemostatic fashion. If bleeding persists, ligate or cauterize the vessel before further closing. If suturing a landmark such as vermilion borders on lip edges, consider marking opposing points before instilling anesthesia, then place an aligning suture there first.

Planning excision of an ellipse with a 3:1 to 4:1 length/width ratio has been the standard recommendation, but recent data suggest less tissue removal and better healing if a round excision is used, with adequate margins and repair of any subsequent dog-ears that develop. With this technique, 59% of the repairs required dog-ear repair (Seo et al., 2008).

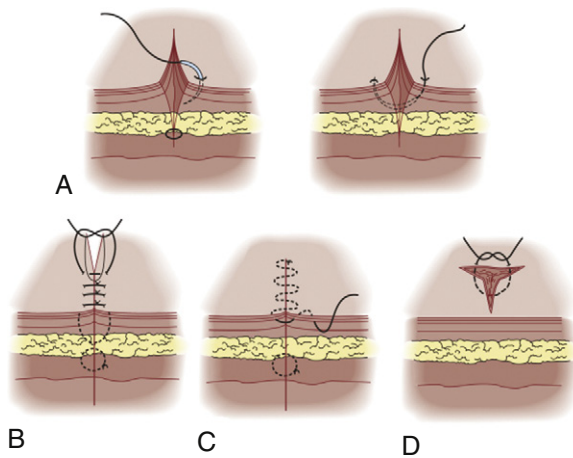

Figure 28-11 Suture technique and methods. **A**, Sutures are placed through the entire thickness of the dermis at right angles to the skin and suture line while everting the wound edge. **B**, Sutures are placed 2 to 3 mm apart and 2 to 3 mm from the wound edge. **C**, The subcuticular stitch prevents crosshatch scarring. **D**, Intradermal sutures help preserve peninsular flaps in this stellate wound.

(Modified from Wright CV, Ronaghan JE: Office surgery. In Rakek R. *Textbook of Family Practice*, 5th ed. Philadelphia, Saunders, 1995.)

Running Sutures

If rapid suture placement is needed and an area is not over a joint with movement, the physician can use a running suture. If the suture breaks, however, the entire wound would open up. If the running sutures are left too long, “baseball lacing” tracks may remain visible on the skin. In one study (not funded by manufacturers), deeply buried absorbable suture used along with running subcuticular polyglactin 910 (Vicryl) suture left in place resulted in the best results on trunk and extremity scar healing from elective excision of atypical moles (Alam et al., 2006).

Subcuticular Sutures

Halstead first described the subcuticular suturing technique in 1889 as a way to approximate wound edges with the least scarring. A running intradermal, buried subcuticular suture is useful in places where the dermis is shallow and when skin edges are well approximated under minimal tension, such as on the face. Placing subcuticular sutures on the back, chest, and other areas under tension without deep interrupted sutures may give poor results.

For subcuticular suture placement, use either absorbable or nonabsorbable 4-0 suture and anchor it on one end external to the wound. Enter the skin and come out in the apex of one end of the wound. Place horizontal subcuticular zigzagging sutures with symmetric bites and level entry and reentry sites on each side of the wound. If using absorbable suture, tie and bury a knot at the end of the wound by tying the knot and then placing a stitch to come out through the skin near the wound, then cut the suture flush with the skin while pulling upward on the suture. The knot will be retracted below the skin. Alternatively, with either absorbable or nonabsorbable suture, enter and exit the skin away from the wound, and tie off the suture externally. A nonabsorbable suture may be removed after 1 to 3 weeks by cutting one end of suture and gently pulling with countertraction from the other end of the wound. (See Tuggy Video: Subcuticular Running Stitches.)

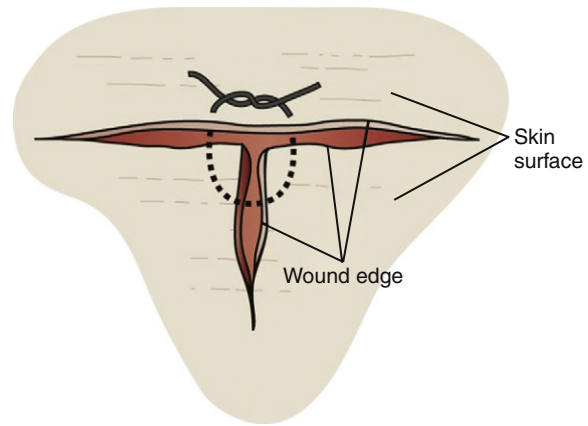

Figure 28-12 View from above stellate laceration, showing closure with half-buried mattress stitches. For some stellate lacerations, it is best to cover with Steri-Strips and revise the scar later or, if small, excise the laceration and convert it to a linear repair.

(From Lammers RL. *Methods of wound closure*. In Roberts JR, Hedges JR [eds]. *Clinical Procedures in Emergency Medicine*, 5th ed. Elsevier, Philadelphia, 2010.)

Half-Buried Mattress or Tip Sutures

Half-buried mattress sutures can be used on stellate edges and on triangular defects to reapproximate the skin edges with reduced tension on the tips (Fig. 28-12). Tip sutures are similar and used to secure a laceration tip with minimal tension. This tension can reduce blood and oxygen flow to the distal tip. (See Tuggy Video: Mattress Stitches.)

Pulley Sutures

The far-near, near-far pulley sutures are a modification of the vertical mattress suture and may be used as a temporary measure to reduce tension and approximate skin edges to place interrupted sutures. These sutures are used for longer repairs, but do not leave them in too long or place them too tightly because cross-hatching scars may occur. Enter with the needle 4 to 6 mm back from the wound edge, come out on the opposite side 2 mm from the wound, and loop back across the wound opening, then enter the skin 2 mm from the edge and come out on the opposite side 4 to 6 mm back from the edge (Wu, 2006).

Modified pulley sutures offer some mechanical advantage in vitro by requiring less force to achieve closure compared with horizontal mattress or single interrupted sutures. These pulley sutures are generally used when a wound is under moderate tension (Austin and Henderson, 2006).

Z-Plasty

The Z-plasty technique is used to improve the appearance of long scars, correct contractures over joints, and change the orientation of the scar line to align better with RSTLs. The key is to measure the laceration, then draw a line of the same length as the laceration on each side of the laceration at 60-degree angles for proper alignment on the repair (Fig. 28-13).

Complications

Dog-ear formations occur when the two edges of a wound are not equal length. Tissue may be trimmed before suturing. An ellipse can be cut around the dog-ear, or an

Figure 28-13 Classic equilateral triangle 60-degree Z-plasty.

(Modified from Thomas JR, Holt GR. *Facial Scars, Incisions, Revision, and Camouflage*. St Louis, 1989, Mosby; and Thomas JR, Moblely SR. *Scar revision and camouflage*. In Cummings CW, Flint PW, Haughey BH, et al. *Otolaryngology: Head and Neck Surgery*, 4th ed. Mosby-Elsevier, Philadelphia, 2005.)

extension laterally at an angle, and then repaired (Fig. 28-14). Another technique is called “leashing the dog-ear.” Tie off the repair near the start of the dog-ear. Place a single, interrupted suture by diving through the wound along the axis of the wound and out behind the dog-ear. When tied down, this suture may flatten a small dog-ear (Khachemoune et al., 2005).

Excisions

Incisions should be made perpendicular to the skin with symmetric edges and no angulation. Poor technique may jeopardize healing. For best results, the physician should make an ellipse with the length three to four times the width. If a portion of a pigmented lesion has a worrisome appearance, complete excision is recommended. The American Cancer Society uses the ABCDE mnemonic to recognize lesions of most concern: *A*, asymmetry; *B*, border irregularity; *C*, more than one color; *D*, diameter greater than 6 mm; and *E*, increased elevation or enlargement. If a lesion has one or more of these concerns, an excisional biopsy should be considered. In other lesions, the clinician may consider a shave biopsy or punch biopsy. (See **Tuggy Videos: Excisional Skin Biopsy, Punch Biopsy, Shave Biopsy**.)

Atypical Moles and Pigmented Lesions

Elliptic full-thickness excisional biopsies are preferred for any suspicious pigmented mole. Punch biopsies can easily miss a high number of positive findings because of fusiform invasion of the margins (Chang et al., 2009).

Management of dysplastic nevi with positive margins remains controversial. Although a National Institutes of Health (NIH) Consensus Conference established margin guidelines for reexcision of dysplastic nevi (0.2-0.5 cm), it did not specify indications for reexcision. No clear guidelines exist regarding whether an incompletely removed nevus with a mild or moderate degree of dysplasia should be reexcised. Dermatopathologists are discordant in identifying dysplasia and differing degrees of atypia, further complicating

Figure 28-14 Dog-ear repair.

(Modified from Simon BC. *Skin and subcutaneous tissue*. In Rosen P et al [eds]: *Atlas of Emergency Procedures*. St Louis, Mosby, 2001; and Simon B, Hern HG. *Soft tissue injuries*. In Marx JA. *Rosen's Emergency Medicine*, 7th ed. Philadelphia, Mosby-Elsevier, 2009.)

decision making. Most dermatologists recommend that nevi with severe atypia should be reexcised because they may represent early melanoma or a lesion evolving into melanoma (Goodson et al., 2009).

Despite recurrence rates of 8% to 20% and a growing body of literature suggesting the inadequacy of a 5-mm marginal excision, a definitive change has not been made in recommended guidelines. In 2008 the National Cancer Comprehensive Network published guidelines indicating that a 5-mm excisional margin may be inadequate for lentigo maligna and lentigo maligna melanoma (Bosbous et al., 2009).

Melanomas account for 90% of the deaths associated with cutaneous tumors. Confirmed melanomas are initially excised with 10- to 20-mm safety margins both in depth and laterally if possible. Full-thickness depth is therefore important in diagnosis and prognosis of melanomas. Unsuspected melanomas found in excisional biopsies should have their bases reexcised for appropriate 1- to 2-cm margins as a second procedure. Sentinel lymph node dissection is routinely offered as a staging procedure in patients with tumors more than 1 mm in thickness, although there is as yet no resultant survival benefit. Interferon- α can be offered as adjuvant therapy to patients with melanoma more than 1.5 mm thick and stage II to III because it increases relapse-free survival.

KEY TREATMENT

Elliptic full-thickness excisional biopsies are preferred for suspicious pigmented moles (Chang et al., 2009) (SOR: A).
 A 5-mm excisional margin may be inadequate for lentigo maligna and lentigo maligna melanoma (Bosbous et al., 2009) (SOR: A).
 Confirmed melanomas are initially excised with 10- to 20-mm safety margins (SOR: A).

Basal Cell Cancer

The excision of small basal cell cancers (BCCAs) of less than 20 mm with well-defined borders and a 3-mm peripheral surgical margin will remove the tumor in 85% of cases. A 4- to 5-mm peripheral margin will increase the clearance rate to approximately 95%. Approximately 5% of small, well-defined BCCAs extend more than 4 mm beyond their apparent clinical margins. Morpheic (morpheaform) and large BCCAs require wider surgical margins to maximize the chance of complete histologic removal. On initial removal of morpheic lesions, the rate of complete excision with a 3-mm margin is 66%; 5-mm margin, 82%; and 13- to 15-mm margin, over 95% (Telfer et al., 2008).

Standard vertical-section processing of excision specimens allows the pathologist only to examine representative areas of the peripheral and deep surgical margins, and at best an estimated 44% of the entire margin can be examined in this manner. Therefore, tumors that appear fully excised occasionally recur (Telfer et al., 2008). If the BCCA is on an area with little excisable tissue, consider Mohs microscopic surgery to obtain adequate margins and minimize tissue removal.

If the BCCA lesion is completely excised, the recurrence rate is about 1%. If not completely excised, BCCAs have recurrence rates of 17% to 35% for lateral-margin positivity and 33% for deep-margin positivity. Only a third of positive-margin BCCA lesions recur, so the physician might reexcise the margins or consider reexcision only if a recurrence develops, with the following exceptions: lesions of long duration, size greater than 2 cm, previous recurrence, and aggressive histologic features, including perineural and perivascular invasion and infiltrative, morpheaform, or micronodular appearance. If marginal positivity is detected in such cases after excision, reexcision and removal of the residual tumor is advised over watchful observance (Ünlü et al., 2009). (See **Tuggy Video: Basal Cell Curettage and Cautery.**)

KEY TREATMENT

A 4- to 5-mm peripheral margin will increase the cure rate of BCCAs to approximately 95% (Telfer et al., 2008) (SOR: A).
 Morpheaform and large basal cell cancers require wider surgical margins (Telfer et al., 2008) (SOR: A).

Cryotherapy

Cryotherapy can be easily mastered for treatment of many skin lesions. Cryotherapy is well tolerated and results in minimal to no scar. It is best used in those with lighter skin and in non-hair-bearing areas because of occasional pigment changes or hair loss with deeper treatments. Liquid nitrogen, the most widely available, cost-effective cryogen for medical therapy,

boils at -196°C , and temperatures of -25°C to -50°C can be achieved in 30 seconds of appropriate skin application. Destruction of benign lesions occurs at -20°C to -30°C , and malignant lesions often require temperatures of -40°C to -50°C for destruction (Andrews, 2004). Correct use of cryotherapy results in selective cell destruction while sparing the tissue matrix of collagen and fibroelastic tissue and reducing the risk of scar formation. Repeated freeze-thaw applications can increase tissue damage.

Indications and Contraindications

Cryotherapy can be an important treatment option for many lesions commonly encountered in a primary care clinical practice. It can be used in all age groups to treat a number of dermatologic lesions. Even though well tolerated, cryosurgery also has contraindications (**Box 28-2**). Some body areas or conditions should be approached with prudence because of increased complication risks. Basal cell cancers, particularly in the nasolabial fold or periauricular area, tend to be

Box 28-2 Cryotherapy: Indications and Contraindications**Indications**

Verruca (warts)
 Condylomata acuminata
 Papular nevi
 Selected basal cell cancer

more extensive than expected and more likely to recur. The vermilion border, periorbital area, and areas overlying cutaneous nerves present confounding variables to safe application of a cryogen for therapy.

Equipment and Technique

Liquid nitrogen can be applied with a regular or modified cotton-tipped applicator, cryogen spray device, or cryoprobe, all readily available to providers. The cotton-tipped applicator is the least expensive and can be modified to hold more cryogen or to match the size or shape of the lesion with a cotton ball. Liquid nitrogen can be stored in an insulated device in the office and taken out in small aliquots in a polystyrene cup for individual use with patients.

Handheld cryogen spray devices have recently been improving. Traditional cryotherapy systems provide a reservoir for the liquid nitrogen and an applicator tip to dispense the cryogen. The applicator tip can have a varying aperture for altering cryogen dispersion. Some providers use an otoscopy cone to protect surrounding skin and direct the spray onto a small central lesion. The unit is generally held 1 to 2 cm above the lesion and the spray directed at a 90-degree angle and aimed at the lesion center. Newer spray devices use a continuous infrared sensing device to determine the treatment site skin temperature and ensure consistent freeze times. These modifications can improve accuracy and assist in achieving optimum cryotherapy results (Cry-Ac Tracker, www.brymill.com).

Prior to cryotherapy, the depth and diameter of the freeze must be anticipated to minimize injury to surrounding tissues. Mark the skin to ensure adequate treatment in critical cryotherapy sessions. Keratin layers are very resistant to cryotherapy and can be treated for 1 to 2 weeks with topical 40% salicylic acid plaster or mechanically pared away before freezing. Application of salicylic acid alone is equally efficacious to cryotherapy of warts for many patients (Gibbs and Harvey, 2006). A well-hydrated skin lesion can increase cryotherapy success rates.

For superficial benign skin lesions, the cryotherapy applicator should almost cover the lesion and should be applied for 20 to 40 seconds to create an ice ball edge 2 to 3 mm beyond the edge of the lesion. In contrast, deeper or premalignant lesions should be treated with an applicator smaller than the lesion to ensure a depth more equal to the radius of treatment. It should be applied for 40 to 90 seconds to form an ice ball 3 to 4 mm outside the lesion. Superficial malignant lesions also require a smaller applicator, but applied for 1 to 3 minutes for an ice ball 5 to 8 mm beyond the lesion. Malignant cells are more resistant to cryotherapy, and destruction requires temperatures at -40° to -50° C. In most cases the depth of a freeze is similar to the radius of the superficial ice ball formed. The lethal zone for tissue destruction is 2 to 3.5 mm inward from the outer margin of the ice ball (Pfenninger, 2003).

Complications

Cryotherapy results in minimal scarring. Vascular or hypertrophic lesions are resistant and sometimes require multiple treatments 2 to 3 weeks apart. Most patients may experience pain and burning for 1 to 2 days. During these first days, the skin may be red and sensitive and may form a hemorrhagic bulla followed by sloughing. Infection and pyogenic granuloma formation are rare complications. In deeper cryotherapy,

the potential damage to underlying neural structures must be considered. (See Tuggy Video: Wart Treatment.)

KEY TREATMENT

A significant keratin layer is resistant to cryotherapy (SOR: B).
The lethal zone for cryogen tissue destruction is 2 to 3.5 mm inward from the outer margin of the ice ball (Pfenninger, 2003) (SOR: A).
Salicylic acid application alone to warts is equally efficacious to cryotherapy (Gibbs and Harvey, 2006) (SOR: A).

Incision and Drainage of Cutaneous Abscess

A cutaneous abscess is identified by a fluctuance or compressible softness in skin surrounded by induration, inflammation, warmth, and tenderness. *Furuncles* are superficial and result from abscess formation in a sweat gland or hair follicle. *Carbuncles* are deeper and extend into the subcutaneous tissue. Offending bacteria include *Staphylococcus aureus*, streptococci, and occasionally gram-negative rods. These infections can be severe in patients with diabetes or vascular disease. Primary treatment of an abscess is surgical drainage. An area of induration alone with no fluctuance indicates isolated cellulitis and is treated with antibiotics and warm compresses.

When performing an incision and drainage of an abscess, the skin is prepared with a sterilizing and cleansing agent. Local anesthetics do not work well in the acidic environment of an abscess, so a ring or field block can be infiltrated around the periphery of the lesion. Superficial cooling of the surface of the skin with ethyl chloride or liquid nitrogen can also provide brief anesthesia for a stab incision.

A linear incision is made over the area of maximal fluctuance and has been shown to heal in a shorter time than derroofing procedures used in the past (Sørensen et al., 1987). Once the incision is made into the center of the abscess with a #11 blade, the abscess cavity is probed with a curved hemostat to disrupt any loculations. The abscess cavity is packed with ¼- to 1-inch gauze to prevent early superficial wound closure and allow secondary healing. Primary closure is not recommended (Korownyk, 2007). A bulky sterile dressing can be applied to absorb any drainage and the packing and dressing changed every 1 to 2 days or when soiled. Evidence does not support using oral antibiotics after surgical drainage. Routine swabbing for culture in immunocompetent individuals is not recommended (Korownyk, 2007). Patients are educated on wound care and return in 2 to 7 days for follow-up. (See Tuggy Video: Abscess Incision and Drainage.)

Recurrent skin abscesses should be investigated based on location. Crohn's disease, subcutaneous fistulas, and pilonidal cysts can present as recurrent cutaneous abscesses. MRSA should be suspected in recurrences as well.

KEY TREATMENT

Primary treatment of an abscess is surgical drainage (SOR: A).
Incision and drainage of an uncomplicated abscess does not require oral antibiotic treatment (SOR: A).
Routine culture of abscess drainage in immunocompetent individuals is not recommended (SOR: A).

Korownyk, 2007.

Lipomas

Lipomas are mature adipose tissue arranged in a nodular formation surrounded by a capsule and commonly located in the subcutaneous tissues. Lipomas can be diagnosed by clinical examination and identification of their unique, well-circumscribed, round, mobile character with a doughy consistency. Although most do not require it, excision may be considered for large tumors, rapidly growing lipomas, and those causing pain. Lipomas can occur in isolation or with other systemic diseases, as a component of genetically inherited disorders, or in other connective tissue layers.

A steroid injection or liposuction can be used to treat select lipomas. Steroid injections can be used to treat painful lipomas less than 1 inch (2.5 cm) in size and in which pathologic examination is likely unnecessary. An injection of 1 to 3 mL of triamcinolone diluted with 1% lidocaine to a 10 mg/mL concentration can be performed into the center of the lipoma monthly to shrink the tumor to the desired size. Formal liposuction can be done with cannula or 16-gauge syringe under local anesthesia (Salam, 2002). Neither of these procedures is likely to eliminate the lipoma in its entirety, and recurrences are frequent.

Surgical excision of a lipoma removes the neoplasm from the tissue and allows for pathologic examination. Marking the boundaries of the lipoma is helpful for identification of the tumor edges before a local anesthetic field block is placed. The skin is prepared with a povidone-iodine or chlorhexidine solution. Small lipomas can be enucleated with their capsule using blunt dissection through a small incision. Larger lipomas require excision through a linear or elliptical incision. Blunt and sharp dissection can be used to free the mass from the surrounding tissues using hemostats or clamps for traction. Hemostasis should be confirmed and cautery or ligature placement used to ensure a dry wound base. The remaining dead space is closed with buried, interrupted, dissolvable subcutaneous sutures and the skin closed with interrupted sutures or staples depending on location and cosmetic need. A compression dressing should be used for 1 to 2 days to prevent formation of a hematoma, and sutures are removed in 5 to 10 days depending on location. Submit any specimen for pathologic examination. (See Tuggy Video: Lipoma Removal.)

Surgery of the Nail and Digits

Ingrown Nail (Onychocryptosis)

The great toe's lateral and distal nail beds are the most common locations for ingrown nails. Poorly fitting shoes, poor nail-trimming techniques, and trauma can result in their formation. Most ingrown nails respond to conservative local treatment of warm soaks and elevation of the distal nail with cotton to allow unobstructed nail growth. If poor toenail trimming is the cause, a shard of nail is impaling the distal lateral nail groove and can be simply trimmed and removed for resolution of pain with standard curved or straight iris scissors.

When conservative measures fail, a partial or complete nail excision is performed to remove the portion of offending nail. The digit is prepared and a digit block placed using

1% lidocaine. A tourniquet at the base of the toe can help with hemostasis. A nail elevator is used to separate the section of nail to be removed from the underlying nail bed down to the base of the nail and germinal matrix and from the cuticle. Once elevated, an iris or bandage scissors can be used to cut the nail longitudinally to the matrix. A straight hemostat is used to grasp the nail, and the nail is rolled laterally for removal. Hemostasis can be obtained with compression or silver nitrate. A bulky tube-gauze dressing can be placed for protection. Recurrent ingrown nails unresponsive to conservative measures can be ablated after nail removal. A phenol solution is applied to a hemostatic germinal nail matrix under the proximal nail fold for 30 to 60 seconds before neutralizing the phenol with rubbing alcohol. (See Tuggy Video: Ingrown Toenail Removal.)

Nail Plate Avulsion for Onychomycosis

Conservative treatment of onychomycosis is the first-line choice for management. A fungal culture of nail clippings can be done to confirm the diagnosis but may take up to 1 month for growth and identification. There is good evidence that oral terbinafine, 250 mg daily for 3 months, is the most effective oral treatment for fungally infected toenails (Crawford et al., 2002). Even with terbinafine, failure rates can reach 50%. When onychomycosis causes dystrophic nails resulting in pain or toe dysfunction, a complete nail plate avulsion can be performed, with high patient satisfaction (see Ingrown Nail).

KEY TREATMENT

Oral terbinafine, 250 mg daily for 3 months, is the most effective oral treatment for fungally infected toenails (Crawford et al., 2002) (SOR: A).

Paronychia

An *acute* paronychia is caused by a bacterial infection of the lateral or proximal nail folds after minimal to significant trauma, whereas a *chronic* paronychia results from an inflammatory condition caused by repetitive irritant contact exposure. Acute paronychia can be treated conservatively with warm soaks, gentle compression, topical steroid creams, and topical or oral antibiotics (Rigopoulos et al., 2008). Chronic paronychias respond to removal of the offending agent or treatment of the underlying condition or inflammatory cause.

When the local cellulitis of an acute paronychia develops into an abscess, drainage is indicated. If the fluctuant pocket of the abscess is superficial and underlying the cuticle or nail fold, a 23-gauge needle or #11 blade tip can be used to lift the edge of the fold and allow drainage without local anesthesia. A digital nerve block can be performed if the infection is deeper and requires more extensive drainage or for patient comfort. Once anesthetized, an incision can be placed parallel to the nail fold with a stab incision using a #11 bladed into the abscess with subsequent drainage and exploration to break up loculations as needed. Warm soaks should follow with oral antibiotics for the cellulitis (Fig. 28-15).

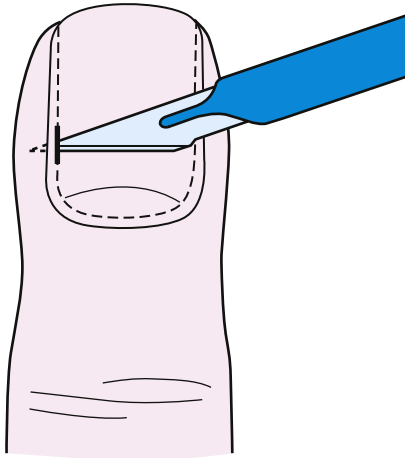

Figure 28-15 Incision and drainage of paronychia. The tip of a #11 scalpel is advanced just under the cuticle and parallel to the nail. The size of the incision should be large enough to include all fluctuant areas and no more. (From Chavez MC, Maker VK. Office surgery. In Rakel RE. *Textbook of Family Medicine*, 7th ed. Saunders-Elsevier, Philadelphia, 2007.)

Evacuation of Subungual Hematoma

Trauma to the nail causing bleeding between the nail plate and nail bed can be excruciatingly painful. Subungual hematomas can be drained easily in an office setting by creating a 2-mm hole in the nail and draining the blood, using a handheld cautery unit or heated end of a metal paper clip. If trauma was significant, with the hematoma involving more than 50% of the nail, the provider should consider a nail bed laceration requiring primary closure, and this should be radiographically evaluated. Frequently, phalanx tuft fractures can underlie the hematoma after significant trauma (Wang and Johnson, 2001).

Anorectal Disease

Bleeding, pain, discharge, or change in bowel habits can indicate active anorectal disease, and all warrant medical evaluation. The patient history and a complete anorectal examination lead to a clear diagnosis in most complaints. Inflamed internal hemorrhoids or rectal polyps typically cause painless rectal bleeding. Painful anal bleeding can result from anal fissures, proctitis, thrombosed external hemorrhoids, or a draining perianal abscess. Palpable chronic masses can indicate an anal skin tag, polyp, or prolapsed rectal mass, and acute masses are usually caused by abscesses or thrombosed hemorrhoids. More than 90% of anorectal complaints can be managed in the primary care physician's office using simple techniques (Pfenninger and Zainea, 2001).

Anoscopy

Anoscopy is performed easily in the office to evaluate and treat many anorectal conditions. Scopes can be 7 to 10 cm long and 2 to 3 cm wide and range from a slotted or beveled metal version to a disposable plastic tubular version. The tubular version can be used for diagnosis, whereas the slotted style allows for ease in treating most anorectal conditions.

For a thorough examination, the patient can be placed in a comfortable lateral decubitus position with hips flexed. The examiner may require nonpermeable protective clothing and eyewear. The anal tissues should be examined for tags, hemorrhoids, fissures, dermatitis, condylomata, and masses. A digital rectal examination should precede anoscopy to assess for internal pain or mass.

During examination the thumb can be pressed against the internal index finger to determine tenderness, induration, or abscess formation in the perianal tissues in all quadrants. The lubricated anoscope with obturator is introduced fully into the anal canal with gentle, constant pressure. Once fully inserted, the obturator is removed and the anorectal mucosa visualized through 360 degrees during gradual withdrawal. Adequate lighting is essential. Valsalva maneuver may distend vascular lesions for ease in visibility. Anal Pap smears can be obtained if warranted for anorectal cancer concerns and biopsies performed using a Kevorkian or Tischler biopsy forceps. Hemostasis is obtained using silver nitrate sticks. (See Tuggy Video: Anoscopy.)

Hemorrhoids

Hemorrhoids are submucosal vascular beds located in the anal and rectal canal that assist with defecation and the sensation of anorectal fullness. These vascular beds can occur in insensate areas above the dentate line as *internal* hemorrhoids or below the dentate line as *external* hemorrhoids in exquisitely sensitive areas. Hemorrhoid development may result from genetic factors, aging or serial local trauma. One study found that 4.4% of the U.S. population, or 10 million people, complain of hemorrhoid disease (Reese et al., 2009).

Internal Hemorrhoids

Internal hemorrhoids are classified according to the severity of prolapse. No rectal prolapse occurs with first-degree hemorrhoids, and spontaneously reducible prolapse occurs with second-degree disease. These can be treated with conservative or surgical methods. Third-degree hemorrhoids prolapse and require manual reduction, and fourth-degree hemorrhoids have irreducible prolapse. As the prolapse progresses, surgical treatment becomes a more common treatment.

Painless, bright-red rectal bleeding is the primary symptom of internal hemorrhoids. Anoscopy can be used for identification of the site of bleeding acutely. Internal hemorrhoids typically occur in three locations in the anal canal: right anterior, right posterior, and left lateral. A flexible sigmoidoscopy or colonoscopy is performed if the patient's symptoms or history warrant more extensive colonic evaluation, or if the site of colorectal bleeding is not easily identified or persists after treatment. Patients over age 40 who have hemorrhoidal bleeding may have other colorectal pathology and should have further colorectal evaluation (Chong and Bartolo, 2008).

Dietary management consisting of adequate fluid and fiber intake is the primary noninvasive treatment of symptomatic hemorrhoids (Cataldo et al., 2005). Persistent hemorrhoid symptoms decreased by 53% in those receiving dietary fiber for hemorrhoid care (Alonso-Coello et al., 2005). Conservative therapy can be offered for mild first- and second-degree hemorrhoids, but more advanced disease may require surgical

management. Rubber band ligation or hemorrhoid banding is known to be highly effective in outpatient treatment of first-, second-, and some third-degree internal hemorrhoids (Reese et al., 2009). Other options include sclerotherapy, infrared coagulation, radiofrequency coagulation, and cryotherapy (Cataldo et al., 2005).

Prolapsing internal hemorrhoids can be easily treated in the office with *rubber band ligation* using a McGillvney ligator or similar device. After appropriate consent is obtained, a slotted or beveled anoscope is inserted into the anus. The hemorrhoid is then identified, and with the circular McGillvney ligator in place within the anoscope, the hemorrhoid is grasped with a forceps and drawn into the ligator cylinder. Sensation of the hemorrhoid is assessed to prevent ligation of a high external hemorrhoid. Care is taken not to draw too much tissue into the ligator to avoid denuding the anal lining. Once the base of the hemorrhoid is in the ligator, two rubber bands are released from the ligator by one cylinder sliding over the other. The bands cause ischemic necrosis of the hemorrhoid, and the tissue sloughs over days. Bleeding can occur for up to 1 to 2 weeks and is occasionally significant. Patients may feel some rectal fullness, a spasm, or dull ache for a few days after banding. Rare episodes of pelvic cellulitis have been reported. Only one site should be treated per patient visit (Fig. 28-16). (See **Tuggy Video: Internal Hemorrhoid Banding.**)

Sclerotherapy can be performed on first- and second-degree hemorrhoids using a sclerosant of 5% phenol or saline. The base of the hemorrhoid is injected with 1 to 2 mL of the sclerosant through a syringe while viewed through an anoscope. More late complications can be seen with sclerotherapy when compared to banding. In a recent systematic review, sclerotherapy had unknown effectiveness in treating hemorrhoids. Infrared photocoagulation was found to be likely beneficial and as effective as rubber band ligation in the same review. The infrared coagulator light is fired three to five times at the base of the hemorrhoid through an anoscope for 1.5 seconds during one treatment session. Multiple sessions may be required for infrared treatment of first-degree through small third-degree hemorrhoids. Radiofrequency coagulation is performed with a Bicap probe placed at the base of the hemorrhoid above the dentate line and activated four to six times for 2 seconds, forming a white coagulum.

Because of prolonged healing after cryotherapy, it is no longer recommended (Reese et al., 2009).

KEY TREATMENT

Patients over the age of 40 who have hemorrhoidal bleeding cannot be assumed to have no other colorectal pathology and should have further colorectal evaluation. (Chong and Bartolo, 2008) (SOR: B).

Dietary management of symptomatic hemorrhoids consists of adequate fluid and fiber intake (Alonso-Coello et al., 2005) (SOR: B).

Rubber band ligation is known to be highly effective outpatient treatment for first-, second-, and some third-degree hemorrhoids (Reese et al., 2009) (SOR: B).

External Hemorrhoids

A nonpainful or painful anal swelling can represent an external hemorrhoid. Hemorrhoids should be differentiated from anal skin tags, condylomata, fissures, and

Figure 28-16 Rubber band ligation for internal hemorrhoid. The band is advanced onto the end of the ligator instrument using a conical attachment (*insets*). The hemorrhoid is identified at a level proximal to the dentate; this area is tested for sensation before banding. Occluding the suction port of the ligator instrument draws the hemorrhoid into the open end of the ligator, and the instrument is fired. The banded hemorrhoid typically sloughs in 1 week. (Courtesy Mayo Foundation; and Nelson H, Cima RR. Anus. In Townsend CM, Beauchamp RD, Evers BM, Mattox KL [eds]. *Sabiston Textbook of Surgery*, 18th ed. Saunders-Elsevier, Philadelphia, 2008.)

abscesses on anal examination. Symptomatic external hemorrhoids can be excised if conservative treatment fails. The patient is placed in the lateral decubitus position with hips flexed. The external hemorrhoid or tag is identified and anesthetized at its base with buffered 1% lidocaine with epinephrine. The area is cleansed with povidone-iodine or chlorhexidine. A radially oriented elliptic incision is made around the hemorrhoid or tag and the center removed with the hemorrhoid vein. The resulting defect is frequently left open and allowed to heal. Stool softeners and topical anesthetics may be very beneficial. Because of the vascularity, healing can occur in 5 to 10 days. (See **Tuggy Video: External Hemorrhoid Excision.**)

Thrombosed External Hemorrhoids

An external hemorrhoid can become thrombosed and may be identified by an acute onset of perianal pain and development of a purplish nodule with or without bleeding. Thrombosed hemorrhoids can be managed conservatively with avoidance of constipation, patient analgesia, and ice or sitz baths (Cataldo et al., 2005). Office surgical excision, not incision, of a thrombosed external hemorrhoid results in a lower recurrence rate and earlier resolution of symptoms (Greenspon et al., 2004). Simple incision of the thrombosed hemorrhoid may not remove multiple clots and can result in higher recurrence rate and even extension.

To excise a thrombosed hemorrhoid, the patient is placed in the lateral decubitus position with buttocks separated for visualization. The surface can be cleansed and anesthesia provided with a local injection of buffered lidocaine or bupivacaine with epinephrine at the base of the hemorrhoid. Once anesthetized, an elliptic incision is made in a radial orientation over the hemorrhoid, and all thrombus is removed with excision of the hemorrhoidal vein at its base. Bleeding can be controlled with pressure, Monsel's solution, or careful electrocautery. More complex hemorrhoids or those associated with partial rectal prolapse should be referred to a colorectal specialist.

KEY TREATMENT

Office surgical excision, not incision, of a thrombosed external hemorrhoid results in a lower recurrence rate and earlier resolution of symptoms (Greenspon et al., 2004) (SOR: B).

Anorectal Abscess

An anorectal abscess can lead to severe pain and disability in patients. Abscesses occur most often in the third or fourth decade of life and in a 3:1 to 2:1 male/female ratio (Hebra, 2009). An anorectal abscess develops from an infection originating in the anal glands and crypts at the level of the dentate line and tracking along the lines of least resistance. This tracking results in up to 50% of abscesses being associated with simultaneous fistula development. Locations of the abscess can vary and may be located in the perianal area (60%), ischioanal area (20%), intersphincter region (5%), supralevator region (4%), and submucosal location (1%) (Fig. 28-17). Abscesses can result from other anorectal infections or pathology such as Crohn's disease fistulas, adenocarcinoma, trauma, immunosuppression, and sexually transmitted diseases. A thorough anorectal examination, frequently under anesthesia, is required for complete evaluation. Most abscesses can be localized by physical examination. Deep or large abscesses require a pelvic CT scan to determine the extent of tracking and to plan surgical intervention.

An anorectal abscess should be treated by incision and drainage. The lack of fluctuance should not delay a timely drainage procedure. Antibiotics are an unnecessary addition to routine incision and drainage of uncomplicated perianal abscesses (Whiteford et al., 2005). No conclusive evidence exists for a simple drainage versus sphincter-cutting procedure in the treatment of anorectal abscess (Quah et al., 2006). Antibiotics should be considered only as an adjunct to drainage in patients with immunosuppression, diabetes, prosthetic devices, or significant systemic illness.

Before surgical decompression, an anoscopy should be performed to identify a potential internal draining fistula source at the dentate line. Injecting an agent over or under the mass can provide local anesthesia, although rarely patients may need spinal or general anesthesia. Incision and drainage of superficial abscesses can be accomplished with use of an 11 blade over the area of maximal fluctuance or swelling in a radial orientation. Loculations can be broken by probing with a forceps or gloved finger. A Penrose drain or gauze packing can be placed for continued drainage with appropriate follow up in 1 to 2 days. Recurrent abscesses can occur when there is an unrecognized and untreated underlying fistula. A fistulotomy must be performed in these cases.

KEY TREATMENT

About 50% of perirectal abscesses are associated with simultaneous fistula development.
The lack of fluctuance should not delay a timely drainage procedure for perianal abscesses (Whiteford et al., 2005) (SOR: B).
Antibiotics are an unnecessary addition to routine incision and drainage of uncomplicated perianal abscesses (Whiteford et al., 2005) (SOR: A).

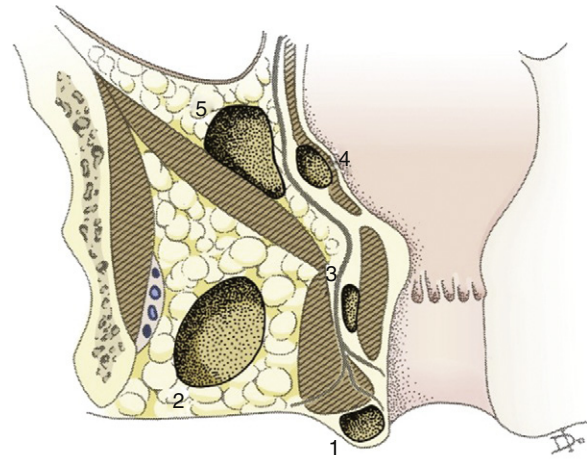

Figure 28-17 Classification of perirectal abscesses: 1, perianal; 2, ischioanal; 3, intersphincteric; 4, high intramuscular; and 5, pelvirectal.

(From Hill GJ II [ed]. *Outpatient Surgery*, 3rd ed. Philadelphia, Saunders, 1988; and Coates WC. *Anorectal procedures*. In Roberts JR, Hedges JR [eds]. *Clinical Procedures in Emergency Medicine*, 5th ed. Elsevier, Philadelphia, 2010.)

Anal Fissure

An anal fissure is a tear in the anal mucosa that can cause severe anal pain and rectal bleeding and results from local stool trauma. Most occur posteriorly in the midline. Other causes or locations should prompt a more complete anorectal evaluation. On examination, the anus is exquisitely tender and may demonstrate internal anal sphincter spasm. Evaluation can occur with gentle spreading of the anus, but some require anoscopy to assess their extent. A radial tear is seen that can be bleeding and very tender.

Most *acute* anal fissures can be managed conservatively with dietary fiber, prevention of constipation, adequate hydration, and stool softeners. Sitz baths may provide symptomatic improvement. Topical anesthetics such as 5% lidocaine ointment or gel can be used for comfort or before defecation until healing. No surgical treatment is warranted in uncomplicated occurrences. *Chronic* anal fissures do not resolve after the 3-month acute phase and are generally less tender. Chronic fissures are still associated with significant internal sphincter spasm and may present with a large, protuberant sentinel tag, sometimes confused with a hemorrhoidal tag.

Conservative therapy includes continued constipation prevention. Other therapeutically equal treatment options include topical nitroglycerin ointment, botulinum toxin injections, or calcium channel blockers such as diltiazem or nifedipine for 30 days. However, no conservative medical therapy approximates the efficacy of surgical sphincterotomy for chronic fissures (Nelson, 2006). An open or closed partial lateral internal sphincterotomy appears to be equally efficacious as surgical treatment (Nelson, 2008). An experienced specialist in the technique and anorectal anatomy should perform this procedure.

KEY TREATMENT

No conservative medical therapy approximates the efficacy of surgical sphincterotomy for chronic fissures (Nelson, 2006) (SOR: A).

Pilonidal Cyst and Abscess

Pilonidal disease may manifest itself as a chronically draining sinus or fistula at the base of the spine in the intergluteal crease 5 to 10 cm from the anus. Pilonidal cysts can also become infected and may lead to extensive presacral abscess formation. Multiple hair shafts may be seen within the cyst. Incision and drainage or an elliptic incision under local anesthesia over the sinus track is performed. Drainage is the preferred office management technique and is similar to standard abscess treatment. Packing of the wound should be done, and referral is recommended for excision of the extensive presacral complex. Recurrence is common without excision.

Gynecologic Office Procedures

See also Chapters 25 and 26.

Paracervical Block

A paracervical block can be placed before any uterine procedure requiring instrumentation of the cervix or cervical dilation. Contraindications include current desired pregnancy, infection, and bleeding disorders. The local anesthetic used is determined by the length of anesthesia required, most often 0.5% lidocaine or bupivacaine for injection.

The patient is placed in a dorsal lithotomy position and a vaginal speculum placed to allow adequate visualization of the cervix. Two 10-mL syringes are drawn up of a 1:1 ratio of 1% lidocaine or bupivacaine and sterile saline. The cervix and vaginal canal is cleansed with chlorhexidine or povidone-iodine. An injection of 1 to 2 mL of this mixture is placed in the anterior cervical lip, where a single-toothed cervical tenaculum is placed. The cervix is lifted upward and deviated laterally to obtain access to the lateral posterior fornix. The 4 and 8 o'clock positions are identified on the cervix, and 8 to 10 mL of the mixture is injected at each site. This injection starts into the cervicovaginal reflection at the apex of the posterior fornix at these positions and is advanced 2 to 5 cm in depth along the external serosa of the uterus, to provide anesthesia to the uterine plexus of nerves near the uterine arteries. Intravascular injection is avoided by pulling back on the syringe plunger before infiltration.

Women have less pain during uterine intervention with paracervical block than with placebo injections (SOR: B).

Contraceptive Devices

Diaphragms

Diaphragms have an arcing, coil, or flat spring with the latex brands and a wide-seal rim, arcing or coil spring with the silicone devices. The arcing spring diaphragm is used most often because it is easier to place in the posterior fornix without an introducer. When fitting a diaphragm, the size can be determined with a simple pelvic examination.

With the patient in a dorsal lithotomy position, the provider inserts the lubricated and gloved index and middle finger straight into the vagina to the posterior fornix. Once there, the spot where the inferior pubic arch impacts the index finger is noted. The fingers are withdrawn, and the

distance from that point on the index finger to the end of the middle finger is noted; this is about the diameter of diaphragm needed. Diaphragms come in 5-mm increments from 60 to 90 mm, with 75 and 80 mm most common. The diaphragm is then inserted and size confirmed with placement posteriorly in the posterior fornix behind the cervix and anteriorly behind the pubic arch. Removal of the diaphragm can be accomplished by hooking the anterior rim with a finger and gently extracting. Women should be given an opportunity to remove and replace the diaphragm to confirm placement before use.

The diaphragm can be placed in the posterior vagina covering the cervix up to 6 hours before intercourse. Generally, women have used 5 mL of spermicide within the diaphragm at insertion, although a Cochrane review failed to prove its contribution to contraceptive effectiveness (Cook et al., 2003). Additional spermicide can be inserted in front of the diaphragm before each act of intercourse without dislodging the diaphragm. The diaphragm is removed at least 6 hours and not more than 24 hours after the last intercourse. An increased risk of urinary tract infections exists with diaphragm use and risk of toxic shock syndrome if the diaphragm is left in place more than 24 hours. The diaphragm size needs to be reestablished after a weight change of 10 to 15 pounds, pregnancy, or pelvic surgery. Failure rate for the diaphragm is 18% but may be better with perfect use.

Cervical Caps

Two brands of cervical caps are currently approved and marketed in the United States. Although neither requires specific fitting by a practitioner, both require a prescription for pharmacy or manufacturer dispensation. FemCap comes in three sizes and is ordered based on pregnancy history, whereas Lea's Shield comes in one size for all women with normal anatomy.

The FemCap is a silicone rubber nonhormonal intravaginal contraceptive (IVC). The smaller rim size (22 mm) is for women who have never been pregnant. The medium size (26 mm) is intended for women who have been pregnant, even for up to as little as 2 weeks with no vaginal delivery. The larger-diameter cap (30 mm) is for women who have had a full-term vaginal delivery. When in doubt of prior pregnancy, the 26-mm cap should be used. The patient places the cap over the cervix with up to $\frac{3}{4}$ tsp of 2% nonoxynol-9 spermicide used around the outside groove at least 15 minutes before sexual arousal. Placement over the cervix is critical and accomplished best while squatting. Once in place, the cap should be pushed in opposition to the cervix for at least 10 seconds to ensure firm placement against the vaginal wall, because it does not fit snug against the cervix. Additional spermicide should be placed with each act of intercourse without removing the cap. Hooking a finger under the removal strap in a squatting position and withdrawing gently removes the cap. The cap must be removed at least 6 hours but not longer than 48 hours after the last act of intercourse. During a 6-month clinical trial for approval, the FemCap was 86.5% successful in preventing pregnancy (FemCap, 2010). The device is washed and dried thoroughly between uses.

Lea's Shield is a silicone rubber IVC placed vaginally at any time before intercourse. It is inserted with spermicide to the

depth of the vagina, and any trapped air is vented through a one-way valve, creating a tight fit between the vaginal wall and the device. The Shield is removed using the incorporated removal loop with a finger more than 8 hours after intercourse. Women had an 8.7% chance of becoming pregnant within 6 months when using the Lea's Shield (Yama, 2010). The shield is cleaned with warm soapy water and dried for reuse.

KEY TREATMENT

Failure rates for the diaphragm are 18% but may be better with perfect use (Cook et al., 2003) (SOR: A).
FemCap was 86.5% successful in preventing pregnancy over 6 months of use (FemCap, 2010) (SOR: B).
Women have an 8.7% chance of becoming pregnant within 6 months when using Lea's Shield (Yama, 2010) (SOR: B).

Intrauterine Devices

Insertion

Long-acting reversible contraception has become increasingly popular in the form of intrauterine devices (IUDs). IUDs are T-shaped devices that are very easy to place in an office setting and have a failure rate less than 1% to 2% per year. They can be used in nulliparous and parous women and have a high continuance rate after 1 year of use (78%-81%). Both device types have attached strings at the end for removal in the office, and pregnancy rates return to normal soon afterward. IUDs are contraindicated in women with a current or suspected pregnancy, abnormal uterine cavity, pelvic inflammatory disease or endometritis, known endometrial or cervical malignancy, genital bleeding of unknown etiology, artificial heart valve placement, or allergy to IUD components.

A pregnancy during use of an IUD is more likely to be ectopic, but the overall rate of ectopic pregnancy is less than in sexually active women who use no contraception. Complications of IUD placement include pelvic infection, embedment in the uterine wall, IUD migration or expulsion, and perforation of the uterus. Unlike oral contraceptives, IUDs can be used during lactation and are not contraindicated in women with a history of venous thromboembolic events, those at increased risk of myocardial infarction or stroke, or those who smoke. Perforation rates are 0.6 to 1.6 per 1000 insertions but are higher in the 6 to 8 weeks after delivery, so postpartum placement is delayed until a later visit (McCarthy, 2006).

Prior to placement of an IUD, the federally mandated patient information included with the IUD should be fully reviewed with the patient and formal written consent obtained after discussion of risks and benefits. Confirm a pregnancy test is negative, and consider placement during the first 5 to 7 days of her menstrual cycle. A pelvic examination must be performed before insertion to assess the uterine size and location and evaluate for current cervical infection. A prescription dose of an NSAID (e.g., ibuprofen 600-800 mg) should be provided 30 to 60 minutes before placement to help with analgesia. After placement, the patient may continue to use an NSAID for cramping and can expect to have some spotting for a few days. She should be willing to check for the IUD strings monthly to confirm proper retention.

KEY TREATMENT

IUDs have a failure rate less than 1% to 2% per year (SOR: A).
IUDs (e.g., Mirena) can be used during lactation and are not contraindicated in women with a history of venous thromboembolic events, those at increased risk of myocardial infarction or stroke, or those who smoke (SOR: A) (McCarthy, 2006).

Mirena

The Mirena IUD is a levonorgestrel-releasing IUC system placed for up to 5 years for extremely effective contraception. The levonorgestrel is released into the uterus, with minute amounts entering systemic circulation. Variable to no menstrual bleeding is the norm for patients after 3 to 6 months.

The Mirena device is supplied in its own delivery system aiding with placement. The patient is placed in a dorsal lithotomy position and a sterile speculum introduced into the vagina. The cervix and vaginal mucosa is cleansed with a chlorhexidine or povidone-iodine solution. A paracervical block can be placed as described earlier. The anterior or posterior cervix is grasped with a single toothed cervical tenaculum for stabilization of the cervix during the procedure. If normal, the uterus should be sounded to depths of 6.5 to 8.5 cm. If the uterus is sounded to a different depth, consider misplacement, cervical stenosis, or uterine perforation. The cervix can be dilated for placement, if significant stenosis is present.

Open the Mirena package, release the IUD threads, position the IUD arms, and position the flange at the proper sounded depth. Once in the same plane as the inserter system, retract the arms into the inserter by pulling on the strings at the end of the system and pushing forward on the green thumb slider. Lock the strings into the cleft at the end of the inserter. Insert the IUD system gently through the cervix into the uterus, but stop 1.5 to 2 cm before the fundus. Pull back on the thumb slider to the designated mark, and release the arms outward. Wait for 10 to 15 seconds to allow the arms to fully extend. Hold the slider with the thumb and advance the system fully forward to place the IUD arms against the uterine fundus. Now pull only the slider all the way outward to release the threads at the proximal end of the inserter, then remove the entire inserter system from the cervix, leaving behind the IUD with threads. Cut the two threads to a length of 3 to 5 cm. Remove the tenaculum and observe for any significant bleeding. Monsel's solution or pressure can be used for hemostasis. Remove the speculum, and give the patient instructions for follow-up visits and postinsertion care. (See Tuggy Video: IUD insert.)

Paragard T380A

The Paragard can be placed for up to 10 years and in a similar manner as the Mirena IUD. Patients should receive counseling and informed consent for the Paragard IUD, with specific warnings about contraindications in patients with Wilson's disease because of the copper content of the Paragard. Positioning of the patient, placement of the speculum, cleansing of the vagina and cervix, placement of the tenaculum, and uterine sounding are the same as described for the Mirena. However, the IUD arms are loaded differently into the Paragard inserter, folded backward with the distal arms inserted into the end of the inserter tube to lie next to the IUD shaft.

The IUD system is then inserted through the cervix to the uterine fundus. The white inserter plunger is held steady and the outside clear tube retracted 1 to 2 cm to release the arms. The clear tube is then advanced back to the fundus to assist in extending the arms and placing them in the apex of the fundus. The central plunger is then removed before the outside tube to prevent inadvertent removal of the IUD (Fig. 28-18). Once the inserter is removed, the two threads can be cut to 3 to 5 cm in length and the tenaculum and speculum removed, with hemostasis as needed. The patient is instructed in post-placement care and subsequent monthly cervical thread checks. Warning signs for infection, perforation, and bleeding are given. (See Tuggy Video: IUD Insertion.)

Removal

Removal of an IUD is quite simple for the majority of devices. An oral NSAID is beneficial to assist with analgesia. The patient is placed in a dorsal lithotomy position and a speculum placed in the vagina. The two IUD strings are identified and grasped with a ring forceps. The strings are gently pulled on, and the IUD should easily follow for removal. If the strings are not present, the IUD strings are generally just inside the cervical os. One can use a Cytobrush to dislodge the strings, attempt to grasp the strings in the os with a straight hemostat, or consider cervical dilation and use of an IUD hook or extractor for removal of the IUD. In some women the IUD may be malpositioned, and an ultrasound or plain abdominal film can locate the system for removal. If the IUD does not come out easily or is disconnected from the strings with the initial traction, hysteroscopy-assisted IUD removal may be necessary in a few rare cases.

Intradermal Contraceptive Device

Implanon is a device 4 cm long and 2 mm wide containing 68 mg of etonogestrel. It is inserted on the inner side of the nondominant upper arm above the medial epicondyle in a subdermal location for up to 3 years of contraception. Insertion should occur during the first week of a patient's menstrual cycle. The site for insertion is selected, marked, and locally anesthetized. The device is placed using a subdermal insertion trochar. Complications from insertion are 1% and from removal 1.7%. Irregular bleeding is the most common side effect (11% of patients). The manufacturer requires providers to complete a 3-hour comprehensive training program, which should be completed before device placement (www.implanon-usa.com).

Bartholin's Gland Abscess or Cyst

The Bartholin's glands are located between the hymen and labia minora bilaterally at the 4 and 8 o'clock positions. Cysts occur when the duct is blocked from trauma or edema, and abscesses occur when retained secretions become infected. Abscesses are frequently surrounded by some level of cellulitis of the tissues and can be very painful and indurated. Treatment relies on drainage of the cyst or abscess, treatment of any associated cellulitis with oral antibiotics if indicated, and creation of a track that eventually epithelializes, allowing normal gland drainage and reduced recurrence.

For drainage, the patient is placed in the dorsal lithotomy position and the cyst or abscess identified in the introitus in

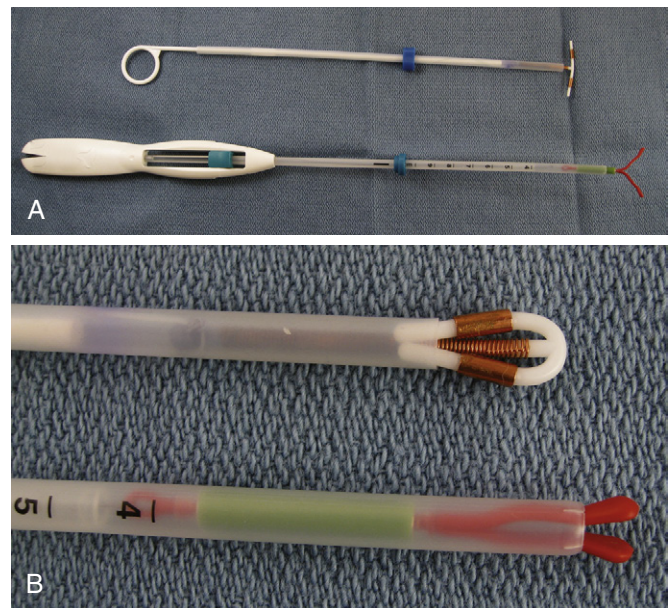

Figure 28-18 **A**, Paragard T380A is displayed above Mirena. Note that both intrauterine devices have IUD arms extended. **B**, End of Paragard T380A is displayed above end of Mirena with both IUDs having arms fully retracted in opposite directions and ready for placement.

the area of maximal swelling and fluctuance. Topical anesthesia can be used on the surface or a local anesthetic injected under the mass for patient comfort. The cyst wall is grasped through the mucosal surface with two clamps 3 to 5 mm apart and a #11 blade used to puncture and open the site. The contained fluid is removed and cultured. The cyst can be packed with gauze, but recurrence is frequent. To prevent recurrence, a Word catheter can be placed into the open cyst or abscess. The catheter is a latex stem attached to an inflatable balloon. The catheter is inserted into the incision between the clamps, with care taken to place it in the center of the cyst wall. The balloon is then filled with 2 to 3 mL of normal saline and left in place for 4 to 6 weeks until epithelialization of the track occurs. The catheter can then be removed. If the incision was done inside the hymen ring, the catheter end can be tucked into the vagina for comfort during the healing process. (See Tuggy Video: Bartholin's Cyst Word Catheter Placement.)

Colposcopy

Colposcopically directed cervical biopsy and cervical curettage is primarily used to investigate abnormal findings on routine pelvic examination or an abnormal Pap smear. Consensus guidelines for the management of cervical intraepithelial neoplasia (CIN) have been developed (Wright et al., 2007). Colposcopy requires diligent record keeping and patient communication with follow-up arranged pending pathologic results. Contraindications to colposcopy are current infection and delivery within the preceding 6 weeks. Pregnancy does not preclude colposcopy but may impact the decision to biopsy the cervix or perform endocervical curettage based on increased bleeding and miscarriage risks. A pregnancy test is best performed before a biopsy is contemplated. Patients should receive informed consent and understand the risk and benefits as well as their responsibility to follow up based on exam findings.

Colposcopy is performed with a stereoscopic operating microscope with correct focal length. The patient is placed in the dorsal lithotomy position. The vulva and introitus are inspected for lesions. A speculum is placed in the vagina, with the size selected to maximize visualization of the cervix and minimize patient discomfort. The vaginal canal and cervix are visualized and any abnormal lesions of concern noted. Acetic acid (3%-5%) is applied to the vaginal canal and cervix liberally with a cotton swab. Abnormal areas will display as acetowhite or leukoplakia with the acetic acid and may also show signs of punctation, mosaicism, or frank abnormal changes of superficial vessels. A green light filter can assist with visualizing atypical vascular changes. Lugol's solution can also be applied to improve identification of abnormal tissue, taken up by glycogen in normal mature squamous cells and not by dysplastic, metaplastic, or columnar epithelial tissues. Any findings are recorded in a drawing to correlate with biopsy sites or abnormal pathology. Satisfactory examination includes full visualization of the entire transformation zone between squamous and columnar epithelium at the cervical os. Most pathology is located in this zone. An endocervical speculum can be used to assist in visualization. Types of future treatment for any lesion seen should be considered and noted for ease in planning future management.

Endocervical Curettage

Endocervical curettage frequently precedes external cervical biopsies so as not to cross-contaminate the specimens. Endocervical lesions can require much more extensive and invasive treatment. Endocervical sampling is done if the cause for the abnormal Pap smear is not identified or if an ectocervical lesion extends into the cervical canal. An endocervical curette is placed into the cervix with the sharp edge against the wall of the canal. The curette is then drawn back and forth against the cervical canal in a 360-degree sampling twice around. The sample removed can be retrieved with an endocervical brush and sent for pathologic assessment separate from any other specimens. Endocervical curettage is contraindicated in pregnant patients. (See **Tuggy Video: Colposcopy.**)

Cervical Biopsy

If abnormal areas are identified on the ectocervix, a correlation for consistency with Pap results is required. A biopsy of the abnormal areas identified by the colposcope can be undertaken using a Kevorkian or Tischler biopsy forceps. To aid in visualization and prevent cross-contamination, biopsies are done on the posterior cervix first, followed by the anterior aspect. The fixed end of the biopsy forceps is usually placed into the cervical os, and biopsies are done in a radial orientation to obtain a sampling of the squamocolumnar transition zone in the area of concern. Samples should be deep enough to include the epithelial surface and a small amount of underlying stroma.

Once biopsies are completed, hemostasis is best achieved with use of a Monsel's paste applied with a cotton applicator or silver nitrate sticks. The vagina is wiped of remaining debris and the speculum withdrawn. The patient is instructed to use analgesics as needed, to abstain from intercourse or tampon use for 10 to 14 days, and to expect some intermittent spotting. Any excessive bleeding, fever, discharge, or significant

pelvic pain should warrant a return visit and assessment and treatment of the cause. Confirm a method of contact with the patient and relay the results and treatment recommendations when the pathologic results return.

Endometrial Biopsy

An endometrial biopsy can be performed to evaluate abnormal uterine bleeding in women who are premenopausal or postmenopausal in conjunction with ultrasound. It can also be used to assess for a short luteal phase in infertility and abnormal or atypical glandular cells seen on Pap smear in women over 40. Women with spontaneous postmenopausal bleeding and an endometrial thickness greater than 5 mm should be further evaluated with an endometrial biopsy (Amann et al., 2006).

A number of endometrial biopsy devices are available; the disposable flexible plastic aspirator is easiest to use. This aspirator can be used with most women and even those with mild cervical stenosis. Before biopsy, a pregnancy test should be completed if the patient is of childbearing age and an oral NSAID given. The patient is placed in the dorsal lithotomy position, and uterine size and location and any pelvic abnormalities are assessed. A speculum is placed to allow full visualization of the cervical os. The vaginal canal and cervix are cleansed with a chlorhexidine or povidone-iodine solution, and a single-toothed tenaculum is placed on the anterior cervix to aid in stabilization later. A paracervical block can be placed for patient comfort.

Once the preparation is complete, the aspirator is inserted into the cervical os using the tenaculum to straighten the cervical canal as needed. It is advanced to the fundus, and then the central plunger is retracted to create intrauterine negative pressure for suction of endometrial contents. The aspirator catheter is then withdrawn to the lower uterine segment and advanced again repetitively to the fundus and rotated to sample all aspects of the uterine body cavity. The catheter is then removed from the uterus. Endometrial cells and blood will have entered the aspirator catheter and can be sent for pathologic examination. The tenaculum and speculum are then removed and withdrawn. The patient may experience uterine cramping and bleeding for a few days and should refrain from intercourse until this resolves. Excessive bleeding, fever, or pelvic pain warrants immediate evaluation in the postoperative period. Pathology results are discussed with the patient when available and any treatment arranged as needed. If the sample is insufficient, the patient should be triaged to a transvaginal ultrasound in a low-risk group, with full dilation and curettage for any high-risk patients (Brand et al., 2000). (See **Tuggy Video: Endometrial Biopsy.**)

KEY TREATMENT

An endometrial biopsy can be performed with ultrasound to evaluate abnormal uterine bleeding in premenopausal or postmenopausal women.

Women with spontaneous postmenopausal bleeding and an endometrial thickness >5 mm should be further evaluated with an endometrial biopsy (Amann et al., 2006) (SOR: B).

If the endometrial sample is insufficient, the patient should be triaged to a transvaginal ultrasound in a low-risk group, with dilation and curettage for high-risk patients (Brand et al., 2000) (SOR: B).

Cervical Polyp Removal

Cervical polyps are generally benign, asymptomatic, and noted most often during a routine gynecologic examination. Most polyps arise from the endocervical mucosa, and most occur in perimenopausal women age 30 to 50. For their removal, the patient is placed in the dorsal lithotomy position and a speculum inserted vaginally. A Pap smear should be obtained and the base of the polyp identified to prevent inadvertent removal of a prolapsed endometrial polyp. The polyp is then grasped as close to its base as possible with a ring forceps and twisted. This twisting motion will dislodge the polyp, which should be sent for pathologic assessment. Hemostasis is obtained with Monsel's solution or silver nitrate sticks if direct pressure is not sufficient. (See Tuggy Video: Polyp Removal.)

Uterine Aspiration for Biopsy or Miscarriage Management

Manual vacuum aspiration (MVA) can be used in the office setting for easy sampling of the uterine endometrium with a 4-mm or 5-mm cannula when a small endometrial biopsy catheter is insufficient (Fig. 28-19). The MVA can also be used in the office for removal of retained products of conception after an incomplete or missed miscarriage up to 12 weeks without the added cost of an emergency room visit, surgical suite, and general anesthesia. The MVA device is a hand-held plastic aspirator syringe attached to a plastic cannula of varying sizes. The cannula can be flexible or rigid to allow for provider preference. Vacuum aspiration is safe, quick to perform and less painful than sharp curettage and should be recommended for use in the management of incomplete abortion (Forna and Gulmezoglu, 2001).

Confirmation of a non-viable pregnancy or incomplete abortion is verified with a falling serum β -hCG level, an appropriately timed ultrasound, or by clinical findings of uterine bleeding in pregnancy with significant cervical dilation in the first trimester. A blood type is obtained to determine if Rh-GAM is necessary. A hematocrit may be obtained if bleeding has been significant. Once informed consent outlining the risks of bleeding, pelvic infection, uterine perforation, Asherman's adhesions, and possible need for reaspiration is obtained, the patient may receive a sedative, analgesia, or anesthesia. Most women do well with an oral NSAID for analgesia and a paracervical block for local anesthesia. For comfort, the patient should void before the procedure.

The patient is placed in the dorsal lithotomy position, and uterine size, location, and shape are assessed. A transvaginal or transabdominal ultrasound can be performed at this time to confirm findings but is not required. A speculum is placed intravaginally, vagina and cervix are cleansed, and a paracervical block is placed before the procedure. A single-toothed tenaculum is placed on the anterior cervix.

The uterus is sounded to the fundus to determine intracavitary size and position. If not already dilated, the cervical os is successively dilated to a size in millimeters corresponding to the gestational age, using Denniston, Pratt, or Hegar dilators. The MVA curette is generally chosen in millimeters to correspond to the gestational age in weeks as well. Thumb buttons are used to occlude the opening to the MVA barrel, and the plunger is retracted and allowed to snap into place

Figure 28-19 The Ipas manual vacuum aspirator (MVA) is displayed with 4-mm and 5-mm cannulas used for miscarriage management in outpatient setting. Note thumb buttons that close the barrel entrance to hold negative pressure in the canister when the plunger is retracted. The buttons are then released to transfer the suction pressure to the cannula once in place.

to develop the negative pressure for suction. The cannula is attached to the MVA and placed through the cervix to the uterine fundus. The thumb buttons on each side are released, and the negative suction from the syringe is transferred to the endometrial cavity. The MVA barrel can be rotated and then brought in and out in a piston motion to dislodge the remaining products of conception. These can be observed passing through the cannula and can be evaluated fully by visual or pathologic examination after the procedure. The syringe may need to be emptied and the negative pressure reapplied based on the volume of the uterine contents. A sensation of grittiness is present in the fundus and all four uterine quadrants when the products of conception are completely removed and the cannula makes contact with the myometrium.

On completion, the MVA cannula is removed from the uterus, tenaculum from the cervix, and speculum from the vagina. The patient is observed for 15 to 30 minutes to assess for excessive bleeding, hemodynamic stability, and unusual pain. Intrarectal or intravaginal misoprostol, intracervical or intramuscular methylergonovine, and intramuscular carboprost may be used for excessive bleeding. The patient may be discharged and instructed to refrain from intercourse for 2 weeks or until the bleeding resolves. She should return for excessive bleeding, significant pelvic or abdominal pain, and fever. A form of contraception is provided if the patient desires.

Breast Mass

In a patient who presents with a breast mass, a careful clinical and family history with focused physical examination, a mammogram or ultrasound, and fine-needle aspiration of the mass is termed a *triple test*. Most primary care physicians can perform the triple test with radiologic assistance for the evaluation of a breast mass. A positive triple test (indeterminate, suspicious, or malignant) was found in 99.6% of breast cancers. On the other hand, if all three test components are negative and the patient is deemed low risk by personal or family history, the patient requires no further workup and has a less than 1% risk of cancer (National Breast Cancer Centre, 2006).

Breast Cyst Aspiration

When a discrete breast mass is first discovered, a determination of solid or cystic must be made to assist with further evaluative decisions. A rapid determination can be made with one of two methods. Ultrasound can be used to identify a cystic or solid mass rapidly with minimal discomfort to the patient. If ultrasound is not available or if a therapeutic intervention is needed for drainage of a palpated cyst, a breast cyst aspiration can be performed.

The patient can be placed in a recumbent position and the skin over the breast cleansed. The mass is stabilized between the thumb and index and middle fingers on the nondominant hand. Anesthesia can be used locally, but most women feel minimal discomfort. A 1.5-inch, 20- to 23-gauge needle is attached to a 10- to 30-mL syringe. The skin is punctured and the end of the needle directed into the mass with continuous suction on the syringe. The fluid of a cyst is aspirated completely before the needle is removed. Fluid should be sent for pathologic evaluation. Straw- to green-colored fluid is usually benign, and bloody brown to red fluid is more suspicious for malignancy. If bloody fluid is obtained in an atraumatic aspirate or if a lump remains, the patient should be referred for a core needle or open biopsy. (See **Tuggy Video: Breast Cyst Aspiration.**)

KEY TREATMENT

Vacuum aspiration is safe, quick to perform, and less painful than sharp curettage and recommended in the management of incomplete abortion (Forna and Gulmezoglu, 2001) (SOR: B).

The triple test of (1) careful clinical examination, (2) mammogram or ultrasound, and (3) fine-needle aspiration of a breast mass approaches the false-negative rate of surgical breast biopsy and the false-positive rate of frozen section (National Breast Cancer Centre, 2006) (SOR: B).

If bloody fluid is obtained on an atraumatic breast mass aspirate or if a lump remains after drainage, the patient is referred for surgical consult for core or open biopsy (National Breast Cancer Centre, 2006) (SOR: B).

Fine-Needle Aspiration Cytology or Biopsy

Fine-needle aspiration (FNA) can be performed in the office with minimal equipment for diagnosis of a discrete, solid breast mass. FNA testing results in a sensitivity of 90% and a false-negative rate of 3% to 10% in experienced hands (Valea and Katz, 2007). Contraindications include an overlying skin infection, underlying pulsatile mass, and a history of bleeding disorders.

The patient is properly given informed consent. She is recumbent in position, and the area of puncture is identified, marked, and cleansed. A local injection of 1 to 2 mL of anesthetic is infiltrated into the skin over the mass. The mass is stabilized with the three-finger technique previously mentioned. A 10- to 20-mL syringe with 18- to 22-gauge needle attached is advanced into the mass. Full aspiration suction is performed, and the needle is passed through the mass in different planes three to five times for an adequate sample. The suction is released and the needle removed. The cell sample, frequently only in the needle itself, is placed on a cytology slide and fixed for proper pathologic assessment.

FNA provides histologic diagnosis but cannot determine architectural features. FNA should not be used to investigate microcalcifications, and it cannot distinguish ductal carcinoma in situ from invasive cancer. A core or open biopsy should be performed in these patients for more definitive diagnosis before excision or definitive treatment. (See **Tuggy Video: Needle Aspiration.**)

Neonatal Circumcision

Circumcision has been used in religious rites for centuries and was used in ancient Egypt as a method for hygiene. Modern data in the United States is conflicting as to the benefits versus risks. By age 5 years, 90% of boys have a spontaneously retractable foreskin. The incidence of phimosis decreases with age and may be treated with a steroid cream. The medical approach to phimosis is initially successful in about 80% of cases and a year later 60% had no phimosis (Ku and Huen, 2007). Many parents still elect to have their male infants circumcised.

The American Urological Association revised their policy to say that circumcision should be presented for health benefits (Tobian et al., 2010). The American Academy of Pediatrics, American Medical Association, and American College of Obstetrics and Gynecology all consider the procedure elective with minimal benefits (Lannon et al., 1999). The WHO–United Nations program on HIV/AIDS concluded that male circumcision is efficacious in reducing sexual transmission of HIV from women to men. In Africa, circumcision decreased HIV acquisition by 53% to 60%. Herpesvirus type 2 is decreased by 28% to 34% and HPV prevalence by 32% to 35% in circumcised men. Among female partners of circumcised men in these African studies, the incidence of bacterial vaginosis was reduced by 40% and *Trichomonas vaginalis* by 48%; genital ulcers decreased as well (Tobian et al., 2010).

The incidence of urinary tract infection (UTI) is reduced with circumcision in some populations. If a population has a baseline UTI incidence of 3% or higher and circumcision complication rate less than 2%, circumcision is helpful in reducing UTIs. In normal infants the risk of UTI is 1% or less, in those with prior UTI 10%, and in those with vesicoureteral reflux 30% (Singh-Grewal, 2005). The main risk is bleeding, followed by infection. Actual rates of hemorrhage in medically indicated or ritual hospital-based circumcision range from 0.2% to 3% (Bocquet et al., 2010).

Although numbers may be declining in some U.S. areas, circumcision remains one of the most common procedures performed. A neonatal circumcision is normally performed at 12 to 48 hours old once the infant has stabilized after birth, but may be performed up to 4 to 6 weeks of age. Before the procedure, each patient should be examined thoroughly for signs of congenital anomalies of the penis, urethra, or urinary tract. If hypospadias is present, circumcision is stopped or not performed, to allow the tissue to be used in a corrective surgical procedure to repair the urethra and glans.

Many locations recommend no oral intake for 1 hour before the procedure to prevent aspiration. Oral sucrose can be used to reduce pain during the procedure (Gatti, 2003). A dorsal penile block or penile ring block is more effective than EMLA cream or sucrose. EMLA cream provides

anesthesia but has a risk of methemoglobinemia (Brady-Fryer et al., 2010).

Inspect first to make sure there is no hypospadias or hidden penis. If the penis is normal and parental consent has been obtained, the infant is placed on a circumcision restraint board and the skin prepared. A dorsal block is achieved by injecting 0.4 to 0.5 mL of 1% lidocaine without epinephrine at the base of the penile shaft at both the 10 and 2 o'clock positions and 5 mm distal to the skin reflection onto the pubic area. Inject 1 to 3 mm deep under Buck's fascia after aspirating to ensure you are not in a blood vessel. A ring block can also be done, slightly higher on the penile shaft circumferentially in the subcutaneous tissues, taking care to avoid injury to the urethra or vasculature (Fig. 28-20).

Once anesthesia is complete, grasp the foreskin distally at 3 and 9 o'clock with two hemostats. All techniques require freeing of adhesions with blunt dissection, usually done with a straight Kelly clamp inserted between the foreskin and glans in a superior direction to avoid the urethra. Open the clamp and sweep laterally. Avoid the highly vascular frenulum. Free the adhesions to the coronal sulcus of the glans. Use a straight hemostat to clamp the free dorsal foreskin, again making sure the tip is held up and away from entering the urethra. Clamp three-fourths the length of the foreskin dorsally. Insert iris scissors and carefully cut the foreskin along the crushed line. Peel the foreskin back to reveal the glans. Avoid degloving the shaft and damage to the frenulum.

Gomco Clamp

The Gomco is the most common circumcision clamp. Test the clamp's fit with the base before use. Estimate the correct size so that the bell covers at least seven-eighths of the glans (1.1, 1.3, and 1.5 sizes available). The glans is then covered with the Gomco bell and the foreskin pulled over it, sometimes with the aid of a clamp or safety pin. The bell and foreskin are then pulled through the hole in the base plate and the foreskin is arranged to ensure even tissue removal. The clamp is then placed on the base plate and the bell stem hooked over the clamp bar. Once positioning is confirmed, the clamp is tightened for 5 to 10 minutes and the remaining foreskin removed with a #10 scalpel. If hemostasis is confirmed, the clamp is removed and the glans is covered regularly with petroleum jelly at each diaper change. Healing should take 4 to 10 days. Complications include bleeding, infection, and trauma to the penis. Bleeding can be controlled with silver nitrate or a simple suture if not resolved with pressure. (See Tuggy Video: Neonatal Circumcision.)

Plastibell

The Plastibell device is a plastic ring on the end of a central removable post. The ring is placed between the glans and foreskin. A tight ligature of moistened suture is placed around the foreskin and tightened into a sulcus on the ring. Foreskin distal to the ring is excised and the handle of the device broken off. The plastic ring stays in place, with the ligature tied tightly around the protective ring, for 5 to 10 days and falls off spontaneously. The appearance of the small amount of necrotic skin may worry parents, and it may be

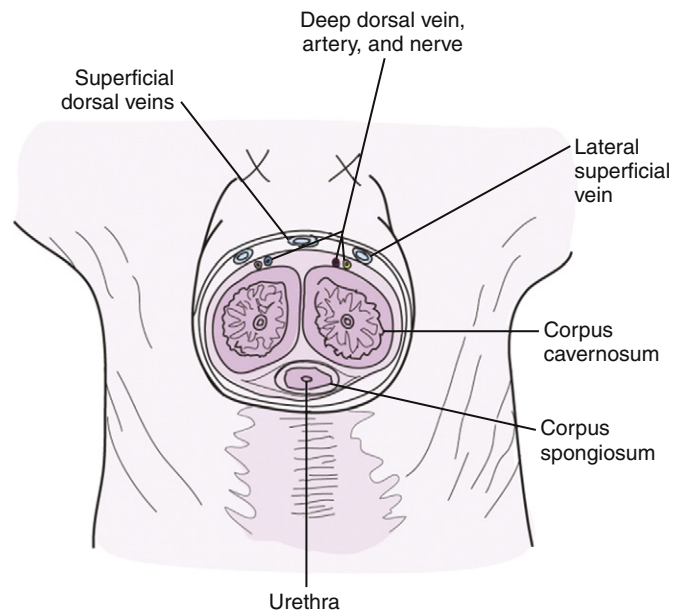

Figure 28-20 Dorsal penile block. The dorsal penile nerve is anesthetized using no more than 1.0 mL total of 1% lidocaine without epinephrine. The anesthetic is administered at the dorsum of the penis approximately 0.5 cm distal to the penile root at the 12 and 2 o'clock positions.

(From Pfenninger JL, Fowler G [eds]: *Procedures for Primary Care Physicians*, 2nd ed. St Louis, Mosby, 2003; and Chavez MC, Maker VK. *Office surgery*. In Rakel RE. *Textbook of Family Medicine*, 7th ed. Saunders-Elsevier, Philadelphia, 2007.)

complicated with incomplete or irregular skin edges if the ligature is not tied tightly enough.

Mogan Clamp

The Mogan clamp is used in traditional Jewish circumcisions and may cause less pain by being faster. The foreskin is grasped with the nondominant hand and the glans pushed downward. The foreskin is slid into the clamp from anterior to posterior, taking care not to trap the glans. The clamp opens only 3 mm to prevent major glans entrapment. Once in place and the glans is confirmed below the plate, the clamp is closed and the distal foreskin removed. The clamp is left in place for a few minutes, then removed, and the foreskin retracted over the glans.

KEY TREATMENT

- Oral sucrose reduces painful procedures in infants (Gatti, 2003) (SOR: A).
- Dorsal penile block or penile ring blocks are more effective than EMLA cream or sucrose (Brady-Fryer et al., 2010) (SOR: A).
- EMLA cream provides anesthesia but has a risk of methemoglobinemia (Brady-Fryer et al., 2010) (SOR: A)

Musculoskeletal Office Procedures

Aspiration of Knee Joint (Arthrocentesis)

The knee is one of the largest and most accessible joints for arthrocentesis or joint injection. Aspiration of joint fluid from the knee is performed to assess for infection, inflammation,

crystal deposition, or traumatic complications. Infections may show a significantly high white blood cell infiltrate with visible organisms on Gram stain. Inflammation may show the same without organisms seen. Crystal disease may show urate or calcium pyrophosphate crystals. Trauma may produce a bloody aspirate with tears of a ligament or cartilage and fat lobules with an intra-articular fracture.

Prior to the aspiration, the patient is consented and placed in a recumbent position with the knee flexed slightly with a rolled towel. The knee is assessed for effusion and the aspiration site marked and cleansed with a sterilizing wash. The knee joint space can be entered with a 22-gauge needle on a syringe on either side, but usually from the lateral aspect 1 cm lateral and superior to the patella, and directed 45 degrees downward angling under the patella, with aspiration done during insertion. When the joint space is entered, fluid should enter the syringe rapidly. Milking the lateral and medial recesses of the knee toward the needle tip will remove more fluid. The needle is removed after aspiration, or it is left in place and the syringe changed under sterile conditions for a steroid injection to follow, if necessary. Large joints can be injected with 20 to 40 mg of triamcinolone or 6 to 12 mg of betamethasone with 3 to 6 mL of 1% lidocaine for inflammatory conditions unrelated to infections. Procedural risks include septic arthritis, mild injury to the

articular cartilage, and hemarthrosis. (See **Tuggy Video: Knee Aspiration.**)

Shoulder Injection

The subacromial bursa is another location frequently treated with steroid injection for bursitis or tendonitis. Injections of 10 to 20 mg of triamcinolone with 2 to 4 mL of lidocaine can be performed into the subacromial bursa. The easiest approach to the subacromial space is with the patient seated comfortably and arms resting at the side. The lateral shoulder is prepared with a sterile solution after palpating landmarks. The acromial process is identified on the lateral shoulder above the humeral head. In the sulcus between the humeral head and the acromial process lies the subacromial bursa. Marking the lateral border of the acromial process can provide some assistance. A 22- to 25-gauge needle on a syringe with the injection is then aimed directly into the sulcus between the bones 1 cm below the acromial process perpendicularly through the deltoid muscle. Ligamentous or muscular structures will resist injection, but the bursa should allow free infusion. Relief of pain may be noted in a few minutes if lidocaine is used and confirms the injection was placed appropriately. (See **Tuggy Video: Joint Injection—Shoulder.**)

Sports medicine involves the care of patients with illnesses and injuries related to sports and exercise. Both orthopedic and medical conditions affect a wide spectrum of patients during sports and recreational activities. The field of primary care sports medicine has emerged over the last 30 years as a leader in the comprehensive care of athletes, teams, and exercising individuals. Although sports medicine is often viewed in the context of professional and elite athletes, the principles and practice of sports medicine apply to athletes of all levels and ages.

The role of a sports medicine physician is to promote the health and safety of exercising individuals, prevent injury and illness, optimize function, and minimize disability that would preclude sports participation. Sports medicine physicians work

closely with a multidisciplinary team of health care providers (specialty physicians and surgeons, athletic trainers, physical therapists, nutritionists, psychologists, and conditioning coaches) to satisfy the complete medical needs of athletes.

Sports medicine includes a rapidly expanding core of knowledge related to medical issues in sports and exercise for which the primary care sports medicine physician is uniquely trained. *Primary care sports medicine* is a subspecialty designation obtained through completion of an accredited sports medicine fellowship and passing the Certificate of Added Qualification examination. Many practicing primary care providers also gain vast experience in sports medicine through office treatment of orthopedic injuries, event coverage, and preparticipation screening evaluations.

Musculoskeletal problems account for up to 20% of all primary care office visits (Urwin et al., 1998; Woodwell and Cherry, 2004), and approximately 90% of all sports injuries are treated nonsurgically. Thus, a sound clinical foundation in the evaluation and treatment of musculoskeletal disorders is critical to primary care providers and helps guide appropriate referral to orthopedic and rehabilitative specialists.

This chapter focuses on both the medical aspects of sports medicine and common orthopedic injuries in athletes. Detailed reviews cover the preparticipation physical evaluation, cardiac disorders in athletes, concussion assessment and management, cervical spine injuries, on-the-field assessment of the injured athlete, facial trauma, environmental influences such as exertional heat illness, common infections in athletes, and a systems-based review of dermatologic, pulmonary, hematologic, gastrointestinal, and genitourinary disorders in athletes. Orthopedic areas common in primary care sports medicine are also included, such as athletic low back pain, muscle strains, tendinopathy, shin pain, stress fractures, and issues unique to the pediatric or female athlete. See Chapters 30 and 31 for a comprehensive review of additional musculoskeletal problems relevant to sports medicine and the care of exercising individuals.

Preparticipation Physical Evaluation

Key Points

- The primary objective of the preparticipation physical evaluation is to detect preexisting medical or musculoskeletal conditions that predispose an athlete to injury, disability, or catastrophic injury.
- Syncope that occurs during exercise is a serious warning sign and warrants a comprehensive cardiology evaluation to rule out an underlying cardiac disorder that predisposes to sudden death.
- Any athlete with a systolic murmur of grade 3/6 in severity, a murmur that gets louder with a Valsalva maneuver or on standing (suspicious for hypertrophic cardiomyopathy), a diastolic murmur, a family history of premature sudden cardiac death, or concerning exertional symptoms should be further evaluated by a cardiovascular specialist.

A preparticipation physical evaluation (PPE), or “sports physical,” is frequently required for medical clearance before participation in organized sports. The *Preparticipation Physical Evaluation* monograph, first introduced in 1992, provides recommendations for the content and format of the evaluation (AAFP et al., 2005). The third edition of the monograph, updated in 2005, is supported by six national medical societies: American Academy of Family Physicians (AAFP), American Academy of Pediatrics, American College of Sports Medicine, American Medical Society for Sports Medicine, American Orthopaedic Society for Sports Medicine, and American Osteopathic Academy of Sports Medicine. The fourth edition published in 2010 also includes collaboration with the American Heart Association (AHA) regarding the preparticipation cardiovascular evaluation.

The primary objectives of the PPE include the following:

1. Detection of potentially life-threatening or disabling medical or musculoskeletal conditions before athletic clearance.
2. Identification of preexisting conditions that may predispose athletes to injury.

3. Satisfying legal or administrative requirements.

Secondary objectives of the PPE include the following:

1. Promoting the health and safety of athletes in training and competition.
2. Serving as an entry point into the health care system for adolescents.
3. Providing an opportunity for a general health assessment.

The recommended frequency of the PPE varies widely according to the requirements of the specific school, organization, or state. AHA first published consensus recommendations for cardiovascular screening in athletes in 1996 and reaffirmed these recommendations in 2007, which have influenced the format and timing of the PPE (Maron et al., 1996b, 2007). A comprehensive PPE is recommended on entry into middle school, high school, and college before participation in competitive sports. For youth and high school athletes, a comprehensive PPE should be repeated every 2 years. For years not requiring a comprehensive PPE, annual updates consisting of a comprehensive history and determination of height, weight, and blood pressure, along with a problem-focused evaluation of new concerns, illnesses, or injuries, should occur on interval years for youth and high school athletes and on all subsequent years for college athletes.

The PPE history focuses on symptoms related to exercise, such as exertional syncope, lightheadedness, chest pain, palpitations, dyspnea, wheezing, or fatigue with less than expected activity (Box 29-1). A past medical history of preexisting cardiac or pulmonary conditions, murmurs, hypertension, coronary artery disease risk factors, asthma, concussions, illicit drug use, prior orthopedic injuries, or other medical conditions that place an athlete at risk of injury should be noted. Specific questions to identify a family history of premature death, cardiovascular disease, and hereditary cardiac disorders, such as hypertrophic cardiomyopathy, Marfan’s syndrome, and long QT syndrome, are also recommended.

The PPE examination consists of both medical and musculoskeletal components. The cardiovascular examination is a major focus of the medical evaluation and consists of a blood pressure measurement, palpation of the radial and femoral artery pulses, cardiac auscultation with the patient both supine and standing, and recognition of the physical manifestations of Marfan’s syndrome (Maron et al., 1996b; Maron et al., 2007). Any heart murmur detected should be further assessed during the Valsalva maneuver or while moving the patient from a squatting to a standing position. These maneuvers decrease venous return and may accentuate the murmur of hypertrophic cardiomyopathy, the leading cause of sudden cardiac death in young athletes. However, hypertrophic cardiomyopathy is difficult to detect on examination alone because outflow tract obstruction, which causes the harsh systolic murmur, is present in only about 25% of patients with the disorder (Maron, 1997) (Fig. 29-1).

The musculoskeletal assessment serves as a screening evaluation of the spine and upper and lower extremities. Joint range of motion, strength, and stability should be tested. Several functional tests, such as hopping, squatting, and “duck walking,” assess many anatomic areas at once and make the evaluation more efficient. Previous orthopedic injuries can also be evaluated in more detail to detect problems that require further rehabilitation or protective bracing before sports participation.

Box 29-1 Preparticipation Physical Evaluation (PPE): Cardiovascular History Questions

- Have you ever passed out or nearly passed out during or after exercise?
- Have you ever had discomfort, pain, pressure, or tightness in your chest during exercise?
- Do you get lightheaded or feel more short of breath than expected during exercise?
- Does your heart ever race or skip beats (irregular beats) during exercise?
- Has a doctor ever told you that you have a heart problem, high blood pressure, high cholesterol, a heart murmur, a heart infection, Kawasaki's disease, or an unexplained seizure disorder?
- Has a doctor ever ordered a test for your heart, for example, an ECG or echocardiogram?
- Has any family member or relative died of heart problems or had an unexpected or unexplained sudden death before age 50 (including drowning, motor vehicle crash, or sudden infant death syndrome)?
- Has anyone in your family had unexplained fainting, seizures, or near-drowning?
- Does anyone in your family have a heart problem, pacemaker, or implanted defibrillator?
- Does anyone in your family have hypertrophic cardiomyopathy, Marfan's syndrome, arrhythmogenic right ventricular cardiomyopathy, long QT syndrome, short QT syndrome, Brugada syndrome, or catecholaminergic polymorphic ventricular tachycardia?

Figure 29-1 Hypertrophic cardiomyopathy. **A**, Gross appearance; **B**, histologic appearance. Note the myocardial fiber disarray.
(From Braunwald E. *Essential Atlas of Heart Diseases*, 3rd ed. Philadelphia, Current Medicine, 2000.)

Warning Symptoms in Athletes

Warning or “red flag” symptoms that may indicate the presence of an underlying cardiovascular disorder should be recognized and further assessed before medical clearance. Syncope that occurs during but not after exercise is of great concern and warrants a comprehensive cardiology evaluation to rule out the presence of an occult cardiac disorder that may lead to sudden death. Other worrying symptoms include palpitations, chest pain, lightheadedness, and fatigue or dyspnea greater than expected for the level of activity. Athletes with warning symptoms should be evaluated by an electrocardiogram (ECG), echocardiogram, and exercise stress test and referred to a cardiologist. In addition, systolic murmurs of grade 3/6 in severity, all diastolic murmurs, any murmur that becomes louder with a Valsalva maneuver or on standing (suspicious for hypertrophic cardiomyopathy), and a concerning family history of premature sudden cardiac death or hereditary cardiac disorder should be further evaluated by a cardiovascular specialist.

If a cardiac abnormality is identified, the decision to withhold medical clearance for participation in competitive sports is difficult and should be carefully considered on an individual basis. The American College of Cardiology 36th

Bethesda Conference defined eligibility recommendations for athletes with cardiovascular abnormalities (Maron and Zipes, 2005).

Limitations of Cardiovascular Screening

Despite efforts to standardize the format and approach to the PPE, several limitations of the screening process still exist. In 2007, only 19% of U.S. states used forms that were considered adequate by AHA, and 35% of states allowed practitioners with limited cardiovascular training to perform the evaluation (Glover et al., 2007). Unfortunately, recommendations to use a comprehensive personal and family questionnaire to guide the PPE are not widely adopted, and recommended screening protocols are often incompletely or inadequately implemented. In addition, the PPE is screening for medical conditions that place an athlete at increased risk of sudden death, and no outcomes-based research has demonstrated that the PPE is effective in preventing sudden death or potentially catastrophic events, or for identifying athletes at risk. A complicating feature of the screening process is that athletes who harbor underlying structural heart disease may be asymptomatic until the sudden cardiac arrest. In a review of 134 cases of sudden cardiac death, only

18% of athletes had symptoms of cardiovascular disease in the 3 years before their death, and only 3% were suspected of having a cardiovascular condition after PPE (Maron et al., 1996a).

Limitations in the traditional screening process have led to widespread debate regarding the addition of noninvasive cardiovascular screening techniques, such as electrocardiography (ECG), to the PPE. In 2007, AHA reaffirmed recommendations against universal ECG screening in athletes, citing a low prevalence of disease, poor sensitivity, high false-positive rate, poor cost-effectiveness, and a lack of clinicians to interpret the results (Maron et al., 2007). In contrast, the European Society of Cardiology, International Olympic Committee, and the governing associations of several U.S. and international professional sports leagues endorse the use of ECG in the screening of athletes (Corrado et al., 2006; Ljungqvist et al., 2009). These recommendations are supported by studies showing that ECG is more sensitive than history and physical examination alone in identifying athletes with underlying cardiovascular disease, including a 77% greater power to detect hypertrophic cardiomyopathy (Corrado et al., 1998).

In 2006, Corrado and associates reported results from screening 42,386 athletes over 25 years from the national PPE program in Italy. Disqualification on the basis of a screening protocol using history, physical examination, and ECG produced a 10-fold reduction in the incidence of sudden cardiac death in young competitive athletes and an 89% reduction of sudden death from cardiomyopathy. Although only 0.2% of athletes were disqualified for potentially lethal cardiovascular conditions, the study reported a 7% false-positive rate and a 2% overall disqualification rate. This raised concerns that adopting such a program in the United States would lead to an unacceptable number of disqualifications in athletes with a low risk of sudden death.

Complex issues regarding feasibility, cost-effectiveness, appropriate physician, and healthy system infrastructure remain before large-scale implementation of ECG screening in the United States can be considered. However, some physicians are using ECG during PPE to improve detection of potentially lethal cardiovascular abnormalities. When used, ECG interpretation must be based on modern criteria to distinguish abnormal findings from physiologic alterations in athletes, to ensure acceptable accuracy and a low false-positive rate (Drezner, 2008). In a study of 2720 competitive athletes and physically active schoolchildren, a U.K. study reported a false-positive rate of 3.7% using history, physical examination, and ECG, with only 1.9% of false-positive results determined by ECG alone (Wilson et al., 2008). Nine athletes (0.3% of those screened) were found to have a cardiovascular condition known to cause sudden cardiac death in young persons, and all athletes were detected by ECG, not by history or physical examination. Physicians interpreting ECGs in athletes should be familiar with common training-related ECG alterations that are normal variants. In contrast, training-unrelated ECG changes suggest the possibility of underlying pathology, require further diagnostic workup, and should be considered abnormal. Current recommendations for ECG interpretation in athletes to distinguish pathologic ECG abnormalities from physiologic ECG alterations have been recently provided (Corrado et al., 2009).

Cardiac Disorders in Athletes

Key Points

- Bradyarrhythmias caused by increased resting vagal tone are common in athletes and include sinus bradycardia, sinus arrhythmia, first-degree atrioventricular block, and Wenckebach (Mobitz I) second-degree AV block.
- Mobitz II second-degree and complete third-degree AV blocks are always pathologic and warrant cardiologic evaluation.
- Supraventricular tachyarrhythmias in the athlete are abnormal and require further evaluation and treatment, often with radiofrequency ablation, before participation in strenuous exercise.
- Ventricular arrhythmias are life-threatening events and usually occur in the presence of structural heart disease or ion channel disorders.
- Hypertrophic cardiomyopathy, coronary artery anomalies, and commotio cordis are the most common causes of sudden cardiac death in young U.S. athletes.

Arrhythmias

Cardiac arrhythmias in athletes range from benign to life threatening. Bradyarrhythmias are more common in athletes than in the general population because of an increase in resting vagal tone as a response to regular strenuous exercise. Common bradyarrhythmias include sinus bradycardia, sinus arrhythmia, first-degree atrioventricular (AV) block, and Wenckebach (or Mobitz I) second-degree AV block (Huston et al., 1985; Link et al., 2001). These bradyarrhythmias are usually asymptomatic and should resolve during exercise by the withdrawal of vagal tone and associated catecholamine influx.

Athletes with symptomatic Wenckebach block, such as presyncope or syncope during exertion, require further evaluation by a cardiologist and often placement of a permanent pacemaker and restriction of activities. Higher degrees of heart block, such as Mobitz II second-degree and complete third-degree AV blocks, are always pathologic in any individual, including athletes (Fig 29-2). Mobitz II and complete heart blocks signify marked disease in the His-Purkinje system and are generally accepted as a class I indication for permanent pacemaker placement, even in the absence of symptoms (Link et al., 2001).

Tachyarrhythmias in the athlete are abnormal and require further evaluation and treatment before participation in strenuous exercise. The treatment of many supraventricular

Figure 29-2 Mobitz II second-degree atrioventricular block. Note that every alternate P wave is blocked.

(From Goldberger E. *Treatment of Cardiac Emergencies*, 5th ed. Philadelphia, Saunders, 1990.)

tachyarrhythmias has been greatly advanced by the use of radiofrequency (RF) ablation, which might offer an actual cure and obviate the need for lifelong pharmacologic treatment.

The most common tachyarrhythmia in athletes is *atrial fibrillation* (AF). Studies have suggested that AF occurs more frequently in athletes than in the general population (Furlanello et al., 1998; Huston et al., 1985). This might be a consequence of increased vagal tone and bradycardia in athletes, which allows dispersion of atrial repolarization and results in a higher susceptibility to AF. Radiofrequency ablation is curative in most cases of paroxysmal AF (Link et al., 2001). If pharmacologic treatment is needed, rate control can be accomplished with beta-adrenergic blockers or calcium channel blockers, and anticoagulation should be considered with aspirin or warfarin, depending on the frequency of AF and other risk factors for thromboembolism. Any athlete receiving anticoagulation therapy with warfarin should be restricted from sports involving collision or bodily contact.

Atrioventricular nodal reentrant tachycardia (AVNRT) is characterized by abrupt onset and termination of symptoms, a narrow QRS complex, and no evidence of atrial activity on the ECG during the tachycardia. AVNRT caused by an accessory bypass tract, known as Wolff-Parkinson-White (WPW) syndrome, may be evident on the ECG by the characteristic delta wave (slurred upstroke of QRS complex), short PR interval, and prolonged QRS complex (Fig. 29-3). Athletes with WPW may be at risk of sudden death and should be strongly considered for RF ablation. Radiofrequency ablation for both AVNRT and WPW offers cure rates higher than 95% (Link et al., 2001; Manolis et al., 1994).

Atrial flutter is an unusual arrhythmia in trained athletes and typically results from an underlying cardiomyopathy.

Ventricular tachyarrhythmias in athletes are life threatening and usually the result of structural heart disease such as hypertrophic cardiomyopathy, anomalous coronary artery, dilated cardiomyopathy, arrhythmogenic right ventricular dysplasia (ARVD), or atherosclerotic coronary artery disease (CAD). Ventricular arrhythmias and sudden death may also occur in individuals with structurally normal hearts. This may occur from ion channel disorders, such as long QT syndrome, catecholaminergic polymorphic ventricular tachycardia (CPVT), and Brugada syndrome, or from commotio cordis. Long QT syndrome is characterized by a prolonged QTc interval, and Brugada syndrome is suggested by an incomplete right bundle branch block and ST-segment elevation in the precordial leads. Exercise may provoke ventricular arrhythmias because of high catecholamine levels and make ventricular fibrillation more difficult to terminate. Athletes who experience a resuscitated sudden death should undergo an extensive workup and treatment with an implantable cardioverter-defibrillator (Link et al., 2001).

Sudden Cardiac Death

Sudden cardiac death in athletes is a catastrophic event and the leading cause of death in exercising young athletes (Maron et al., 2009). The estimated incidence of sudden cardiac death in high school and college athletes is 1 in 100,000 to 200,000 athletes per year (Maron et al., 2009; van Camp et al., 1995). However, these studies are limited by the lack of a mandatory reporting system for juvenile sudden death and their reliance on electronic databases and media reports to identify cases of sudden death. Thus, current reports likely underestimate the true incidence of sudden cardiac death in athletes.

Figure 29-3 Atrioventricular nodal reentrant tachycardia. Notice the characteristic triad of the Wolff-Parkinson-White (WPW) pattern: wide QRS complexes, short PR intervals, and delta waves (arrows) that are negative in some leads (e.g., II, III, aVR) and positive in others (aVL and V₂ to V₆). The Q waves in leads II, III, and aV_F are the result of abnormal ventricular conduction (negative delta waves) rather than an inferior myocardial infarction. This pattern is consistent with a bypass tract inserting into the posterior wall of the left ventricle.

Drugs and stimulants
 Commotio cordis
 Primary pulmonary hypertension (PPH)*

*Familial/genetic etiology.

The cause of sudden cardiac death in young athletes (<35 years) is usually a structural cardiac abnormality, with hypertrophic cardiomyopathy and coronary artery anomalies representing 36% and 17% of U.S. cases, respectively (Box 29-2) (Maron et al., 2009). *Commotio cordis*, involving a blunt, nonpenetrating blow to the chest that leads to a ventricular arrhythmia, accounts for approximately 3% of cases. *Commotio cordis* is most common in younger athletes (mean age, 13 years) with compliant chest walls (Maron et al., 2002). *Commotio cordis* occurs most often in sports using a firm projectile, such as baseball, softball, hockey, and lacrosse, but can also occur from contact with stationary field equipment, the ground, or another player. In older athletes (>35), atherosclerotic CAD accounts for more than 75% of cases of sudden cardiac death.

Automated External Defibrillators in Athletic Medicine

Limitations of the cardiovascular screening process, the overwhelming desire to protect young athletes from a tragic event, and the success of early defibrillation programs (Caffrey et al., 2002; Page et al., 2000; Valenzuela et al., 2000) using accessible automated external defibrillators (AEDs) have propelled the placement of AEDs into the athletic setting (Drezner et al., 2005). Recent research suggests an improved survival rate for young athletes with sudden cardiac arrest if early defibrillation is achieved. A retrospective cohort of 1710 U.S. high schools with an on-site AED program found 14 cases of sudden cardiac arrest in high school student-athletes and a 64% survival rate if early cardiopulmonary

resuscitation (CPR) and prompt defibrillation with an AED were provided (Drezner et al., 2009).

Comprehensive emergency response planning is needed to ensure an efficient and structured response to sudden cardiac arrest in the athletic setting. This includes establishing a communication system to activate the emergency medical services (EMS) system and alert any on-site response team, training of anticipated responders (e.g., coaches) in CPR and AED use, access to an AED, and practice and review of the response plan. High suspicion of sudden cardiac death should be maintained in any collapsed and unresponsive athlete, with application of an AED as soon as possible for rhythm analysis and defibrillation if indicated (Drezner et al., 2007).

KEY TREATMENT

High suspicion of sudden cardiac arrest should be maintained in any collapsed and unresponsive athlete, with application of an automated external defibrillator (AED) as soon as possible for rhythm analysis and defibrillation if indicated (Drezner et al., 2007, 2009) (SOR: B).

Concussion in Sports

Key Points

- Concussion is a neurologic disturbance with variable symptoms, including confusion, headache, vision problems, nausea, balance problems, amnesia, and loss of consciousness.
- Concussion assessment includes evaluation of cranial nerves, pupillary dilation and reactivity, balance and coordination, motor strength, and cognitive function.
- A player should never return to play while symptomatic from a concussion.
- Once asymptomatic, athletes should follow a stepwise and graded exercise program before return to play.
- Neuropsychological testing can aid return-to-play decisions for complex concussions.

In 1966 the Congress of Neurological Surgeons proposed a consensus definition of concussion. Since then, both the definition and our understanding of concussion have been evolving. A concussion is defined as a traumatically induced transient disturbance in neurologic function, usually caused by a direct blow to the head, neck, or face (Aubry et al., 2002).

Symptoms and Incidence

A concussion usually results in the rapid onset of brief neurologic impairment that resolves spontaneously. Symptoms of concussion include loss of consciousness, amnesia, confusion, headache, vision problems, nausea, and balance problems (Box 29-3). A concussion may or may not be associated with a loss of consciousness. Over 90% of concussions are not associated with a loss of consciousness, and unconsciousness is not a marker of the severity of the injury (Lovell et al., 1999). *Amnesia* can include loss of memory of the events before (retrograde amnesia) or

Box 29-3 Signs and Symptoms of Concussion

| | |
|--------------------------------------|----------------------------------|
| Disorientation | Feeling “foggy” or “dazed” |
| Confusion | Inability to focus |
| Amnesia | Difficulty concentrating |
| Loss of consciousness | Irritability |
| Headache | Emotional lability |
| Dizziness | Excessive drowsiness |
| Balance problems | Delayed verbal or motor response |
| Poor coordination, gait | Vacant, “glassy” stare |
| Nausea, vomiting | Slurred, incoherent speech |
| Visual problems (flashing lights) | Decreased playing performance |
| Hearing problems (tinnitus) | Seizure (rare) |

after (posttraumatic amnesia) the concussion, or both, and amnesia appears to be the best predictor of severity in athletic concussion (Collins et al., 2003). Conventional imaging studies such as computed tomography (CT) or magnetic resonance imaging (MRI) are normal in concussion, indicating that concussion is a *functional* rather than a structural injury (McCroory, 2001).

An estimated 300,000 concussions occur each year from sports-related activity (Centers for Disease Control and Prevention [CDC], 1997). In high school football, there are 40,000 concussions per year, for a 3% to 5% incidence (Powell and Barber-Foss, 1999). High-risk sports include contact and collision sports such as football, ice hockey, rugby, wrestling, and to a lesser extent, soccer and basketball. Women may be more prone to concussion in some sports (Tierney et al., 2005), for unclear reasons, with further research needed. Younger players also may be more prone to concussion because of less developed neck muscles and the higher relative weight of the head compared with the rest of the body. In addition, children may sustain more serious concussions because of their immature nervous system.

Sideline Management

When attending to an athlete on the field with a suspected concussion, attention must first be given to basic first aid. Airway, breathing, and circulation (ABCs) and level of consciousness should be initially assessed, followed by an evaluation for potential cervical spine injuries. If loss of consciousness has occurred, the duration of unconsciousness should be determined. A brief loss of consciousness is generally defined as less than 30 to 60 seconds. If a player is unconscious for more than 30 to 60 seconds or still unconscious by the time a physician reaches the athlete on the field, most would consider this “prolonged.” Patients with concussions involving prolonged loss of consciousness, suspected cervical spine injuries, or gross neurologic impairment should be stabilized and transported to a hospital for further evaluation (see Cervical Spine Injuries: On-the-Field Assessment).

After it is determined that the athlete is stable and safe to be moved, further assessment can take place on the sideline. Physical examination should include evaluation of cranial nerves, pupillary dilation and reactivity, balance and coordination, motor strength, and cognitive function. Orienta-

tion to time, place, and person is an incomplete assessment of cognitive function in the sports setting. Memory and recall testing, serial 7s (counting backward by 7 from 100), serial 3s (counting backward by 3 from 100), and listing the months of the year backward and forward are simple sideline tests of cognitive function. Several sideline assessment tools exist to aid medical professionals in the evaluation of an athlete with concussion. The Standardized Assessment of Concussion (SAC) is a validated sideline assessment tool, and the most recent consensus conference on concussion recommended a modified and expanded tool, the Sport Concussion Assessment Tool (SCAT2) (McCrea et al., 1997; McCroory et al., 2009). This includes a symptom scale, standard cognitive assessment, and guided physical examination. Such standardized examinations are useful for serial follow-up and if different medical personnel will be evaluating the athlete. It is important to reassess concussed athletes frequently to monitor for resolution of symptoms or signs of deterioration.

Return to Play

Return-to-play decisions are driven by the concern of preventing potential complications, primarily second-impact syndrome and permanent neurologic deficit. *Second-impact syndrome* occurs when a player returns to play following a first concussion before the symptoms have completely resolved, and a second, often minor, blow to the head is sustained, which leads to diffuse cerebral swelling, brainstem herniation, and death. The risk for catastrophic injury in athletes returned to play while still symptomatic is of particular concern in children and adolescents.

Long-term cognitive deficits from concussion or repetitive blows to the head are also a concern. Repetitive concussions, especially if severe, might put athletes at risk for permanent neurologic deficits (Guskiewicz et al., 2003). However, no evidence indicates that repetitive nonconcussive blows, such as those sustained from heading a soccer ball, lead to short-term or long-term neurologic impairment.

Most concussion guidelines designed to facilitate return-to-play decisions rely on loss of consciousness and the presence of amnesia to grade the severity of the concussion. This approach makes their usefulness limited because most sports-related concussions do not involve loss of consciousness or amnesia. Current recommendations suggest that management of concussion be based on symptoms and severity. The mildest concussion is one that involves transient symptoms that resolve quickly. More severe concussions involve persistent or prolonged symptoms and cognitive deficits on neuropsychological testing. Management of concussion includes both physical and mental rest, until all symptoms have cleared, and the neurologic examination, followed by a graded and stepwise program of exertion before return to sport (Box 29-4). *Repetitive concussions*, which take longer to return to baseline or that occur with progressively less trauma, are also considered of greater severity. Complex or recurrent concussions with persistent cognitive impairment, neurologic findings on examination, or prolonged symptoms may warrant advanced imaging and formal neuropsychological testing and should be managed by physicians with specific expertise in sports-related concussion.

Box 29-4 Graded Return to Play after Concussion*

6. Full contact drills
7. Return to competition

Modified from McCrory P, Johnston K, Meeuwisse W, et al. Summary and agreement statement of the 2nd International Conference on Concussion in Sport, Prague, 2004. *Br J Sports Med* 2005;39:196-204.

*A player should never return to play while symptomatic from a concussion. In this supervised stepwise progression, the athlete can proceed to the next level if asymptomatic at the current level. If any postconcussion symptoms occur, the athlete should return to the previous asymptomatic level and try to progress again after 24 hours. Athletes with simple concussions may progress through these stages over several days. In cases of complex concussion, recovery is more prolonged.

Neuropsychological testing in concussion, initially a comprehensive battery of conventional written tests administered by a trained neuropsychologist, has evolved into a variety of computer assessment tools. These neuropsychological assessment tools are gaining acceptance in high-risk sports at the collegiate and professional levels and are most useful when there is a baseline assessment done before injury. Widespread use of these tests in youth and high school sports with limited budgets and medical personnel might not be practical.

In summary, concussion is a common injury in sport, and athletes sustaining a concussion should be medically evaluated by a physician. No symptomatic athlete should be allowed to return to play, and an athlete should not be allowed to return to play in the same game or practice during which an injury has occurred. Once asymptomatic, athletes should follow a graded program before return to play. Referral should be considered in complex or complicated concussions. Further research is needed to provide evidenced-based return-to-play guidelines and preventive strategies.

KEY TREATMENT

A player with a concussion who is still symptomatic should be held from practice and competition and should not return to the field of play.

Once asymptomatic, athletes should follow a stepwise and graded exercise program before a return to sport.
(SOR: C; McCrory et al., 2009).

Cervical Spine Injuries**Key Points**

- “Stingers” result from a blow to the neck and shoulders with transient unilateral upper extremity pain and paresthesias resolving in minutes.

KEY TREATMENT

Axial loading is the most common mechanism for catastrophic injury to the cervical spine during sports competition.

Any athlete with significant neck or spine pain, diminished level of consciousness, or significant neurologic deficits should be immobilized and prepared for transport.

Unconscious athletes are presumed to have unstable spine injuries until proven otherwise.

The football helmet in a downed player wearing shoulder pads should not be removed to avoid hyperextension of the neck and secondary injury to the cervical spine.

Strains and Sprains

Most sports-related neck injuries are mild and self-limiting. Patients with muscle strains and ligament sprains typically present with minor complaints and no neurologic symptoms. More significant injury should be suspected in the presence of significant cervical muscle spasm, tentative active range of motion (ROM), severe pain, or abnormal neurologic signs. Evaluation includes active cervical ROM and strength testing of the neck and upper extremities. Manual compression and axial loading to the cervical spine (Spurling’s maneuver) should not cause pain or radicular symptoms and is helpful in ruling out more significant injury (Magee, 1997). The athlete is cleared to return to play when full pain-free ROM and normal strength of the cervical spine are restored.

Stingers

Stingers or “burners” are characterized by transient unilateral upper extremity pain and paresthesias resulting from a blow to the neck and shoulders. Stingers are common in American football and have been reported in up to 50% to 65% of college players (Clancy et al., 1977; Sallis et al., 1992). Stingers are peripheral nerve injuries and are considered a transient neurapraxia of the cervical nerve roots, usually involving the upper trunk of the brachial plexus (C5-C6). Stingers typically manifest with dysesthesia (burning pain) that begins in the shoulder and radiates down the arm. They often are associated with transient numbness or weakness, and all symptoms typically resolve in minutes.

Stingers can occur from a tensile or compression overload (Watkins, 1986). In most high school athletes, the mechanism of injury involves a tensile or traction injury when the involved arm and the neck are stretched in opposite directions. This occurs when the neck is forcibly flexed away while the shoulder is depressed. In college and professional athletes, who have a higher likelihood of degenerative changes of the cervical spine, a compression mechanism is more likely. This involves a pinch of the cervical nerve root within the neural foramen as the neck is forcibly extended in a posterolateral direction (Levitz et al., 1997).

Stingers are always unilateral, a distinguishing feature from spinal cord injuries, which involve symptoms in multiple limbs. Athletes are safe to return to play when symptoms have fully resolved and the athlete can demonstrate full cervical ROM and a normal neurologic examination.

Radiography and MRI should be considered in athletes with recurrent stingers to evaluate for cervical degenerative disk disease (Levitz et al., 1997). Rarely, more significant nerve injury involving *axonotmesis* (axon disruption) occurs, causing persistent weakness. Athletes with significant weakness 24 to 48 hours after injury may benefit from treatment with a short burst of oral corticosteroids. If weakness persists, electromyography performed 2 weeks or more after the injury will assess the distribution and degree of injury. Fortunately, most cases of axonotmesis recover within 1 year (Clancy et al., 1977).

Cervical Cord Neurapraxia

Cervical cord neurapraxia is characterized by an acute, transient sensory or motor change, or both, to more than one extremity. Symptoms include burning pain, numbness, and tingling with or without paresis or complete paralysis. *Transient quadriplegia* is a type of neurapraxia characterized by temporary paralysis and loss of motor function in all four limbs (Torg et al., 1986). *Burning hands syndrome* is characterized by burning dysesthesias of the hands and associated upper extremity weakness (Maroon, 1977). Episodes of cervical cord neurapraxia usually resolve within 10 to 15 minutes, although gradual resolution may take more than 24 to 48 hours.

Congenital or degenerative narrowing of the anteroposterior (AP) diameter of the cervical spinal canal is an established risk factor for cervical cord neurapraxia (Torg et al., 1997). Athletes with an episode of cord neurapraxia should be held from competition and undergo radiographic evaluation and MRI. Return to play after an episode of cervical cord neurapraxia is a highly controversial area in sports medicine. Several cases of permanent neurologic injury following cervical cord neurapraxia associated with cervical spinal stenosis have been reported (Brigham and Adamson, 2003; Cantu, 1993, 2000). Functional spinal stenosis on advanced imaging in an athlete with a history of cervical cord neurapraxia is an absolute contraindication to return to play in contact and collision sports (Cantu, 2000).

Catastrophic Cervical Spine Injury

Injury to the spinal cord resulting in temporary or permanent neurologic injury is a rare but potentially catastrophic event during sports competition. Cervical spine trauma is most common in contact and collision sports such as American football, rugby, ice hockey, gymnastics, skiing, wrestling, and diving (Cantu and Mueller, 1999; Carvell et al., 1983; Tator and Edmonds, 1984; Wu and Lewis, 1985). Cervical spinal cord injuries are the most common catastrophic injury in American football and the second leading cause of death attributable to football. The National Center for Catastrophic Sports Injury Research reported that the incidence of cervical spinal cord injury in American football between 1977 and 2001 was 0.52, 1.55, and 14 per 100,000 participants in high school, college, and professional football, respectively (Cantu and Mueller, 2003).

Axial loading is the most common mechanism for catastrophic injury to the cervical spine during sports competition (Torg et al., 1979, 1990). Axial loading occurs when a player strikes another player with the top of the head as

the point of initial contact (“spear tackling”). In athletes with cervical spinal stenosis, axial loading followed by forced hyperextension or hyperflexion can further narrow the AP diameter of the spinal canal, resulting in compression of the spinal cord and transient or permanent neurologic changes (Eismont et al., 1984; Penning, 1962; Torg et al., 1993).

Recognition of the axial load mechanism as the major cause of catastrophic cervical spine injury in American football resulted in rule changes that banned “spearing,” defined as intentionally striking an opponent with the crown of the helmet, as well as other tackling techniques in which the helmet is used as the initial point of contact. In 1976 the incidence of quadriplegia was 2.24 and 10.66 per 100,000 in high school and college athletes, respectively. In 1977, only 1 year after rule changes that banned spear tackling, the incidence decreased to 1.30 and 2.66 per 100,000 in high school and college athletes (Torg et al., 2002).

On-the-Field Assessment

Medical providers at sporting events must be prepared to assess, stabilize, and transport athletes with suspected cervical spine injuries. Adequate preparation and anticipation in required personnel and equipment and a well-designed emergency response are critical to the management of catastrophic neck injuries. In general, any athlete with significant neck or spine pain, diminished level of consciousness, or significant neurologic deficits should be immobilized and prepared for transport.

Guidelines for the prehospital care of the spine-injured athlete were established by the Inter-Association Task Force for Appropriate Care of the Spine-Injured Athlete (2001). The initial assessment of an injured athlete begins with a basic assessment of the ABCs and level of consciousness. EMS personnel should be contacted for any concerns regarding basic life support. Unconscious athletes are presumed to have unstable spine injuries until proven otherwise.

The face mask of a protective helmet should be removed as soon as possible, regardless of respiratory status (Inter-Association Task Force, 2001). In football the face mask can be removed with screwdrivers or the loop straps cut with various cutting tools such as pruning shears or a Trainer’s Angel (Knox and Kleiner, 1997). Football helmets and chin straps should be left in place. If the helmet is removed from a downed player wearing shoulder pads, the athlete’s head will hyperextend, which may result in secondary injury to the cervical spine. If the athlete is not breathing, an adequate airway can be established by the jaw thrust maneuver, which allows opening the airway while maintaining the cervical spine in a stable position. Rarely, assisted ventilation may be necessary.

If transport is indicated, the athlete should be immobilized to a spine board. A supine athlete can be transferred to a spine board using a six-plus person lift technique, with one person responsible for stabilization of the head and neck (Inter-Association Task Force, 2001). To transfer an athlete who is facedown, a logrolling technique is recommended. Transport of a spine-injured athlete should be directed to a trauma center or medical facility with diagnostic and surgical capabilities for spinal injury.

KEY TREATMENT

Athletes with an episode of cervical cord neurapraxia involving sensory or motor changes, or both, to more than one extremity should be held from competition and undergo radiographic evaluation and MRI to rule out functional spinal stenosis.

In an athlete with a history of cervical cord neurapraxia, functional spinal stenosis on advanced imaging is an absolute contraindication to return to play in contact and collision sports (SOR: C; Cantu, 2000; Inter-Association Task Force, 2001).

Environmental Influences**Exertional Heat Illness****Key Points**

- Hydration sufficient to replace fluid lost in sweat is essential to prevent heat stroke.
- Athletes exercising in the heat who exhibit mental status changes must be immediately removed from competition and cooled.
- Ice-water immersion produces the most rapid decrease in core body temperature.

Heat stroke is the third leading cause of death in high school athletes (Lee-Chiong and Stitt, 1995). This is tragic because these deaths should be largely avoidable.

The exercising human is an engine operating at about 25% efficiency, resulting in 3 W of heat production for every watt of work, and requires a biologic radiator to avoid overheating. Humans dissipate heat through convection, conduction, radiation, and evaporation, with evaporative sweat loss being the most significant. Higher temperatures limit heat dissipation from convection and conduction, warm sunny days elevate body temperature through radiant heating, and higher humidity decreases evaporative cooling. Thus, the combination of high ambient temperature, radiant heat from the sun, and high humidity works synergistically to create dangerous playing conditions that promote the development of heat illness.

The wet bulb globe temperature (WBGT) index incorporates ambient temperature, relative humidity, and the amount of radiant heat coming from the sun to provide a measure of the risk of overheating. The American College of Sports Medicine Inter-Association Task Force on Exertional Heat Illnesses Consensus Statement (2006) recommends that WBGT readings from 18° to 23° C (64.4°-73.4° F) result in moderate risk, 23° to 28° C (73.4°-82.4° F) in high risk, and more than 28° C (82.4° F) in extreme risk. The cumulative effect of successive days of exercise in the heat must also be considered. In a U.S. Marine Corps, investigators demonstrated that the risk of exertional heat illness was best predicted by considering the current and the previous day's WBGT index (Wallace et al., 2005).

Because evaporative cooling is the primary mechanism for heat dissipation, adequate hydration is essential to keep the biologic radiator functioning. Losses of 2% to 3% of body weight are common with high-intensity exercise in the heat (Galloway, 1999). Below 5% fluid losses, performance and thermoregulation are impaired, and thirst is an inconsistent

stimulus to rehydrate, so regular, planned fluid consumption is essential. Fluid recommendations vary, but experts have suggested about 500 mL of fluid intake 2 hours or less before exercise and then about 250 mL every 20 minutes during exercise (Convertino et al., 1996). Because of differences in sweat rate, acclimatization, intensity of exercise, clothing, protective equipment, and environmental factors, individual fluid requirements vary. Thus, recording an athlete's nude weight in the morning and evening is an effective method for determining adequate rehydration. If athletes are losing more than 2% to 3% of their body weight with training, they need to consume more fluids during training. If they cannot regain the lost weight before the next morning's training, they need to consume additional fluids after training and during recovery time. For every kilogram of body weight lost, 1 L of fluid should be consumed. Cooler, flavored fluids are recommended to increase palatability and absorption.

Heat illness is classified as heat edema, heat cramps, heat syncope, heat exhaustion, and heat stroke (Table 29-1) (Binkley et al., 2002; Eichner, 1998). Heat stroke is of the greatest concern, with hallmark features of an elevated core temperature higher than 40.5° C (105° F) and associated mental status changes. Any athlete exhibiting mental status changes and participating in an environment conducive to heat illness requires immediate removal from participation and active cooling. An ice-water tub should be prepared in advance if rapid cooling may be necessary in high-risk events, and an affected athlete should be fully submerged, with only the head above water (Smith, 2005). Other methods of cooling, such as applying ice bags to the neck, axilla, and groin, or using cold-water spray combined with fanning, can be effective, but the rate of core body temperature loss is slower than in ice-water immersion. Close monitoring of mental status and vital signs (e.g., core temperature) is indicated, and athletes should be transported to the hospital if they do not exhibit improving mental status with normalization of vital signs. The National Athletic Trainers' Association Exertional Heat Illness Position Statement is an excellent reference regarding proper preparedness for heat illness (Binkley et al., 2002).

Exertional Hyponatremia**Key Points**

- Life-threatening hyponatremia develops when excessive hypotonic fluid is consumed, with concomitant sodium sweat loss.
- Exertional hyponatremia most often occurs in women completing endurance races in over 4 hours who drink copiously throughout the race.
- Symptoms of exertional hyponatremia include mental status changes and peripheral edema, without significant elevation in core temperature.

Exertional hyponatremia (serum sodium <130 mmol/L), once considered a rare complication of exercise in the heat, is now recognized as more common and responsible for a number of exercise-related deaths (Almond et al., 2005). Controversy surrounds the exact pathophysiology, but the condition develops in the setting of excessive hypotonic fluid replacement while sodium is progressively lost in

Table 29-1 Exertional Heat Illness

| | Definition | Management | Prevention |
|--|--|---|---|
| Heat edema | Dependent edema usually occurring before acclimation. | Elevation of swollen extremity, rest, cooling. Diuretics contraindicated. | Gradual acclimation to heat. |
| Heat (exercise associated) muscle cramps | Painful spasms of single or multiple muscles. Likely sodium deficiency and salty sweaters most prone. | Rest, stretching, cooling, oral hydration with hypertonic sodium drink. Intravenous fluids (normal saline) if oral treatment limited or to expedite recovery. | Maintain hydration and increase salt intake. Add salt to fluids, especially for those with predisposition based on past history. |
| Heat syncope | Orthostatic dizziness at cessation of exercise, with prolonged standing, or after assuming upright posture. | Rest, cooling, place supine with legs elevated, monitor vital signs, and mental status. Oral fluid hydration. | Adequate hydration and acclimation. If occurs during exercise, requires cardiovascular evaluation. |
| Heat exhaustion | Inability to continue exercise in heat. Symptoms: weakness, fainting, dizziness, headache, nausea, vomiting, cramps, dehydration with low urine output. Minimal mental status symptoms; core temperature <40° C. | Immediate rest, rapid cooling (ice bath), close monitoring of mental status, vital signs (e.g., core temperature). Serum sodium if hyponatremia considered. Oral fluid hydration with IV fluids (normal saline) if hypotension present. | Adequate acclimation, monitor hydration, adjust training to climate, follow player's weight, and close monitoring for symptoms of heat illness. |
| Heat stroke | Heat exhaustion with core temperature >40° C and mental status alteration or central nervous system collapse. | As for heat exhaustion, with hospitalization as soon as possible. | As for heat exhaustion, be prepared with ice baths, monitoring equipment, and access to emergency medical services. |

sweat (Levine and Thompson, 2005; Noakes, 2002). Typical victims are relatively inexperienced female marathon runners who tend to be light sweaters, finish in over 4 hours, and drink copiously throughout the race. Nonsteroidal anti-inflammatory drugs (NSAIDs) taken before the race may be a contributing factor (Hsieh, 2004). Athletes with a history of exercise-induced hyponatremia do not seem to be predisposed to water overload at rest, although there may be some physiologic mechanism beyond pure water overload that accounts for the condition in some susceptible individuals (Speedy et al., 2001). Symptoms are similar to those of heat exhaustion, including weakness, dizziness, headache, nausea, vomiting, and cramping, but the headache is more prominent and progressively severe, extremity swelling may be noted, and progressive mental status changes occur despite a core temperature lower than 40° C (104° F). Cerebral edema underlies the mental status changes, and pulmonary edema may also occur.

The serum sodium level must be assessed in athletes in whom the diagnosis is suspected, to differentiate hyponatremia from heat stroke. Intravenous (IV) fluids, often indicated in heat stroke, can actually worsen hyponatremia if related to excessive hypotonic fluid intake. Prompt hospitalization is indicated for any athlete with mental status changes or persistently altered vital signs once the diagnosis of hyponatremia has been established. Exertional hyponatremic encephalopathy is treated with 3% hypertonic saline boluses (100 mL) (Hew-Butler et al., 2008). Prevention includes following an athlete's weight change with exercise to understand the fluid requirements more precisely, not deviating from established fluid intake on race day to avoid overhydration, incorporating sodium/electrolyte-containing fluids, and limiting fluid intake to 1 L/hr unless higher fluid requirements have been established (Gardner, 2002).

KEY TREATMENT

Any athlete exhibiting mental status changes and participating in an environment conducive to heat illness requires immediate removal from participation and active cooling (American College of Sports Medicine, 2006) (SOR: B). Exertional hyponatremic encephalopathy is treated with 3% hypertonic saline boluses (100 mL) (Hew-Butler et al., 2008) (SOR: B).

Cold Injury

Key Points

Cold-weather exercise requires proper layering of synthetic clothing with a waterproof, breathable outer layer to maintain body temperature, but excessive sweating or environmental dampness should be avoided.

Hypothermia victims should be sheltered, dried, and warmed, and resuscitation attempts should continue until body temperature is higher than 32° C.

Outdoor sports participation, particularly winter sports, places athletes at risk for cold-induced injury. Two problems commonly encountered are frostbite and hypothermia.

Frostbite most frequently affects the toes, fingers, and exposed skin of the face. As tissue cools, a progressive cell membrane leak results initially in increased extracellular fluid, with progression to extracellular ice crystal formation and then ischemic necrosis. Prevention includes dry layering of clothing that is not constricting; avoidance of skin exposure, especially in windy, cold conditions; and maintaining the core temperature, because hypothermic shunting of blood centrally promotes distal extremity freezing. Treatment involves warming, although this is not recommended until the victim has been safely evacuated—warming and then

refreezing is more damaging. Antibiotics, tissue debridement, and possibly amputation may be required, depending on the extent of injury. Sallis and Chassay (1999) provide a more in-depth discussion of frostbite and other cold-induced injuries.

Hypothermia is defined as a core temperature at or below 32° C (90° F). Lower ambient temperatures and longer exposure times increase the risk for hypothermia, but *moisture* is the most dangerous variable that must be controlled. Wet clothing results in significant increases in conductive heat loss, which is made worse in the wind. Prevention of hypothermia requires proper clothing for outdoor exercise in the cold. Clothing should be layered so that with increased exertion and endogenous heat production, layers can be removed to avoid excessive sweating. Underlayers should consist of breathable wicking fabrics that move sweat moisture away from the skin. Outer layers should be windproof, waterproof, and breathable. Midlayers, which can be added depending on the temperature and exertion level, should provide loft (synthetic pile or down) to trap air; this provides a temperature gradient between the warm underlayers and cold outer layers, much like the blubber on a marine mammal. Heat loss from the head is significant, so a hat or hood that wicks moisture is necessary, and mittens are warmer than gloves for very cold weather. Dehydration must be avoided, because low plasma volume results in peripheral vasoconstriction and increases the risk of frostbite.

Treatment of mild hypothermia involves finding warm shelter away from the wind, removing wet outer layers, and covering with dry blankets. Sharing a sleeping bag with a warm climbing partner can be lifesaving in a desperate situation. In the setting of severe hypothermia, warm IV fluid (40° C), warm humidified oxygen, and warming lamps are indicated, if available. The adage “one is not dead until warm and dead” applies, and ventricular fibrillation or asystole in the setting of hypothermia should be treated with advanced cardiac life support (ACLS) protocols until the patient has a core temperature above 32° C (Sallis and Chassay, 1999; Tom et al., 1994).

Altitude Illness

High-altitude medicine, once the preoccupation of research pulmonologists and physicians practicing at high altitude or caring for climbers, has become essential for many primary care providers because of increasing numbers of recreational athletes engaging in skiing, hiking, trekking, and other high-altitude pursuits.

Acute mountain sickness (AMS) and its two most significant manifestations, high-altitude pulmonary edema and high-altitude cerebral edema, are complications of travel to higher altitude with insufficient acclimatization. Symptoms of AMS include headache, sleep difficulty, and gastrointestinal (GI) upset, including loss of appetite, nausea, and vomiting. Symptoms occur a few hours after rapid ascent in 25% of individuals at as low as 8500 feet (Harris et al., 1998), with a higher percentage being affected at higher altitudes. Individuals vary in their susceptibility to AMS, and a high level of physical fitness is not protective. Gradual ascent, allowing acclimatization, will prevent symptoms. If symptoms occur, delaying any further ascent with relative rest for 1 to 3 days usually results in improvement. More significant symptoms respond to decreasing altitude. Individuals with a history of AMS are likely to have it recur when they return to a higher altitude.

Planning time for acclimatization and avoiding excessive exercise when first arriving at a higher altitude are helpful. Nocturnal periodic breathing probably contributes to worsening hypoxia and subsequent AMS symptoms, so avoiding alcohol or other sedatives is also helpful. Acetazolamide, 125 to 250 mg twice daily, started the day of initial ascent and continuing for 48 hours, has been shown to decrease AMS symptoms and hasten acclimatization, possibly by decreasing nocturnal periodic breathing (Bartsch et al., 2004).

High-altitude cerebral edema (HACE) is defined as a progression of AMS symptoms to include ataxia, mental status changes, lassitude, and eventual coma. HACE is fatal if untreated. Treatment requires immediate descent. Hyperbaric treatment can be lifesaving if immediate descent is not possible; portable hyperbaric chambers are available for mountaineering expeditions. In addition to immediate descent, treatment includes oxygen at 2 to 4 L/min and dexamethasone, 4 to 8 mg orally, followed by 4 mg every 6 hours.

High-altitude pulmonary edema (HAPE) is the development of pulmonary edema, dyspnea, and hypoxemia in the setting of AMS. Rapid descent to lower altitude is also the primary treatment. The administration of supplemental oxygen, 4 to 6 L/min, and nifedipine, 10 mg once, followed by 30 mg of sustained-release nifedipine every 12 to 24 hours, is helpful if immediate descent is not possible (Rodway et al., 2003).

KEY TREATMENT

Hypothermia victims should be sheltered, dried, and warmed and resuscitation attempts continued until body temperature is higher than 32° C (90° F) (Sallis and Chassay, 1999; Tom et al., 1994) (SOR: B).
Pharmacologic prophylaxis can be helpful, but definitive treatment of high-altitude pulmonary or cerebral edema (HAPE, HACE) requires descent to lower altitude as rapidly as possible (Rodway et al., 2003) (SOR: B).

Sports Trauma to the Teeth, Face, and Eyes

Key Points

- Dental trauma is common in many sports and can be largely prevented with a custom-molded mouth guard.
- Avulsed teeth or tooth fragments should be wrapped in saline-soaked gauze, with urgent transport to a dentist and luxated teeth repositioned if possible.
- Facial and nasal injuries requiring immediate referral include those with prolonged loss of consciousness, visual abnormalities suggesting orbital fracture, malocclusion of the teeth suggesting maxillary or mandibular fracture, facial paresthesias suggesting infraorbital nerve injury, open or significantly displaced nasal fractures, and uncontrollable epistaxis.
- Acute auricular hematomas should be fully evacuated to avoid chronic fibrosis and deformity (cauliflower ear).
- Eye trauma is usually preventable using appropriate eye protection.
- Loss of visual acuity, evidence of globe rupture or leaking aqueous humor, limitation or asymmetry of extraocular movements, persisting pupil abnormalities, and evidence of hyphema all require urgent ophthalmologic consultation.

Dental Trauma

Dental trauma is common, with one third of all dental injuries in the United States occurring with sports activities (Honsik, 2004). Mouth guards are recommended by the American Dental Association for participation in all collision and contact sports as well as weightlifting, skydiving, skateboarding, gymnastics, racquetball, squash, and skiing. Dental injury is especially common in sports combining collision and a hard ball or puck, such as ice hockey or field hockey. A study of college basketball found a significant decrease in tooth injuries in participants using custom-fitted mouth guards; however, there was no decrease in oral soft tissue injury or concussion (Labella et al., 2002). Sports physicians and dental professionals agree that although off-the-shelf molded mouthpieces are less expensive and more readily available, they do not protect teeth as effectively as a custom mouthpiece (Honsik, 2004).

Teeth rest in a bony socket, each with a neurovascular root connected to the socket by a periodontal ligament. Above the gum the tooth consists of three layers: dentin, pulp, and superficial enamel. Injuries involve fracture of the tooth or some degree of luxation. *Fractures* range from an enamel chip to those involving the deeper components. *Luxation* can result in a normally positioned loose tooth or a displaced tooth still positioned in the socket. Injury can also result in complete tooth avulsion.

After injury, tooth fragments or avulsed teeth should always be recovered, if possible, and transported to a dentist in saline-soaked gauze. Fractures involving only enamel and dentin can be managed by dental evaluation within 48 hours. Pulp involvement (visible pink or blood in center of the tooth) mandates urgent dental referral, and medical-grade cyanoacrylate (Super Glue) can be placed on the tooth acutely for pain and to prevent infection. Luxation without impaction can be reduced if jaw fracture is not suspected, and return to play with a custom mouth guard can be considered, depending on successful reduction, level of pain, and level of competition. If the tooth is easily repositioned, dental consultation can be delayed 24 hours. Players with impacted luxation or teeth that cannot be repositioned should not return to play, and dental consultation sought immediately. Avulsed teeth should be rinsed with sterile saline and replaced, if possible, taking care not to handle or damage the root, followed by immediate dental consultation (Honsik, 2004).

Facial Trauma

Nasal injuries are frequently encountered in sports. The higher the impact velocity, the higher is the probability of concomitant injury requiring urgent referral. Situations requiring emergency department (ED) evaluation include associated prolonged loss of consciousness, vision abnormalities suggesting orbital fracture, malocclusion of the teeth suggesting maxillary or mandibular fracture, facial paresthesias suggesting infraorbital nerve injury, open or significantly displaced nasal fractures, and uncontrollable epistaxis. Examination findings prompting early referral include clear rhinorrhea suggesting cribriform plate injury with cerebrospinal fluid (CSF) leak and impaired extraocular movements, especially unilateral limited upward gaze, which suggests an

orbital fracture with inferior oblique or rectus muscle entrapment, or both. Nasal septal hematoma should be referred to an otolaryngologist expeditiously for incision and drainage. If left untreated, subsequent cartilage degeneration can result in a nasal saddle deformity (Stackhouse, 1998).

If initial assessment does not mandate immediate referral, subsequent management requires assessing the extent of deformity and controlling epistaxis. In the first few days, swelling can make assessment for bony deformity difficult, but close follow-up is helpful. Any persistent obstruction of the nares or cosmetic abnormality unacceptable to the patient should be referred to an otolaryngologist within 5 days, because reduction is best performed within 10 days of injury. Epistaxis is best managed with a topical decongestant such as oxymetazoline nasal 0.05% (Afrin) and compression of the anterior plexus by pinching the nose for 15 minutes. A short nasal tampon soaked with oxymetazoline can be placed into the bleeding nostril to assist with hemostasis and return to play, but anterior packing should only be performed with appropriate visualization, to avoid further injury.

Ear trauma in sports can result in auricular hematomas or injury to the tympanic membrane. *Auricular hematomas* mainly occur in wrestling, rugby, and boxing and result in hemorrhage between the perichondrium and the underlying cartilage. Failure to evacuate the hematoma can lead to fibrosis, necrosis, and a chronic deformity known as *cauliflower ear*. An acute auricular hematoma should be drained by needle aspiration under aseptic conditions, and a pressure dressing (using cotton wool soaked in collodion or a silicone splint) carefully applied against the contours of the outer ear and reexamined daily. Occasionally, incision and drainage are required.

Blows across the side of the head can also result in *tympanic membrane rupture*, marked by pain, bleeding, fluid drainage, and impaired hearing. Tympanic membrane ruptures usually heal spontaneously over 4 to 6 weeks. Antibiotic prophylaxis in the first week should be considered, especially if the rupture occurred in a contaminated environment. The ear canal should be kept clean and dry, and a cotton ball coated with petroleum jelly and placed gently into the ear canal can be helpful while showering.

Eye Trauma

Ocular injury is common in sports and largely preventable if athletes wear appropriate eye protection. The highest risk sports are those in which intentional injury can occur (e.g., boxing and combative martial arts) and those in which hard projectiles, sticks, or fingers are likely to encounter the eye. High-risk sports include basketball, baseball, softball, cricket, lacrosse, squash, racquetball, fencing, and all varieties of hockey. Squash and racquetball are particularly concerning because of the high likelihood of severe injury. Athletes with preexisting monocular visual impairment must understand the importance of protecting the good eye, and preparticipation visual acuity assessment of binocular and monocular vision is essential. The American Society for Testing and Materials (ASTM) is the primary U.S. organization for certifying eyewear for sports, and experts have provided recommendations for eye protection for different sports (Vinger, 2000).

Common sports-related eye injuries include presence of a foreign body and corneal abrasion. More significant impact results in possible iris injury, posttraumatic iritis, hyphema, or globe perforation or rupture. Athletes presenting with eye pain should be removed from participation and have a thorough eye examination, as follows:

1. Assessment and documentation of visual acuity
2. Inspection for evidence of globe rupture or leaking aqueous humor
3. Assessment of extraocular movements, limitation, or asymmetry suggesting orbital fracture
4. Assessment of pupil reactivity (A dilated, constricted, or sluggish pupil can be transient secondary to iris trauma or may indicate hyphema or globe injury.)
5. Inspection of anterior chamber for blood indicating hyphema

Abnormalities identified on this initial examination require consultation with an ophthalmologist. If the examination is normal, lid inversion should be performed, inspecting for a foreign body, with slit-lamp evaluation using fluorescein staining to assess for corneal abrasions. Anesthetic eyedrops may be required to facilitate the examination and for initial pain management but should not be used to allow return to play or for ongoing pain management (Moeller and Rifat, 2003).

Corneal abrasions are treated with antibiotic eyedrops to prevent infection and topical NSAIDs given for pain, if necessary (Weaver and Terrell, 2003). Once pain-free, with a normal follow-up examination, athletes might return to play. After ocular injury, an athlete is often more receptive to counseling on protective eyewear.

Infectious Disease

Key Points

- Upper respiratory infections are more common in heavily training athletes, and team physicians must consider both infection control measures and avoiding banned substances when treating high-level athletes.
- Infectious mononucleosis is associated with splenomegaly and a risk of splenic rupture. It requires that athletes avoid heavy exertion and contact sports until the spleen is of normal size, usually within 4 weeks.

Upper respiratory tract infection (URI) is a common complaint in primary care sports medicine. Regular, moderate exercise may decrease the risk for contracting a URI, but acute bouts of heavy exercise, such as running a marathon, and prolonged heavy training increase the risk for URI (Niemann, 2003). Treatment of URI is symptomatic, but health care providers of competitive athletes must consider which substances are banned by the governing body overseeing their sport. Banned substances are subject to change, and physicians must be aware of current regulations. For example, the World Anti-Doping Agency (WADA), responsible for drug regulation for many international sports organizations, bans stimulants and many sympathomimetics. Ephedrine is banned above a urine concentration threshold, and pseudoephedrine was banned until a rule change in 2005.

Most governing bodies, such as WADA (2009) and the National Collegiate Athletic Association (NCAA, 2009), have websites posting current banned substances (see Web Resources). These sites should be consulted before prescribing or recommending any medication for athletes subject to drug testing.

Physicians caring for teams must also consider infection control measures. URI, viral gastroenteritis, skin infection, and mononucleosis are of particular concern. Vectors that must be considered include common source spread (enteroviruses), person-to-person spread from sharing secretions (viral, fungal, bacterial skin infection), and airborne droplet spread (picornaviruses). Sharing of water dispensers, bottles, and towels should be eliminated. Handwashing must be encouraged and antibacterial soap or alcohol-based hand sanitizers provided. Shared equipment must be disinfected. Simple infection control measures are often not practiced in the setting of team sports, and educating athletes, coaches, and training staff is the responsibility of the team physician.

Mononucleosis

Infectious mononucleosis (mono) caused by Epstein-Barr virus (EBV) or occasionally by cytomegalovirus (CMV) deserves special mention. Splenomegaly and spleen fragility are often associated with mono and are a concern for team physicians because of the risk of splenic rupture. The prolonged fatigue accompanying mono is also especially difficult for athletes trying to return to training as soon as possible.

Epstein-Barr virus is prevalent and shed in saliva, thus, mono's reputation as the "kissing disease." About 50% of the U.S. population seroconverts by age 5 years, with a mild viral syndrome or asymptotically. If an individual reaches college age (18-22) without infection, seroconversion results in a 30% to 70% incidence of mono (Schooley, 1999). Symptoms include 1 week of significant flulike symptoms with anterior and often significant posterior cervical lymphadenopathy and exudative pharyngitis. Splenomegaly occurs in 50% of cases during weeks 2 to 3 of illness and usually resolves by weeks 4 to 6. Splenomegaly is difficult to confirm on examination alone and should be suspected in all athletes with mono. Significant fatigue is often prevalent, and although most symptoms resolve by 4 weeks, fatigue can last 12 weeks or longer (Rea et al., 2001).

Once suspected, the diagnosis of mono should be confirmed because of the risk of splenic rupture and implications for withholding sports participation. The diagnosis can be confirmed by a positive EBV heterophile antibody (Monospot) with 90% sensitivity by 3 weeks. False-negative results are common in the first 2 weeks, with a positive test in only 40% of those infected during the first week of illness. Therefore, an initially negative Monospot test in a suspicious case should be repeated 1 week later. An EBV or CMV viral capsid antigen (VCA) immunoglobulin M (IgM) assay can also provide evidence of acute infection, with 90% sensitivity at the onset of symptoms (Cohen, 1998).

There is no clear evidence-based answer for when an athlete with mono can safely return to sports. The risk of splenic rupture associated with sporting activity occurs almost exclusively in the first 3 weeks of illness (Kinderknecht, 2002). Many authorities recommend restriction from noncontact sports for 3 weeks, until symptoms have largely resolved and

the spleen is not palpable. Returning athletes to contact sports can be considered after 4 weeks of illness, when all symptoms have resolved and splenomegaly is absent (Auwaerter, 2004). The range for normal spleen size varies significantly, and splenic ultrasound is not necessary in most cases but can be considered before returning an athlete to contact sports. Larger-than-normal ranges for splenic size have been described for taller athletes (Spielmann et al., 2005).

KEY TREATMENT

For athletes with confirmed mononucleosis, return to sport can be considered after 3 weeks for noncontact sports and after 4 weeks for collision sports once symptoms have largely resolved and the spleen is not palpable (Auwaerter, 2004) (SOR: C).

Sports Dermatology

Key Points

- Fungal, viral, and bacterial skin infections are usually transmitted through person-to-person contact in sports activities.
- Management requires a high index of suspicion, prompt treatment, restriction of participation for contagious athletes, covering lesions when appropriate to allow participation, and appropriate prophylaxis and treatment.
- Skin problems are usually caused by laceration or abrasion, environmental exposure, inflammation, or infection.

Fungal Infections

Tinea (ringworm) is one of the most common fungal infections. Tinea pedis is frequently seen in athletes secondary to group showering, and it can be prevented to some extent by having athletes regularly change socks and use wicking materials in socks to keep feet dry, drying powders (many of which contain prophylactic topical antifungals), and shower shoes. Treatment with topical antifungals and oral therapy for severe cases are effective.

Fungal infections are spread directly from person to person through contact sports, with the type seen in wrestlers (tinea corporis gladiatorum) being the most problematic. Tinea tonsurans occurs most often, with infection rates in high school wrestlers of 24% to 75% (Adams, 2000; Beller and Gessner, 1994). Infection is caused by contact with an infected opponent and usually occurs on the arms, neck, or head. The lesions often appear initially as annular plaques with raised erythematous borders and may progress without the central clearing often appreciated with ringworm (Adams, 2002). Microscopic evaluation of skin scrapings with potassium hydroxide (KOH) may reveal fungal elements. Topical treatment with azole agents and oral treatment have been studied. A randomized prospective study of topical clotrimazole 1% cream twice daily versus oral fluconazole, 200 mg weekly, showed equal symptomatic improvement after 10 days and a similar 50% lesion reduction at 17 days. However, 50% culture eradication took 11 days with oral treatment and 22 days with topical treatment, leading to the conclusion that weekly fluconazole should be first-line treatment (Kohl et al., 1999). For

multiple lesions, a 3-week treatment course with an oral antifungal is recommended.

Return-to-play recommendations after tinea corporis gladiatorum infection vary. The NCAA requires 72 hours of topical therapy for skin lesions and 2 weeks of oral therapy for scalp lesions, and also stipulates that athletes may participate with an active lesion provided it is covered entirely by an adhesive nonpermeable dressing (NCAA, 2009). The National Federation of State High School Associations does not allow participation with communicable lesions even if covered (Landry and Chang, 2004). Prophylaxis using oral itraconazole every other week and oral fluconazole weekly has been shown to be effective (Hazen and Weil, 1997; Kohl et al., 2000), but the potential for exposure and time loss morbidity of an active infection must be weighed against the cost and potential side effects.

Viral Infections

Herpes gladiatorum, caused by herpes simplex virus (HSV), is highly contagious and spread by person-to-person contact, with a predilection for the face, arms, and upper trunk. As the name suggests, herpes gladiatorum is common in wrestling, although epidemics are also reported in other sports, such as rugby (Adams, 2002) (Fig. 29-4). Because herpes lacks definitive treatment, it is considered more serious than tinea. Herpes gladiatorum has a prevalence as high as 40% in collegiate wrestlers (Anderson, 1999). Outbreaks generally occur 2 to 5 days after exposure. Lesions typically manifest with prodromal pain or itching, followed by clear vesicles on an erythematous base. Primary infections may cause systemic flulike symptoms, and recurrent infections occur in the same dermatome. Often, the vesicles have been traumatized before evaluation, making the rash appear nonspecific, although the prodromal symptoms or history of previous outbreak in the same location suggests herpes. Traditionally, diagnosis was confirmed with Tzanck testing or culture, but the direct fluorescent antibody test is widely available and provides rapid detection of HSV in specimens with greater sensitivity than traditional methods.

The natural history of a herpes outbreak is to resolve and possibly recur, with frequency and severity dependent on both host and environmental factors. Treatment with oral antiviral agents can shorten the duration of the outbreak,

Figure 29-4 Herpes gladiatorum. Lesions may be numerous in wrestlers and involve a wide area of the skin surface.

(From Habif T. *Clinical Dermatology*, 5th ed. Philadelphia, Elsevier, 2009.)

decrease contagion, and prevent recurrent infection. No one agent has proved superior. The most cost-effective regimen is acyclovir, 400 mg three times daily for 10 days for primary infections and for 5 days for recurrent infections. Treatment is most effective when started at the first sign of infection. Prophylaxis with valacyclovir (500-1000 mg daily) limited herpes gladiatorum recurrence (Anderson, 1999), and acyclovir (400 mg twice daily) has demonstrated effectiveness comparable to valacyclovir, limiting recurrent genital herpes (Reitano et al., 1998). Research using antivirals for primary prevention is lacking, but entire teams may be placed on prophylactic doses if a team member or opposing team member has an outbreak. Some team physicians offer prophylactic treatment to the squad before large tournaments or for the entire competitive season.

Return to play after herpes infection is more conservative than with tinea infection. The NCAA requires that wrestlers be free of any systemic symptoms, have no new blisters for 72 hours, have all lesions crusted over, and have taken treatment doses of antiviral medication for 120 hours before competition (NCAA, 2009).

Bacterial Infections

Bacterial infections are common in sports, and treatment is similar for both athletes and nonathletes. Bacterial infections of the skin generally manifest as furuncles, carbuncles, impetigo, cellulitis, or erysipelas. Staphylococcal and streptococcal infections are most common, but community-acquired methicillin-resistant *Staphylococcus aureus* (CA-MRSA), first reported in the late 1990s, has become a significant problem in athletic training facilities (Lindenmighter et al., 1998; Nguyen et al., 2005).

Sports activities provide a favorable environment for the acquisition and spread of bacterial skin infection. Abrasive surfaces such as artificial turf can harbor bacteria and become a source of infection. Shared equipment, improperly laundered practice gear, person-to-person contact, and inadequate showering facilities without antibacterial soap have all been implicated in the spread of bacterial skin infections in athletes.

Controlling infection in athletes involves prevention, good surveillance, and prompt, appropriate treatment. Shared equipment requires regular cleaning with antibacterial disinfectant. Athletes should shower with antibacterial soap after practice and competition. Abrasions should be addressed expeditiously, scrubbed with antibacterial wash, and covered with sterile dressings, which are changed regularly. Athletes must be instructed to report suspected infections as soon as identified. Topical antibiotics are appropriate for mild infections, with oral or IV antibiotics required for more severe infections. Any significant abscess should have incision and drainage with bacterial culture, including MRSA. Thus far, most CA-MRSA infections in athletes have shown sensitivity to trimethoprim-sulfamethoxazole, with some isolates sensitive to macrolides and quinolones (Arnold and Wojda, 2005). The resistance patterns are susceptible to rapid change, however, making routine culture of these wounds essential. Athletes with recurrent MRSA infections should be assessed by nasal culture for colonization with MRSA and treated with topical mupirocin ointment if positive.

Pulmonary Problems

Key Points

- Exercise-induced bronchospasm is the transient narrowing of the airways in response to exercise.
- Symptoms of EIB include wheezing, coughing, dyspnea, and chest tightness.
- The diagnosis should be confirmed by spirometry testing before and after exercise showing a 10% to 15% reduction in FEV₁.

Exercise-Induced Bronchospasm

Exercise-induced asthma or, more accurately, exercise-induced bronchospasm (EIB) is a transient narrowing of the airways following vigorous exercise. Ninety percent of known asthmatics and 40% of patients with allergic rhinitis have bronchoconstriction caused or worsened by exercise (Feinstein et al., 1996). In some patients, the only manifestation of airway hyperresponsiveness is EIB, with up to 50% of athletes having EIB in some high-risk sports (Langdeau and Boulet, 2001).

The pathophysiology of EIB involves mucosal drying secondary to large volumes of dry (often cool) air, which causes changes in mucosal pH, osmolarity, and temperature and triggers the release of inflammatory mediators, leading to bronchoconstriction (Hallstrand et al., 2005). This osmotic hypothesis explains the relationship between the intensity and duration of exercise to EIB, the role of inflammation and bronchoconstriction in EIB, and the increased prevalence of EIB in outdoor winter sports, such as cross-country skiing. A refractory period typically follows EIB, in which the patient has fewer symptoms on reexercise. This probably occurs because of increased bronchial blood flow following exercise, which enhances water delivery to airway mucosa and makes it more resistant to osmotic changes. The mechanism of EIB in swimmers may be different and related to exposure to direct bronchial irritants, such as chlorine.

Symptoms of EIB include exercise-related wheezing, coughing, dyspnea, and chest tightness. The diagnosis of EIB, however, is difficult, and screening by medical history and physical examination alone is often inaccurate. In a study of 256 adolescent athletes participating in organized sports, 39.5% reported symptoms or a previous diagnosis suggestive of EIB, although only 9.4% were found to have EIB based on an exercise challenge test and serial spirometry (Hallstrand et al., 2002). Thus, any athlete with suspected EIB should be tested with an exercise challenge test. A decrease in forced expiratory volume in 1 second (FEV₁) greater than 10% to 15% is indicative of EIB.

Management of EIB involves both nonpharmacologic and pharmacologic methods. Nonpharmacologic treatment includes emphasis on a good warm-up to precipitate the refractory period, exercising in warm and humid environments, and covering the mouth and nose during cold weather. The goal of pharmacologic therapy is for the athlete to be asymptomatic during exercise. First-line pharmacologic treatment involves the use of an inhaled beta-2 agonist (e.g., albuterol metered-dose inhaler, 2 puffs) 15 to 30 minutes before exercise. If the athlete is still symptomatic,

the addition of a leukotriene modifier (e.g., montelukast, 10 mg) taken at least 1 hour before exercise can provide additional relief (Coreno et al., 2000). Another treatment alternative is an inhaled mast cell stabilizer (e.g., cromolyn) before exercise. Inhaled corticosteroids are not as useful for acute prophylaxis because of their delayed onset of action, but can be very useful in patients with chronic persistent asthma and EIB. Any underlying chronic asthma or allergic rhinitis should also be optimally controlled.

Pneumothorax

Spontaneous and traumatic pneumothorax can occur in the setting of sports. Spontaneous pneumothorax should be suspected in tall, thin male athletes with the acute onset of dyspnea, pleuritic chest pain, and shortness of breath. Traumatic pneumothorax should be considered when an athlete is short of breath after sustaining a blow to the chest, particularly if a rib fracture is suspected (Partridge et al., 1997). Diagnosis is confirmed by chest radiograph, and treatment depends on the amount of lung involved. If the patient is stable and there is less than 15% to 20% volume loss, this can generally be treated with observation. Return to play after a pneumothorax can usually occur safely in 3 to 4 weeks (Putukian, 2004).

KEY TREATMENT

Treatment of exercise-induced bronchoconstriction involves an adequate warm-up and use of an inhaled beta-2 agonist 15 to 30 minutes before exercise, with the addition of montelukast or cromolyn, if needed (Coreno et al., 2000; Hallstrand et al., 2005) (SOR: B).

Hematologic Problems

Key Points

- Sports anemia is a dilutional anemia caused by the expansion of plasma volume in the trained athlete.
- Exertional hemolysis occurs from increased destruction of red blood cells, and diagnosis is confirmed by low hemoglobin or hematocrit and low haptoglobin level.
- Low iron stores, even in the absence of anemia, can adversely affect performance in endurance athletes.
- Athletes with sickle cell trait, especially if poorly hydrated, exercising in hot conditions, at altitude, or unconditioned, have a higher risk of exertional rhabdomyolysis and sudden death; screening at-risk populations should be considered.

There are several hematologic issues specific to athletes. This section reviews dilutional pseudoanemia or sports anemia, exertional hemolysis, iron deficiency anemia and low iron stores without anemia, and special considerations regarding athletes who are sickle cell trait-positive.

Sports Anemia

Sports anemia is not representative of true pathology. Rather, it represents an adaptive response to strenuous training and is caused by an expanded plasma volume. The

degree of anemia typically correlates with the intensity of training. Plasma volume can expand by 5% to 20%. This adaptive response begins a few days after starting or intensifying training. Moderate exercisers may see a decrease in hemoglobin (Hb) of 0.5 g/dL, and elite athletes may have an apparent Hb decrease of 1 g/dL. Athletes with low Hb or hematocrit (Hct) value and a characteristic history should be checked for iron deficiency. A normal ferritin level, iron level, and total iron-binding capacity (TIBC) confirms the diagnosis of dilutional anemia, or sports anemia, which does not need to be treated (Eichner, 1992; Shaskey and Green, 2000).

Exertional Hemolysis

Exertional or “foot strike” hemolysis is another problem often encountered in athletes. Exertional hemolysis was initially described in endurance runners but is also seen in swimmers, rowers, and weightlifters. Hypothesized mechanisms for red blood cell (RBC) destruction include trauma secondary to impact, turbulence in the blood vessel, acidosis, and elevated temperature encountered in working muscles. Diagnosis is made with an elevated mean corpuscular volume (MCV) and reticulocyte count and a low haptoglobin level. Treatment consists of mitigating impact by having the athlete run in biomechanically correct shoes and on cushioned surfaces and by recommending slow, incremental increases in training (Telford et al., 2003).

Iron Deficiency Anemia

As in the general population, iron deficiency anemia is common in athletes, especially among female athletes. This is typically caused by low intake of dietary iron, but can also be caused by exertional GI or genitourinary bleeding or GI bleeding related to NSAID use. Iron requirements of athletes, particularly endurance athletes, may also be higher than for sedentary individuals (Beard and Tobin, 2000). The diagnosis of iron deficiency anemia is made by a low Hb or Hct level and a low ferritin or iron level. Treatment consists of increasing dietary iron, iron supplementation, and treating the underlying cause if present.

Low Ferritin in Nonanemic Athlete

The common belief among coaches and endurance athletes is that a low ferritin level can cause fatigue, poor recovery, and poor performance. The ferritin level generally reflects total body iron, and 82% of female endurance athletes have a low ferritin level (Shaskey and Green, 2000). Many studies have examined whether improvements in performance seen in nonanemic athletes are caused by small increases in Hb level (from a normal to a higher normal Hb level) or by an increase in iron alone (Garza et al., 1997). A review of eight randomized, controlled trials (RCTs) indicates that iron has a positive effect on performance in iron-deficient athletes without anemia, independent of Hb increases (Fogelholm et al., 1992; Friedmann et al., 2001; Hinton et al., 2000; Klingshirm et al., 1992; LaManca and Haymes, 1993; Newhouse et al., 1989; Rowland et al., 1988; Zhu and Haas, 1998).

Sickle Cell Trait and Sudden Death

Sickle cell trait occurs in 6% to 8% of the African American population (Kerle and Nishimura, 1996). Among black military recruits, the likelihood of sudden death is 28-fold higher in individuals with sickle cell trait than in those without (Kark et al., 1987). Most of these deaths are associated with *exertional rhabdomyolysis*. This typically occurs when the athlete is poorly hydrated, exercising in hot conditions, at altitude, or unconditioned. Athletes with sickle cell trait are generally not restricted from competition; however, consideration should be given to screening high-risk populations, with special precautions taken to ameliorate risk.

Gastrointestinal Problems

Key Points and Treatment

- Gastroesophageal reflux can be worsened by exercise; treatment with dietary modifications and proton pump inhibitors is usually successful.
- Exercise-induced diarrhea is common in endurance sports; treatment focuses on dietary manipulation before competition and antidiarrheal medications such as loperamide in refractory cases.
- Gastrointestinal bleeding in athletes ranges from microscopic blood loss to ischemic hemorrhagic gastritis or colitis, but pathologic causes of bleeding should be ruled out.

Gastrointestinal problems are common in the general population and in exercising individuals. Although diagnosis and treatment for many of these issues are similar, exercise may make some issues worse or may present special treatment challenges. See online discussions for the following at www.expertconsult.com.

- Gastroesophageal reflux
- Exercise-induced diarrhea
- Gastrointestinal bleeding

Genitourinary Problems

Hematuria and proteinuria are also common findings in athletes. They may be caused by repetitive mechanical trauma to the bladder or by exercise-related changes in renal physiology. Initial workup is to rule out infection, refrain from exercising for 48 to 72 hours, and retest. If hematuria or proteinuria persists, a full evaluation should be performed (Abarbanel et al., 1990).

Genitourinary problems in male cyclists are particularly common. Pressure from the bicycle saddle can cause compression neuropathies (pudendal nerve), impotence, urethritis, or prostatitis (Leibovitch and Mor, 2005). Pudendal neuropathy manifests with numbness or tingling in the scrotum or penile shaft. Treatment involves relieving pressure by changing seat type, proper bicycle fitting, and wearing padded shorts.

Low Back Pain

See the discussion online at www.expertconsult.com.

Spondylolysis

Spondylolysis, a stress fracture of the pars interarticularis, is a common cause of low back pain (LBP) in athletes and is the most common cause of athletic LBP in adolescents (Standaert and Herring, 2000; Standaert et al., 2000). Athletes who participate in sports involving repeated and forceful hyperextension of the spine (e.g., gymnastics, American football) are more likely to develop spondylolysis from the cumulative effect of repetitive loading of the bone imposed by physical activity. Athletes generally have an insidious history of increasing focal back pain reproduced by lumbar extension.

Spondylolysis can be identified by plain radiography in approximately 5% of the general population, but the vast majority of these lesions occur without associated symptoms. Identification of spondylolysis on radiographs in an athlete with LBP must be correlated with the clinical presentation and advanced imaging. Single-photon emission computed tomography (SPECT), high-resolution (thin-slice) computed tomography (HRCT), and MRI are helpful to determine the metabolic activity of the stress fracture, the acuity of the lesion, and potential for fracture healing, and to exclude other spinal pathology that may be present.

Conservative treatment is usually successful in controlling symptoms and restoring function. Treatment requires activity restriction and temporary discontinuation of the aggravating sport or activity. Some patients may require lumbosacral bracing to achieve treatment goals, and only a small percentage of patients require surgical intervention for pain or progressive spondylolisthesis (Standaert and Herring, 2000; Standaert et al., 2000).

Muscle and Tendon Injuries

Key Points

- Eccentric loading produced when the muscle is contracting and lengthening is a common mechanism for muscle and tendon injuries.
- Tendinosis is the predominant pathologic feature in painful overuse tendinopathies.

Mechanism of Injury

Muscle and tendon injuries occur from repetitive micro-trauma or a single traumatic event that causes overload to the tensile strength of the myotendinous unit or muscle fiber itself. *Eccentric loads*, produced when the muscle is contracting and lengthening at the same time, are a common mechanism of injury and can produce higher forces compared with concentric contractions (Stanton and Purdam, 1989). Sports activities with repetitive eccentric demands place the athlete at higher risk of injury. In sprinters, for example, hamstring muscle strains typically occur during the late swing phase of the running cycle as the hamstring muscle contracts while lengthening in an attempt to decelerate the lower leg in preparation for foot strike (Stanton and Purdam, 1989). Achilles tendinopathy and patellar tendinopathy (jumper's knee)

also result from repetitive eccentric loading of the tendons during running and jumping.

Histopathology

Acute muscle injuries go through a predictable cycle of healing and repair. Exercise-induced muscle injury first causes fiber disruption and local microhemorrhage, followed by extravasation of inflammatory cells and a phagocytic phase to remove injured tissue, and finally a regenerative phase of muscle fiber healing occurs (Armstrong et al., 1991). Limiting overall inflammation decreases pain and minimizes secondary tissue injury caused by hypoxia and inflammatory mediators. However, some amount of inflammation is required in the healing process to remove necrotic muscle fibers and allow scar tissue to bridge the defect (Almekinders and Gilbert, 1986), but how far to limit this inflammation through pharmacotherapy remains uncertain.

In contrast to acute muscle injuries, the pathologic findings in most tendon injuries are consistent with tendinosis, a degenerative condition of the tendon, and not a tendinitis involving inflammation, as was formerly believed. Healthy tendon contains parallel bundles of tightly packed collagen fibers, with little extracellular matrix (ground substance) and no fibroblasts or myofibroblasts. In contrast, symptomatic tendons contain disorganized collagen fibers, increased mucoid ground substance, prominent capillary proliferation, and increased numbers of fibroblasts and myofibroblasts (Khan et al., 1999). Histopathologic examination is notably devoid of inflammatory cells. Animal models have also suggested that inflammatory cells are absent by 1 week after induced overuse injury (Zamora and Marini, 1988). These findings are present in the most common tendon injuries, including the patella, Achilles, rotator cuff, and extensor carpi radialis brevis tendons, and have important implications in the treatment of tendon disorders (Khan et al., 1999). Use of the term *tendinopathy*, rather than tendinitis, is recommended to describe a painful tendon condition.

The generation of pain in chronic tendon injuries appears to involve more than just inflammation. A biochemical hypothesis to explain tendon pain states that biochemical agents are leaked from a degenerated tendon and irritate nociceptors (pain receptors) on adjacent structures (Khan and Cook, 2000). In patellar tendinopathy, higher levels of glycosaminoglycans have been found in the infrapatellar fat pad (Khan et al., 1996), and in patients with partial rotator cuff tears higher levels of substance P were found in the adjacent subacromial bursa and were significantly associated with pain (Gotoh et al., 1998).

Muscle Strains

Muscle injuries can be classified as *mild* (grade 1, strain), *moderate* (grade 2, partial tear of myotendinous units), or *severe* (grade 3, complete tear of myotendinous units). Mild injuries are tender and painful with active use but cause minimal strength loss. Moderate injuries demonstrate clear *weakness* with resisted muscle testing and *pain* with passive stretching. Severe injuries cause significant functional and strength deficits and may show ecchymosis and a palpable defect on examination.

In running and sprinting athletes, hamstring muscle strains are the most common muscle injury (Lysholm and Wiklander, 1987; Meeuwisse et al., 2000; Orchard and Seward, 2002). Other common muscle strains include those of the quadriceps (especially the rectus femoris) and the gastrocnemius. The most significant risk factor for a muscle strain is a recent or past history of that same injury, and incomplete rehabilitation may also contribute to recurrent injuries (Ekstrand and Gillquist, 1983; Orchard, 2001). Other risk factors for muscle injury include poor warm-up, muscle fatigue, and muscle imbalance (Agre, 1985; Croisier et al., 2002; Garrett, 1996; Safran et al., 1989).

Initial treatment of an acute muscle strain involves ice application to limit pain and swelling and relative rest to protect the muscle from more significant injury. A short 3- to 5-day course of NSAIDs can help limit overall inflammation and pain in acute muscle injuries. Gentle stretching to restore flexibility should begin when pain allows, and rehabilitation should progress through isometric, concentric, and finally eccentric strengthening exercises before returning to sports-specific activities.

Tendinopathy

Tendon injuries can involve acute overuse tendinopathy, chronic tendinosis, partial-thickness tears, or complete rupture of the tendon. The exact role of NSAIDs in the treatment of tendinopathy remains uncertain. NSAIDs are potentially helpful initially following acute tendon injury, when inflammation is most likely to be present. For tendinopathy of longer duration, use of NSAIDs, although an adjunct to pain control, does not contribute to tendon healing. The exact mechanism of action of corticosteroid injections, such as in the treatment of lateral epicondylitis and rotator cuff tendinopathies, is also unclear. Corticosteroid injections bathe the region of tendinosis, alter the chemical composition of the matrix, and may modify nociceptors on nearby structures (Khan and Cook, 2000). NSAIDs and corticosteroids also may have an effect on other biochemical irritants (yet to be defined) that play a role in the generation of tendon pain.

The use of therapeutic methods to stimulate collagen repair is also a major focus in the treatment of tendinopathy. Common strategies to induce collagen remodeling include manual therapies such as deep-friction massage, eccentric conditioning of the tendon, tenotomy (needling a degenerated tendon), and injection of autologous growth factors. Eccentric strengthening programs have shown favorable results for patients with chronic Achilles tendinopathy as well as for athletes with chronic patellar tendinopathy (Alfredson et al., 1998; Purdam et al., 2004). When conservative treatments such as physical therapy fail, treatment options are limited and often lead to either the discontinuation of exercise or surgery. In competitive athletics, chronic tendon injuries can lead to persistent pain, lost time from participation, and suboptimal performance. In occupational injuries, chronic tendon trauma leads to significant cost and morbidity.

With a better understanding of the pathogenesis of tendon injury and healing, newer therapies strive to stimulate the failed healing response in tendinopathies, including percutaneous tenotomy with or without injection of autologous blood or growth factor into the degenerative tendon

(McShane et al., 2006; Housner et al., 2009). The most common form of autologous growth factor therapy is platelet-rich plasma (PRP) and is increasingly used to treat tendinosis. Although a relatively novel option for sports-related injuries, PRP has been used in other medical conditions for two decades. The use of PRP migrated to orthopedic procedures, where it has been used effectively to augment bone and soft tissue healing in the operating room, especially in poorly healing fractures and those at high risk for nonunion. Most recently PRP has been used in the outpatient setting for a variety of sports-related soft tissue injuries, including the treatment of chronic tendinopathies, as well as moderate to severe acute ligament, muscle, and tendon injuries. Autologous growth factor therapy in the treatment of chronic tendinosis can initiate a stalled or failed healing response, leading to a healthier and less symptomatic tendon. In the management of chronic lateral epicondylitis (tennis elbow), injection of PRP demonstrated significant pain reduction at 6 months versus injection of anesthetic alone (Mishra and Pavelko, 2006). In the setting of acute soft tissue injury, it is hypothesized that PRP augments the healing response, leading to faster healing, more rapid recovery, and earlier return to sport or activity. In a series of acute muscle injuries in elite soccer players, PRP therapy was found to significantly shorten the time to return to play (Sanchez et al., 2009).

Although research is still needed to understand the optimal indications and treatment protocols for autologous growth factor therapies, initial findings provide optimism that a new, minimally invasive therapeutic option is available in the management of chronic tendinopathies.

KEY TREATMENT

Treatment of an acute muscle strain involves ice application to limit pain and swelling, relative rest and protection from more significant injury, gentle stretching to restore flexibility, and progressive rehabilitation through isometric, concentric, and finally eccentric strengthening exercises before returning to sports-specific activities (SOR: C).

Eccentric strengthening programs can be effective for patients with chronic Achilles or patellar tendinopathy (Alfredson et al., 1998; Purdam et al., 2004) (SOR: B).

Novel therapies using autologous growth factor injections (platelet-rich plasma) show favorable results in the treatment of chronic tendinopathy (Mishra and Pavelko, 2006; Sanchez et al., 2009) (SOR: C).

Shin Pain

Key Points

- Medial tibial stress syndrome is the most common cause of lower leg pain in running athletes.
- Chronic exertional compartment syndrome is characterized by cramping or burning lower leg pain or numbness, which may radiate to the foot and ankle and resolves within minutes of rest.

Medial Tibial Stress Syndrome

Exercise-related lower leg pain is an extremely common condition among athletes. The most common presentation is shin pain exacerbated by exercise and diminished with

rest. *Shin splints* is a nonspecific term used to describe shin pain in running athletes from almost any cause. *Medial tibial stress syndrome* (MTSS) is the most widely accepted term to describe pain along the medial border of the tibia experienced by running athletes and is considered to be the most common cause of athletic lower leg pain (Kortebein et al., 2000).

The pathogenesis of MTSS is not fully understood. Some support the concept of a traction periostitis along the posteromedial border of the tibia at the origin of the soleus, flexor digitorum longus, and posterior tibialis muscles (Beck and Osternig, 1994; Michael and Holder, 1985). Scintigraphic and biopsy studies, however, have not consistently shown an inflammatory process of the periosteum to support periostitis as the pathogenesis of shin pain. Others suggest that MTSS is caused by a traction fasciitis (involving the crural fascia) or possibly a bony stress reaction and precursor to stress fracture (Batt, 1995). Bone scan and MRI studies indicate that MTSS is part of a continuum of stress response in bone. Investigation of runners with medial tibial pain demonstrated a spectrum of bone injury, beginning with periosteal edema, progressive marrow edema, and finally frank cortical defects (Fredericson et al., 1995). The mechanism of injury in MTSS probably involves bony overload from the pull of muscle contraction and the impact forces with running.

Athletes with MTSS complain of shin pain that is aggravated with running. Examination reveals tenderness in a broad distribution along the medial border of the tibia, usually spanning the middle and distal thirds of the tibia. In contrast, tibial stress fractures manifest with a focal area of tenderness. Management of MTSS includes rest, activity modification, ice, and anti-inflammatory medications. Correction of biomechanical abnormalities is also helpful. Poor hip abductor and external rotator muscle function may contribute to internal femoral rotation and excessive stress on the medial tibia during running. Extreme foot types, both pes planus and pes cavus, may also contribute to impaired shock absorption and force distribution to the tibia and may improve with orthotic devices.

Chronic Exertional Compartment Syndrome

Chronic exertional compartment syndrome (CECS) is another cause of athletic lower leg pain. Patients with CECS complain of cramping, burning, or aching lower leg pain with pain or numbness that may radiate to the foot and ankle. The pain is clearly associated with exertion. Pain onset is characteristically at a fixed point in the patient's activity, with progressively increasing pain if the exercise continues and a dramatic reduction in pain within minutes of rest. The pathophysiology of CECS involves elevated intracompartmental pressure, which causes relative ischemia of the involved muscles and pressure on neurovascular structures. The diagnosis of CECS can be confirmed by compartment pressure testing after exercise demonstrating increased intracompartmental pressure correlated with symptom reproduction. Patients with CECS should be questioned about the use of nutritional supplements, such as creatine, that may increase muscle water content and overall muscle mass and contribute to the development of CECS. Surgical treatment by fasciotomy provides good functional improvement and

symptomatic cure in a high proportion of cases (Blackman, 2000).

Stress Fractures

Key Points

- Stress fractures typically occur weeks after an abrupt increase in activity level, running distance, or training frequency.
- Navicular stress fractures, anterior tibial stress fractures with a “dreaded black line,” and femoral neck stress fractures are high-risk stress fractures for nonunion or progression to a complete fracture and should be referred to an orthopedic specialist.

Stress fractures result from a failure of bone to adapt successfully to repetitive loads encountered during running. Wolff's law of adaptation suggests that a bone responds to external stress by mechanical remodeling. Bone strain may become excessive as a result of increases in load magnitude, rate of loading, or number of loading cycles (Crossley et al., 1999). Advances in imaging techniques and understanding of bone pathophysiology indicate that stress injury to bone occurs on a continuum, ranging from normal bone remodeling to bone strain, to stress reaction, to stress fracture, to frank cortical fracture (Fredericson et al., 1995).

A stress fracture, or *fatigue fracture*, occurs when abnormal stress is applied to normal bone. In contrast, an *insufficiency fracture* occurs when normal or physiologic stress is applied to abnormal bone. Female athletes with premature osteoporosis, as seen in the female athlete triad, may have stress fractures resulting from abnormal stress applied to abnormal bone (Callahan, 2000).

Most stress fractures occur in the lower extremities because of impact forces produced from weight bearing during exercise. Common locations for stress fractures include the metatarsals, navicular, tibia, fibula, femoral shaft, femoral neck, and sacrum. The tibia is the most common site of stress fractures in running and jumping athletes and represents about 50% of all cases (Matheson et al., 1987). Less frequently, stress fractures can occur in the upper extremities, ribs, and clavicle from repetitive activity such as throwing, rowing, or weightlifting.

Lower baseline conditioning and training errors are usually involved in the development of stress fractures. A careful history will often reveal an abrupt increase in activity level, running distance, or training frequency within the 2 or 3 months before symptom onset. Many studies have analyzed bone geometry as a risk factor for stress fracture. In male military recruits and runners, studies have demonstrated that a narrower tibia in combination with a smaller tibial cross-sectional area is a risk factor for tibial stress fractures (Beck et al., 1996; Crossley et al., 1999; Giladi et al., 1987).

Female athletes with a history of eating disorders, oligomenorrhea or amenorrhea, and delayed menarche are more likely to develop stress fractures (Arendt, 2000; Bennell et al., 1995). Inadequate caloric intake relative to energy expenditure, also known as a negative energy balance, has been implicated as the primary cause of menstrual dysfunction in young female athletes and is thought to be responsible in part for bone density changes.

Pain from a stress fracture begins with mild pain during activity that resolves with rest. As the stress fracture progresses, pain increases during activity and continues for hours afterward, usually forcing the athlete to stop exercising. With further progression, pain is present with walking and sometimes at rest. On examination, there is local tenderness at the site of the stress fracture. The hop test (asking the patient to hop on one leg) is a useful functional test for suspected lower extremity stress fractures. If a stress fracture is present, the athlete either is reluctant to hop or will have pain reproduction with hopping. Stress fractures may be seen on radiographs as an area of cortical thickening (periosteal reaction) and may have a linear fracture line visible. Radiographs are positive in only about 50% of cases, and an advanced imaging study such as MRI or bone scanning is often needed to confirm the diagnosis.

Stress fractures are treated with rest, activity modification, and avoidance of aggravating activities. Ambulation must be pain-free to allow for fracture healing. If the athlete cannot achieve pain-free ambulation, a period of non-weight bearing on crutches is indicated. Foot stress fractures may benefit from the use of a rigid walking boot, and tibial stress fractures may benefit from a compressive pneumatic leg brace (Swenson et al., 1997). The time for healing of a stress fracture can vary (range, 4-12 weeks), depending on the site and severity. To maintain overall conditioning, athletes can engage in nonimpact cross-training activities, such as swimming or cycling, assuming that the activity is performed without pain. Athletes with two or more stress fractures should be screened for osteopenia or osteoporosis with a bone density scan. Low bone density requires further investigation to rule out secondary causes of osteoporosis, such as vitamin D deficiency or thyroid abnormalities. Menstrual irregularities, disordered eating, and a negative energy balance in female athletes should also be corrected.

Some stress fractures are at higher risk for nonunion or progression to a complete fracture. High-risk stress fractures include navicular, anterior tibial (diagnosed by the “dreaded black line” on lateral radiograph), and femoral neck stress fractures (Fig. 29-5). Athletes with a confirmed or suspected high-risk stress fracture should be made non-weight bearing and referred to a sports medicine or orthopedic specialist.

KEY TREATMENT

Treatment of lower extremity stress fractures include rest, avoidance of aggravating activities, and pain-free ambulation with use of crutches or immobilizing walking boots if needed (SOR: C).

The Pediatric Athlete

Key Points

- Children are not “little adults.” Sports competition and training must be age appropriate to prevent injury to developing bone and soft tissue and prevent psychological trauma, which could lead to an aversion to physical activity.
- Overuse injuries common in pediatric athletes include articular cartilage injuries (osteochondritis dissecans), chronic physeal injuries, and apophysitis.

Figure 29-5 Stress fracture. Lateral tibial radiograph shows the “dreaded black line.” Note cortical disruption on the anterior cortex. (From Delee and Drez’s *Orthopaedic Sports Medicine*, 3rd ed. Philadelphia, Elsevier, 2009.)

Pediatric sports injuries are increasing in frequency secondary to increased sports participation, prolonged and overlapping seasons, and children being subjected to adult levels of training and competition prematurely. Although the benefits of exercise and sports participation for children are well recognized, overtraining can have adverse physiologic and psychological consequences. In a review of age-appropriate sports participation from a neurodevelopmental and psychological perspective, Patel and colleagues (2002) suggested that children are not prepared for full competitive participation in complex sports before age 12 years. Children obtain the developmental tools to accomplish complex sports tasks at different ages, and future athletic talent cannot be predicted by childhood performance. Children subjected to age-inappropriate levels of competition or sports-specific skill development are likely to stop participating and create negative associations with sports and exercise, an unfortunate outcome that may affect them adversely for life. Primary care physicians must counsel parents to recognize these issues and not make physical activity and sports participation a negative experience for children.

Physeal and Apophyseal Injuries

The adage that “children are not little adults” applies when considering sports injuries. Open physes in long bones and apophyses at tendon attachments to bone provide weak links through which acute and repetitive overuse injury can occur. These growth centers usually close within defined age ranges throughout adolescence, but significant variation between

individuals exists. Thus, physeal and apophyseal injury must always be considered when evaluating children or adolescents with musculoskeletal complaints.

Physeal fractures are common and must not be missed, because growth arrest can occur if they are not recognized and treated appropriately. The diagnosis of an ankle or knee sprain in a young adolescent with open physes should only be considered after physeal injury has been ruled out. Acute physeal injuries and the Salter-Harris classification system are addressed in greater detail in Chapter 30.

Overuse injuries are increasing in frequency in pediatric athletes, with the most common being articular cartilage injuries (osteochondritis dissecans), chronic physeal injury, and apophysitis. Osteochondritis dissecans (OCD) involves a focal loss of cartilage and the underlying bone fragment and may be idiopathic or associated with overuse activities. Apophysitis is the pediatric equivalent of tendinopathy in adults. The growth center at the tendon-bone interface is susceptible to injury similar to that sustained by the physes of long bones. Risk factors contributing to the development of pediatric overuse injuries include overtraining; strength and flexibility deficits somewhat inherent in bone and soft tissue development; prior injury with inadequate rehabilitation; faulty technique, often resulting from poor coaching; and excessive pressure from adults to train and perform. The diagnosis is usually straightforward and requires a familiarity with the demands and common overuse injuries of that sport (Lord and Winell, 2004; Thordarson and Shean, 2005). **Table 29-2** lists common apophyseal injuries in pediatric athletes.

The treatment of OCD varies according to location, but the offending activity should be stopped immediately and the upper extremity joint immobilized or the lower extremity joint made non-weight bearing. The patient should be referred to an orthopedist for further management, which may involve prolonged rest with radiographic follow-up, reattachment of loose fragments, or removal of fragments with drilling or grafting of joint surfaces.

The treatment for chronic physeal injury or apophysitis consists of initial rest, followed by rehabilitation directed at improving flexibility and strength, then a gradual return to activity. Parents and young athletes should be counseled that low-level recurring symptoms can be expected until growth plates have closed, but that escalating symptoms should be managed with rest and physician follow-up. The most challenging aspect of treatment is ensuring proper coaching, educating parents regarding appropriate levels of participation and competition for children, and having adults accept reasonable limits for childhood participation in sports.

Special Concerns for the Female Athlete

Key Points

- An energy deficit is the primary cause of amenorrhea in athletic women, and treatment should focus on the restoration of a normal energy balance.
- Menstrual dysfunction or hypothalamic-pituitary axis suppression caused by an energy deficit in exercising women is a diagnosis of exclusion, and workup should include evaluation for medical causes

Table 29-2 Common Apophyseal Injuries in Pediatric Athletes

| Eponym/Common Injury | Body Part and Pathophysiology | Common Sports/Activity |
|---|--|--|
| Little League shoulder | Proximal humeral epiphysiolysis from repetitive microtrauma | Overhead sports: baseball, softball, tennis, swimming, volleyball |
| Little League elbow | Medial epicondylar apophysitis from traction to ulnar collateral ligament | Baseball (especially pitchers) |
| Lateral Little League elbow/ osteochondritis dissecans (OCD) | OCD of capitellum or less likely radial head from repetitive compression-rotation forces | Baseball, gymnastics, overhead throwing and arm weight-bearing sports |
| Osgood-Schlatter's disease | Traction apophysitis of tibial tubercle | Soccer, basketball, running/jumping sports |
| Sinding-Larsen-Johansson disease | Traction apophysitis to distal patella | Soccer, basketball, running/jumping sports |

of amenorrhea, including a pregnancy test and determination of prolactin, follicle-stimulating hormone (FSH), luteinizing hormone (LH), thyroid-stimulating hormone (TSH), dehydroepiandrosterone (DHEA), and testosterone levels.

- Bone mineral density is adversely affected by menstrual dysfunction and, although treatment with hormone replacement (e.g., oral contraceptives) should be considered, this does not fully address the mechanisms of bone loss.

Exercise results in many benefits for both male and female athletes. In female athletes, exercise coupled with low energy intake can lead to a spectrum of disorders, culminating in the *female athlete triad*, strictly defined as the presence of an eating disorder, amenorrhea, and osteoporosis. It is important to recognize the precursors to the development of the female athlete triad when they may be more amenable to treatment, resulting in less severe long-term sequelae.

The menstrual cycle in the female athlete represents a complex and delicate interplay of hormones. The array of menstrual function seen in athletes ranges from normal ovulatory cycles to luteal-phase defects, to anovulation, to oligomenorrhea, and to amenorrhea. Menstrual dysfunction can exist even in women with normal cycle length, and various types of cycles are common in an individual athlete (De Souza and Williams, 2004).

Athletic amenorrhea is caused by hypothalamic-pituitary axis suppression and is a diagnosis of exclusion. Other causes of amenorrhea must be ruled out, including pregnancy, hyperthyroidism, hyperprolactinemia, primary deficiency of gonadotropin-releasing hormone, and hyperandrogenic anovulatory syndrome (polycystic ovarian syndrome) (Ahima, 2004). When amenorrhea occurs in the setting of exercise or weight loss and initial hormonal testing is normal, a diagnosis of athletic amenorrhea can be made. Recent research has established that energy deficit is the primary cause of amenorrhea in athletic women

(De Souza and Williams, 2004). Strenuous exercise alone in the setting of adequate energy intake does not disrupt the menstrual cycle. An energy deficit results in low concentrations of leptin and in changes in the neuroendocrine axis, including low levels of reproductive hormones, thyroid, and insulin-like growth factor-1 (IGF-1) and an increase in cortisol and growth hormone levels. Similar changes can be seen with psychogenic stress in sedentary women, and stress-induced changes may also contribute to menstrual dysfunction in both normal and underweight female athletes (Ahima, 2004).

The attainment of peak bone mineral density is adversely affected in both the short term and the long term by menstrual dysfunction (Keen and Drinkwater, 1997). The degree of menstrual dysfunction is related to the severity of osteopenia or osteoporosis (Hartard et al., 2004). Initially, the low estrogen state associated with athletic amenorrhea was thought to be solely responsible for bone density problems similar to those seen in postmenopausal women. More recent research has indicated that micronutrient deficiency and low levels of leptin, IGF-1, and other bone trophic factors also contribute to bone mineral deficits (Chan and Mantzoros, 2005).

Treatment of menstrual dysfunction and low bone density has traditionally consisted of hormone replacement therapy, most often with oral contraceptives. Oral contraceptives are not associated with complete bone recovery, most likely because of the multifactorial nature of bone metabolism. Bisphosphonates can increase bone density in adolescents with anorexia, although not as effectively as weight restoration (Golden et al., 2005). Bisphosphonates have extremely long half-lives and remain in the skeleton for many years. Because of concern about potential teratogenicity, bisphosphonates should not be used in young women of childbearing age until further studies on their long-term safety.

The primary treatment for athletic amenorrhea should be restoration of a normal energy balance. Disordered eating patterns must be addressed. Anorexia nervosa and bulimia nervosa are common in women, particularly those competing in sports in which there is an emphasis on leanness or appearance, such as gymnastics, figure skating, and cross-country running. Eating disorders are best addressed with an interdisciplinary management team that includes both psychological and nutritional counseling (Otis et al., 1997).

Menstrual dysfunction, although common in female athletes, should prompt evaluation for medical causes and eating disorders. It is never normal or desirable for a female athlete to cease menstrual function, and this should not be seen as a marker of adequate training. Exercise alone should not be blamed for menstrual dysfunction. Treatment should focus on the restoration of energy balance and a safe continuation of activity.

KEY TREATMENT

The primary treatment for athletic amenorrhea should be restoration of a normal energy balance by addressing disordered eating and training patterns (Otis et al., 1997) (SOR: C).

Fractures

Key Points

- Always obtain two different radiographic perspectives of a bone or joint when evaluating for fractures.
- Always examine the joint above and below a fracture to look for associated injuries.
- Open fractures are orthopedic emergencies and need to be urgently washed out in the operating room.
- Be particularly alert for growth plate fractures in children.

The most common reason for not identifying a fracture is failure to examine or radiograph the area or extremity appropriately. When evaluating a patient for a fracture, the primary care physician must be sure to palpate and examine the joint above and below the fracture for potential concomitant injuries. Always obtain orthogonal views from at least two perspectives (e.g., AP and lateral). Additional radiographs are necessary only if a fracture is suspected. When communicating about fractures, health care professionals require a similar vocabulary to visualize the description accurately. This is especially true when family physicians and emergency physicians communicate with orthopedic consultants to make treatment decisions.

Fractures can be oriented in a variety of planes, and certain patterns are associated with greater risk of instability. Typical

fracture orientations are transverse, spiral, oblique, compression, buckle, avulsion, stress, and greenstick. Additional features include the specific bone, region within the bone (diaphysis, metaphysis, epiphysis) (Fig. 30-1), and whether the fracture is complete or incomplete, open or closed, intra-articular or extra-articular, displaced or nondisplaced, angulated, shortened, or comminuted. In children, physal involvement is a special concern.

Open fractures are surgical emergencies and require immediate irrigation and debridement, tetanus prophylaxis, and antibiotic coverage. Orthopedists typically refer to the Gustilo-Anderson classification for open fractures, which is based on the size of skin wound, soft tissue damage, and bone comminution (Box 30-1). Even a small puncture wound over a fracture may allow skin flora to infiltrate the fracture site and initiate an infection. Any open fracture warrants an immediate referral to an emergency department (ED) for orthopedic evaluation.

Growth Plate Fractures

The physal plate is a cartilaginous plate present in ends of long bones, adjacent to the metaphysis. This is the area that provides longitudinal growth to bones and eventually matures into bone. During growth, the physal cartilaginous plate is weaker than the surrounding bone and often weaker than the ligaments and tendons that attach nearby, causing it to fracture before other areas. The Salter-Harris classification system describes these injuries (Fig. 30-2).

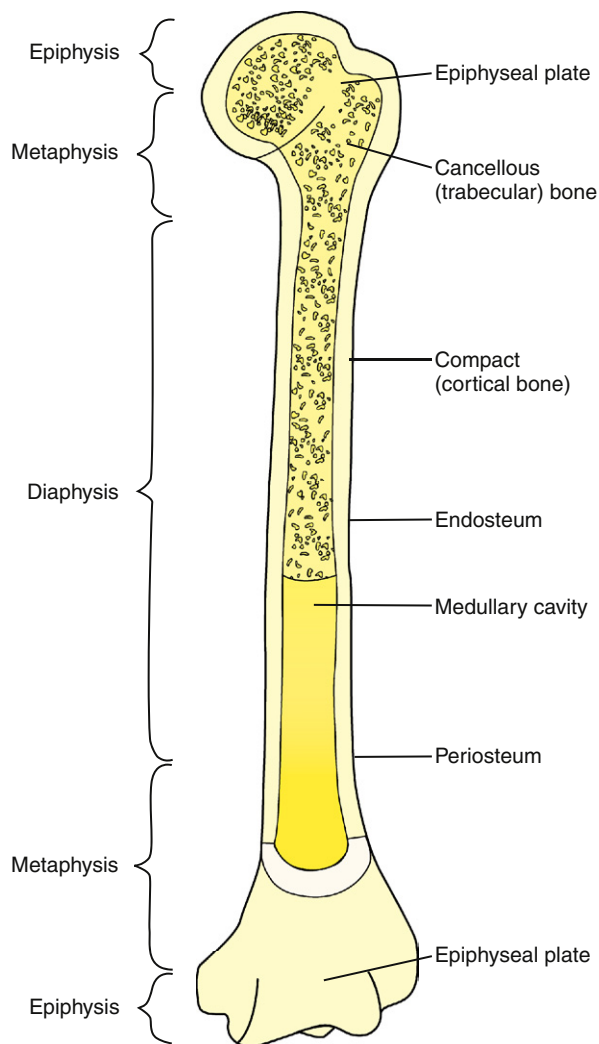

Figure 30-1 Bone regions: diaphysis, metaphysis, and epiphysis.

Salter-Harris Type I

The epiphysis is separated from the metaphysis along the physis, without an associated fracture through the metaphyseal or epiphyseal bone. The injury goes directly through the cartilaginous physal plate. These injuries can be displaced or nondisplaced. A nondisplaced Salter-Harris I fracture will have a normal-appearing growth plate on radiographs, but patients will have pain on palpation directly over the growth plate. Stress radiographs or magnetic resonance imaging (MRI) may be necessary to reveal the injury. Displaced type I injuries are typically easy to reduce because the periosteal attachment remains intact. These injuries have an excellent chance of normal healing with full growth of the injured bone. Despite this, growth delay and growth arrest are complications of growth plate injuries, which should be discussed with the patient and family.

Salter-Harris Type II

The fracture line incompletely extends through the physal plate and then turns into the metaphysis in an extra-articular fracture pattern. The Salter-Harris II fracture is the most common type of growth plate fracture. The periosteum remains

Box 30-1 Gustilo-Anderson Open-Fracture Classification

Type I

Wound is less than 1 cm, with minimal soft tissue injury. Wound bed is clean. Fracture is usually a simple transverse, short oblique fracture, with minimal comminution.

Type II

Wound is greater than 1 cm, with moderate soft tissue injury. Fracture is usually a simple transverse, short oblique fracture, with minimal comminution.

Type III

Fracture involves extensive damage to the soft tissues, including muscle, skin, and neurovascular structures. Fracture is often accompanied by a high-velocity injury or a severe crushing component.

Special patterns classified as type III:

- Open segmental fracture, regardless of the size of the wound
- Gunshot wounds: high-velocity and short-range shotgun injuries
- Open fracture with neurovascular injury
- Farm injuries, with soil contamination, regardless of size of wound
- Traumatic amputations
- Open fractures more than 8 hours after injury
- Mass casualties (e.g., war, tornado victims)

Subtype IIIA

Adequate soft tissue coverage despite soft tissue laceration or flaps or high-energy trauma, regardless of size of wound; includes segmental fractures or severely comminuted fractures.

Subtype IIIB

Extensive soft tissue lost with periosteal stripping and bony exposure; usually associated with massive contamination.

Subtype IIIC

Fracture with major arterial injury requiring repair for limb salvage.

intact on the concave side of the injury, creating a “hinge” and making reduction relatively easy. Prognosis is excellent for future growth when anatomically reduced, with only minor risk of angular deformity.

Salter-Harris Type III

The fracture line extends incompletely along the physis and then turns through the epiphyseal bone into the joint. Salter-Harris III fractures are intra-articular injuries that imply an increased risk of arthritis, especially if they are not anatomically reduced. Alignment of the joint surface is the top priority, and open reduction is often necessary. Prognosis is good, provided the blood supply to the fracture fragment remains intact.

Salter-Harris Type IV

This intra-articular fracture pattern extends from the epiphysis, across the physal plate, and through a portion of the metaphysis. Open reduction with internal fixation is usually needed to ensure anatomic alignment of the joint surface and perfect alignment and apposition of the physal plate.

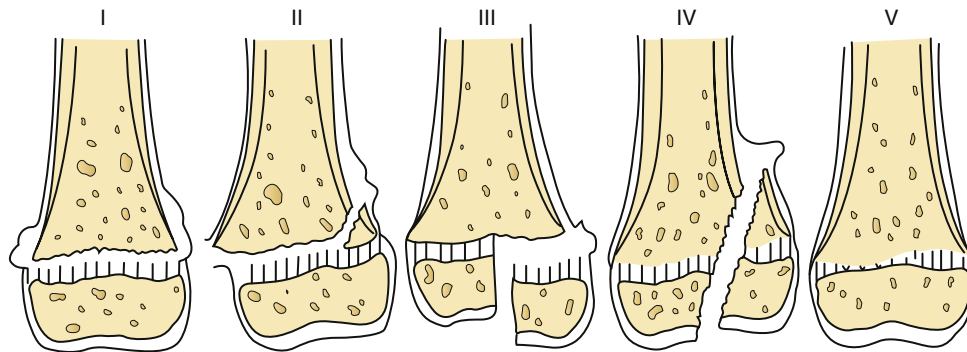

Figure 30-2 Types of growth plate injury (I to V) as classified by Salter and Harris. (From Salter RB, Harris WR. Injuries involving the epiphyseal plate. *J Bone Joint Surg (Am)* 1963;45:587.)

Premature growth arrest and angular deformities can occur with Salter-Harris IV fractures. Prognosis can be good but depends on ability to restore growth plate.

Salter-Harris Type V

Salter Harris V fractures are crushing injuries in which an axial load compresses the epiphysis into the metaphysis, squeezing the actively growing physis between them. Prognosis for future growth is poor, with a high rate of premature closure of the physis and resultant joint deformity. Fortunately, these are rare injuries.

Shoulder

Key Points

- Diagnosis of joint injuries is usually clinical based on the subcutaneous anatomy. Special care should be taken to rule out injury to associated neurovascular structures.
- Baseline imaging studies of the shoulder should *always* include a second tangential view of the scapula and glenoid. The best radiographic screening series is an anteroposterior view in internal rotation, AP view in external rotation, and axillary view of shoulder.
- Impingement, rotator cuff injuries, and shoulder instability are best diagnosed with a panel of clinical assessment tools rather than an isolated maneuver.
- Performance, injury prevention, and injury recovery of shoulder problems are optimized when the entire kinetic chain is addressed, including a sound base, core strength, scapular stability, antagonist capsular and muscle stretching, and classic rotator cuff–strengthening program.

The true functional shoulder joint comprises the glenohumeral joint, scapular thoracic joint, acromioclavicular joint, and sternoclavicular joint. Problems around the shoulder can be acute or chronic and include pain, weakness, dysfunction, stiffness, and instability. To ensure optimal outcome of treatment, an accurate, anatomic-based diagnosis is necessary. Less targeted treatment regimens tend to be less successful. Several evidence-based reviews remain inconclusive regarding specific interventions when a nonspecific diagnosis such as “shoulder pain” is targeted.

Injuries of Clavicular Complex

Key Points

- Most clavicle fractures can be definitively treated nonsurgically with a sling or a figure-eight dressing if they are minimally or nondisplaced.
- Grade 1 (tenderness) and grade 2 (tenderness and displacement with intact coracoclavicular ligaments) acromioclavicular injuries are managed conservatively with ice, pain control and a sling for comfort.
- Anterior shoulder dislocations are common, whereas posterior dislocations are less common but more dangerous with risk of compressing the great vessels.

The diagnosis of clavicle, acromioclavicular, and sternoclavicular injuries is straightforward; direct palpation along the clavicular complex should lead to an area of focal pain. Imaging studies should include the entire clavicle and a clear view of the targeted area from at least two planes. All injuries around the shoulder should include examination of the cervical spine and distal neurovascular evaluation. The brachial plexus, subclavian vein, and axillary artery lie immediately beneath the clavicle and can be at risk of injury.

Clavicle fractures account for 5% to 10% of all fractures and can be classified as either displaced or nondisplaced as well as by their specific location (proximal-distal) on the clavicle. Most fractures involve the midshaft (80%); however, distal third (15%) and proximal third (5%) fractures are also possible. Fortunately, most clavicle fractures can be definitively treated nonoperatively with a sling or a figure-of-8 dressing if they are minimally displaced or nondisplaced. Figure-of-8 bracing has been linked with skin necrosis over the fracture site, indicating the need for careful observation of skin integrity when used. In most cases, a simple sling for comfort is adequate over the first few weeks, followed by progressive range of motion (ROM) activities. More significant displacement (>100%), any tenting of the skin, significant comminution, or excessive shortening (>2 cm) may warrant surgical intervention, and referral to an orthopedist is recommended. Distal clavicle fractures have a higher rate of nonunion with nonsurgical treatment than midshaft or medial fracture patterns, so careful follow-up is necessary (Kahn et al., 2009; McKee et al., 2004).

Acromioclavicular Joint

Acromioclavicular (AC) joint injuries are classified by the ligamentous structures involved and the degree of separation of the AC joint (Fig. 30-3). A *grade 1* injury involves only a partial injury to the AC ligaments, no displacement occurs, and the coracoclavicular (CC) ligaments are intact. A *grade 2* injury involves the complete injury of the AC ligaments, and therefore mild superior translation of the distal clavicle occurs (<100% translation), and CC ligaments are intact. Both grade 1 and grade 2 injuries have an excellent prognosis with conservative treatment, which includes local application of ice, reduction of stresses, and a sling for comfort. Most patients will have substantial active motion and functional use of the arm within 6 weeks. A *grade 3* involves the complete rupture of both AC and CC ligaments. The distal end of the clavicle and acromion are now separated by more than a full clavicular width (>100% displacement). Stress radiographic views may magnify this separation even further; however, stress views rarely alter the treatment plan and are painful to patients and thus no longer considered required diagnostic images.

Treatment of grade 3 AC injuries is controversial and ranges from surgical to conservative treatment with a sling. With conservative treatment, the distal clavicle may ultimately heal in a superiorly translated position, leaving a prominent bump over the lateral aspect of the shoulder. However, nonelite athletes can function well and have a full return to activities. Acute repair of grade 3 injuries is suggested more for elite athletes, but has not been proved in randomized, controlled trials (RCTs) because subtle changes occur at this important point in the kinetic chain. Chronic reconstructions have been suggested in patients who have grade 3 injuries but with residual pain or dysfunction. The more severe injuries of the AC joint have significant posterior, superior, or inferior displacement and require surgical reduction and repair.

A *grade 4* AC separation is a complete injury of both AC and CC ligaments with a posterior subluxation of the distal clavicle relative to the acromion. These are frequently missed on routine anteroposterior (AP) radiographs but can be easily identified if routine axillary shoulder views are obtained. Fundamental management of bone and joint injuries requires a view from two perspectives. *Grade 5* injuries are basically equivalent to severe grade 3 injuries where the distal clavicle is riding so high that it either buttonholes through the fascia or tents beneath the skin (300% translation). The fascial injury prevents reduction, and the pressure on the undersurface of the skin risks skin slough or an open injury. Finally, *grade 6* AC injuries are extremely rare and are associated with an inferior dislocation of the distal clavicle beneath the coracoid.

Sternoclavicular Joint

Patient with sternoclavicular (SC) injuries present with a history of trauma (e.g., landing on lateral aspect of shoulder) or a history of chronic overuse that has led to popping and pain over the medial aspect of the clavicle (Matave et al., 2005). Acute SC joint dislocations can be identified clinically with localized tenderness over the medial clavicular aspect, and gross deformity may be present. More often, however, patients present with a subtle chronic situation caused by esthetic findings with a palpable or gross asymmetry. The examination should always include an assessment of the patient's airway and circulation,

including cervical venous distention, because the great vessels and trachea lie immediately posterior to the SC joints (Fig. 30-4). Imaging studies should include an AP radiograph of the chest, views of the entire clavicle, and a tangential or serendipity view of the SC joint (Fig. 30-5). Because of overlapping shadows, these studies may be difficult to interpret. When suspicious, the best test is computed tomography (CT).

Traumatic SC joint dislocations can be either anterior or posterior. *Anterior dislocations* are generally easily palpated, with the proximal clavicle anteriorly displaced and painful. Anterior injuries may be reduced by placing a rolled towel or beanbag between the shoulder blades, then creating a distraction force along the arm in extension. Anterior dislocations tend to be unstable and to redisplace after attempted reduction. Fortunately, anterior injuries usually heal uneventfully, leaving an asymptomatic medial prominence and occasional popping, with minimal effect on the patient's activities of daily living. *Posterior dislocations* can be dangerous because of proximity to the great vessels posteriorly. If patients have venous engorgement in the neck and difficulty breathing, closed reduction may be attempted. A towel clip is used at the medial end of the clavicle, pulling anteriorly and creating the reduction. If this is attempted, a vascular surgeon should be available in case the proximal clavicle was actually tamponading an injury to the great vessels. This reduction should never be performed on the sideline in the absence of immediate cardiothoracic surgical response, unless the patient's life is at risk and there is no other option.

When treating injuries to the proximal clavicle, age of the patient and normal maturation of the proximal epiphysis are also important considerations. The medial clavicle epiphysis is one of the last to appear, at 19 to 23 years of age, and then the last to fuse, at 23 to 25 years of age. In patients younger than 23, these injuries are generally physeal injuries and not true dislocations, reducing the need for aggressive treatment (Fig. 30-6).

KEY TREATMENT

Subacromial injection for rotator cuff disease or intra-articular injection for adhesive capsulitis may be effective, although the effect may be minimal and not well maintained (Buchbinder et al., 2003) (SOR: A).

The use of some physiotherapy interventions is indicated in specific and circumscribed cases of shoulder pain (Green et al., 2003) (SOR: B).

Little evidence supports the benefit of manual therapy for adhesive capsulitis, shoulder pain, or subacromial impingement syndrome (Ho et al., 2009) (SOR: A).

The use of acupuncture for shoulder pain can be neither recommended nor refuted (Green et al., 2005) (SOR: A).

Shoulder Impingement and Rotator Cuff Disease

Key Points

- Tests to diagnose impingement syndrome include a positive Hawkins test, a painful arc of motion, and weakness with external rotation.
- Tests to diagnose a complete cuff tear include a positive drop-arm test, a painful arc of motion, and weakness to external rotation.
- Incomplete tears of the rotator cuff improve with physical therapy, anti-inflammatory medications, or subacromial injection.

Figure 30-3 Progressive severity of acromioclavicular (AC) joint injuries. Grade 1 indicates incomplete injury of ligaments. Grade 2 has complete injury of the AC ligaments but intact coracoclavicular (CC) ligaments. Grade 3 injuries have complete injury of both AC and CC ligaments. Grade 4, 5, and 6 injuries are progressively severe, with posterior displacement of clavicle, severe superior displacement of clavicle, and inferior displacement of clavicle beneath the coracoid process.

By far the two most common diagnostic categories about the shoulder are rotator cuff impingement and shoulder instability. The rotator cuff is a group of four muscles—supraspinatus, infraspinatus, teres minor, and subscapularis—that originate from the scapular surface, traverse just outside of the glenohumeral capsule, and insert onto the tuberosities of the humerus (Fig. 30-7). The rotator cuff initiates motion in the shoulder and stabilizes the humeral head in the glenohumeral joint.

The diagnosis of rotator cuff impingement is actually a continuum of pathologies, including subacromial bursitis, AC joint hypertrophy and spurring, rotator cuff tendinosis, partial rotator cuff tears, complete or massive rotator cuff tears, and ultimately, rotator cuff arthropathy; that is, degenerative disease related to chronic rotator cuff insufficiency (Almekinders, 2001). Patients generally present with shoulder pain exacerbated by repetitive overhead activities, perhaps weakness, and occasionally difficulty sleeping on the shoulder. Physical examination of the shoulder includes provocative maneuvers that exacerbate impingement findings and evaluate the function of each rotator cuff muscle (Tennent et al., 2003a, 2003b). Impingement

Figure 30-4 Drawing shows proximity of major neurovascular structures to sternoclavicular joint.

testing includes straight, forward flexion of the shoulder (Neer sign), abduction and internal rotation of the shoulder (Hawkins sign), and adduction of the shoulder in a 90-degree, forward-flexed position (Figs. 30-8 and 30-9). The examiner must be cautious with the latter test because it may be positive with impingement but also with AC joint hypertrophy alone or with degenerative change of the AC joint.

Isolated testing of the rotator cuff is performed in sequence. To isolate the supraspinatus muscle, the examiner should perform the “empty can” test. This is performed with the arm slightly forward-flexed in the plane of the scapula, abducted to 90 degrees, with full internal rotation (i.e., with thumbs down, or empty can). The examiner should then place resistance on the patient’s distal hand in an inferior direction. If this exacerbates pain, it is a positive finding of impingement or rotator cuff tendinopathy. If the patient has a positive “drop arm” sign, unable to maintain the arm in this position, a complete rotator cuff tear should be suspected. However, this does not confirm a complete rotator cuff tear because the patient may be guarding secondary to pain. Clinically, the examiner can clarify the difference by performing a diagnostic subacromial injection with lidocaine. The injection should significantly diminish pain complaints but not affect the motor function of an intact rotator cuff (Park et al., 2005).

To evaluate the infraspinatus and teres minor muscles, the examiner should evaluate external rotation against resistance. This is best done with the arm at the side, keeping the elbows near the torso, and asking the patient to rotate externally against resistance. Isolating the subscapularis muscle is more difficult. Resisted internal rotation with the arms at the side will recruit the pectoralis muscles and not isolate the subscapularis. To isolate the subscapularis, two tests have been described. In the *lift-off test*, the patient places the arm behind the back and lifts the hand into further internal rotation against resistance (Fig. 30-10). If able to do this, the patient’s subscapularis muscle is likely intact. Modification of this test has been described as the “tummy pat” or the “Napoleon” test, in which the patient abducts the elbow, which must be away from the body in the plane of the torso, and is then asked to pat the stomach against resistance

Figure 30-5 Technique in obtaining a tangential radiographic image, the serendipity view, to assess sternoclavicular joint injuries.

(Fig. 30-11). Weakness or inability to press against resistance is considered to be a positive test. Once the diagnosis is made clinically, AP and axillary shoulder x-ray studies can be obtained to evaluate the extent of injury further or assess for concomitant injuries. MRI is not routinely indicated with an intact rotator cuff clinically, and we usually recommend trying a course of physical therapy for 6 to 12 weeks before ordering MRI (Park et al., 2005).

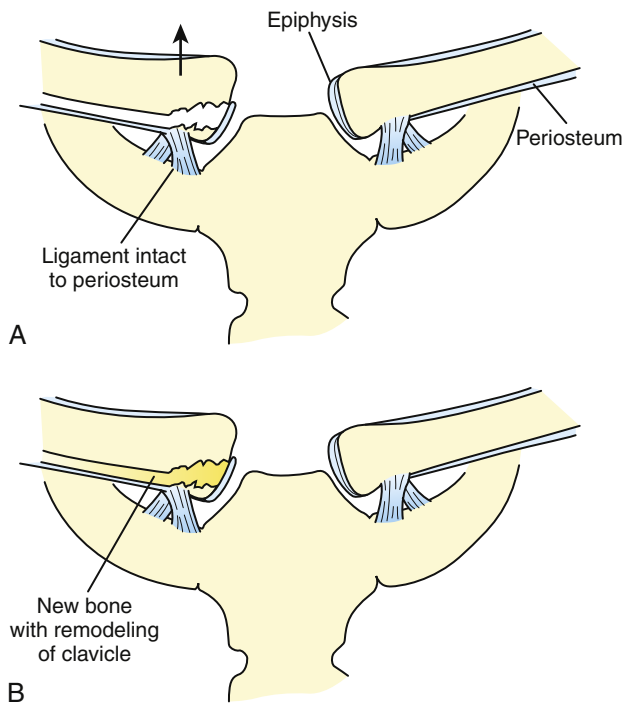

Figure 30-6 Medial clavicle injuries in patients younger than 23 to 25 years are likely physal injuries and have the potential to remodel.

If the patient has intact rotator cuff function on clinical examination and otherwise normal findings on radiographs, a conservative course of physical therapy is indicated for the impingement symptoms. From 90% to 95% of patients with incomplete tears of the rotator cuff improve with the course of physical therapy, anti-inflammatory medications, or a subacromial injection, although some may require surgery eventually (Matava et al., 2005). Physical therapy should focus on rotator cuff strengthening, ROM, posterior capsular stretching, and scapular stabilization. If patients fail a 6- to 12-week course of conservative treatment, a corticosteroid injection should be considered before surgery. If a patient is refractory to both corticosteroids and physical therapy, surgical intervention may be indicated. This is a more appropriate time to order an MR image because preoperative MR scanning can evaluate the extent of rotator cuff pathology, associated spurring, and degeneration within the shoulder joint. Although not necessary for making the diagnosis, MRI can assist the surgeon at surgery.

For incomplete rotator cuff tears (<50% of surface), a partial debridement and subacromial decompression using arthroscopy can provide effective, long-term relief of impingement pain. Management of rotator cuff tears greater than 50% or complete with clinical dysfunction is generally surgical. If the tear is identified before chronic retraction and muscle changes, primary arthroscopic or open repair has been effective in reducing pain and improving function. Rehabilitation after rotator cuff repair requires at least 6 weeks of passive ROM only, to protect the repair, followed by a gradual increase to resistance activities for the rotator cuff. Patients usually begin strengthening at 12 weeks. In patients with nonreparable chronic rotator cuff tears or those with advanced rotator arthropathy and degenerative disease, surgical interventions include muscle transfers, soft tissue grafts, hemiarthroplasties, and reverse shoulder hemiarthroplasties.

Figure 30-7 Anteroposterior (A) and lateral cross-sectional (B) drawings of the shoulder demonstrate the relationship of the rotator cuff muscles (supraspinatus, infraspinatus, teres minor, and subscapularis) to the bony structure of the shoulder.

EVIDENCE-BASED SUMMARY

- In a review of eight clinical trials (>390 patients), no definitive evidence supports or refutes the efficacy of common interventions, including physiotherapy, NSAIDs, corticosteroid injections, or open and arthroscopic surgery, for rotator cuff tears in adults (Ejnisman et al., 2003) (SOR: A).
- Based on limited data from two quality RCTs, no evidence supports the superiority of conservative versus surgical treatment for subacromial impingement syndrome (Dorrestijn et al., 2009) (SOR: B).
- Review of 14 RCTs evaluating rotator cuff surgery showed no long-term pain benefit of surgical decompression versus exercise programs (Coghlan et al., 2009) (SOR: A).

Shoulder Instability

Bony anatomy provides minimal stability to the glenohumeral joint; therefore the primary stability depends on both static and dynamic soft tissue structures. The static soft tissue structures include the fibrocartilaginous labrum,

Figure 30-10 Lift-off test is used to assess subscapularis muscle function. Patients are asked to lift their hand off their back against resistance. Weakness or pain indicates subscapularis pathology.
(Courtesy Mark R. Hutchinson, MD.)

Figure 30-11 “Napoleon” or “tummy pat” test is a modified lift-off test to evaluate subscapularis function. Patients are asked to maintain their elbow laterally while pressing into their belly. (Ensure that patients do not drop their arm and use their humerus extensors to mimic subscapularis function.)
(Courtesy Mark R. Hutchinson, MD.)

glenohumeral ligaments, and capsule. The labrum attaches to the periphery of the glenoid and serves to deepen the socket, reducing translation out of the socket. The glenohumeral ligaments attach to the labrum, are thickenings in the capsule, and connect to the humeral head. The intrinsic dynamic stabilizers are the rotator cuff and biceps, which help to maintain the humeral head in the glenoid socket. The extrinsic dynamic stabilizers include the rhomboid, levator scapulae, serratus, and trapezius muscles, which position the glenoid beneath the humeral head.

The diagnosis of shoulder instability begins with the patient’s history and mechanism of injury, which often include episodes of subluxation, dislocation, or apprehension. Classically, anterior instability is appreciated when the arm is placed in abduction and external rotation (Tennent et al., 2003a, 2003b) (Fig. 30-12). *Inferior* instability is appreciated

Figure 30-12 Apprehension test is performed with the arm in full abduction and external rotation. Sensation of impending subluxation is a positive finding. (Courtesy Mark R. Hutchinson, MD.)

when the patient tries to hold a heavy object and the shoulder subluxes inferiorly. *Posterior* instability is frequently associated with a fall on an outstretched arm, or occasionally with weightlifters who lock out their arms in extension while bench pressing. The clinical examination targets these specific pathologies with the classic *apprehension test* for anterior instability, performed with the arm in abduction and external rotation, and the patient having the sensation of the arm going out of place. In the *relocation test* the examiner then presses the humeral head back into a reduced position, thus eliminating the sensation of apprehension. Posterior instability is assessed in a supine position with the arm forward-flexed 90 degrees with a posteriorly directed force. Inferior instability is assessed by pulling inferiorly on the arm and looking for or feeling the humerus come out the socket and looking for a concavity just below the acromion, called the “sulcus sign” (Fig. 30-13).

Some patients may have generalized ligamentous laxity, but laxity itself is not a painful process and is therefore not pathologic. However, some patients with generalized ligamentous laxity do have symptoms of instability and pathology that can be assessed by comparison to the opposite side or looking at the elbows, fingers/thumb, or knees for excessive recurvatum. In general, patients with generalized ligamentous laxity should undergo an extensive course of conservative treatment because of the increased risk of failure associated with most surgical interventions compared to simple unidirectional instability.

The conservative treatment of shoulder instability is targeted at balancing the flexibility, optimizing the motor strength, and optimizing the function of the kinetic chain. The core component is rotator cuff–strengthening exercises as well as scapular stabilizer exercises. Controversy surrounds the ideal treatment for a first-time shoulder anterior dislocation. In young athletes or military populations, the risk of recurrence and future shoulder problems approaches 90%. Surgical treatment with repair of labral detachments has led to a high rate of return to play and return to performance, with a low risk (<10%) of recurrent instability for a first dislocation. Older nonathletic patients (>40) with first-time dislocation have a reduced risk of recurrent instability (<50%), so surgical treatment is unnecessary. However, if any patient has recurrent instability

Figure 30-13 Presence or absence of a sulcus sign is evaluated by distracting the arm inferiorly to subluxe the humeral head out of the socket. If a sulcus is appreciated as the glenoid is emptied of the humeral head, the clinician should suspect multidirectional instability. (Courtesy Mark R. Hutchinson, MD.)

or pain, surgery to repair the torn capsule or labral lesions is strongly recommended, with outcomes ranging from 75% to 95% good to excellent results. The Bankart procedure is most often performed and involves direct repair of the torn labrum back to the glenoid from which it was detached (Fig. 30-14). Classically, this procedure was performed open, although the current trend is toward arthroscopic assistance.

Posterior instability accounts for only 10% to 15% of isolated instability of the shoulder. The classic treatment for posterior instability is to initiate a course of conservative treatment focused on strengthening the posterior capsular muscles, including infraspinatus and teres minor. If a conservative course fails, surgical treatment can once again address either capsular laxity or posterior labral injuries.

Multidirectional instability is usually not secondary to a single acute traumatic event. More frequently, the patient will have underlying generalized ligamentous laxity that may or may not be exacerbated by a single traumatic event. These patients are generally loose jointed in all directions and in other joints. Initially, treatment is conservative, although in resistant cases, surgical capsular tightening can be successful in improving symptoms. A thorough history is necessary to rule out psychologic factors (e.g., voluntary dislocation for attention or party trick). These patients have an extremely high failure rate with surgical intervention.

KEY TREATMENT

Primary surgical repair is indicated for young athletes engaged in highly demanding physical activities who have sustained their *first* shoulder dislocation (Handoll et al., 2004) (SOR: A).

Surgical repair of shoulder instability from dislocation results in significantly lower recurrent instability than conservative treatment, especially for younger athletes and those in collision sports (Brophy and Marx, 2009) (SOR: B).

No significant difference exists between arthroscopic and open techniques in the surgical treatment of recurrent shoulder instability in adults (Pulavarti et al., 2009) (SOR: B).

Elbow

Key Points

- Chronic lateral epicondylitis is more likely to be a degenerative process than an inflammatory process.
- Topical or oral NSAIDs and corticosteroid injections provide short-term relief of lateral epicondylitis pain.
- Steroids must not be injected into an infectious bursitis.

Lateral Elbow Tendinopathy

Lateral elbow tendinopathy or *lateral epicondylitis*, commonly called “tennis elbow,” is caused by repetitive overuse of the wrist extensor and forearm supinator muscles that originate at the lateral epicondyle of the humerus—more specifically, the extensor carpi radialis brevis tendon. Once thought to result from inflammation, lateral elbow tendinosis is probably caused more by chronic changes in the musculotendinous matrix (Nirschl, 1992), with minimal inflammation present, particularly with symptoms present for more than 4 to 6 weeks. Microtears, chronic granulation tissue, and scar tissue formation are often seen in pathologic specimens of surgical cases of tennis elbow.

Patients present because of pain in the lateral aspect of the elbow and may complain of weakness or restricted elbow motion, but this is not as common. Pain is worsened by gripping, turning handles, and lifting activities, particularly with the hand in a palm-down position, as in lifting a suitcase, briefcase, or purse. Common positive physical examination findings include tenderness to palpation of the lateral epicondyle of the elbow and over the proximal wrist extensor and forearm supinator muscle tendons. Pain is intensified with resisted wrist extension and forearm supination. Pain can also limit patient strength. There should be no tenderness

directly over the radial head, with normal ligamentous stability and neurovascular status.

Plain radiographs are not needed to make an accurate diagnosis of lateral epicondylitis but should be considered in patients with a history of trauma, motion loss, or locking or with a prolonged period of pain.

Management focuses on pain control and restoration of normal elbow function. Cryotherapy, ice massage, and nonsteroidal anti-inflammatory drugs (NSAIDs) or acetaminophen are excellent pain relievers. NSAIDs and corticosteroid injection have been mainstays of treatment, although they are now questioned because inflammation no longer seems a main factor in the injury process. Corticosteroid injections help quickly reduce the pain of lateral elbow tendinosis, but do not alter long-term outcome (Smidt et al., 2002). Cortisone injection may lead to a short-lived increase in pain in a large percentage of patients (Wang et al., 2003).

Counterforce straps can effectively reduce discomfort in some patients (Fig. 30-15). The strap is applied just distal to the area of maximal tenderness. The strap may relieve some of the tension exerted on the affected muscle tendon units during activities, thereby reducing pain. However, straps, medications, and injections should not replace therapeutic exercises, which include massage, stretching, and strengthening exercises. The most effective stretch is performed with the elbow extended, forearm fully pronated, and wrist flexed. From this position, gentle traction is applied to the middle and ring fingers toward the olecranon. Strengthening exercises with light weights for wrist extension and forearm supination can be done.

Most patients with lateral elbow tendinopathy will obtain excellent relief of symptoms with the program just described, although minimal evidence exists to support these plans (Bissett et al., 2005). If these measures do not lead to adequate relief, other protocols can be added. Formal physical therapy is often used in recalcitrant cases. Treatments such as

Figure 30-15 Lateral elbow counterforce brace. Note that wide, nonelastic support is curved to fit the conical forearm shape. This does not allow for full muscular expansion, thereby diminishing intrinsic muscular force on the lateral epicondyle.

(From Morrey BF [ed]: *The Elbow and Its Disorders*. Philadelphia, Saunders, 1985.)

prolotherapy, dry needling, platelet-rich plasma injections, and extracorporeal shock wave therapy are still experimental, and studies have not fully proved their effectiveness. Surgical intervention is sometimes needed and has excellent results.

KEY TREATMENT

No specific physical therapy modality is preferred over another in the treatment of lateral elbow tendinopathy (Smidt et al., 2003) (SOR: A).

Topical and oral NSAIDs are both effective in providing short-term pain relief from lateral epicondylitis; topical NSAIDs have fewer adverse effects (Green et al., 2002) (SOR: A).

Corticosteroid injections are helpful in reducing pain from lateral epicondylitis but do not alter the long-term outcome (Smidt et al., 2002) (SOR: A).

Little evidence exists to support the use of therapeutic exercises or braces in the treatment of lateral epicondylitis (Bisset et al., 2005) (SOR: A).

Extracorporeal shock wave therapy provides little or no benefit in terms of pain and function in lateral elbow pain (9 placebo-controlled trials, 1006 participants; Buchbinder et al., 2009) (SOR: A).

Medial Elbow Tendinopathy

Medial elbow tendinopathy or *medial epicondylitis*, commonly called “golfer’s elbow,” is caused by repetitive overuse of the wrist flexor and forearm pronator muscles that originate at the medial epicondyle of the humerus. Patients present due to pain in the medial aspect of the elbow, rarely weakness, and loss ROM. Pain is worsened by gripping and lifting activities, particularly with the hand in palm-up position. Common

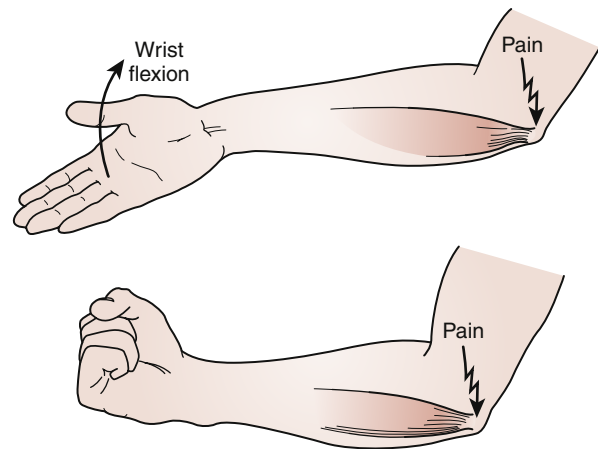

Figure 30-16 Medial epicondylitis may be diagnosed clinically by pain localized to the medial epicondyle during wrist flexion and pronation against resistance. There is often pain elicited after making a tight fist, and grip strength is usually diminished on the affected side.

(From Morrey BF [ed]: *The Elbow and Its Disorders*. Philadelphia, Saunders, 1985.)

positive findings include tenderness to palpation of the medial epicondyle of the elbow and over the proximal wrist flexor and forearm pronator muscle tendons. Pain is intensified with resisted wrist flexion and forearm pronation (Fig. 30-16). Patient discomfort often limits strength. Elbow motion, ligamentous stability, and neurovascular status are typically intact.

As with lateral elbow tendinopathy, plain radiographs are not needed to make an accurate diagnosis of medial elbow tendinopathy, but should be considered with a history of trauma, motion loss, locking, or chronic pain. Also similar to lateral epicondylitis, management of medial epicondylitis includes ice, medications, injections, and straps. However, corticosteroid injections are not recommended because of possible ulnar nerve injury. In medial elbow tendinopathy, the most effective stretch is performed with the elbow extended and the wrist and fingers gently pulled into full extension. The forearm can be pronated or supinated. Strengthening focuses on wrist flexion and forearm pronation exercises.

Olecranon Bursitis

Olecranon bursitis is a common cause of painless elbow swelling from repetitive friction of the olecranon against a firm surface or traumatic impact. Patients most often present with a painless swelling at the dorsal tip of the elbow, described as “a golf ball” or “goose egg” (Fig. 30-17). With trauma-induced swelling, pain and a hematoma may be present. Pain, redness, warmth, and lymphadenopathy may accompany septic bursitis. ROM loss, instability, neurovascular compromise, and strength loss are uncommon. On examination, there is a soft, fluctuant area of swelling directly over the olecranon. Diagnostic studies are generally not necessary to make a diagnosis of olecranon bursitis. However, plain radiographs should be obtained if trauma preceded the bursitis or fracture or dislocation is suspected.

Treatment includes compression, ice, and avoidance of impact at the olecranon. NSAIDs may help to reduce swelling. If the fluid collection is large or infection is suspected, aspiration of the bursa can be done in the office with a large-bore needle under sterile conditions. The bursa fluid should be clear and straw colored but may be bloody in a

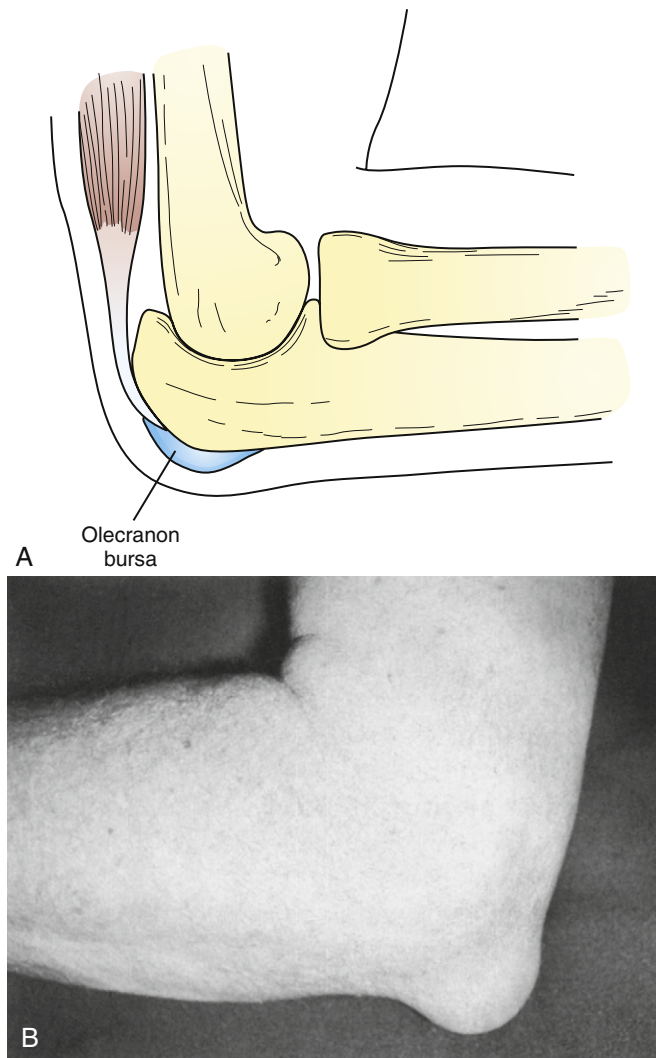

Figure 30-17 **A**, Relation of the olecranon bursa to the skin and olecranon. **B**, Photograph of an enlarged olecranon bursa. (From Singer KM, Butters KP: Olecranon bursitis. In DeLee JC, Drez D [eds]. *Orthopedic Sports Medicine: Principles and Practice*, vol 1. Philadelphia, Saunders, 1994, pp 890, 892.)

traumatic injury. If an infection is not suspected clinically once the fluid is withdrawn, a corticosteroid can be injected. Corticosteroids should never be injected if infection is a possibility. Oral antibiotics can be started if an infection is present. A local incision and drainage (I&D) may be required in the presence of an infection and abscess. Aspiration does not replace compression wrap, ice, and avoidance of impact. Fluid may reaccumulate but should decrease. Serial aspirations are an option in a recurrent aseptic bursitis, but bursectomy is occasionally needed for definitive treatment.

Wrist and Hand

Key Points

- Both bracing and cortisone injection may reduce carpal tunnel syndrome pain in the short term.
- Surgical treatment of carpal tunnel syndrome leads to better symptom relief than bracing.

- Immobilization of suspected scaphoid injuries should be instituted while workup is completed.
- Initial immobilization of any scaphoid fracture should be in a thumb spica cast.
- Proximal pole and displaced scaphoid fractures should be treated by an orthopedic surgeon.

Carpal Tunnel Syndrome

Carpal tunnel syndrome (CTS) is the most common nerve entrapment syndrome encountered in primary care. CTS is more common in women than men and affects about 3% of the adult American population. Of the many possible etiologies, the most common is tenosynovitis of the hand flexors, leading to median nerve compression. CTS can develop during pregnancy as well. Nine flexor tendons course through the carpal tunnel along with the median nerve (Fig. 30-18).

Patients typically present due to pain, numbness, paresthesias, and loss of grip strength in the wrist and hand. Symptoms may even radiate into the shoulder region. Symptoms usually involve the radial 3½ digits as supplied by the median nerve and are noted more with repetitive hand motion activities and at night. Physical examination may reveal thenar atrophy and decreased sensation over the radial 3½ digits. These two clinical findings, along with a history of pain in the distribution of the median nerve, are highly suggestive of CTS and correlate to positive nerve conduction study findings (D'Arcy and McGee, 2000).

Tinel's test (sign) at the wrist is performed by tapping over the wrist flexor retinaculum and having increased or reproducible symptoms of pain, numbness and tingling in the radial 3½ digits. The most sensitive test is the carpal compression test, in which direct compression over the tunnel elicits the symptoms. Phalen's maneuver is performed by having the patient flex the wrists to a 90-degree position, holding the dorsal aspects of the hands back-to-back. The patient maintains this position up to 1 minute, until symptoms develop.

Diagnostic imaging is not necessary to make a diagnosis of CTS. Electrodiagnostic tests can be used to confirm the diagnosis but are not needed to initiate or direct early treatment in most patients. Although up to 25% are false negative in patients with clinical CTS, electrodiagnostic tests should be done before surgery.

Treatment begins with attempts to avoid or at least modify activities known to cause pain for the patient. This may include ergonomic changes in the workplace, such as wrist support pads for computer use. Wrist splinting, particularly at night, may prove helpful. Nerve gliding exercises are routinely prescribed and can provide relief (Fig. 30-19). Oral analgesic and NSAID use may also lead to relief, although studies show these are no more effective than placebo. Corticosteroid injection is a helpful adjunct in many patients and may relieve symptoms better than placebo (Germisten et al., 2002). A majority of patients will experience good relief of symptoms if these conservative measures are followed. Unfortunately, most of these patients will have a return of symptoms in 1 year (Kanaan and Sawaya, 2001). Surgery is considered in patients who have recurrence of symptoms despite adequate conservative measures, and outcomes are excellent. Both open and endoscopic techniques are available, with equivalent long-term results.

KEY TREATMENT

Oral analgesic and NSAID use to treat symptoms of CTS are no more effective than placebo (Gerritsen et al., 2002) (SOR: A). Corticosteroid injection is more effective than placebo in relieving symptoms (short term) (Gerritsen et al., 2002) (SOR: A). Bracing for CTS may lead to significant short-term pain reduction (O'Connor et al., 2003) (SOR: A). Surgery relieves CTS symptoms significantly better than bracing (Verdugo et al., 2005) (SOR: A).

DeQuervain's Tenosynovitis

DeQuervain's tenosynovitis is a painful repetitive and over-use condition of the abductor pollicis longus and extensor pollicis brevis along the dorsal radial aspect of the wrist. Patients present due to pain and swelling along the dorsal radial side of the wrist, which is worsened with activities. Physical examination reveals tenderness with palpation, and the classic clinical finding is a positive Finkelstein test. This is performed by having the patient flex and adduct the thumb to the palm, then close the remaining fingers over the thumb. The examiner then passively takes the patient's wrist into ulnar deviation. Pain along the tendons with this

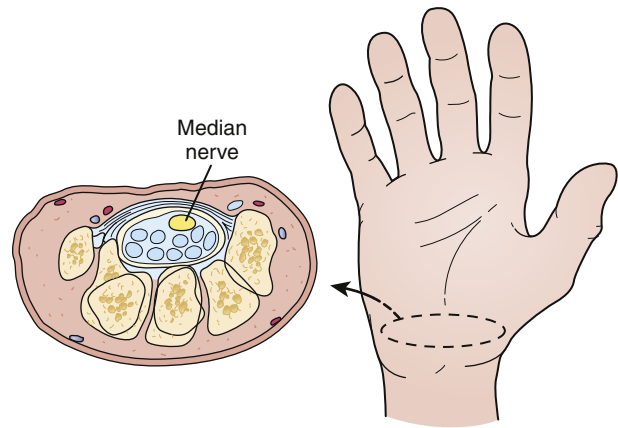

Figure 30-18 Cross-sectional anatomy of the carpal tunnel, bounded on three sides by the carpal bones and volarly by the transverse carpal ligament. Nine flexor tendons and the median nerve pass through the tunnel. Anything that causes increased pressure in this canal can produce the symptoms of carpal tunnel syndrome. (From McCue FC, Bruce VF: *Hand and wrist*. In Delee JC, Drez D [eds]. *Orthopedic Sports Medicine: Principles and Practice*, vol 1. Philadelphia, Saunders, 1994, p 997.)

Figure 30-19 Carpal tunnel nerve glide exercises.

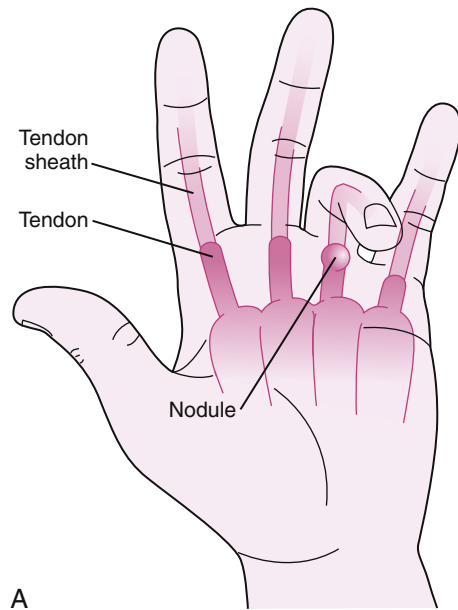

Figure 30-20 Flexor tendon nodule.

maneuver is considered a positive test (Finkelstein, 1930). Radiographic tests are not necessary to make an accurate diagnosis.

Treatment begins with avoidance of the inciting activities. Ice may reduce pain and swelling, and analgesic medications are often used as well. Thumb spica splinting is very helpful, allowing the irritated tendons to rest (Winzler and Rosenstein, 1996). Prolonged splinting may be needed to reduce pain significantly. Corticosteroid injection along the tendon sheath is often used to reduce pain more acutely (Peters-Veluthamaningal et al., 2009a; Wood and Dobyns, 1986). In refractory cases, surgical decompression of the tendons can be performed.

Digital Flexor Tenosynovitis

Tenosynovitis of a digital flexor tendon, also called “trigger finger,” is quite common. Patients present with the complaint of a finger that “sticks” with motion, primarily flexion, and they must painfully force the finger back into extension. Usually, a painful palpable nodule on the flexor tendon is present along the distal palmar crease or at the base of the thumb, at the level of the metacarpophalangeal (MCP) joint (Fig. 30-20). Motion and activities may be associated with pain. Radiographs and other diagnostic tests are not needed to make an accurate diagnosis.

Treatment options for digital flexor tenosynovitis include anti-inflammatory medications, modification of activities, ice, massage, stretching of the flexor tendons, and gentle-grip strength exercises, although these usually provide little relief. Corticosteroid injections are often used to relieve pain and triggering symptoms (Marks and Gunther, Peters-Veluthamaningal et al., 2009b). Symptoms may return, and repeat injections are considered if the first injection provided reasonable pain relief. However, surgery may be needed in patients with frequent recurrence.

Figure 30-21 **A**, Disruption of scapholunate and radiocarpal ligaments leads to progressive dissociation between scaphoid and rest of carpal bones. This injury is frequently mistaken for a persistent wrist sprain. **B**, Chronic dissociation of scapholunate joint allows scaphoid to rotate downward toward the palm. This increases the angle between scaphoid axis and radiolunate-capitate axis. The capitate then slowly migrates toward the radius, and osteoarthritis rapidly develops. (From Connolly JF: *DePalma's The Management of Fractures and Dislocations: an Atlas*, 3rd ed. Philadelphia, Saunders, 1981.)

Scapholunate Sprains

Ligament sprains of the wrist usually result from falls on an outstretched hand. Most are mild and resolve with splinting and symptomatic treatment. However, the clinician must be careful not to miss potentially catastrophic injuries that could compromise a patient's hand and wrist function, including carpal dislocations, carpal instability (more specifically, scapholunate ligament instability), scaphoid fractures, and displaced intra-articular distal radius fractures. Injury to the scapholunate joint may be missed by physicians who do not consider it in their differential diagnosis of wrist injuries (Fig. 30-21).

Patients with scapholunate sprains have pain in the wrist with motion, gripping, and lifting and along the dorsal aspect

Figure 30-22 **A**, Posteroanterior radiograph of left wrist in 27-year-old soccer player who fell, landed on his left palm, and complained of pain. Note the abnormal widening of the scapholunate interval. **B**, Comparison view of the uninjured right wrist demonstrates the same scapholunate separation (>3 mm) ("David Letterman" sign). Patient recovered with only splint support.

(From Nicholas J, Hershman E. *The Upper Extremity in Sports Medicine*, 2nd ed. St Louis, Mosby, 1995, p 456.)

of the wrist at the scapholunate joint just distal to Lister's tubercle (bump on distal radius) on the dorsal aspect of the wrist. Physical examination typically reveals no gross deformities, although dorsal swelling may be noted. The pain may be exacerbated by flexion and extension while palpating directly over the scapholunate joint on the dorsal aspect of the wrist.

Impacts strong enough to cause scapholunate sprain are sufficient to cause fracture. Therefore, plain radiographs should be obtained in all patients with suspected scapholunate sprain to look for associated fracture or avulsion. The series should include a standard AP view, AP with a clenched fist (accentuates scapholunate joint widening), standard lateral view, and posteroanterior (PA) view in ulnar deviation (assess scaphoid bone better for fracture). It is often helpful to obtain a comparison AP view of the opposite wrist. An increased gap between the scaphoid and lunate bones of 2 to 3 mm on the AP projection (e.g., "Terry Thomas" [U.K.] or "David Letterman" [U.S.] sign, for their gapped-tooth grin) is indicative of scapholunate dissociation (Fig. 30-22).

Patients with a "simple" scapholunate sprain require protection and rest with a period of splinting. This can be accomplished with a custom fiberglass or plaster splint, or a prefabricated cock-up wrist splint until the patient is asymptomatic. After initial treatment, the patient is weaned from the wrist splint and begins active ROM and hand-strengthening therapy. In patients with scapholunate dissociation, surgical consultation should be considered early, and referral to a hand specialist is encouraged. Fixation of the joint is often needed to maximize future wrist function (Fig. 30-23).

Distal Radius Fractures

Patients with distal radius fractures most often present with wrist pain and deformity immediately after a fall. All patients with wrist pain after a fall should have AP, lateral,

Figure 30-23 Postoperative radiograph with scapholunate joint reduced and two K wires properly positioned to stabilize the joint.

(From Nicholas J, Hershman E. *The Upper Extremity in Sports Medicine*, 2nd ed. St Louis, Mosby, 1995, p 393.)

and oblique radiographs of the wrist. Deformity may or may not be present, and some patients may complain of paresthesias in the affected extremity. A patient's ability to move the wrist does not rule out fracture. It is important to palpate the entire extremity to assess any injury above or below the primary injury site for concomitant fractures. If suspected, radiograph those areas as well. Neurovascular status should always be evaluated and documented.

Treatment is based on fracture type, patient age, and demand. A nondisplaced or minimally displaced fracture can be initially treated in a splint for 5 to 7 days until swelling subsides, then casted in a short-arm cast. Average healing time is 4 to 8 weeks, and repeat radiographs should be obtained during the healing process at an interval of every 2 to 3 weeks. An extra-articular, angulated fracture is initially treated with closed reduction with block (lidocaine injection into fracture hematoma). If postreduction alignment is adequate, a splint can be placed for 5 to 7 days to maintain the alignment pending casting. Because displacement or angulation of fracture fragments is a high risk even when appropriately splinted or casted, radiographic follow-up is important, and distal radius fractures are often treated by an orthopedic surgeon. Comminuted or displaced intra-articular fractures usually require closed reduction with percutaneous pinning or open reduction, internal fixation to maintain position and articular surface integrity; orthopedic surgery referral is recommended.

Scaphoid Fracture

Patients typically present after a fall onto an outstretched hand and complain of pain and swelling in the radial aspect of the wrist, worsened by motion. Gross deformity is not usually seen. The most common physical examination finding is tenderness with palpation over scaphoid tubercle or in the anatomic snuffbox. Radiographs should be obtained in all patients with suspected scaphoid injury, including AP, lateral, and oblique views, as well as PA ulnar deviation or scaphoid views (Fig. 30-24). Importantly, radiographs are often negative shortly after immediate injury and up to 14 days; radiographs should be repeated in 2 weeks if suspicion remains high. Because a fracture is suspected, interim splinting or casting is necessary. Other diagnostic tests may be obtained if repeat x-ray films are negative after 2 weeks and the patient is still symptomatic, or if definitive diagnosis is needed sooner than the planned 2-week follow-up. These tests may include radionuclide bone scan (usually positive within 2-3 days of injury), CT, or MRI.

Treatment of scaphoid fracture is initiated if suspicion is high, even though radiographs are initially negative. If fracture is ruled out at follow-up visits, treatment is adjusted accordingly. Nondisplaced scaphoid fractures are treated with cast immobilization. Thumb spica casting is essential, but whether the initial cast needs to be a long-arm or short-arm variety is controversial. Studies have shown decreased time to union and reduced rates of delayed union and non-union with a long-arm thumb spica cast (Gellman et al., 1989). However, union rates of up to 95% with short-arm casting have been reported. A combination, with a long-arm cast for the initial 6 weeks followed by short-arm casting from 6 weeks until radiographic healing is present, addresses both these key issues.

Healing rates and average healing time depend on location of the fracture because the blood supply differs throughout the scaphoid. Nondisplaced distal pole fractures tend to receive a better blood supply and have a healing rate of close to 100%, with average healing time of 10 to 12 weeks. Scaphoid waist fractures have a healing rate of 80% to 90%, with average healing also 10 to 12 weeks. Proximal pole fractures have a healing rate of only 60% to 70%, with average healing time of 12 to 20 weeks. Poor outcomes (i.e., nonunion,

malunion) in any scaphoid fracture are more likely to occur if the diagnosis or appropriate treatment is delayed; this is why it is important to initiate treatment based on suspicion of injury with normal radiographs.

Fractures that are displaced (≥ 1 mm) can be treated with closed immobilization, but the risk of poor outcome is high. These fractures should be referred to an orthopedic surgeon for consideration of surgical fixation.

EVIDENCE-BASED SUMMARY

- One controlled study showed significant benefit of steroid injections for DeQuervain's tenosynovitis. Because of a limited number of patients and limited quality supportive studies, however, definitive recommendations cannot be made (Peters-Veluthamaningal et al., 2009a) (SOR: B).
- Pain and symptoms of people with "trigger finger" may improve with a corticosteroid injection (Peters-Veluthamaningal et al., 2009b) (SOR: A).
- Bone scintigraphy and MRI have equally high sensitivity and high diagnostic value for excluding scaphoid fracture. However, MRI is more specific and better for confirming scaphoid fracture (Yin et al., 2009) (SOR: A). We believe additional studies are needed to assess diagnostic performance of CT.

Knee

Key Points

- In clinical examination of ligament injuries about the knee, the Lachman test is the most sensitive for anterior cruciate ligament (ACL) instability.
- The clinician should maintain a high level of suspicion of associated ligament injuries, especially the lateral collateral ligament (LCL) and posterolateral corner. Acute surgical intervention (within 3 weeks) of LCL and posterolateral corner injuries significantly improves prognosis.
- Viscosupplementation, therapeutic exercise, and oral supplementation with glucosamine and chondroitin sulfate may all provide some symptomatic relief and functional improvement for generalized knee arthritis. Arthroscopic debridement alone (in the absence of loose bodies, cartilage flaps, and meniscus tears) may not provide relief.
- Vertical, peripheral meniscus tears in the vascular zone of the meniscus of young patients should be treated with meniscus repair whenever possible to avoid focal increased pressures in the articular surface and future risk of degenerative joint disease.
- In older patients with degenerative meniscus pathology and no locking, prevention of arthritic progression may be surgical or nonsurgical. When performed, partial is preferred to complete meniscectomy.

Degenerative Osteoarthritis

Degenerative osteoarthritis (OA) of the knee is caused by loss of the hyaline cartilage along the knee joint surfaces. This can occur in an isolated compartment or diffusely throughout all three compartments of the knee. OA more often develops in the medial side or medial compartment of the knee, first

Figure 30-24 24 Transverse fracture through waist of scaphoid.
(Courtesy James L. Moeller, MD.)

Figure 30-25 Weight-bearing knee radiographs showing osteoarthritis.

leading to joint space narrowing and varus or bowleg deformity. Loss of articular cartilage and joint space on the lateral aspect of the knee leads to valgus or knock-knee deformity. Weight-bearing (standing flexed-knee PA) radiographs are strongly recommended to evaluate joint space narrowing and OA extent. Lateral and patella sunrise tangential views complete the study (Fig. 30-25). MR images are not routinely required and should not be ordered instead of plain x-ray films. MRI is best reserved for mechanical pathology or preoperative planning. X-ray findings include loss of the joint space, presence of osteophytes, subchondral sclerosis, and cysts.

Patients with OA typically complain of knee pain and stiffness with walking, after prolonged sitting, descending stairs, and early in the morning. Swelling of knees and worse symptoms are typical with weather changes. Physical exam findings often reveal decreased ROM (flexion contractures), knee varus or valgus deformity, joint line tenderness, and crepitus with palpation during ROM.

Treatment of OA is based on the patient's age, demand, comorbidities, and severity of osteoarthritis. Conservative

treatment for knee arthritis should include a generalized conditioning program, weight loss, a knee sleeve to improve the proprioceptive control, cushioned shoes, and NSAIDs. Oral supplementation with glucosamine and chondroitin sulfate may also be considered. If these do not provide relief after 4 to 6 weeks, corticosteroid or viscosupplement injections can be administered, typically with variable pain relief and duration. Injections may be repeated depending on patient response. In resistant cases, total or partial knee replacement can provide excellent pain relief and improve function. The effect of arthroscopy in patients with degenerative arthritis remains controversial (Hunt et al., 2002; Mosely et al., 2002). However, arthroscopy in the absence of loose bodies, cartilage flaps, or meniscal pathology is unlikely to be unsuccessful.

EVIDENCE-BASED SUMMARY

- The short-term benefit of intra-articular corticosteroid in treatment of knee osteoarthritis is well established; however, longer-term benefits have not been confirmed, and the response to hyaluronic products appears to have more durability (Bellamy et al., 2005a) (SOR: A).
- Based on a single RCT, bracing for OA may provide additional benefit compared to medical treatment alone (Brouwer et al., 2001) (SOR: B).
- Land-based therapeutic exercise programs reduce pain and improve physical function for patients with OA of the knee (Brosseau et al., 2003; Fransen et al., 2001) (SOR: A).
- Viscosupplementation (injection of hyaluronate) is an effective treatment for OA of the knee, with beneficial effects on pain and function (Bellamy et al., 2005b) (SOR: A).
- Nonglucosamine preparations failed to show benefit, whereas glucosamine preparations were superior to placebo in the treatment of pain and functional impairment resulting from symptomatic OA (Towhead et al., 2009) (SOR: A).
- Arthroscopic debridement has no benefit for undiscriminated OA with mechanical or inflammatory causes (Laupattarakasem et al., 2009) (SOR: A).
- In OA patients, exercise results in a modest reduction in pain and a modest improvement in physical function (Fransen and McConnell, 2009) (SOR: B).

Infections

Intra-articular joint infections are orthopedic emergencies and require urgent surgical irrigation and debridement as well as long-term antibiotic therapy. The most common source of infection is *Staphylococcus aureus*, which aggressively and quickly destroys cartilage and leaves the patient with permanent OA. Patients with a knee joint infection present with increased pain, swelling, warmth, redness, fever, and decreased ability to ambulate on that leg. Most patients will not want to move their knee at all. The knee should be aspirated and the fluid inspected and sent for laboratory analysis (Gram stain, cell count, culture, crystal evaluation). Crystalline arthropathy such as gout should always be considered because the aspirated fluid often appears cloudy and may mimic a joint infection. C-reactive protein (CRP) and erythrocyte sedimentation rate (ESR) should also be obtained. Appropriate antibiotic treatment is initiated based on the offending organism. Although proposed in the medical literature for low-virulent organisms, serial aspiration is discouraged in the orthopedic literature, with surgical irrigation the preferred treatment.

Inflammatory Conditions

Bursae are synovial fluid-filled structures or “cushions” that pad bony prominences as protection against repetitive impact from external forces or snapping anatomic structures, such as ligaments or tendons. Several bursae around the knee can become inflamed, irritated, and rarely, infected, including the prepatellar bursa, infrapatellar bursa, pes anserine bursa, and iliotibial (IT) band bursa (beneath IT band laterally). Knowing their anatomic location is important so that these bursae can be palpated directly (Fig. 30-26).

Treatment of *bursitis* includes compression, ice, protective padding, and avoidance of impact on the bursa. NSAIDs may help to reduce swelling. If the fluid collection is large or an infection is suspected, aspiration of the bursa can be performed in the office with a large-bore needle under sterile conditions. The bursa fluid should be clear and straw colored or may be bloody in a traumatic injury. If an infection is not suspected clinically once the fluid is withdrawn, a corticosteroid can be injected. Corticosteroids should never be injected if infection is a possibility. Oral antibiotics can be started if an infection is present. Local I&D may be required with infection and abscess. Aspiration does not replace compression wrap, ice, and avoidance of impact. Reaccumulation of fluid may occur, but total volume usually decreases. Serial aspirations are an option in patients with recurrent aseptic bursitis.

Extensor Mechanism Problems

The extensor mechanism comprises the quadriceps muscle, quadriceps tendon, patella, and patellar tendon. Differential diagnosis of problems in the extensor mechanism is broad, including muscle or tendon rupture, patellar fracture, patellar tendinopathy, patellofemoral syndrome, patellar instability, Osgood-Schlatter’s disease, and symptomatic medial plica. Examination of patients with anterior knee pain or extensor mechanism problems should always include a careful evaluation of the lumbar spine and hip to rule out

referred pain, as well as assessment of the antagonist hamstring muscles posteriorly. Hamstring tightness can exacerbate problems of tendinosis, patellofemoral syndrome, and instability.

If the patient presents with focal tenderness over the patellar tendon at the distal pole of the patella, or potentially at the quadriceps insertion onto the patella, the likely diagnosis is tendinosis. Numerous studies show that chronic repetitive overuse does not actually lead to inflammation of the tendon itself, but rather to a central degeneration or tendinosis of the fibers of the tendon (Fithian, 2002). Steroid injections into patellar tendinosis are highly discouraged because they may predispose the tendon to complete failure. Treatment protocols for patellar tendinosis, or “jumper’s knee,” should include hamstring stretching, quadriceps strengthening with eccentric loading, and occasionally the use of a counterforce brace such as a Cho-Pat strap (Fig. 30-27).

Alternative treatments, including deep friction massage, prolotherapy, platelet-rich plasma injections, topical anti-inflammatory drugs, ultrasonic waves, and radiofrequency (RF) probes, show mixed results. Although no RCTs have yet proved their efficacy, these modalities have had some success. Surgical intervention for debridement of the tendinosis is uncommon but may be necessary to provide long-term relief. In the skeletally immature patient, tenderness at the distal pole of the patella may represent an avulsion apophysitis called Sinding-Larsen-Johansson disease. If the skeletally immature patient has pain at the insertion of the patellar tendon on the tibia, the most likely diagnosis is an apophysitis of the tibial tubercle, or Osgood-Schlatter’s disease. Both problems are more common during active phases of growth and are generally treated conservatively with rest, flexibility exercises, and gradual return to activity. Complete failure or rupture of the extensor mechanism at the patellar or quadriceps tendon requires surgical repair (Ilan et al., 2002).

Patellofemoral Syndrome

Anterior knee pain has been variously termed patellofemoral syndrome and chondromalacia patellae. When treating anterior knee pain, the physician should identify the specific pathology to initiate targeted treatment. *Chondromalacia patellae*, or degenerative changes on the undersurface of the patella, is more common in young females. Pain complaints related to chondromalacia are exacerbated by sitting for an extended period with a flexed knee, doing deep squats, or going up and down stairs. Each of these activities increases the posteriorly directed forces of the patella, directing increased pressure onto the chondral surfaces.

Treatment of these early arthritic changes is typically rehabilitation. Surgical intervention, such as cartilage scraping and debridement, has not been shown to provide long-term relief or benefit. In rare patients who have associated tight lateral retinacular structures and patellar tilt, surgical release of the lateral retinaculum can provide benefit. Conservative treatment of patellofemoral syndrome includes cushioned shoes, rehabilitation focused on the vastus medialis obliquus muscle, reductive taping techniques, hamstring stretches, and NSAIDs. Correction of the foot alignment with orthotic devices is also a treatment option, but supportive evidence is limited. From

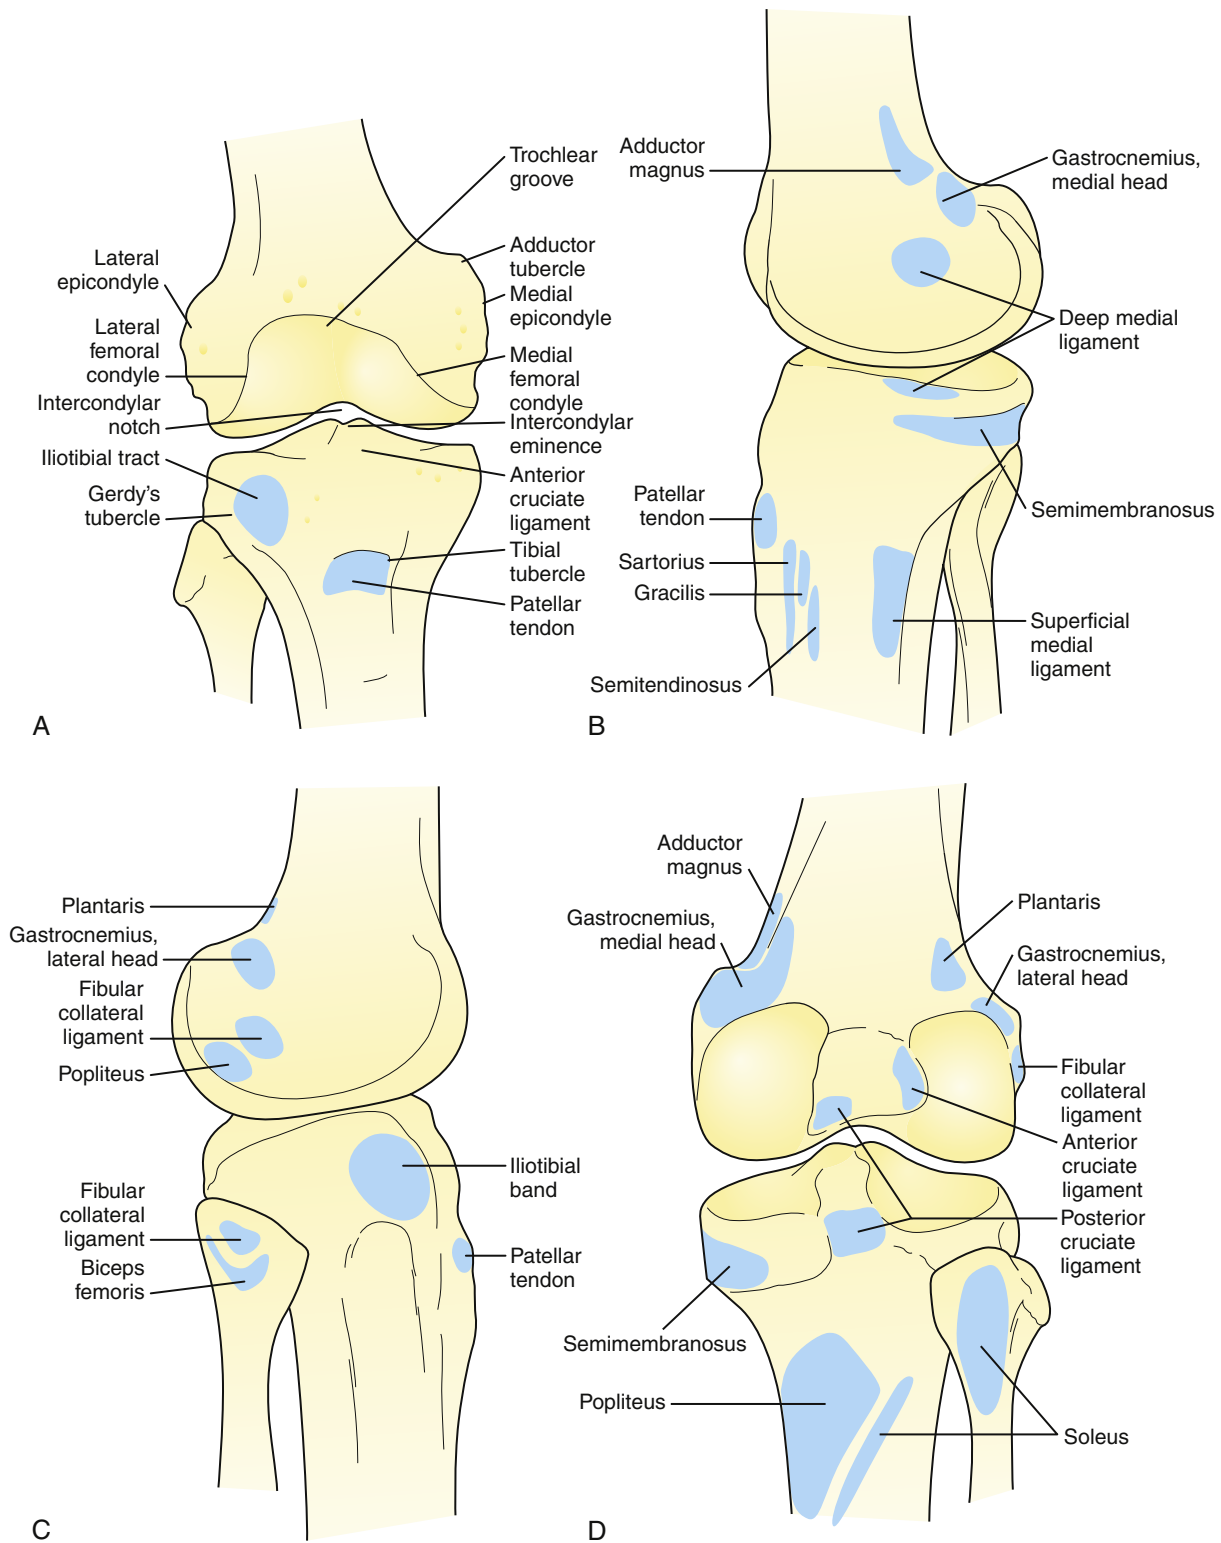

Figure 30-26 Line drawing shows anatomic sites of bursae around the knee.

70% to 80% of patients will improve with this conservative treatment. Unfortunately, the remaining patients with resistant symptoms can have a frustrating long-term therapeutic course, with guarded prognosis for any surgical intervention. Ultrasound therapy had no clinically important effect on patients with patellofemoral pain syndrome (Brosseau et al., 2001).

Meniscus Injuries

The menisci are fibrocartilaginous structures situated on the tibial plateau both medially and laterally that help disperse the weight-bearing contact forces across the knee joint cartilage surfaces (Fig. 30-28). In the presence of a meniscus tear or the complete absence of a meniscus, focal stresses

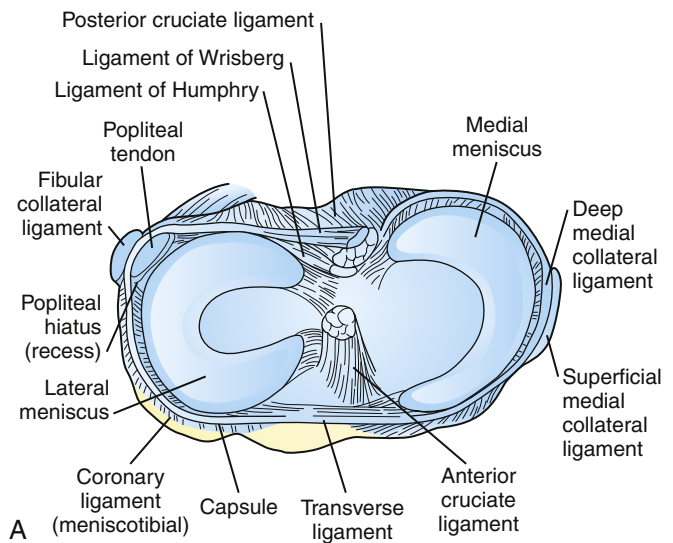

Figure 30-27 Counterforce brace (Cho-Pat strap) can be effective in reducing symptoms of patellar tendinosis (jumper's knee).

increase. This in turn increases the loading of the hyaline cartilage and early progressive degenerative arthritis (Sherman, 1996). Meniscus tears can occur with axial loading but primarily occur because of twisting, cutting, or rotational forces. In older patients, meniscus tears may simply be a progression of the normal degenerative process. On physical examination, patients have pain over the medial or lateral joint line and may complain of snapping, popping, or catching within the knee (Greis et al., 2002a, 2002b). Varus or valgus loading may exacerbate pain as the meniscus is squeezed between the bony structures. Recurrent effusions may also represent intra-articular pathology. The most common test for meniscus injury is McMurray's test (Fig. 30-29). The knee is hyperflexed, stressed with varus or valgus load, as well as internally and externally rotated, as the knee is brought into full extension. More simply, the examiner uses the lower leg and tibia to try to trap the torn meniscus between the tibia and the femur through a full knee ROM. If the examiner feels a snapping or a pop along the joint-line and the patient simultaneously complains of pain, the test is considered positive and highly indicative of a meniscus tear. A single finding may raise suspicion of a tear but does not confirm its presence. Indeed, sensitivity of both findings, the pop and pain, is over 90%. MRI can be used to confirm the diagnosis or assist preoperative planning but should never replace a thorough physical examination.

Definitive treatment of meniscus pathology depends on the actual damage and pattern of the meniscus injury on MRI (Sherman, 1996; Greis et al., 2002a, 2002b) (Fig. 30-30). Depending on the pattern, the meniscus can either be repairable or nonrepairable. Because of its essential role in sharing load and preventing the progression of degenerative arthritis, salvageable meniscus tears should always be repaired if possible. After debridement, patients can bear weight as

B

Figure 30-28 Medial and lateral meniscus anatomy as viewed from above (A) and via cross section (B). Note the circulation provided to the peripheral third of the meniscus only.

tolerated and usually return to full activities by about 3 or 4 weeks. With meniscus repair, recovery is extended and requires restricted weight bearing for 3 to 6 weeks, with 2 to 3 months needed before return to unrestricted activities.

EVIDENCE-BASED SUMMARY

- With no RCTs, no conclusions about surgical or nonsurgical treatment of meniscal injuries can be drawn, or about meniscal tear repair versus excision. Partial meniscectomy seems preferable to total removal and improves overall recovery in the short term (Howell and Handoll, 2005) (SOR: B).
- In a meta-analysis, sensitivity and specificity were 70% and 71% for McMurray's test, 60% and 70% for Apley's test, and 63% and 77% for joint line tenderness; no single test appears to diagnose a torn tibial meniscus accurately (Hegedus et al., 2007) (SOR: A).

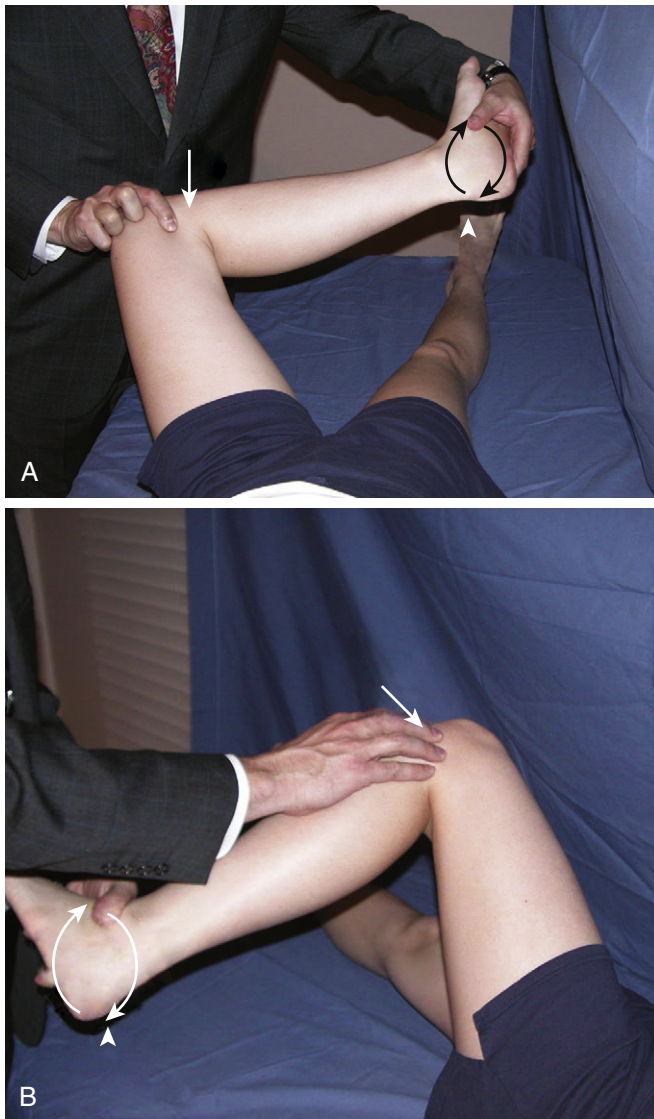

Figure 30-29 Classic examination for meniscal pathology. **A**, Medial McMurray's test is performed by palpating along the medial joint line (*thin arrow*) while creating a varus force (*solid triangle*), ranging the knee through flexion and extension, and internally and externally rotating the leg (*yellow arrows*). A positive finding is noted when the maneuver recreates the symptoms and the examiner feels a palpable click. **B**, Lateral McMurray's test is done in a similar manner with valgus stress.

Ligamentous Injuries

Four major ligaments keep the knee stable: anterior cruciate ligament (ACL), posterior cruciate ligament (PCL), medial collateral ligament (MCL), and lateral collateral ligament (LCL). They can be injured in isolation or in combinations related to knee dislocations. Most ligament injuries about the knee are not urgent. However, the primary care physician must remember (1) always to look out for the potential of a multiligament knee injury and the possibility of an arterial injury and (2) always to assess the LCL, based on the significantly poorer prognosis if the diagnosis and treatment are delayed beyond 4 to 6 weeks. Early identification and surgical repair of acute LCL injuries improve patient outcomes from 50% to 90%.

Medial Collateral Ligament

The MCL is the most frequently injured ligament of the knee and often associated with concomitant ligamentous injuries; 95% are associated ACL ruptures. The MCL is the primary knee restraint to valgus loads. The MCL is tested in isolation at 30 degrees of knee flexion with a valgus load (Fig. 30-31); at 0 degrees, bony constraints contribute to stability. Valgus laxity at near or full extension implies concurrent injury to the posteromedial capsule and/or cruciate ligaments. Grade 1 injuries have pathologic laxity, indicated by increased medial joint space widening, of 1 to 4 mm; grade 2, laxity of 5 to 9 mm; and grade 3, more than 10 mm of increased laxity compared to the contralateral side.

Imaging studies should include AP and lateral radiographs looking for associated bone injury or avulsions. MR scans may be of benefit in more severe injuries to look for additional associated soft tissue injuries. Initial treatment is nonsurgical for grade 1, 2, and 3 ligament sprains. Protected weight bearing is allowed with crutches and a hinged knee brace until pain resolves medially. Unrestricted ROM is allowed and encouraged. Most patients with MCL injuries do well with conservative treatment. Occasionally, patients with grade 3 injuries who do not respond to non-operative treatment may require surgery. Timing of return to sport or function is related to severity of injury: grade 1 injuries, usually 1 week; grade 2, 2 to 4 weeks; and grade 3, 4 to 8 weeks.

Lateral Collateral Ligament and Posterolateral Ligament Complex

When evaluating the lateral side of the knee, the physician should evaluate the function of the LCL but also the stability of the knee to posterolateral rotation. The LCL is assessed with the knee unlocked at about 20 to 30 degrees of flexion with varus stress (Fig. 30-32). The posterolateral corner is tested by externally rotating the tibia when the knee is flexed at 30 and 90 degrees. If an increased spinout to external rotation is visualized compared with the opposite knee at 30 and 90 degrees, the patient has a posterolateral corner and PCL injury. If the knee spins out only at 30 degrees compared with the opposite side, an isolated posterolateral corner injury is present (Fig. 30-33). Imaging usually includes AP/lateral radiographs and MR image. Perhaps the simplest rule for primary care physicians is that any patient with acute varus instability (injury of LCL) should be referred to an orthopedic surgeon as soon as possible.

Treatment is based on the severity of the injury. Nonsurgical treatment with protected weight bearing and protected ROM early for a few weeks is recommended for isolated grade 1 or 2 LCL; grade 1 is an opening of the lateral joint line less than 5 mm, and grade 2 is an opening of 6 to 10 mm. Progressive ROM and functional rehabilitation are initiated. Return to sports can be expected in 6 to 8 weeks. Surgical indications are recommended for isolated grade 3 LCL injuries (>10 mm gapping) and any rotator instability of the posterolateral corner. Acute surgery has more favorable outcomes, and early referral to an orthopedic surgeon is recommended.

Figure 30-30 Representations of meniscus pathology. Degenerative tears tend to be complex, fibrinous, and horizontal. Acute tears that are vertical in the periphery may be repairable.

Figure 30-31 Valgus stress is used to assess function of the medial collateral ligament. To best isolate the MCL, the knee is unlocked to 30 degrees of flexion when stress is applied. If the knee is still unstable in full extension, other structures (PCL, ACL, posterior capsule) have been injured.

(Courtesy Mark R. Hutchinson, MD.)

Figure 30-32 Varus stress is used to assess function of the lateral collateral ligament. Varus laxity noted in an acute knee injury should *always* be referred to an orthopedic surgeon; urgent primary repair of injured structures has a better prognosis than delayed reconstruction.

Posterior Cruciate Ligament

The PCL is the primary restraint to posterior tibial translation in the knee. The most sensitive test for the PCL is the posterior drawer, which is a posterior-directed force on the knee with the knee flexed to about 90 degrees (Fig. 30-34). The PCL is usually injured secondary to a posteriorly directed force on the tibia, from a fall or potentially from a dashboard injury during a motor vehicle crash. Grading of the PCL

injury is based on the posterior drawer test and the relationship of the proximal tibia to the femoral condyles. In grade I PCL injuries, the tibial plateau is slightly anterior to the femoral condyles; in grade II, plateau and condyles sit flush at the same level; and in grade III the tibia is posterior to the level. Treatment of a PCL injury is guided by injury severity and associated ligamentous injuries (Cosgarea and Jay, 2001; Wind et al., 2004). Typically, grades I, II, and III are treated nonsurgically with bracing and functional rehabilitation, to

Figure 30-33 Dial test is used to assess the posterior cruciate ligament (PCL) and posterolateral corner and is best done with patient prone and knees together. **A**, Normal examination should reveal symmetry with forced external rotation. **B**, If increased external rotation is identified with knee flexed 30 degrees, an injury to the posterolateral corner is identified. If asymmetry persists as knee is flexed to 90 degrees, the PCL is likely also involved. (Courtesy Mark R. Hutchinson, MD.)

focus on quadriceps strengthening. PCL ruptures, unlike ACL ruptures, tend to heal, and often a grade III will heal as a grade II, and a grade II as a grade I, with appropriate bracing and protection. Mild PCL laxity is usually not symptomatic for patients. If the knee becomes unstable, however, reconstruction can be delayed.

Anterior Cruciate Ligament

The ACL is perhaps the most famous of knee ligaments because of its notoriety in twisting and cutting sports. The common presentation of an ACL injury is an athlete landing in a twisting and cutting sport, feeling a pop, and having an acute hemarthrosis within 24 hours. The most sensitive test

Figure 30-34 Posterior drawer is the most sensitive test for evaluating posterior cruciate ligament function. Place thumbs on femoral condyles, feeling the tibial offset at the level of the joint line (black arrow). Then create a posteriorly directed force (white arrows) and reassess the tibial step-off. (Courtesy Mark R. Hutchinson, MD.)

Figure 30-35 Lachman test is the most sensitive approach to assess anterior cruciate ligament function. The femur is stabilized (white arrows) with the knee flexed about 15 to 20 degrees and the tibia drawn anteriorly (yellow arrow). Comparison to the opposite side and assessment of a ropelike end point are key.

for ACL rupture is a Lachman test, which is basically an anterior translation of the tibia on the femur with the knee flexed 20 to 30 degrees (Fig. 30-35). The anterior drawer test is also used but is less sensitive (Fig. 30-36). The most specific test is the "pivot shift."

Initial treatment of ACL injury focuses on rehabilitation to regain ROM and strengthen the knee. Surgical indications are based on patient's function as well as future demands (Beynon et al., 2005). For young athletes who want to play a twisting or cutting sport more than two or three times per week, ACL reconstruction is strongly recommended. The key reason for that indication is the absolute requirement to avoid the current instability or pivoting. Recurrent wobbling or pivoting of the knee leads to an increase in stress along the meniscus, meniscal failure, meniscal degeneration, hyaline cartilage degeneration, and degenerative changes in

Figure 30-36 Anterior drawer test is less sensitive for isolating anterior cruciate ligament injuries but may assist in diagnosing associated pathology. The knee is flexed 90 degrees and the tibia drawn anteriorly. (Courtesy of Mark R. Hutchinson, MD.)

the knee. If the athlete is willing to give up his sport, with no complaints of instability performing activities of daily living, surgical ACL reconstruction is not always necessary.

Skeletally immature athletes pose a unique challenge because of their open growth plates. Treatment options include delay of definitive surgical reconstruction until maturity, extra-articular reconstruction, and reconstruction with soft tissue across the physis (Bates et al., 2004). Most studies have shown that children are not fully cooperative with programs that have them reduce activities until skeletal maturity. This leads to recurrent episodes of instability with associated meniscal and cartilage damage. Based on this there has been a strong trend to surgically stabilize these young athletes to reduce the risk of arthrosis at a young age.

EVIDENCE-BASED SUMMARY

- No RCTs have compared surgical and nonsurgical outcomes in reduction of future osteoarthritic change for PCL injuries (Peccin et al., 1995) (SOR: A).
- Based on two clinical trials in the 1980s and insufficient RCTs, no conclusions can be drawn about conservative versus surgical treatment of ACL ruptures in adults (Linko et al., 2005).
- Surgical stabilization should be considered for skeletally immature patients with ACL injuries because they carry a high risk of recurrent instability and subsequent injury and damage to the meniscus (Bates et al., 2004) (SOR: B).

Ankle and Foot

Key Points

- Radiographs for foot and ankle imaging should be weight bearing if a fracture does not preclude it.
- Radiographs are not necessary in all cases of suspected ankle sprain.

- Early mobilization with external supportive device usually leads to a quicker recovery from ankle sprain, although it may not affect the long-term outcome.
- Surgical repair of Achilles tendon tears leads to a reduced risk of reupture, although surgical complications exist.
- Although corticosteroid injections can provide short-term relief of plantar fasciitis pain, no single intervention appears superior to another.
- Fractures through the watershed area of blood supply in the proximal fifth metatarsal (Jones' fracture) has a high risk of nonunion/malunion and is often best treated surgically.

The foot and ankle are complex structures that provide the foundation to the musculoskeletal system and are intimately related to a person's ability to ambulate, run, jump, and traverse unstable and variable terrain. Optimal foot and ankle function implies a higher level of function for activities of daily living. Thorough examination and imaging should consider a broad differential diagnosis of common problems, ranging from ligament sprains, stress fractures, fractures and avulsions, chronic tendinopathies, and tendon ruptures. A more expansive differential diagnosis includes nerve entrapment, circulatory dysfunction, and systemic disease, as well as congenital and developmental problems. All x-ray imaging of the foot and ankle for pain should be weight-bearing views in the absence of suspicion of a fracture, to allow a more accurate clinical picture because the patient usually experiences pain when weight bearing and not at rest (Stiell et al, 1992, 1993).

Ankle Sprains

Sprains are injuries to the ligamentous structures of the ankle. About 85% of ankle sprains involve the lateral ligaments; medial and syndesmosis sprains make up the remaining 15%. Diagnosis is based primarily on history and physical examination, although radiographs are often helpful. Advanced diagnostic testing is not usually necessary. The family physician must be aware of the many potential pitfalls in the diagnosis of ankle sprain as well.

Lateral Ankle Sprains

The anterior talofibular ligament (ATFL), calcaneofibular ligament (CFL), and posterior talofibular ligament (PTFL) are the three ligaments of the lateral ankle (Fig. 30-37). The ATFL primarily restricts anterior motion of the talus within the ankle mortise; the CFL restricts inversion; and the PTFL restricts posterior translation. The most common mechanism of lateral ankle sprain is an *inversion* ankle injury. Inversion events with the ankle in a plantar-flexed position often lead to ATFL injury (Fig. 30-38), whereas inversion events with the ankle in a dorsiflexed position more often lead to CFL injury (Fig. 30-39). Patients present due to ankle pain that may be associated with swelling, bruising, decreased motion, and increased pain with weight bearing, if able.

Examination begins with observing the patient's gait; a limp is often noted. Gross observation of the foot and ankle often reveals lateral edema and ecchymosis. Active motion may be severely restricted. Neurovascular structures are usually normal. Along with palpation of the ATFL, CFL, and PTFL, important structures to palpate on the lateral aspect

of the ankle include the fibula (entire length), peroneal tendons, lateral process of the talus, neck of the talus, cuboid, and base of the fifth metatarsal. Stress testing is performed to assess the integrity of ligamentous structures. The anterior drawer test translates the talus within the mortise and assesses the ATFL, performed with the ankle in slight plantar flexion to place the ATFL under tension while decreasing CFL tension. Both the amount of excursion compared to the opposite side and the end-point feel to the test are important determinants in the evaluation. The CFL is tested by the talar tilt. The ankle is placed in a neutral position, putting tension on the CFL and decreasing tension on the ATFL. The talus is then inverted within the mortise while the examiner assesses excursion and end-point feel. Once again, these findings are compared to the opposite side to determine severity of injury.

Figure 30-39 Forceful inversion of the hindfoot with a dorsiflexed ankle, possibly tearing the calcaneofibular, cervical, and interosseous talocalcaneal ligaments.
(From Meyer JM, Garcia J, Hoffmeyer P, et al. *The subtalar sprain: a roentgenographic study*. *Clin Orthop* 1988;226:169-173.)

In the United States, patients presenting for ankle injury often undergo radiographic evaluation, but the utility of routine radiographs to evaluate ankle injury is under debate. Well-designed studies from Canada have shown that many patients with ankle injury can be managed safely without routine radiographs. Indications for lateral ankle radiograph include age under 18 or over 55; inability to bear weight for four consecutive steps, either immediately after injury or in the examination room; and pain over the posterior portion of the distal 6 cm or at the tip of the fibula (Stiell et al., 1992, 1993). If pain is noted in the proximal or midshaft fibula, tibia/fibula films should be obtained, and pain over the base of the fifth metatarsal indicates the need for foot radiographs.

Various scales are available to grade ankle injuries, and interexaminer variability is high. The most common scale is mild (grade 1), moderate (grade 2), and severe (grade 3). However, grading does not significantly affect treatment, complication rates, or long-term outcomes. Grading may have a predictive role in duration of recovery.

Treatment of lateral ankle sprains has changed drastically over the past 25 years. Complete immobilization and rest were once thought to be important initial components of treatment. Currently, early mobilization with an external support device and rehabilitation are common therapies. Early immobilization may lead to greater stability and patient compliance, and the risk for early reinjury is low. In the early mobilization and rehabilitation plan, recovery tends to occur slightly quicker (based on full return to work), and early discomfort may be decreased (Eiff et al., 1994; Karlsson et al., 1996). With immobilization, the ankle joint can become stiff and lead to muscle atrophy. This may require a prolonged postimmobilization program focused on regaining motion and strength. Long-term outcomes of early mobilization and immobilization treatment plans are not significantly different.

Basic stages of treatment include early external support and, depending on severity, limited weight bearing, pain control, reducing swelling with ice and elevation, and maintaining motion. Once the initial acute injury subsides, weaning from supportive devices such as crutches, walking boots or casts

should be done and formal rehabilitation initiated. Rehabilitation should focus on motion, strength, and proprioception activities. The final phase of rehabilitation is reintroduction of sport-specific tasks and return to sport. Participation in a prevention training program with a focus on balance and proprioception reduces the incidence of ankle sprain without increasing the incidence of other injuries (Bahr et al., 1997). Bracing the ankle on return to sport may reduce the risk of recurrent injury. Whether bracing reduces the risk of an initial sprain is under debate (Sitler et al., 1994; Surve et al., 1994).

When treating skeletally immature patients, it is important to remember that physeal plate fractures through the distal fibula result from the same mechanism as an ankle sprain. If the physical examination reveals tenderness along the distal fibular growth plate, a growth plate fracture must be considered, even if the radiographs are negative. In this case, a short period of immobilization followed by repeat imaging in 2 weeks is appropriate.

Medial Ankle Sprains

The main ligament on the medial side of the ankle is the deltoid ligament (Fig. 30-40). Deltoid injuries are typically caused by an eversion mechanism. Medial ankle examination is similar to that of the lateral ankle. Observation of gait usually reveals a limp, and gross observation of the ankle often reveals medial edema but no other deformity. Active motion may be severely restricted, and neurovascular status should be normal. Careful palpation of bony, tendinous, and ligamentous structures of the medial ankle include the deltoid ligament, medial malleolus, medial process of talus, neck of talus, medial cuneiform, cuboid, navicular, and medial ankle tendons (posterior tibialis, flexor digitorum longus, and flexor hallucis longus).

Stress testing of the deltoid ligament is performed by an eversion stress test, usually performed with the ankle in neutral position. Amount of excursion compared to the opposite side and the end-point feel determine the severity of the injury. Deltoid function can also be assessed by stressing the ankle, translating it from medial to lateral and assessing for instability or mortis widening. Any offset increases the stresses on the articular cartilage and increases the risk of arthritis. Obtaining radiographs in the patient with medial ankle injury is decided on a case-by-case basis but should be done more readily than for the typical lateral ankle sprain. Treatment plans are similar to those for lateral ankle sprains. It is widely believed that medial sprains take longer to heal than their lateral counterparts.

Syndesmosis Ankle Sprains (High Ankle Sprains)

The ankle *syndesmosis* is the area of the distal tibia-fibula joint. The five soft tissue structures in the syndesmosis region include the anterior tibiofibular, posterior tibiofibular, transverse tibiofibular, and interosseous ligaments and the interosseous membrane; of these, the anterior tibiofibular ligament is most often injured. Syndesmosis sprains account for 1% to 18% of ankle sprains, with a higher incidence in high-level athletes. Syndesmosis sprains are generally thought to take longer to heal than lateral or medial sprains (Hopkinson et al., 1990), and persistent ankle pain and persistent dysfunction are more common (Gerber et al., 1998);

Figure 30-40 Anatomy of medial ankle ligaments.

(From Nicholas J, Hershman E. *The Lower Extremity and Spine in Sports Medicine*, vol 1, 2nd ed. St Louis, Mosby, 1995, p 424.)

syndesmosis injuries are often associated with fractures. The mechanism of injury is different than for the more common lateral and medial sprains; syndesmosis sprains are most often caused by forceful external rotation and hyperdorsiflexion injuries.

Physical examination often reveals an antalgic gait limp and anterolateral ankle swelling over the anterior tibiofibular ligament just proximal to the joint line. Ecchymosis is often a delayed finding and is usually noted proximal to the ankle joint, in contrast to that noted in lateral and medial sprains, which is often below the ankle and occasionally throughout the foot. Careful palpation reveals tenderness directly over the anterior tibiofibular ligament. Syndesmosis injuries may be present along with medial ankle injury, so tenderness over deltoid ligament may be noted as well. Be sure to palpate the proximal fibula, because extreme forced external rotation may lead to Maisonneuve's fracture (proximal fibular fracture). Strength testing is often limited by pain, and neurovascular status remains intact.

Special stress tests to evaluate the syndesmosis include the squeeze, external rotation, and dorsiflexion-compression tests. The squeeze test is performed by compressing the fibula and tibia above the midpoint of the calf (Hopkinson et al., 1990) (Fig. 30-41). The test is positive if compression causes pain in the region of the syndesmosis ligament. The external rotation test is performed with the knee at 90-degree flexion and the ankle in neutral position. An external rotation force is applied to the foot while stabilizing the remainder of the leg. Pain in the anterior tibiofibular region is a positive test. The external rotation test is thought to be the most reliable of the common clinical tests used to diagnose syndesmosis sprains.

Because of the risk of concurrent fracture with syndesmosis sprains, radiographs should be obtained. Plain radiographs are adequate to assess for frank *diastasis* (widening between fibula and tibia). Stress radiographs may be necessary to discover latent diastasis. The three major radiographic considerations are the (1) *tibiofibular clear space*, the distance between medial border of fibula and lateral border of posterior tibia,

Figure 30-41 Squeeze test.
(From Hopkinson WJ, St. Pierre P, Ryan IB, et al. *Syndesmosis sprains of the ankle*. *Foot Ankle Int* 1990;10:325-330. Copyright American Orthopedic Foot and Ankle Society, 1990.)

measured 1 cm above tibial plafond; (2) *tibiofibular overlap*, the maximum amount of overlap of distal fibula and anterior tibial tubercle; and (3) *medial clear space*, the distance between medial malleolus and medial border of talus, measured 1 cm below tibial plafond (Fig. 30-42).

Additional testing such as CT scan can be helpful early in the workup to look for occult fracture and later to assess for heterotopic ossification, a common complication of syndesmosis sprains. MR scan is sometimes used and has a high sensitivity and specificity for detecting anterior and posterior tibiofibular ligament injuries (Oae et al., 2003).

Initial treatment begins with protection of the joint, relative rest, ice, compression, and elevation. Various modalities to reduce swelling and inflammation can be used. Rehabilitation includes ROM exercises, strengthening and balance exercises, and proprioception training. Activities can be advanced when pain is reduced, and rehabilitation exercises can be performed pain-free. Return to full activities can be entertained when the patient has full motion, full strength, no tenderness on examination, and no functionally limiting pain.

Latent diastasis can be treated nonoperatively if reduction can be achieved. Therapy includes immobilization with non-weight bearing followed by progressive weight bearing beginning at about 4 weeks and full weight bearing by 2 months. Surgery is needed if reduction cannot be achieved or if diastasis recurs despite immobilization. Frank diastasis is treated surgically.

A common adverse outcome of syndesmosis sprain is heterotopic ossification. Plain radiographs are adequate to make the diagnosis in patients with persistent pain (Fig. 30-43). Affecting 25% to 90% of patients, heterotopic ossification may or may not be symptomatic. Ossification may cause pain without causing frank synostosis. The discomfort

Figure 30-42 Normal anteroposterior radiograph of the ankle revealing a normal tibiofibular clear space (1), normal tibiofibular overlap (2), and normal medial clear space (3). Significant mortise widening is noted with widening of all three of these parameters. Note the distal fibula fracture. This injury is best treated with internal fixation of the fracture and stabilization of the ankle mortise with a syndesmosis screw. **B**, Football eversion injury shows widening medial mortise with associated deltoid tear, widening distal tibiofibular syndesmosis, high fibular fracture, and small posterior malleolus fracture (not seen here). (A courtesy James L. Moeller, MD; B from Nicholas J, Hershman E. *The Lower Extremity and Spine in Sports Medicine*, vol 1, 2nd ed. St Louis, Mosby, 1995, p 465.)

comes from an inflammatory response in early stages, then from pressure on adjacent bones. Fracture of the ossification is also a potential cause of pain. Frank synostosis can occur. Pain typically results from restricted tibiofibular motion, particularly during full ankle dorsiflexion. Conservative treatment may reduce the pain, but surgical excision may be required (Hopkinson et al., 1990; Taylor et al., 1992).

Achilles Tendinopathy

Achilles tendinopathy is a common problem, especially in running and jumping athletes. The Achilles tendon consists of the distal ends of the gastrocnemius and soleus muscles and attaches broadly across the posterior aspect of the calcaneus. Contraction of the Achilles results in plantar flexion of the ankle. Activities that cause eccentric loading of the tendon may result in tendonitis. Achilles tendonitis is considered an overuse injury.

Patients present with pain in the posterior aspect of the distal lower leg or heel. Pain is worsened with push-off activities, such as walking up hills or stairs, running, or jumping. Examination reveals tenderness to palpation of the distal portion of the tendon. A palpable area of swelling and firmness may be noted as well as “wet crepitus” from fluid in the peritenon. Strength may be limited because of discomfort. This can be assessed by direct manual testing or by having the patient perform repeated single-foot toe-raise exercises.

Assessment of the integrity of the Achilles tendon is essential and best done by the Thompson test. Asking the patient simply to plantar-flex the ankle actively is not sufficient because there are several secondary plantar flexors. Lay the patient prone on the examination table with the knee flexed to 90 degrees and the ankle in neutral position. Squeeze the midgastrocnemius area and observe for passive ankle plantar flexion. If the Achilles is intact, the ankle will plantar-flex (negative test). If the Achilles is torn, the ankle will remain in neutral position (positive test).

Radiographs generally are not necessary to make an accurate diagnosis of Achilles tendinopathy or to initiate treatment. X-ray films are considered in chronic cases, primarily to rule out calcific tendinopathy and Haglund deformity (bump on back of calcaneus near Achilles insertion).

Ultrasound and MRI are not routinely needed early on but may be used to assess for partial tears, as well as assess the vascular integrity of the injured area. Ultrasound and MR changes in the tendon can persist even after functional recovery (Khan et al., 2003).

Treatment of Achilles tendinopathy is similar to that for other forms of tendinopathy and includes ice treatment, relative rest, NSAIDs, stretching and strengthening programs, and proprioception exercises. An exercise program focused on eccentric training has been described and renders promising results in many cases (Alfredson et al., 1998). Most experts agree that corticosteroid injection should not be considered due to the risk of tendon rupture. For recalcitrant cases, treatments such as prolotherapy and extracorporeal shock wave therapy have been studied, but short-term follow-up and isolated reports of effectiveness are mixed. Platelet-rich plasma injections for chronic Achilles tendinopathy have no benefit over saline injections. Surgical debridement is reserved for chronic cases and involves debridement of the diseased tendon and may require tendon transfers for grafting.

Achilles Tendon Rupture

Tears of the Achilles tendon are most often encountered in males 40 to 60 years old. The most common mechanism of injury is sudden, forceful eccentric loading of the tendon. This can occur from a sudden forceful push-off from a single foot, or landing on a single foot. Patients present due to sudden onset pain in the posterior heel and decreased push-off strength. Patients often describe a feeling of being kicked or hit in the heel, often hearing or feeling a pop at the time of injury. Examination may reveal a palpable gap in the tendon, usually distally. Thompson’s test is positive, with no ankle plantar flexion when the examiner squeezes the calf. Imaging studies are not typically needed to make an accurate diagnosis of Achilles tendon rupture.

Both surgical and nonsurgical treatment options exist (McComis et al., 1997; Weber et al., 2003). Patient selection and including the patient in the decision-making process are important. Generally, younger patients who desire or require greater posttreatment push-off power are likely to be good surgical candidates, whereas older patients or patients who require less push-off power are nonsurgical candidates. Nonoperative risk of repeat rupture is as high as 10%, versus up to 2% with surgery. Skin necrosis of the surgical wound occurs in 5% to 10% of patients.

Conservative treatment entails a period of immobilization accomplished through casting or brace use, usually 8 to 10 weeks; early weight bearing is controversial. After immobilization, progressive rehabilitation to regain motion, strength, and proprioception is initiated. Surgery is associated with improved push-off power and reduced rate of repeat rupture and generally allows for the best functional recovery (Wong et al., 2002).

Plantar Fasciitis

Plantar fasciitis is the most common cause of plantar heel pain in active individuals. The plantar fascia is a fibrous band of tissue that originates at the medial calcaneal tubercle, fans out across the plantar aspect of the foot, and then splits before inserting into the plantar aspects of the proximal

phalanges. Plantar fasciitis is an overuse injury often seen in people who stand for prolonged periods, as well as in runners and regular exercisers. Many believe plantar fasciitis is an inflammatory condition, but it is more likely caused by chronic changes and microtears of the fascia.

Patients present with plantar heel pain. Pain has often been present for several months before presentation. The pain is often described as sharp and stabbing and tends to be worst in the morning, on arising from prolonged sitting, and after standing for prolonged periods. Other symptoms, such as bruising, swelling, weakness, numbness, and tingling, are uncommon. The primary finding on physical examination reveals tenderness over the origin of the plantar fascia.

Treatment protocols are variable, and it may take several months for the patient to feel significant pain relief. Most treatment plans include plantar fascia stretching, ice or ice massage, heel cushioning, and analgesic medication. NSAIDs are often used, but are helpful most likely because of their analgesic, not anti-inflammatory, effects. Other common treatment options include night splints, physical therapy, orthotic devices, and cortisone injection. Cortisone injection reduces pain from plantar fasciitis, but the mechanism is unclear (Hunt and Sevier, 2004). Cortisone is a potent anti-inflammatory, but as previously stated, chronic plantar fasciitis is probably not an inflammatory problem. Risks with cortisone injection include plantar fascia rupture and necrosis of the plantar fat pad, the natural heel cushion. These adverse outcomes should be reviewed with patients before injection.

New modalities for the treatment of plantar fasciitis are under investigation. Extracorporeal shock wave therapy has shown mixed results (Rompe et al., 2002, 2003). Prolotherapy and autologous blood injection involve injecting substances into the area of pathology. Dry needling is also being

studied. None of these options has proved to be consistently helpful. Surgical intervention is sometimes needed in recalcitrant cases.

Metatarsal Fractures

Nondisplaced fractures of the midshaft and distal portions of the metatarsals are treated with immobilization. Short-leg casting and immobilizer boots can lead to adequate healing in 6 to 8 weeks in most cases. Postoperative shoe use without formal immobilization can also lead to adequate healing of metatarsal fractures, although the risk of adverse outcome is higher. Displaced, angulated, and rotated fractures may require operative fixation.

Fractures of the proximal portion of the metatarsal (first through fourth metatarsals) should be approached with great care. Nondisplaced fractures may be associated with injury to the intermetatarsal ligaments, leading to widening of these joints; surgical consultation is recommended in these cases. If there is no apparent injury to the tarsometatarsal (Lisfranc) joint, cast immobilization typically leads to adequate fracture healing.

Fractures of the base of the fifth metatarsal deserve special discussion. A watershed area of blood flow in the proximal portion of the fifth metatarsal puts it at particular risk for malunion and nonunion. Avulsion fractures off the most proximal portion of the bone have an opportunity to heal with conservative management. Fractures that occur in the watershed area, so-called Jones fractures, have a high chance for malunion and nonunion that should be discussed with the patient. Jones fractures occur in the proximal one third of the metatarsal and do not involve the tarsometatarsal joint. Screw fixation of Jones fractures often leads to more acceptable outcomes.

EVIDENCE-BASED SUMMARY

- Early mobilization with an external support device after ankle sprain leads to better short-term outcomes (reduction of pain and return to work/sport activities) compared to early immobilization; long-term outcomes are similar (Eiff et al., 1994; Karlsson et al., 1996; Kerkhoffs et al., 2004) (SOR: A).
- Use of an external ankle brace after ankle sprain reduces the risk of recurrent sprain. Evidence also supports balance and proprioception training for reducing risk of recurrent sprain (Bahr et al., 1997; Surve et al., 1994) (SOR: B).
- An eccentric training program is effective in treating chronic Achilles tendinopathy (Alfredson et al., 1998) (SOR: B).
- Surgery for acute Achilles tendon ruptures reduces the risk of repeat rupture compared to nonsurgical treatment but produces a significantly higher risk of other complications, including wound infection (Khan et al., 2004) (SOR: A).
- Corticosteroid injection can reduce plantar fasciitis pain in the short term (Hunt and Sevier, 2004) (SOR: B).
- For acute Jones fractures in recreationally active patients, early intramedullary screw fixation results in lower failure rates and shorter times to both clinical union and return to sports than non-weight-bearing short-leg casting (Vu et al., 2006) (SOR: B).

Cervical Spine

The cervical spine provides support and stability for the head. Articulation at the joints of the vertebrae allows for the range of motion of the head. The spine is also the route through which the nerve roots travel out from the spinal canal to the extremities. As with back pain, chronic neck pain or disorders related to limited function from neck problems are common reasons for office visits. A careful history and examination help elucidate the cause and the level and extent of compromise affecting cervical function.

Anatomy

The cervical spine is made up of seven vertebrae (C1-C7). A typical vertebra has a body and neural arch. The neural arch is made up of two pedicles and two vertebrae; the laminae meet at the spinous process posteriorly. A transverse process projects out laterally on each side of the pedicle and lamina (Fig. 31-1). The articular processes on the superior and inferior parts of each vertebra at the junction of the pedicle and lamina meet at the facet joints. The first two vertebrae have distinct features. The atlas, C1, articulates with the occipital bone and has no spinous process or body. The axis, C2, has an odontoid process that articulates with C1 (Fig. 31-2); much of the rotational function of the neck occurs at this joint. C7 has a long spinous process, resulting in a palpable prominence below the skin in the lower neck.

Several ligaments stabilize the neck. The anterior and posterior ligaments support the entire vertebral column (Fig. 31-3). The spinous process of each vertebra is attached by the

nuchal ligament to the neck and the interspinous ligaments. Intervertebral disks separate each vertebra. Their function is to distribute the pressure over a wider area of the vertebra and allow mobility. Each disk consists of a gelatinous central nucleus and outer fibrous annulus fibrosus. Eight pairs of nerves originate from the cervical spine. The first seven nerve roots exit the spinal canal above the corresponding vertebra, and the eighth nerve root exits from below C7 (Fig. 31-4).

History

The relevant history includes age of the patient, location of any pain, acute or gradual onset, radiation and duration of pain, and any related associated symptoms that indicate whether the pain is of cervical origin or referred from another condition. An older patient is more often affected by arthritis and a younger person by musculoskeletal pain. Rest or nighttime pain may be a symptom of a tumor or infection. Other symptoms include neck stiffness, headache, and symptoms of radiculopathy such as tingling, numbness, and loss of strength in the upper extremities. Where the pain is caused by nerve entrapment, the pain may radiate along the distribution of the involved nerve. Events leading up to the presentation may also give clues to the problem.

Physical Examination

The neck examination includes inspection for any neck lesions, masses, or scars as well as posture and normal cervical lordosis, characterized by a slight anterior curvature (Fig. 31-5). The neck is palpated for points of tenderness.

Figure 31-1 Typical cervical vertebra. S, Spinous process; L, lamina; A, articular facet; P, pedicle; T, transverse process; B, body. (Redrawn from Mercier L. *Practical Orthopedics*, 5th ed. St Louis, Mosby, 2000, p 27.)

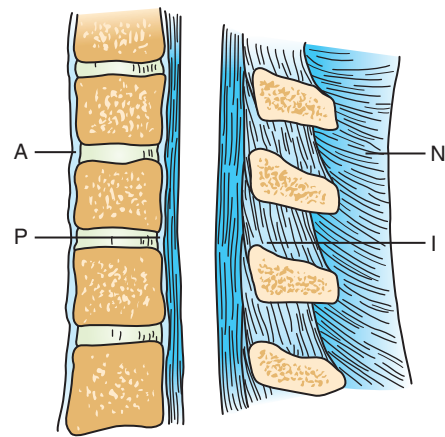

Figure 31-3 Ligaments of the cervical spine. A, Anterior longitudinal ligament; P, posterior longitudinal ligament; N, nuchal ligament; I, interspinous ligament. (Redrawn from Mercier L. *Practical Orthopedics*, 5th ed. St Louis, Mosby, 2000, p 27.)

Figure 31-2 1, Axis. 2, Atlas and transverse ligament (T). 3, Articulation of the atlas and axis. (Redrawn from Mercier L. *Practical Orthopedics*, 5th ed. St Louis, Mosby, 2000, p 27.)

Figure 31-4 Spinal cord and nerve roots in relation to the vertebrae. (Redrawn from Brinker MR, Miller MD. *Fundamentals of Orthopedics*. Philadelphia, Saunders, 1999, p 242.)

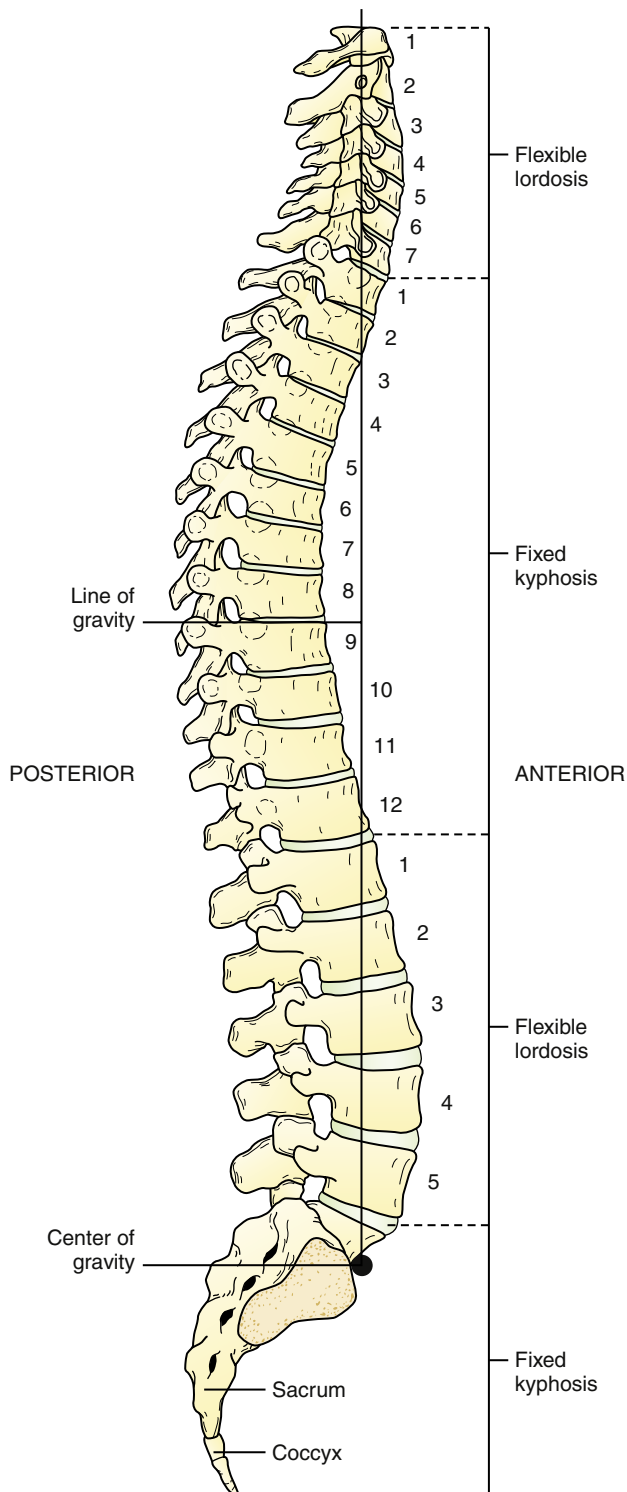

Figure 31-5 Vertebral spine. Note that thoracic spine has relatively fixed kyphosis and lumbar spine relatively flexible lordosis. (Redrawn from Brinker MR, Miller MD. *Fundamentals of Orthopedics*. Philadelphia, Saunders, 1999, p 241.)

The range of movement is assessed by observing *forward flexion* with chin tilted down toward the chest and *backward extension* with the head tilted backward so that the eyes are looking toward the ceiling (Fig. 31-6). Lateral flexion to the right and left is the lateral bending of the neck, pointing the ear toward the shoulder on the same side. Lateral rotation

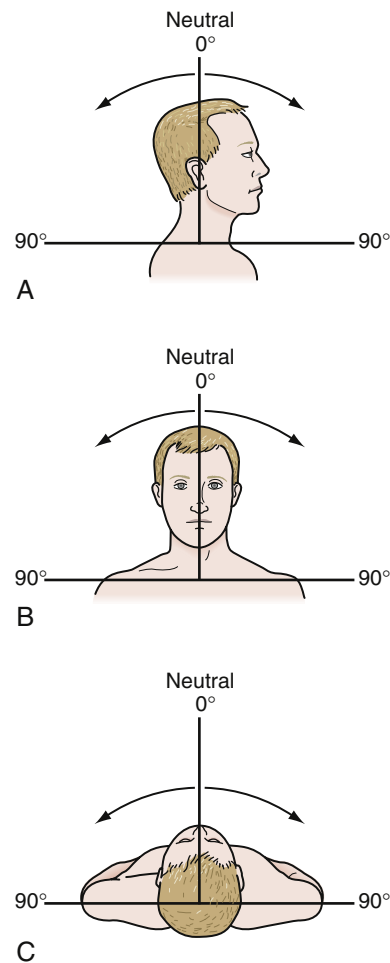

Figure 31-6 Range of motion. **A**, Flexion. **B**, Lateral flexion. **C**, Rotation. (Redrawn from Carr AJ, Harnden A. *Orthopedics in Primary Care*. Newton, Mass, Butterworth-Heinemann, 1997, p 56.)

Table 31-1 Normal Range of Movement: Neck (Cervical Spine)

| Motion | Range |
|-----------------|--------------|
| Flexion | 0-45 degrees |
| Extension | 0-45 degrees |
| Lateral flexion | 0-45 degrees |
| Rotation | 0-60 degrees |

Modified from Carr AJ, Harnden A. *Orthopedics in Primary Care*. Newton, Mass, Butterworth-Heinemann, 1997.

to the right and left is the chin turned toward each shoulder while the head is kept upright (Table 31-1).

Examination should also include examination of the extremities. Inspection of the upper limbs may reveal muscle wasting or fasciculations. A detailed examination of the nervous system includes assessment of the power and tone of the muscles, reflexes, and sensory system, using sharp and light touch. Mapping the sensory loss by dermatomes and demonstrating asymmetry of deep tendon reflexes may show the cervical level with nerve compression. A complete general

examination, including the head, neck, lower extremities, and gait, allows for evaluation of other potential causes and effects of neck problems. Specific tests to evaluate the cervical spine also include the axial compression test, which may increase symptoms of radicular pain. The distraction test may relieve radicular symptoms. Spurling's test may produce pain on the same side as nerve root encroachment.

Diagnostic Tests

Diagnostic tests include radiographs of the cervical spine. Computed tomography (CT) may assess the bone further, and magnetic resonance imaging (MRI) is useful to assess the soft tissue, especially with associated neurologic symptoms.

Torticollis

Key Points

- Torticollis may be congenital or acquired.
- Congenital torticollis may be characterized by a palpable tumor in the sternomastoid muscle in some cases.
- Acquired torticollis may be caused by a spinal tumor.
- Traumatic injury and retropharyngeal abscess require emergency treatment.
- Management of acquired torticollis includes treating the underlying cause.

Torticollis, also called *wry neck*, is characterized by contraction of the sternomastoid muscle on one side of the neck, in which the head is tilted to the same side as the contracted muscle, and the chin is rotated to the opposite side. The condition may be congenital or acquired.

Congenital torticollis is caused by the contraction of the sternomastoid muscle. The cause is unclear but may be associated with birth trauma or an abnormal fetal uterine position causing local muscle ischemia. Children with hip dysplasia and breech delivery have a higher incidence of torticollis. Also, delayed development of the face on the affected side may result in facial asymmetry and changes in the cervical vertebrae. On examination, a small lump may be palpable in the muscle, known as a *sternomastoid tumor*.

In mild cases, treatment is initiated early and includes gentle stretching exercises several times daily. Supervised physical therapy may be considered. Surgery may be considered in special circumstances with patients who do not respond to conservative treatment. The procedure includes surgical release of the sternomastoid muscle, followed by corrective exercises.

Acquired torticollis usually does not involve contraction of the sternomastoid on the same side of the neck. The torticollis has a particular cause, such as upper respiratory tract infections, cervical lymphadenitis, trauma minor neck injury, unilateral subluxation of the vertebrae, or fractures, as well as unusual causes such as spinal tumor or retropharyngeal abscess. Torticollis may also be seen in relation to ocular disturbance, such as strabismus, known as *ocular torticollis*.

History includes duration and onset of symptoms, whether sudden or gradual, associated symptoms (e.g., fever, sore throat), and history of injury. Clinical examination, in addition to the clinical appearance of torticollis, requires

careful general examination of the head and neck, looking for a cause. Diagnosis may be apparent from the history and physical examination. Radiographs of the cervical spine may be obtained, if indicated, to rule out a vertebral cause.

Management includes referral for emergency evaluation and treatment of traumatic injury and retropharyngeal abscess. Pain is relieved and the underlying cause treated. Persistent pain requires further evaluation.

KEY TREATMENT

Treatment of congenital torticollis includes gentle stretching exercises; surgical treatment may be considered in special circumstances (Do, 2006) (SOR: C).

Whiplash

Whiplash is a hyperextension injury. The injury is caused by abnormal stretching of the muscles and soft tissue structures. There may be an associated disk herniation and tracheal and esophageal injury, resulting in hoarseness and dysphagia. Clinical features are pain in the lower neck and shoulders radiating to the occipital area, which may cause headaches. The neck pain may continue for weeks to months. The patient may have tenderness on palpation of the neck, perhaps some limitation in range of movement, and usually a normal neurologic examination. Radiographs are usually normal. Treatment is conservative with rest, a cervical collar, cold compresses, and pain relief, followed by simple range of motion (ROM) exercises. If symptoms improve, structured physical therapy may be considered.

Cervical Strains and Sprains

Cervical strains and sprains are characterized by pain in the neck because of irritation and spasm of muscles at the back of the neck. Common related factors are poor posture (e.g., while working or studying), carrying heavy bags on one shoulder, emotional or physical stress, and trauma. The patient has a history of pain in the lower neck and upper back; stiffness in the neck, back, and shoulders; and perhaps a new work environment, working in a certain posture (e.g., at computer), and trauma. Clinical findings include tenderness posterior to neck, with or without ROM limitation. Diagnosis may be apparent from the history and physical examination. Uncomplicated pain is managed by conservative treatment and correction of causative factors, such as changes in associated environmental factors (e.g., adjustment of height of desk or chair, avoiding straps on shoulders). Stress reduction is beneficial to aid reduction of muscle tension. Warmth applied to the neck is helpful, as are ROM exercises, pain relief, and referral to physical therapy. Persistent symptoms, history of trauma, or neurologic signs in the extremities require further evaluation with radiography.

Cervical Radiculopathy

Radiculopathy occurs when nerve root compression at the neck or spine results in pain, tingling, and numbness, with or without loss of function in the area supplied by the affected nerve. Common causes of cervical radiculopathy are neural

foramen narrowing, usually caused by cervical arthritis in older adults, and cervical disk lesion caused by disk degeneration or herniation. *Disk degeneration* results in loss of disk space, with closer approximation of the vertebrae on either side of the involved disk space and subsequent impingement on the neural foramen (Fig. 31-7). The decrease in size of the neural foramen results in nerve root compression. The C5-C6 and C6-C7 disk spaces are more often affected. *Disk herniation* also occurs more often in these disks (Fig. 31-8). Some of the gelatinous pulp protrudes through the annulus fibrosus at the weakest point, usually where the posterolateral longitudinal ligament crosses the disk. In a smaller disk herniation, mild local pain may be caused by pressure on

the posterior ligament. A larger disk herniation may impinge on the nerve and may be posterolateral or central herniation with resultant radicular symptoms.

The patient has a history of pain radiating to the shoulder or down the upper extremity, which may be aggravated by coughing, sneezing, or straining; paresthesias of the fingers; and less often, weakness in the extremity. There may be a history of prior trauma. Cervical radiculopathy on examination may reveal tenderness on the neck, limitation in certain movements of the neck, focal neurologic findings such as sensory loss in the dermatome pattern corresponding to the distribution of the affected nerve root, and asymmetric tendon reflexes in the upper extremities (Fig. 31-9).

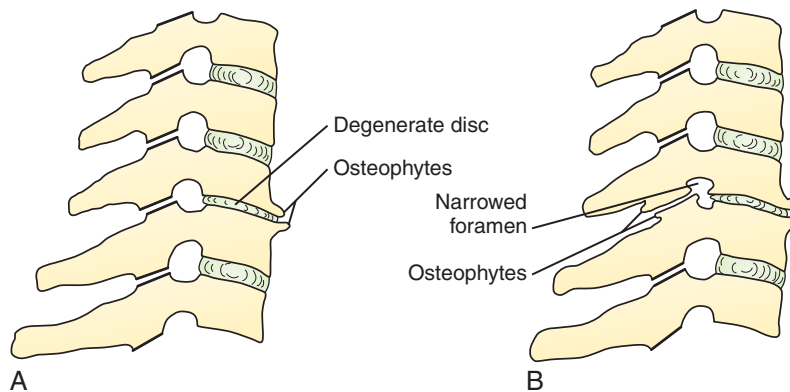

Figure 31-7 Osteoarthritis of cervical spine. **A**, Initial degeneration and narrowing of intervertebral disk, with formation of osteophytes anteriorly. **B**, Later, posterior or facet joints are affected; articular cartilage is worn away, and marginal osteophytes may encroach on the intervertebral foramen. (Redrawn from Adam JC, Hamblen DL. *Outline of Orthopedics*, 13th ed. New York, Churchill Livingstone, 2001, p 159; and Anderson BC. *Office Orthopedics for Primary Care: Diagnosis and Treatment*, 2nd ed. Philadelphia, Saunders, 1999, p 266.)

Figure 31-8 Prolapsed cervical disk. **A**, Posterior lateral prolapse, with compression of the issuing nerve. **B**, Much less common central prolapse, with impingement on the spinal cord. (Redrawn from Adam JC, Hamblen DL. *Outline of Orthopedics*, 13th ed. New York, Churchill Livingstone, 2001, p 163.)

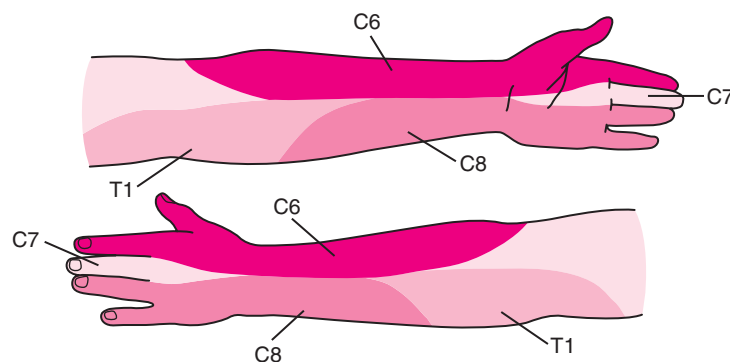

Figure 31-9 Volar and dorsal dermatome patterns of the forearm and hand. Pain and paresthesias may radiate into these areas when the affected nerve root is compressed. Note that extremity symptoms as a result of disk disease are almost always unilateral. (Redrawn from Mercier R. *Practical Orthopedics*, 5th ed. St Louis, Mosby, 2000, p 29.)

General examination should include the lower extremities and gait. Axial compression testing may reproduce the pain.

Diagnostic tests include radiographs of the cervical spine, which may appear normal or may show loss of normal cervical lordosis, narrowing of the disk space, and bone spurs with foramen encroachment. If the patient has neurologic symptoms, MRI identifies soft tissue structures and may show displacement of the disk. CT may also be performed.

Treatment relieves pressure on the affected nerve and is mainly conservative, including rest, pain relief, stress reduction, and short-term muscle relaxants. Patients with persistent symptoms may need structured physical therapy and referral for specialist evaluation. Neurologic signs and symptoms and loss of strength are also indications for referral to neurosurgery. A few patients require surgical intervention.

KEY TREATMENT

Whiplash is usually managed conservatively (Binder, 2007) (SOR: C).
Uncomplicated pain in cervical strains and sprains is managed conservatively (Binder, 2007) (SOR: C).
Range of motion exercises may be beneficial for uncomplicated cervical strain or sprain (Cochrane Review, 2005) (SOR: A).
Treatment of cervical radiculopathy is usually conservative (Binder, 2007) (SOR: C).

Thoracolumbar Spine

The thoracolumbar spine is the cause of frequent patient visits to a family physician. Back pain is the most common and expensive diagnosis of patients age 30 to 60 years. It is responsible for lost time at work, lost wages, increased surgeries, litigation expenses, and economic and psychosocial burden. Appropriate and timely diagnosis and treatment can prevent most of the sequelae of back pain.

Anatomy

The back is supported by 12 thoracic vertebrae (T1-T12) and five lumbar vertebrae (L1-L5). The lumbar vertebrae are larger and thicker than the cervical and thoracic vertebrae because they carry the most amount of body weight and are subject to the largest forces and stresses along the spine (see Fig. 31-5). The alignment of thoracolumbar vertebrae with their disk and ligament is similar to the cervical spine. The joints between the vertebrae, ligaments, and muscles of the back stabilize the vertebral column.

The major longitudinal ligaments connecting the vertebrae are the anterior and posterior ligaments (connect vertebral bodies), ligamentum flavum (between adjacent laminae), and supraspinous and interspinous ligaments (connect spinous processes). The anterior and posterior longitudinal ligaments and supraspinous ligament run along the entire length of the vertebral column and support the spine. The interspinous ligament and ligamentum flavum provide additional posterior stability to the spine (Fig. 31-10).

Intervertebral disks make up about one third of the length of the spine. The normal movements of thoracolumbar spine are forward flexion (by asking the patient to touch toes), extension, lateral bending, and symmetric rotation (Fig. 31-11

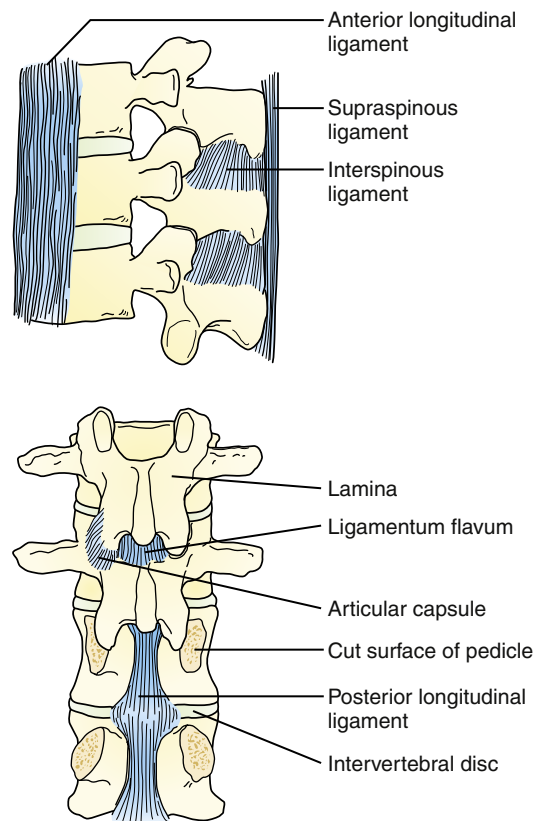

Figure 31-10 Supporting ligaments of the spine. (Redrawn from Brinker MR, Miller MD. *Fundamentals of Orthopedics*. Philadelphia, Saunders, 1999, p 242.)

and Table 31-2). Flexion and extension are limited in the thoracic region because of the rib cage.

History

The patient history of conditions in the thoracolumbar spine is similar to the cervical spine. A complete description of the onset, duration, nature, severity of symptoms, and aggravating and relieving factors should be obtained. Other important history includes medical history (including previous injuries) and psychosocial stressors at work or home. Symptoms may require urgent referral and workup and include unremitting back pain, urinary or bowel paralysis, weakness, fever, and weight loss.

Physical Examination

The physical examination should begin with observing the patient in the sitting and standing positions from the back as well as the front. Observing the patient moving around, dressing, and undressing may also help in confirming the severity of the symptoms. Muscle spasms, swellings, deformities, unusual markings, redness, and hair patches should be noted. The patient's posture and gait should be observed. The area palpated includes soft tissues and bone structures for tenderness and swellings. It helps to isolate the level of the lesion. ROM should be observed. A thorough neurologic examination should be performed to assess for sensations, deep tendon reflexes, and muscle strength. Examining the

Table 31-2 Normal Range of Movement: Thoracolumbar Spine

| Motion | Range |
|--------------|--------------|
| Flexion | 0-80 degrees |
| Extension | 0-20 degrees |
| Lateral bend | 0-35 degrees |
| Rotation | 0-45 degrees |

Modified from Carr AJ, Harnden A. *Orthopedics in Primary Care*. Newton, Mass, Butterworth-Heinemann, 1997.

rectal tone, perineal sensations, and reflexes is essential if the patient has significant nerve root pain and weakness and chord compression is suspected.

Special tests are done for determining nerve root impingement. The straight-leg raise test is performed with the patient lying on the back on the examination table. Passive lifting of the leg with the knee extended produces pain radiating down the posterior or lateral aspect of the leg, distal to the knee and often into the foot. Dorsiflexion of the foot (Lasegue's test) will increase these symptoms (Fig. 31-12). The bowstring

sign is performed after a straight-leg raising test by flexing the knee to reduce radicular pain. Compression is then applied to the popliteal fossa. Return of radicular pain is considered a positive sign (Fig. 31-13). Crossed straight-leg raise is done by performing a straight-leg raise of the unaffected extremity. If the symptoms are produced on the affected extremity, the test is positive for central disk herniation. Femoral nerve traction test aids in the diagnosis of disk herniation that affects the upper lumbar spine (L2, L3, and L4). The patient lies on the stomach on the examination table with the knee flexed to 90 degrees. The physician then extends the patient's hip by lifting it off the table (Fig. 31-14). The test is positive if it produces radicular pain.

The peripheral pulses are palpated, and any abnormalities in the vascular status of the extremities are noted.

Diagnostic Testing

Diagnostic testing for thoracolumbar conditions is similar to that for the cervical spine. Plain radiographs (AP, lateral, and oblique views) can be obtained (Fig. 31-15). CT, MRI, or myelography may be indicated in patients with worsening neurologic deficits or a suspected systemic cause of back pain, such as infection or neoplasm. These imaging studies are also useful when referral for surgery is considered.

Low Back Pain

Key Points

- A careful history and physical examination are essential in diagnosing any case of low back pain.
- Unremitting back pain and loss of bowel control require emergency assessment.
- Radiographs and laboratory tests are generally unnecessary with low back pain.
- With acute low back pain The therapeutic goal is to make the patient ambulatory and return to pre-morbid status.
- Recurrence of back pain and functional limitation can be prevented with appropriate conservative management, early mobilization, exercise, return to normal activity, and patient education.
- Exercise and physical therapy are the most effective treatment for chronic back pain.

Figure 31-15 Plain radiographs of the lumbar spine. **A**, Anteroposterior view. **B**, Lateral view. **C** and **D**, Right posterior oblique (RPO) and left posterior oblique (LPO) views. *b*, Body of vertebra; *f*, intervertebral (neural) foramen; *if*, inferior facet; *l*, lamina; *p*, pedicle; *pi*, pars interarticularis; *s*, spinous process; *sf*, superior facet; *t*, transverse process (denotes interpedicular distance). (From Brinker MR, Miller MD. *Fundamentals of Orthopedics*. Philadelphia, Saunders, 1999, p 249.)

- With chronic low back pain, the therapeutic goal is to provide a long-term increase in function or a decrease in pain and disability.
- Psychological support and therapy may provide relief in chronic low back pain.

Low back pain is the most common cause of both acute and chronic pain. In the United States, approximately 90% of adults experience back pain at some time in their life, and 50% of working persons have back pain annually. As many as 90% of patients with acute back pain return to work within 3 months, but 10% experience symptom recurrence and functional limitations and eventually develop chronic pain. Low back pain is one of the leading causes of both disability and absenteeism from work. Less than half of patients out of work for more than 6 months secondary to low back pain will ever work again, creating an enormous financial strain on the patient, family, and community.

In primary care practice the specific anatomic cause of low back pain is usually not known; only a small percentage of patients have an identifiable underlying etiology. Less than 2% of patients have disk herniation, and only rarely do patients have a life-threatening condition. The most common cause of back pain is the lumbosacral strain following a single action or multiple lifting or twisting maneuvers. Factors that predispose to low back strain include repetitive use of poorly toned muscles, obesity, smoking, poor work habits, high-heeled shoes, and lack of physical activity. Most patients with acute low back pain improve in 2 to 4 weeks. Patients who progress to chronic back pain spend much time and money to become “pain free.”

Assessment and Clinical Features

Most causes of low back pain are benign, but a thorough history and physical examination can identify a small percentage of patients with serious infection, malignancy, rheumatologic disease, or neurologic disorder. These serious conditions need immediate further evaluation. The review of systems includes constitutional symptoms, night pain, bone pain, morning stiffness, visceral pain, and claudication. The history includes exact location of the pain and the day, time, and activity involved in the initial back pain.

The patient's occupational risk assessment includes heavy lifting, prolonged sitting or standing, bending or twisting, and work with heavy, vibrating equipment. Patients often point to a well-localized area of the lower part of the back. Patients may have paraspinal muscle spasm and tenderness. Any movement may be painful, and the patient may walk in a slightly flexed position. Muscle spasm may be severe enough to cause loss of normal lumbar lordotic curve. If the strain is unilateral, the back may tilt to the affected side secondary to muscle spasm. The patient has reduced ROM, especially flexion and lateral bending secondary to pain. Neurologic examination should reveal no signs of radiculopathy in a normal back exam.

At subsequent visits, further assessment and evaluation are based on the history of persistence, recurrence of pain, and functional limitations. Functional overlay and signs of excessive pain behavior should be sought. Complaints without objective findings suggest a psychological role in symptom formation; psychological testing and behavior intervention may be needed. During further encounters, psychosocial obstacles to recovery should be explored. Patients whose work provides

lower job satisfaction are more likely to report back pain and have a delayed recovery. Patients with affective mood disorders (e.g., depression) or substance abuse problems are more likely to have chronic pain and difficulty with pain resolution.

Diagnostic Testing

Radiographic imaging in uncomplicated cases of lumbosacral strain is rarely necessary and usually does not correlate with the patient's pain. Most people older than 40 years have anatomic defects on plain films of the spine. If the low back pain is probably more than a lumbosacral strain or has persisted for more than 6 weeks, radiographs may be helpful. CT or MRI should be reserved for low back pain accompanied by moderate to severe radicular symptoms, in the presence of motor weakness and neurologic deficits.

Treatment

Once it is determined that the patient has an uncomplicated lumbosacral strain, the goal of therapy for acute low back pain is to make the patient ambulatory and return to pre-morbid status. This goal should be explained to the patient, whose active participation is critical. Successful treatment depends on the patient's understanding of the disorder and the prevention of repeat injury. Patients should remain active to assist recovery, compared with short-term bed rest.

Family physicians should begin with conservative therapy. Most patients with acute low back pain improve with conservative management within 2 to 4 weeks. Early mobilization and return to normal activities should be encouraged. Nonsteroidal anti-inflammatory drugs (NSAIDs) and acetaminophen are mainstays of pharmacologic therapy for acute low back pain. Muscle relaxants are effective for short-term relief. Short-term use of a narcotic could be considered for relief of severe, acute pain. As the pain permits, gentle stretching exercises should be initiated (Fig. 31-16). Patients should taper use of the analgesics while gradually increasing their normal activities. Extremes of twisting, bending and tilting should be avoided. If these are work-related activities, the patient may require a change to “light duty.” Teach techniques to lift heavy objects and educate patients about maintaining proper posture (Fig. 31-17).

Most patients recover and require no additional evaluation. Prevention of repeated back injuries is then the focus. The patient should be instructed on overall body conditioning. Exercises that do not stress lower back muscles include swimming, water aerobics, and low-impact walking. Rehabilitation exercises and aerobic conditioning for trunk extensors, abdominal muscles, and back strengthening (modified sit-ups, weighted side bends, gentle extensions) should become part of the patient's daily routine (Fig. 31-18).

The patient with chronic low back pain remains a challenge. The ultimate goal in chronic pain management is long-term increase in function or decrease in pain and disability. Typically these patients already had multiple therapies for acute back pain. Assessment of social and psychological factors may help identify a pain etiology that affects treatment.

Exercise is more effective for chronic low back pain than treatment with medication plus return to usual activity. Exercise is as effective as conventional physiotherapy. Exercise and physical modalities are the mainstays of therapy. Heat, cold, massage, ultrasound, and muscle stimulation

Back-stretching exercises play a vital role in the treatment of lumbosacral muscle spasms. The lower back is heated for 15 to 20 minutes. Sets of 10 to 20 stretches, each held for 5 seconds, are performed on each side. The muscles are kept relaxed. Rest for 1 to 2 minutes between exercises. Mild muscle soreness is to be expected. Severe pain, electric-like sharp pain, or severe muscle spasms suggest overstretching.

Knee-chest pulls

Bring your knee slowly up to your chest, holding it in place with your hands. Relax the buttock and back muscles. Do the left side, then the right side, and then both simultaneously (curling up in the fetal position).

Pelvic rocks

With knees bent, rotate your pelvis forward and then backwards. The abdominal muscles do the work, as the back muscles are relaxed.

Caution: Do not overextend when arching the back!

Side bending

While lying down, crawl your fingers down the side of your thigh. Hold in this tilted position for 5 seconds. Return to a neutral position. Repeat on the other side.

Initially, these exercises should be performed while lying down or floating in the bath or hot tub. With improvement, these exercises can be performed standing or sitting. Follow these movements with exercises to strengthen the back.

Figure 31-16 Back-stretching exercises. (Redrawn from Anderson BC. *Office Orthopedics for Primary Care: Diagnosis and Treatment*, 2nd ed. Philadelphia, Saunders, 1999, p 266.)

are effective modalities. NSAIDs or acetaminophen can be reinitiated. The need for prolonged narcotic therapy should prompt reevaluation of a patient's back pain. Reassurance and psychological support are also important. Often, depression accompanies the pain; addressing psychological issues may provide some relief. Patients often require referral to a specialized pain clinic or multidisciplinary back program. These clinics offer education, physical therapy, pharmacologic treatment, epidural steroid injections, chiropractic therapy, and psychological services.

Family physicians should emphasize the prevention of reinjury, review healthy lifestyle changes, and address weight loss, if indicated, as well as continue primary care for the patient.

KEY TREATMENT

Acetaminophen and NSAIDs are effective for pain relief in patients with acute low back pain; muscle relaxants are effective for short-term relief (Harwood and Chang, 2002) (SOR: A).

Remaining active speeds recovery from low back pain compared with short-term bed rest (Harwood and Chang, 2002) (SOR: A).

For chronic low back pain, exercise is more effective than treatment with medication plus return to usual activity. Exercise is as effective as conventional physiotherapy (Carter and Lord, 2002) (SOR: A).

Lumbar Disk Syndromes

Key Points

- Degeneration of the intervertebral disk can result in herniation, particularly at the L4-L5 and L5-S1 levels.
- The presence of pain, radiculopathy, and other symptoms depends on the site and degree of herniation.
- Initial screening for pathology and monitoring for complications (progressive neurologic defects, cauda equina syndrome, refractory pain) are essential in managing lumbar disk herniation.
- Most patients with herniated disk recover in 4 weeks.

The pattern of lumbar disk herniation is similar to that observed in the cervical spine. The most common levels for a herniated disk are L4-L5 and L5-S1. With aging and repetitive trauma, the disk undergoes significant changes in volume, shape, biochemical composition, and biomechanical properties. Lumbar disk herniations are believed to result from annular degeneration that leads to a weakening of the annulus fibrosus, leaving the disk susceptible to annular fissuring and tearing and subsequently allowing degenerated disk contents to herniate and impinge on adjacent structures (Fig. 31-19). Herniation usually occurs at the weakest area,

Figure 31-17 General postural instructions. **A**, Bend the knees and hips and keep the back straight when lifting. **B**, Hold objects close to the body when carrying. **C**, Place one foot on a stool when standing. **D**, Keep the knees higher than the hips when sitting, and keep the back straight when standing by tucking in the abdomen and tightening the buttocks to decrease sway-back. In addition, patients should avoid high-heeled shoes and sleeping on the abdomen, activities that increase lordosis. (Redrawn from Mercier L. *Practical Orthopedics*, 5th ed. St Louis, Mosby, 2000, p 125.)

the posterolateral aspect of the disk (Fig. 31-20). Disk herniation is most common in the third and fourth decades of life.

Clinical Features

The onset of symptoms is usually gradual; the most common complaint is low back pain. When the disk herniates, it impinges on adjacent structures, causing sharp, burning, stabbing pain radiating down the posterior or lateral aspect of the leg, to below the knee, and finally to the foot. Pain is generally superficial and localized, often associated with numbness or tingling along the dermatome. In more advanced cases, motor deficit, diminished reflexes, or weakness may occur. An occasional massive central herniated disk compresses the cauda equina, resulting in bilateral symptoms, weakness, numbness, difficult urination, incontinence,

or impotence, causing the cauda equine syndrome. Often the difficult aspect of evaluating patients with symptoms of a herniated disk is differentiation from low back strain. Pain caused by low back strain is exacerbated with standing or twisting motions, whereas pain caused by disk herniation, especially central, worsens with sitting or bending, Valsalva maneuver, coughing, or sneezing because of increased pressure on annular fibers.

A complete physical and neurologic examination can reveal defects at specific levels. The physician first assesses for any external manifestations of pain by inspecting body position, gait, and ROM. The patient may be bending laterally or listing away from the affected side, or may stand with the affected hip and knee slightly flexed to relieve the pain or nerve compression. Local guarding and muscle tenderness on palpation of the area may be present. Sensory examination may reveal deficits along the specific nerve root distribution (Fig. 31-21). Motor weakness should be tested to localize the nerve root. Nerve tension tests (straight-leg raising, crossed straight-leg raising, Lasegue's test, bowstring sign) are often positive.

Diagnostic Testing

The major finding on plain radiographs of patients with a herniated disk is decreased disk height. Radiographs have limited diagnostic value for herniated disk because degenerative changes are age related and equally present in asymptomatic and symptomatic persons. Therefore, patients with characteristic herniated disk or chronic disk degeneration usually do not require advanced imaging; it should be performed if suspicion is high for cauda equine syndrome, tumor, infection, progressive neurologic symptoms, trauma, or symptoms inconsistent with monoradiculopathy. CT and MRI should also be reserved for patients who fail conservative management and are being considered for surgery. With herniated disk, waiting 4 to 6 weeks is considered advantageous because herniations tend to reduce and most symptoms resolve. Both CT and MRI can identify disk herniations, but CT with myelography has increased sensitivity and specificity. CT also is less expensive and less sensitive to patient movement. However, MRI better visualizes the spinal chord (Fig. 31-22).

Treatment

Although low back pain and radiculopathy are common causes of disability, most patients experience resolution of their symptoms. Family physician is responsible to determine the goals and optimal management for each patient. The condition should be thoroughly explained to the patient, including the likely natural history and the potential forms of treatment.

First-line treatment of a patient with lumbar disk syndrome or herniation is conservative, with limited bed rest, adequate pharmacologic treatment, and exercise. Patients are advised to remain active to speed recovery; excessive bed rest can result in deconditioning, bone mineral loss, and economic losses. Pain should be treated with NSAIDs or narcotics, muscle relaxants, and moist heat; most patients begin to improve with this regimen. The patient should resume early ambulation and begin gentle stretching exercises (see Fig. 31-16).

Before starting a strengthening program for the back, flexibility must be restored with 3 to 6 weeks of daily back stretching. Strengthening exercises should be performed when the body is well-rested. First, the back muscles are stretched out for 5 to 10 minutes. Then sets of 15 to 20 of the following are performed daily for 6 weeks. As the strength of the back increases, the frequency can be reduced to three times a week.

Modified sit-ups

The knees are kept bent. The lower back is kept flush with the ground. The hands can be kept either behind the neck or held over the chest. The head and neck are raised 3 to 4" and held for 5 seconds. The abdominal muscles will gradually strengthen.

Weighted side-bends

In a standing position, a 5- to 15-pound weight is held in the hand. The back is tilted to the weighted side and is immediately brought back to center. The back should be tilted only a few inches! The farther away from the body the weight is held, the greater is the amount of muscle work! After a set of 15 to 20, the weight is shifted to the opposite side.

These specific exercises are complementary to a regular aerobic exercise program. No single exercise is better than another. If you are having problems doing any specific exercise, discuss it with your health care provider.

Figure 31-18 Back-strengthening exercises. (Redrawn from Anderson BC. *Office Orthopedics for Primary Care: Diagnosis and Treatment*, 2nd ed. Philadelphia, Saunders, 1999, p 268.)

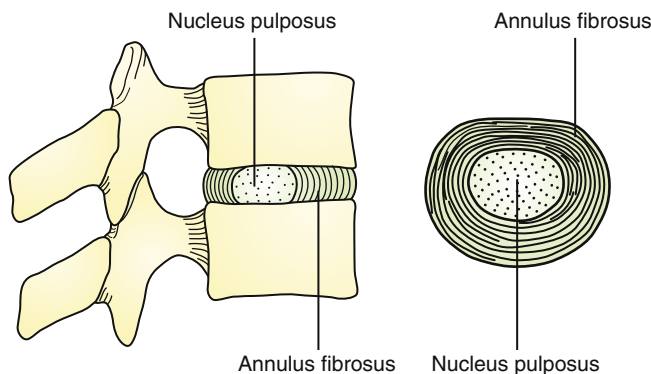

Figure 31-19 Normal intervertebral disk seen in sagittal section (left) and in horizontal section (right). (Redrawn from Adam JC, Hamblen DL. *Outline of Orthopedics*, 13th ed. New York, Churchill Livingstone, 2001, p 199.)

treatment or have persistent symptoms are referred to specialists. Indications for referral include cauda equina syndrome, progressive and profound neurologic deficit, and disabling pain refractory to 4 to 6 weeks of conservative treatment. Any surgical decisions should be firmly based on the clinical symptoms, which are confirmed with results of diagnostic testing.

Percutaneous lumbar discectomy, performed under local anesthesia, is a safe and effective noninvasive alternative to laminectomy. The percutaneous procedure is contraindicated in the presence of tumor, infection, foramina stenosis, loose disk fragments, spondylolisthesis, or severe facet joint arthritis. No long-term difference has been observed in the outcomes of patients treated conservatively versus surgically.

Caudal or epidural steroid injection is controversial. Patients who continue to improve should begin preventive therapy, including overall muscle toning such as swimming or water aerobics; specific toning of the muscles of the back should become part of the patient's daily routine. Lifestyle changes should be incorporated to reduce predisposing factors.

Most patients' disk problem may be effectively treated conservatively; those who do not respond to conservative

KEY TREATMENT

Conservative management is the initial approach in patients with low back pain with radicular symptoms, unless cauda equine syndrome is diagnosed (Snyder et al., 2004) (SOR: C). Procedures for spinal decompression may be considered in patients who have failed conservative therapy (Cochrane Review, 2005) (SOR: C).

Figure 31-20 Stages in prolapse of an intervertebral disk. **A**, Annulus fibrosus is torn, but no extrusion of nucleus pulposus. **B**, Extrusion of nuclear material through the rent. Posterior longitudinal ligament is stretched, but protrusion has not reached the nerve. **C**, The protrusion is larger, and the nerve is stretched over it. Sometimes, a fragment of the torn annulus itself protrudes backward. (Redrawn from Adam JC, Hamblen DL. *Outline of Orthopedics*, 13th ed. New York, Churchill Livingstone, 2001, p 199.)

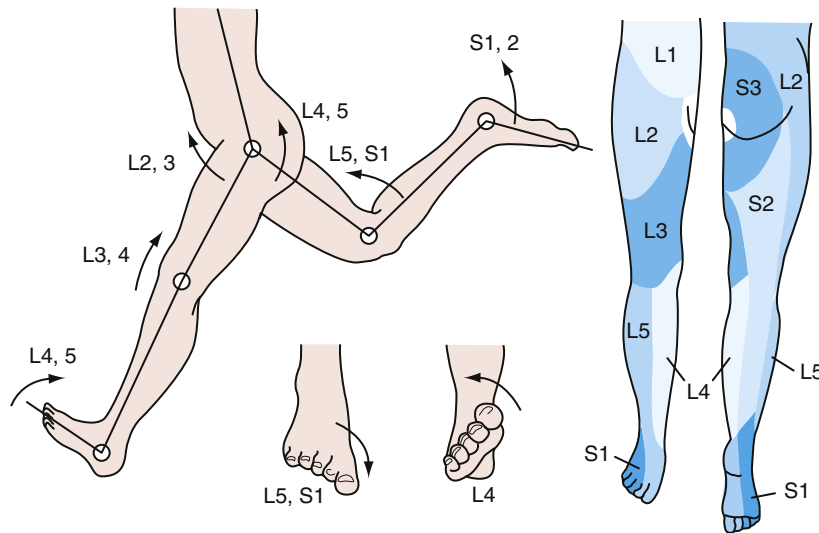

Figure 31-21 Root (segmental) distribution. Note that motion in each joint is controlled by four nerve roots running in sequence. Hip—flexion L2, L3, extension, L4, L5; knee—extension (and knee jerk) L3, L4, flexion L5, S1; ankle—dorsiflexion L4, L5, plantar flexion (and ankle jerk) S1, S2. (Inversion involves L4, and eversion L5, S1.) A useful mnemonic for the low limb dermatomes is that “we kneel on L3, stand on S1, and sit on S3.” (Redrawn from McRae R, Kinninman AWG. *Orthopedics and Trauma*. New York, Churchill Livingstone, 1997, p 26).

Figure 31-22 MR scan showing inflammatory changes in the L3-L4 disk (diskitis) and an L4-L5 prolapse. (From McRae R, Kinninman AWG. *Orthopedics and Trauma*. New York, Churchill Livingstone, 1997, p 52.)

Thoracolumbar Vertebral Compression Fractures

Key Points

- Vertebral compression fractures are common, especially in the elderly. Causing significant disability, deconditioning, and pain.
- The most common site for fractures is thoracolumbar junction (T12-L1).
- Family physicians can prevent compression fractures and sequelae by identifying high-risk patients, educating patients, and encouraging lifestyle modification.

Vertebral compression fractures are common, especially in elderly persons. Vertebral fractures can cause significant pain and impairment in activities of daily living, leading to potentially life-threatening disability and deconditioning in the elderly patient. Patients with preexisting vertebral fractures have greater risk of future vertebral as well as nonvertebral (especially hip) fractures than those without prior fractures.

The most common site for fractures is the thoracolumbar junction (T12-L1) because the change in facet provides poor resistance to anteroposterior displacement. The other common location is the midthoracic region (T7-T8). Osteoporosis is the most frequent cause of vertebral compression fractures in the elderly population. Other causes should be suspected if fracture occurs in a person neither elderly nor postmenopausal or if solitary fracture higher than T7 is seen, ruling out osteomalacia, hyperparathyroidism, granulomatous disease, and hematologic disease.

Clinical Features

Most thoracolumbar compression fractures are asymptomatic, diagnosed as incidental findings on chest or abdominal plain radiographs. Patients with symptomatic fractures usually have no preceding history of trauma, and even minimal trauma (coughing, sneezing) can cause the fracture. The pain from a vertebral compression fracture is variable in quality and sharp or dull. Movements aggravate the pain. The classic patient presents with acute back pain radiating to the anterior abdomen, unlike radiation into the legs seen in herniated disk. Physical examination may reveal tenderness directly over the area of fracture. Thoracic kyphosis and lumbar lordosis may be noted secondary to vertebral height lost. Straight-leg raise and neurologic exam are normal in uncomplicated fractures. Acute episodes usually resolve after 4 to 6 weeks; if pain lasts longer, the physician should suspect more fractures, with chronic pain or other diagnosis.

Diagnostic Testing

A complete blood count, erythrocyte sedimentation rate, and alkaline phosphatase, serum calcium, phosphorus, vitamin D, and parathormone levels should be obtained to rule out malignancy, hyperparathyroidism, or infection, if a cause other than osteoporosis is suspected. Plain radiographs are obtained if compression fracture is suspected. Radiographic characteristics of compression fractures include anterior wedging of one or more vertebrae, with vertebral collapse, demineralization, and vertebral end-plate irregularity. Advanced imaging is not routinely necessary unless the patient has a neurologic abnormality, which may indicate fracture fragments in the spinal canal. Imaging also helps rule out other causes of back pain.

Treatment

Initial management involves pain control and resumption of exercise as early as possible. When osteoporosis is present, inactivity could lead to further bone loss and subsequent fractures. Nonnarcotic analgesics should be used for pain relief. If narcotics are required, laxatives should be used because straining with defecation can cause further fractures. Nasal calcitonin may be a useful adjunct to these analgesics for acute pain relief. Treating the underlying disease is important. Muscle relaxants, external back braces, and physical therapy also may help. Immediate surgical referral should be made if fracture fragments are impinging on the chord and causing neurologic symptoms, or if the fracture is unstable.

Most patients respond to conservative treatment, with significant improvements or full recovery after 6 to 12 weeks. Patients who do not respond to conservative treatment may be candidates for percutaneous vertebroplasty or kyphoplasty.

The family physician can help patients prevent compression fractures and the sequelae by identifying high-risk patients, educating patients about measures to prevent falls, and encouraging lifestyle modifications. A regular weight-bearing exercise program, adequate calcium and vitamin D supplement intake, smoking cessation, and medications to treat osteoporosis may help prevent additional compression fractures.

KEY TREATMENT

Conservative management (pain management, back braces, physical therapy) is the first line of therapy for stable compression fractures (Old and Calvert, 2004) (SOR: B). Patients nonresponsive to conservative treatment may be candidates for percutaneous vertebroplasty or kyphoplasty (Predley et al., 2002) (SOR: B). Diagnosing and treating osteoporosis reduces the incidence of compression fractures of the spine (Old and Calvert, 2004) (SOR: A). Regular activity and muscle-strengthening exercises have been shown to decrease vertebral fractures and back pain (Sinaki et al., 2002) (SOR: B).

Spinal Stenosis

Spinal stenosis is the narrowing of the spinal canal and neural foramina. Spinal stenosis has been classified into congenital and acquired types. The more common acquired spinal stenosis is caused by degenerative changes in the intervertebral disks, ligaments, and facet joints surrounding the lumbar canal. These degenerative changes can be caused by disk or joint disease, back surgery, and repetitive trauma. Stenosis initially becomes symptomatic at 40 to 50 years and older. Congenital narrowing of the spinal canal causes symptoms earlier in life and is uncommon.

Spinal stenosis usually occurs at cervical and lumbar segments. Patients with cervical stenosis present with radiating arm pain, numbness, paresthesia, and motor weakness. The common symptoms with lumbar stenosis are insidious low back pain, leg pain, and numbness. The pain is most often bilateral, involving the buttocks and thighs and spreading distally toward the feet. The classic presentation is radiating leg pain (burning or cramping) that begins or worsens with walking and standing and is relieved by sitting or lying down with hips and knees drawn up in a sitting posture (*neurogenic claudication*). Bending forward diminishes pain. The signs and symptoms of neurogenic claudication should be differentiated from the leg claudication produced by vascular claudication. Vascular disease pain is exercise induced, is localized to the affected group of muscles, and is relieved rapidly with rest in any position. Neurologic symptoms are absent, and vascular disease is associated with skin and trophic changes (pallor, cyanosis, nail dystrophy, decreased or absent pulse).

Severity of symptoms in spinal stenosis may not necessarily be associated with the degree of compression seen on imaging studies. Rarely, patients with spinal stenosis present with

Figure 31-23 Normal (A) and abnormal (B) CT scans of the lumbar spine. Marked narrowing (arrow) is present in B because of hypertrophic spurring. (From Mercier R. *Practical Orthopedics*, 5th ed. St Louis, Mosby, 2000, p 129.)

signs or symptoms of muscle atrophy and loss of bowel and bladder control. Physical examination is frequently normal but may include loss of lumbar lordosis, impairment of spinal mobility, asymmetric knee or ankle reflexes, and muscle weakness. Results of straight-leg raising are characteristically negative.

Advanced imaging studies are obtained to establish and confirm the diagnosis of spinal stenosis when surgery is considered. Plain spine radiographs often reveal degenerative changes. MRI is currently the preferred modality, followed by CT scan (Fig. 31-23).

Conservative treatment is the first line of therapy for spinal stenosis, including adequate pain management, physical therapy, exercise, and weight loss. Progressive symptoms or intractable pain warrant surgical intervention. Wide decompression at the level of stenosis can relieve the symptoms.

KEY TREATMENT

Patients with mild to moderate symptoms of spinal stenosis are managed conservatively (pain/physical therapy, exercise, weight loss) (Snyder et al., 2004) (SOR: C).
Patients with severe symptoms of spinal stenosis benefit from surgery (Amundsen et al., 2000) (SOR: B).

Scoliosis

Scoliosis is characterized by the lateral deviation of the spine from its normal position and is associated with rotation of the vertebrae. Scoliosis may be caused by a structural spine deformity or another problem (e.g., unilateral leg shortening) or may be a protective reaction of muscle spasm in the back for lumbar disk disease or inflammation. Of the structural causes, *idiopathic* scoliosis is most common, affects women more frequently, and is often asymptomatic in young people. Other causes include neurologic deficit,

Figure 31-24 Scoliosis with rib prominence resulting from vertebral rotation is best exhibited on forward bending (Adams position). Cross section of the chest shows rib distortion resulting from vertebral rotation. (Redrawn from Mercier R. *Practical Orthopedics*, 5th ed. St Louis, Mosby, 2000, p 132.)

myopathy, and neurofibromatosis; presence of pain may signify another cause.

The patient with scoliosis may present with apparent deformity, pain, symptoms of difficult movement, or neurologic deficits. The examiner stands behind and observes the patient bending forward at the waist with arms loosely directed toward the feet, which may reveal a prominence of the ribs on one side of the back of the chest and abnormal curvature of the spine (Fig. 31-24). Worsening scoliosis may result in pain, progressive deformity, disability, and cardiopulmonary compromise.

Radiographs aid in the diagnosis and also allow measurement of the angle of curvature of the spine (Fig. 31-25). MRI may be indicated if there are additional symptoms, such as pain or neurologic problems. Early detection is important, and prompt referral to specialists is indicated in certain cases. Spinal growth continues until bone growth has been completed, and serial radiographs are useful to monitor the condition.

Treatment of scoliosis is primarily based on severity and angle of curvature. Braces may be recommended and in special cases, surgery (Janicki and Alman, 2007; SOR C, 3).

Figure 31-25 Cobb method of measuring the severity of a curve. Upper and lower end vertebrae are identified. Upper end vertebra is higher, its superior border converging toward the concavity of the curve, and lower end vertebra has inferior border converging toward the concavity. Lines are drawn along these borders, and the curve is measured directly (*a*) or geometrically (*b*). (Redrawn from Mercier R. *Practical Orthopedics*, 5th ed. St Louis, Mosby, 2000, p 132.)

Arthritis is the most common health complaint in the United States and a common reason for an office visit to the family physician, despite the numerous over-the-counter treatments for joint pain and other musculoskeletal problems. In a Center for Disease Control and Prevention (CDC) National Ambulatory Medical Care Survey, 49 million American adults reported physician-diagnosed arthritis, 21 million of whom reported chronic joint symptoms (Hootman and Helmick, 2006). The 30-year projection rate of patients age 65 and older will increase from 21.4 million to 41.4 million. These statistics lead to 75,000 hospitalizations and 36 million outpatient visits annually.

The term *arthritis* actually applies to more than 180 different disorders, all with pain in or around one or more joints, some with an inflammatory component. Although patients and physicians refer to this collection of diseases as arthritis or "rheumatism," the family physician must attempt to identify the disease process more precisely because of the many treatments available. Musculoskeletal symptoms might be harbingers of other, serious diseases affecting other organs. Patients should know their prognosis, whether their symptoms will most likely be self-limited, chronic, or progressive.

Rheumatic diseases greatly impact the U.S. health care system and society. Approximately 1% of the U.S. gross national product is spent each year on rheumatic diseases alone. Work absences, lost wages, and long-term disability also impact the quality of life of patient and family. Family physicians must be knowledgeable about new treatment

options in the evaluation, assessment, and treatment of these conditions.

Evaluation of Joint and Other Musculoskeletal Symptoms

Precise anatomic localization of pain is the first task of the physician caring for a patient presenting with joint pain, while also evaluating stiffness, redness, warmth, or swelling in the absence of trauma. It is important to distinguish pain that is truly articular from *periarticular* pain. Causes of *localized* periarticular pain include bursitis, tendonitis, and carpal tunnel syndrome, whereas fibromyalgia, polymyalgia rheumatica, and polymyositis all can cause *diffuse* periarticular pain.

The number of involved joints and presence or absence of symmetry are criteria for further diagnosis of articular pain (Figs. 32-1 and 32-2). Monoarticular (one joint) or *oligoarticular* (several joints) arthritides can be caused by conditions such as *osteoarthritis* (OA), gout, pseudogout, or septic arthritis. Asymmetric polyarthritis occurs in ankylosing spondylitis, psoriatic arthritis, Reiter's disease, and spondyloarthropathies. *Symmetric* arthritis, meaning that the same joint is affected on the contralateral side but not necessarily to the same degree, is characteristic of *rheumatoid arthritis* (RA), *systemic lupus erythematosus* (SLE), Sjögren's syndrome, polymyositis, and scleroderma. Fibromyalgia, reflex sympathetic dystrophy, and predominantly psychological

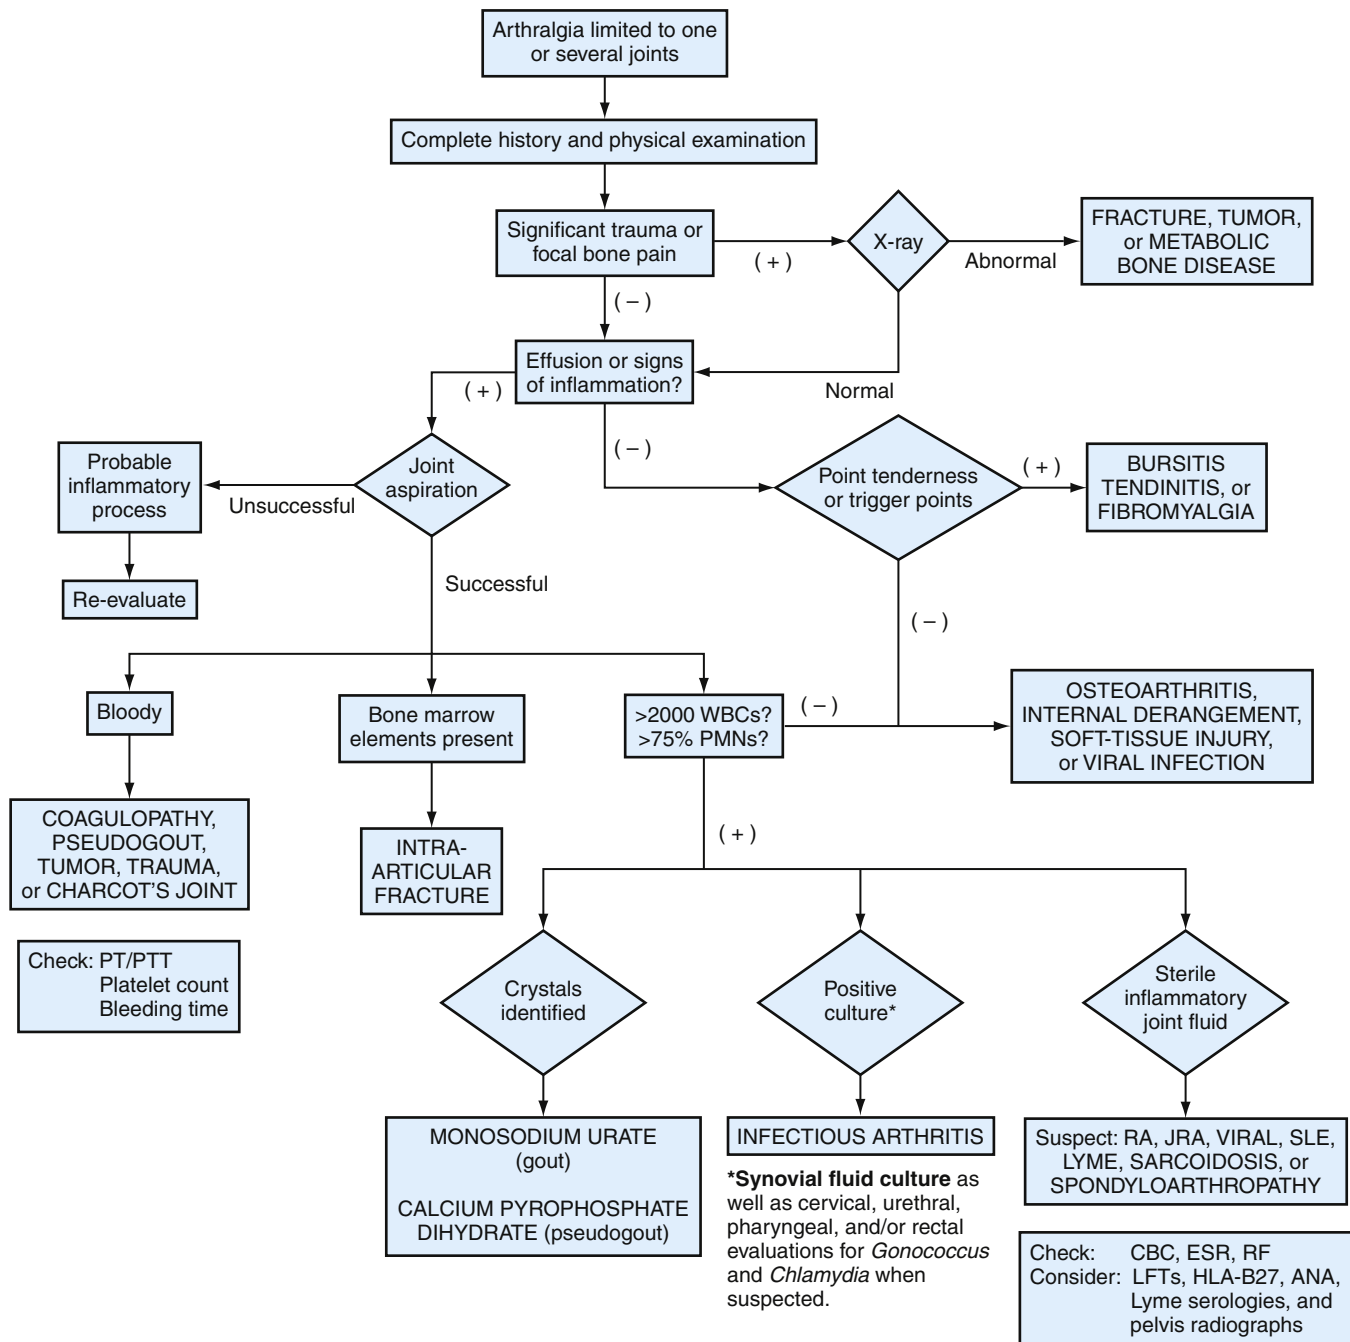

Figure 32-1 Evaluation of monoarticular or pauciarticular symptoms. ANA, Antinuclear antibodies; CBC, complete blood cell count; ESR, erythrocyte sedimentation rate; JRA, juvenile rheumatoid arthritis; LFTs, liver function tests; PMNs, polymorphonuclear (leukocyte) neutrophils; PT, prothrombin time; PTT, partial thromboplastin time; RA, rheumatoid arthritis; RF, rheumatoid factor; SLE, systemic lupus erythematosus; WBCs, white blood cells. (From American College of Rheumatology Ad Hoc Committee on Clinical Guidelines. Guidelines for the initial evaluation of the adult patient with acute musculoskeletal symptoms. *Arthritis Rheum* 1996;39:1.)

factors must be considered when pain is diffuse, not related to specific anatomic structures, or described in vague terms. (See also Chapter 30.)

Other differentiating criteria include the correlation with activity or rest and the character of the pain. Mechanical causes tend to be more directly related to the joint's activity than inflammatory conditions. Neuropathies tend to cause burning or prickling sensations, whereas arthritides often cause an aching pain. The presence of joint stiffness after a period of inactivity might also aid in diagnosis; RA is characterized by morning stiffness lasting 30 to 60 minutes or

longer, whereas OA-related morning stiffness lasts a shorter period, typically less than 30 minutes, but stiffness might also occur during the day. In neurologic conditions such as Parkinson's disease, stiffness might be relatively constant. Vascular pain, such as intermittent claudication, is felt with activity, relieved quickly by rest, and described as a "deep, aching" sensation.

Constitutional symptoms such as fatigue, weakness, malaise, and weight changes are common chief complaints heard in a primary care office practice and often associated symptoms of specific rheumatic diseases. The patient's

functional ability, occupational history, and activities requiring repetitive joint movement, as well as the ergonomics of such activities, should also be considered routinely in initial and serial evaluations. How are the symptoms affecting the patient's ability to perform self-care activities of daily living (ADLs) such as bathing, dressing, and eating? Is the patient able to do instrumental activities of daily living (IADLs) such as buying groceries, cooking, using the telephone, and opening jars? Rheumatic disease can have a devastating effect on quality of life for both the patient and the family, with serious psychosocial and economic consequences. Therefore the physician should address effects on occupational, recreational, and sexual activities in the context of family and other support systems.

Physical Examination

A thorough physical examination should be performed on all patients presenting with joint pain, including examination of asymptomatic joints and other organ systems that might be involved. Joints should be examined for swelling, tenderness, deformity, instability, and limitation of motion. Comparisons with the patient's contralateral side can be made in all these parameters, as well as with the physician's joints as a control. Instability can be tested by moving adjacent bones in the direction opposite to normal movement and observing for greater-than-normal motion. Serial grip strength measurements can be made by asking the patient to squeeze a blood pressure (BP) cuff inflated to 20 mm Hg and

recording the maximal grip force in millimeters of mercury. Signs of systemic disease include fever; weight loss; oral or nasal ulcerations; liver, spleen, or lymph node enlargement; neurologic abnormalities; rashes; subcutaneous nodules; eye iritis; conjunctivitis or scleritis; and pericardial or pulmonary rubs. Because of circadian changes in patients with RA, serial comparisons of the physical examination are more accurate if the time of day is also recorded. Using skeleton diagrams of joint involvement facilitates the recording of a comprehensive joint examination (Fig. 32-3).

Myalgias can be caused by localized trauma or overuse, systemic infection, metabolic disorder, or primary muscle disease. Multiple tender sites in an otherwise healthy patient suggest fibromyalgia. An elevated creatine kinase (CK) level with proximal weakness may be caused by an inflammatory myopathy.

Rheumatic and other musculoskeletal problems are properly diagnosed by careful history and physical examination rather than by just ordering many laboratory tests, the results of which might actually confuse diagnosis. Laboratory tests and radiologic imaging help confirm a presumptive clinical diagnosis made from a careful history and physical examination.

Pathogenesis of Rheumatic and Other Musculoskeletal Diseases

As with most disease, research into the causes of rheumatologic and musculoskeletal diseases shows that the cause for each disease is actually multifactorial. Further identification

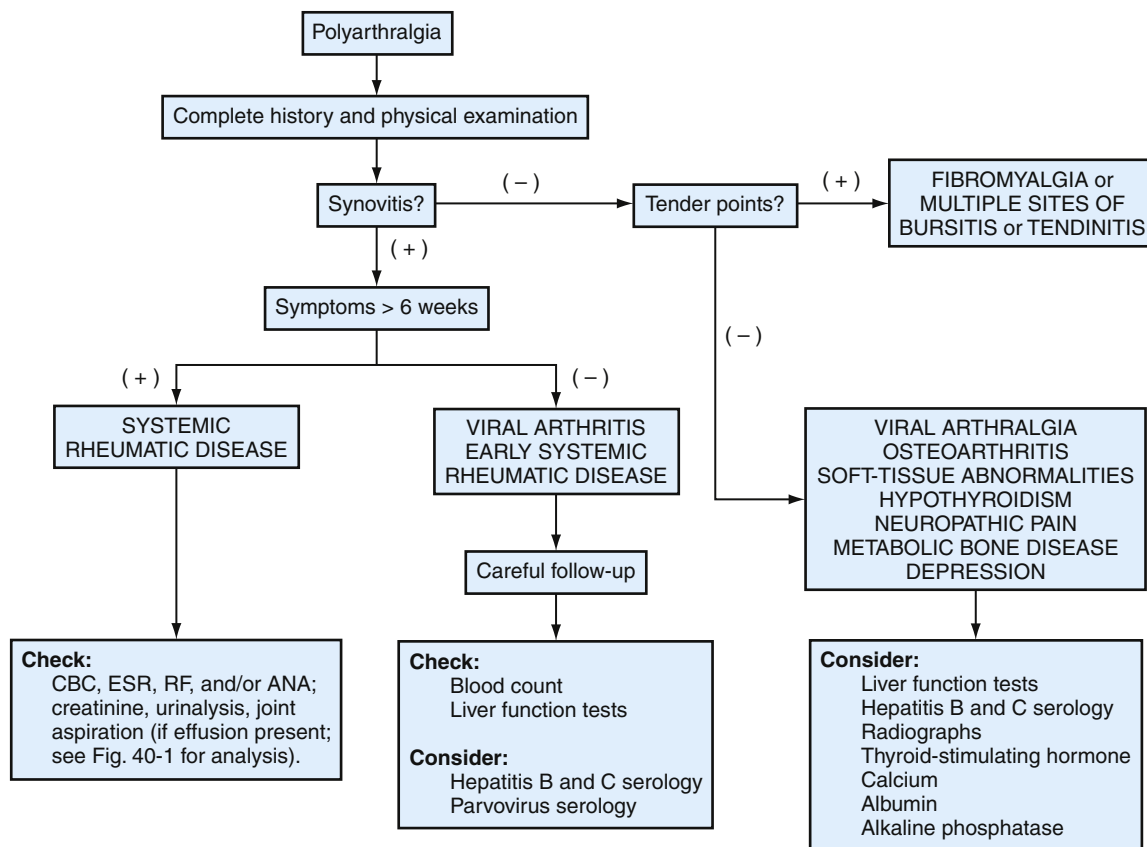

Figure 32-2 Evaluation of polyarticular symptoms. ANA, Antinuclear antibodies; CBC, complete blood cell count; ESR, erythrocyte sedimentation rate; RF, rheumatoid factor. (From American College of Rheumatology Ad Hoc Committee on Clinical Guidelines: Guidelines for the initial evaluation of the adult patient with acute musculoskeletal symptoms. *Arthritis Rheum* 1996;39:1.)

of these factors will help the family physician and rheumatologist modify the course of disease and eventually perhaps even prevent them.

Genetic factors have been identified for several arthritides. Presence of the human leukocyte antigen (HLA) system's HLA-DR4 antigen is associated with increased incidence and severity of RA. The HLA-B27 antigen is found in a higher percentage in patients with ankylosing spondylitis and other spondyloarthropathies than in the general population. Other factors are apparently involved,

Figure 32-3 Skeleton diagram for recording joint examination findings. (From Polley HF, Hunder GG. *Rheumatologic Interviewing and Physical Examination of the Joints*, 2nd ed. Philadelphia, Saunders, 1978.)

however, because its presence or absence neither guarantees nor excludes development of arthritis testing for these antigens if not routinely performed. A National Institutes of Health (NIH) study found that genetic factors contributed 39% to 65% of OA variance. About 80% of patients with chondrodysplasias were found to have a type II collagen gene mutation likely linking these findings to OA (Prockop, 1998).

Inborn errors of metabolism are well known to cause diseases such as gout, in which uric acid is overproduced or underexcreted by the kidneys. Poorly controlled metabolic diseases such as diabetes or hemochromatosis might lead to arthropathies. Mechanical or traumatic factors cause OA in soccer players but not in long-distance runners, indicating that the type and direction of joint stress might be more important than the stress itself. Adduction moment is associated with OA disease severity. Obesity is also an identified factor in OA of the knee, possibly because of metabolic influences as well as mechanical forces (Eaton, 2004).

Infectious agents such as parvovirus B19, human immunodeficiency virus (HIV), *Neisseria gonorrhoeae*, *Borrelia burgdorferi* (Lyme disease), and streptococci (rheumatic fever) are all well-known causes of arthritides. Some speculate that dietary factors might contribute to autoimmune syndromes, and fasting or a vegan diet (or both) can lead to improvement in RA (Kjeldsen-Kragh et al., 1991; McDougall et al., 2002). The imbalance of omega-6 and omega-3 fatty acids in the standard American diet (a ratio of 30:1, as opposed to the ratio of 1:2 that is thought to have been present in Paleolithic diets) is also postulated to contribute to a more inflammatory state. Omega-6 fatty acids are preferentially converted to more inflammatory prostaglandins such as arachidonic acid, whereas omega-3 fatty acids can be converted into eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA), which contribute to anti-inflammatory series-3 prostaglandin production (Fig. 32-4). Omega-3 fatty acids are useful in RA, showing a decrease in use of nonsteroidal anti-inflammatory drugs (NSAIDs) and decreased levels of pain (Oh, 2005).

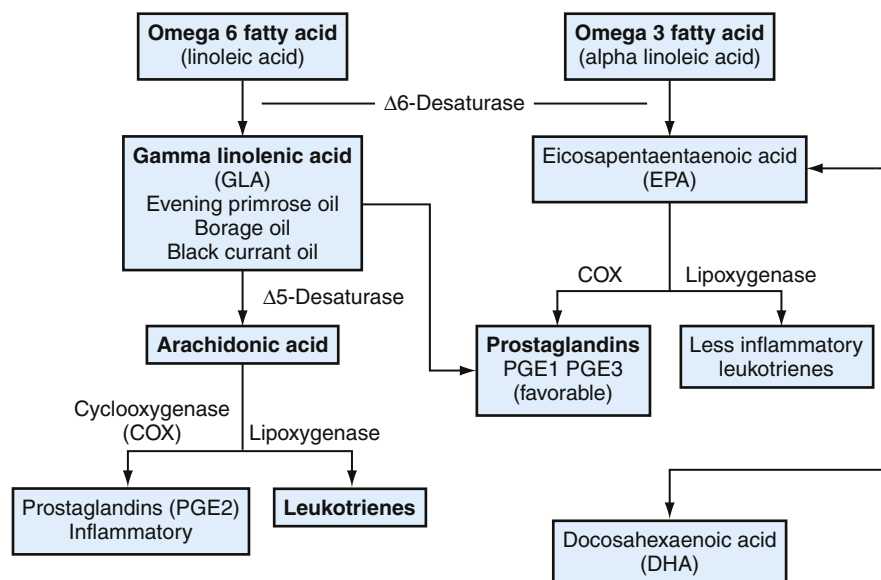

Figure 32-4 Influence of omega-6 fatty acids and omega-3 fatty acids on inflammation. (From Rakel R. *Integrative Medicine*. Philadelphia, Saunders-Elsevier, 2007.)

Other medical systems, such as traditional Chinese medicine (TCM), may have completely different explanations for the changes seen in rheumatologic conditions. Although a conventional practitioner may not be aware of these, it is helpful to know about complementary modalities that may be beneficial (e.g., acupuncture helping patients with OA and fibromyalgia).

Laboratory Studies

A complete cell count (CBC) with differential, urinalysis, and renal and liver function tests should be performed if asymptomatic rheumatic disease is suspected. Importantly, the frequency of abnormal laboratory results increases with increasing age in the normal population, even in the absence of disease, including common tests such as erythrocyte sedimentation rate (ESR), uric acid, antinuclear antibodies (ANAs), and rheumatoid factor (RF). Thus, arthritis panels can confuse the situation and should not be performed routinely. For example, only 80% of patients with RA have a positive RF. RF is a serum autoantibody against immunoglobulin G (IgG). Up to 4% of the healthy population has a positive RF, which is also frequently positive in patients with *chronic obstructive pulmonary disease* (COPD), viral hepatitis, and sarcoidosis, and can also be positive in malignancy, and primary biliary cirrhosis and other autoimmune diseases. The higher the RF titer, however, the more likely it is caused by RA. ANA test results are positive in 95% of patients with lupus, and the test is often used to screen for SLE, but the result is also positive in 5% of the normal population. Drug use, age, and other factors might also cause a positive ANA test result. ANA titer also does not correlate exactly with changes in disease activity, so it should not be ordered in the absence of systemic symptoms. A patient with a positive ANA without clinical features is unlikely to have SLE. However, higher titers of ANA make it more likely that the result is related to lupus or another rheumatologic disorder.

Laboratory studies can be helpful in monitoring disease activity and drug toxicity as well as in establishing a diagnosis. CBC can detect anemia secondary to the chronic disease of RA or from NSAID-induced gastrointestinal (GI) blood loss. Patients with SLE can have hemolytic anemia, thrombocytopenia, or lymphopenia. Urinalysis can detect renal disease secondary to SLE, NSAIDs, or disease-modifying antirheumatic drugs (DMARDs) being used to treat RA. An elevated uric acid level can suggest gout. Acute-phase reactants such as ESR and C-reactive protein (CRP) can be useful to monitor disease activity but are nonspecific; they can also be negative in the presence of active disease. Patients with temporal arteritis and polymyalgia rheumatica almost always have a greatly elevated ESR. With weakness or muscle pain, CK level should be measured and arthralgias with abnormal liver enzyme levels followed up with hepatitis viral serologies.

Other tests, such as HLA-B27, antineutrophil cytoplasmic antibody, Lyme or parvovirus serologies, myositis-specific antibodies (anti-Jo-1), and antiphospholipid antibodies, are useful only when the clinical suspicion is high for spondyloarthropathies, Wegener's granulomatosis, Lyme or parvovirus infection, inflammatory myositis, or antiphospholipid

Table 32-1 Interpretation of Synovial Fluid Cell Count

| Leukocyte Count (WBCs/mm ³) | Interpretation |
|---|--|
| <200 | Normal synovial fluid |
| <2000 | Noninflammatory fluid |
| >2000 | Inflammatory fluid |
| 2000-20,000 | Mild inflammation (e.g., SLE) |
| 20,000-50,000 | Moderate inflammation (e.g., RA, reactive arthritis) |
| 50,000 | Severe inflammation (e.g., sepsis, gout) |
| >100,000 | Sepsis, until proved otherwise |

antibody syndrome, respectively (American College of Rheumatology, 1996).

Synovial Fluid Analysis

Synovial fluid analysis can be helpful in evaluating a febrile patient with an acute joint to rule out septic arthritis or acute monoarthritis. Synovial fluid should be analyzed for white blood cell (WBC) count differential, cultured, and tested with polarized light microscopy for crystals. Purulent synovial fluid with greater than 90% polymorphonuclear leukocytes (PMNs), low viscosity, and turbid clarity can be caused by infection or crystal arthropathy (gout or pseudogout). Urate crystals are needle-shaped and negatively birefringent; calcium pyrophosphate dihydrate crystals are rhomboidal and weakly positively birefringent. Noninflammatory fluids generally have a clear appearance, normal viscosity, fewer than 2000 WBCs/mm³, and less than 75% PMNs (Table 32-1).

Synovial fluid analysis should always be performed on freshly obtained fluid. A simple bedside test is to attempt to read newsprint through the synovial fluid; newsprint can be read through noninflammatory fluid (Fig. 32-5). Traditional tests on synovial fluid that are of limited or no value include measurement of glucose, lactate, and protein levels; subjective determination of viscosity; mucin clot test (examining the friability of the precipitate formed by mixing synovial fluid with dilute acetic acid); and immunologic tests. When looking for crystals and infection, direct examination, Gram stain, culture, and WBC count with differential are the only tests worth performing on synovial fluid. Inflammatory synovial fluid must be considered secondary to infection until proved otherwise by culture. The presence of crystals in the joint does not exclude the possibility of joint infection.

Synovial biopsy can facilitate a diagnosis in some settings. Arthroscopy has greatly simplified the acquisition of synovial tissue. This might be helpful in the diagnosis of granulomatous disease or infiltrative processes such as lymphoma, metastatic disease, or amyloidosis (Klippel, 2001).

Figure 32-5 Synovial effusions. **A**, Normal or edema fluid is clear, pale yellow, or colorless. Print is easily read through the tube. **B**, Fluid from noninflammatory joint disease is yellow and clear. **C**, An inflammatory effusion is cloudy and yellow. Print may be blurred or completely obliterated, depending on the number of leukocytes. The effusion is translucent. **D**, A purulent effusion from septic arthritis contains a dense clump that does not even allow light through the many leukocytes. **E**, Hemorrhagic fluid is red. The supernatant may be darker yellow-brown (xanthochromic). A traumatic tap is less uniform and often has blood streaks. (From Schumacher HR. *Synovial fluid analysis and synovial biopsy*. In Kelley WN, Harris ED, Ruddy S, et al [eds]. *Textbook of Rheumatology*, 5th ed, vol 1. Philadelphia, Saunders, 1997, pp 609-625.)

Imaging Studies

Plain radiographs are still the most common imaging studies done for evaluation and management of rheumatic diseases. Techniques such as magnetic resonance imaging (MRI) and radionuclide scintigraphy (bone scan) are being used more often, although costly and often unnecessary. Many arthritides have characteristic radiographic findings, but these techniques are not indicated for most patients with acute and new symptoms of SLE, gout, mechanical lower back pain, or RA, because radiographs are usually normal early in the course of the disease. Normal radiographs also do not rule out OA. In established RA, the physician might see periarticular osteoporosis, soft tissue swelling, and marginal erosions. Gouty erosions cause characteristic overhanging edges because of reparative changes. (See also Chapter 31.)

The severity of radiographic changes in association with severe symptoms can help guide the aggressiveness of treatment. Overreliance on radiographs, however, can lead to undertreatment or overtreatment of disease. Treatment of RA with a DMARD should usually be initiated long before severe radiographic abnormalities are present. The near-ubiquitous presence of osteophytes on the lumbar vertebrae should not be used to justify aggressive surgical treatment for low back pain; on the other hand, many patients with chronic lower back pain have normal lumbar radiographs. Radiographs for acute joint symptoms might be helpful to rule out fractures, metastases, or infection, especially in older patients. If symptoms persist for more than 10 days, the physician should consider repeat radiography, looking for callus formation.

Besides rotator cuff injuries, MRI studies are particularly useful for possible cruciate ligament, complete lateral collateral ligament (LCL), and meniscal tears in the knee for potential surgical candidates. Although expensive, MRI shows soft tissue destruction long before plain radiographs. Bone scans also are costly and are nonspecific but demonstrate RA changes before radiographs.

Functional Assessment

Instruments such as the Arthritis Impact Measurement Scale and the Health Assessment Questionnaire Disability Index can quantify the impact of the rheumatic disease process on quality of life, pain, physical function, and psychosocial adaptation. However, these tools are more useful in clinical research studies than a busy family physician's office practice. A functional assessment screen is a practical tool for the family physician and takes only minutes (see eTable 32-1 online). Focusing on disease impact on the patient as well as on the patient's joints can be an important contribution by the family physician. Functional assessment helps the primary care physician determine the role of other team physicians (rheumatologist, orthopedic surgeon, physical therapist, occupational therapist, mental health professional). Assessment of function can also lead to a discussion of disease impact on the family and help them deal with this chronic, possibly progressive condition.

Arthrocentesis

Arthrocentesis is most helpful in diagnosing crystal-induced and septic arthritis. Synovial fluid analysis can also be helpful in ruling out the coexistence of two or more types of arthritis in a single patient and even in a single joint. RA might coexist with a septic joint, secondary OA, hemarthrosis, or calcium pyrophosphate dihydrate (CPPD) disease. Hemarthrosis and bacterial infections usually occur in joints already damaged by arthritis. Arthrocentesis is a simple office procedure that can rule out bacterial infection in an acutely inflamed joint. Untreated or delayed treatment of infectious arthritis can cause rapid joint destruction, necessitating prompt diagnosis. A second line of treatment for RA should generally not be started until crystal arthropathy first has been ruled out. A physician is much more likely to harm a patient by not obtaining synovial fluid analysis when needed to make an accurate diagnosis. This is more common than the relatively rare occurrence of iatrogenic infection (particularly if proper sterile technique

is used) or hemarthrosis (usually seen in patients with coagulopathies). The iatrogenic infection rate is generally estimated at 1 in 10,000, much less common than missed diagnosis of a septic joint. Anticoagulation therapy is not an absolute contraindication in the setting of acute arthritis.

The preferred route of entry for arthrocentesis traverses the shortest distance through tissue and avoids major vessels, tendons, and nerves. The knee, ankle, wrist, and elbow are the easiest joints to aspirate, and aspiration can be performed with only a moderate amount of trauma. Other joints normally require more extensive experience. Sterile technique normally does not require draping, but the same needle should not be used to aspirate the joint and to transfer the aspirated fluid to collection bottles.

The knee is the easiest joint to aspirate, best done with a medial or lateral approach at the superior third of the patella between it and the femur. Ankle arthrocentesis entry is midline, equidistant from the medial and lateral malleoli. A lateral entry between the olecranon process and the lateral epicondyle is best for the elbow. The shoulder can be approached posteriorly below the posterolateral aspect of the acromion process or anteriorly just lateral to the coracoid process.

A local anesthetic can be used but might distort landmarks; ethyl chloride spray immediately before needle insertion is usually sufficient. An 18-gauge needle is used for the knee and a 20-gauge needle for other joints; only 1 to 5 mL of synovial fluid is needed for diagnostic purposes. Fluid aspiration by itself is often therapeutic because it reduces articular pressure. Cartilage puncture should be avoided, if possible, by inserting the needle only as deeply as needed to obtain fluid, obtaining as much fluid as possible without risking unnecessary trauma by trying to aspirate every last drop, and avoiding side-to-side needle movement.

Therapeutic Corticosteroid Injection

Arthrocentesis can also be a therapeutic technique to deliver local corticosteroid to a joint that has not responded to systemic therapy and after infection has been excluded. Synovial fluid is first aspirated to ensure proper positioning in the joint space, followed by 1 to 2 mL of corticosteroid to large joints (knees, hips, shoulders); 0.5 to 1 mL to wrists, elbows, and ankles; and 0.25 to 0.5 mL to small joints and soft tissue sites. A 1:2 dilution with lidocaine can be used to provide instant relief, although many believe lidocaine adds to the risk of infection (e.g., requiring a more complex procedure, changing needles) with limited benefit and therefore do not use it. After injection, the joint should be moved through its passive range of motion (ROM), followed by at least 24 hours of rest. Steroid injections should be limited to no more than three to four times per joint per year because of concerns about possible cartilage and ligamentous damage from repeated injections.

Nonsteroidal Anti-Inflammatory Drugs

The NSAIDs are among the most frequently prescribed drugs and are used by family physicians for almost all rheumatic and musculoskeletal pain conditions. By suppressing the synthesis of prostaglandins, NSAIDs reduce inflammation and therefore pain but do not prevent tissue injury or joint damage. Cyclooxygenase-2 (COX-2) inhibitors are used for rheumatologic and musculoskeletal pain because of decreased GI side effects. The VIGOR (Bombardier et al., 2000) and CLASS (Silverstein et al., 2000) studies

for rofecoxib and celecoxib, respectively, showed that the decreased GI effects outweighed any cardiovascular risk. The APPROVe study linked rofecoxib (Vioxx) to an increased risk of cardiovascular disease (Bresalier et al., 2005). An unpublished trial studying celecoxib (Celebrex) and naproxen (Naprosyn, Aleve) in Alzheimer's disease prevention was stopped secondary to a 50% increase in cardiovascular events in subjects not taking placebo (NIH, 2004). Overall, COX-2 inhibitors have produced minimal decrease in GI bleeding and thus should be used cautiously for rheumatologic and musculoskeletal pain because the cardiovascular risk outweighs the GI benefit. Currently, celecoxib has a "black box" warning; rofecoxib was removed from the market.

Patients respond to different classes of NSAIDs for unknown reasons, and no NSAID appears superior to others in efficacy. Treatment is largely empiric. Most clinicians start with a low dose and titrate upward if needed. An adequate trial of an NSAID requires that the patient take a maximum dose for 3 weeks before changing to a different NSAID, although many patients will expect a change in medication before this. It is usually best to switch to an NSAID from a different class. There is no benefit to combining nonsalicylate NSAIDs. All COX-1 NSAIDs can cause dyspepsia and GI toxicity, interfere with platelet function, and prolong bleeding times. Other common side effects include renal toxicity and central nervous system (CNS) symptoms such as drowsiness, dizziness, and confusion. A 2004 Cochrane review of NSAIDs for lower back pain concluded that the various types of NSAIDs (e.g., COX-2 inhibitors) are equally effective, and selection of an NSAID for OA should be based on relative safety and patient acceptability.

Combining NSAIDs with misoprostol (Cytotec), 100 to 200 mg four times daily with meals, or omeprazole (Prilosec), 20 mg daily (Hawkey et al., 1998) has been shown to decrease the incidence of gastric and duodenal ulcers. A meta-analysis of 112 randomized controlled trials (RCTs) found no evidence supporting the effectiveness of H₂ receptor antagonists, while the risk of symptomatic ulcers was significantly reduced by proton pump inhibitors (PPIs), misoprostol, and COX-2 inhibitors (Koch et al., 1996). Omeprazole and other PPIs are better tolerated than misoprostol and famotidine (Hawkey et al., 1998). The physician should monitor for decreased renal function, interaction with antihypertensives, and transaminase (ALT, AST) elevations when starting NSAID therapy or increasing dosage, or when the patient's condition changes.

A common issue for the family physician is whether a patient prescribed aspirin for cardiac prophylaxis needs to stop the aspirin when prescribed a traditional NSAID. Patients taking both do not appear to be at significantly increased risk of GI toxicity. However, the aspirin might not yield any additional cardioprotective benefit, because these patients already benefit from the traditional nonselective NSAID antiplatelet effect. If taking both aspirin and NSAID, it is best to take the aspirin at least 4 hours before the NSAID for its full protective effect.

Arthritis of Systemic Disease

Arthritis can be a component of many systemic diseases, including metabolic disorders, infections, malignancies, and various endocrine, hematologic, and GI diseases. Parvovirus

B19 is responsible for erythema infectiosum and can also cause polyarthritis, especially in the hands, knees, and ankles. HIV infection sometimes causes symmetric polyarthritis, spondylitis, or acute oligoarthritis. Hepatitis B and C can cause acute symmetric polyarthritis in large and small joints. Inflammation in a few large joints and back pain are among the earliest symptoms of infective endocarditis in about 25% of patients with this disorder (Totemchokchyakarn and Ball, 1996).

Lyme arthritis caused by *Borrelia burgdorferi* can cause migratory monoarthritis or oligoarthritis in the knees or shoulders weeks to months after the rash of erythema chronicum migrans has developed. Poorly controlled *diabetes* (affecting foot, ankle, and knee), *hyperthyroidism* (affecting fingers and toes), *hypothyroidism* (causing noninflammatory effusions in knees, wrists, and hands), and *parathyroid disease* (causing chondrocalcinosis) are all endocrine disorders that can cause arthritis.

Metabolic disorders can cause degenerative arthritis. *Hemochromatosis* (caused by iron deposition) typically affects the second and third metacarpophalangeal (MCP) joints, wrists, knees, hips, and shoulders. *Wilson's disease* (caused by copper deposition) can cause premature OA in wrists and knees. Sickle cell disease can be complicated by knee arthritis; arthritis is also often seen in patients with hemophilia and leukemia. Arthritis is associated with inflammatory bowel disease and primary biliary cirrhosis. Reactive carcinoma synovitis can be the presenting symptom of an underlying malignancy, particularly of the breast or the prostate.

Referral to the Rheumatologist

As for all types of disease conditions, referral to the subspecialist largely depends on the family physician's knowledge, interest level, and logistical ability to provide state-of-the-art care to a given patient for a given disease entity at a given time in the disease course. Specific conditions, such as suspected septic arthritis, acute myelopathy or mononeuritis multiplex, suspected acute tendon or muscle rupture, or acute internal derangement, should probably be referred. In addition, referral should be considered for patients without a specific diagnosis after 6 weeks; those with difficulty in symptom control, systemic symptoms in pregnancy, or severe symptoms; patients requiring steroid, immunosuppressive, or other drugs unfamiliar to the primary care physician; or those with end-stage joint disease. The often nonspecific nature and psychosocial impact of rheumatic symptoms require continued active involvement of the family physician in the patient's care, regardless of referral.

Rheumatic Diseases

Osteoarthritis

Key Points

- Osteoarthritis affects 20% of the U.S. population; 44% of OA patients are not active.
- Primary and secondary OA must be differentiated.
- NSAIDs, not COX-2 inhibitors, are still the pharmacologic treatment of choice for OA.

Osteoarthritis, also known as "degenerative joint disease," is the most common form of arthritis and causes more work disability in the United States (17%) than any other disease. Arthritis affects 20% of the U.S. population, about half of whom primarily have OA. Long thought to result from "wear and tear," OA is now known to have genetic, traumatic, metabolic, and developmental causes, which complicates prevention and treatment. OA is found radiographically in almost all 75-year-old patients, most of whom are asymptomatic. OA occurs about equally in men and women ages 45 to 55 but after 55 is more common in women (CDC, 2005). Most OA patients are not seriously affected and are asymptomatic. Others, however, require joint replacement surgery because of its severity.

Although OA is considered a noninflammatory type of arthritis affecting primarily the cartilage, it actually involves active biochemical disease processes as well as mechanical forces that affect the entire synovial joint. An OA variant affecting primarily the hands runs in families and is inflammatory. Women are more prone to this inflammatory variant of OA of the hands that causes Heberden's nodes (in distal interphalangeal [DIP] joints) and Bouchard's nodes (in proximal interphalangeal [PIP] joints). The articular cartilage may not even be involved, with the disease process centered more on subchondral bone turnover (Peterson et al., 1998). Quadriceps muscle weakness might precede the onset of knee OA, indicating the importance of biomechanical factors (Slemenda et al., 1997).

Osteoarthritis can be separated into primary (idiopathic), hereditary (resulting from collagen gene defects), and secondary. Secondary OA results from previous cartilage damage. Occupations causing repetitive joint trauma predispose a patient to OA. Episodic trauma, congenital anatomic abnormalities (slipped capital femoral epiphyses, congenital hip dysplasias), neuropathies, and endocrine-metabolic causes (obesity, hemochromatosis, Wilson's disease, CPPD disease, Paget's disease, acromegaly) all might lead to OA. Inflammatory arthritides such as RA, infections, or gout damage cartilage and are often followed by the development of OA.

Occupational kneelers (e.g., shipyard workers, miners, carpet or floor layers) have a significantly higher incidence of knee OA than control groups of clerical workers (Maetzel et al., 1997). However, repetitive sports activities such as long-distance running are unlikely to cause OA in the absence of joint injury or antecedent joint abnormality (Panush and Lane, 1994). More than 44% of patients with diagnosed OA are inactive (Gordon et al., 1998). Low-impact activity in normal joints is not associated with OA, but high-intensity and high-impact activity resulting in injury is associated with OA. Mechanical risk factors might affect the initiation more than the progression of OA. Most mild OA does not progress to severe joint damage. Mild OA might be a different disease than severe OA, which depends on processes other than early OA.

Clinical Findings

Most OA is asymptomatic, an incidental finding on radiographs performed for other reasons. No treatment or further evaluation is indicated for asymptomatic OA. Early symptomatic OA is characterized by local pain of gradual onset exacerbated by using the involved joint. Pain typically worsens as

the day progresses and is relieved by rest. There is less than 30 minutes of localized morning stiffness and no constitutional or systemic symptoms, and the gel phenomenon (stiffness after periods of rest and inactivity) resolves within several minutes of activity. Damp, cool, rainy weather often exacerbates symptoms because of changes in intra-articular pressure associated with changes in barometric pressure. Patients with OA of the knees might complain of buckling or instability, especially when descending stairs. OA of the hip can manifest as pain radiating from the groin and down the anterior thigh. OA of the neck might be felt in the neck, back, or upper extremities, causing pain, weakness, or numbness. As OA progresses, pain can become continuous, including at night.

Primary OA can be divided into three classifications: generalized OA, large-joint OA, and erosive OA. *Generalized* OA involves five or more joints, most often the DIP joints of the hand (Herberden's nodes), the PIP joints of the hand (Bouchard's nodes), the first carpometacarpal joint, the first MTP joint of the feet, and the knee, hip, and spine. There is a significant familial component. *Large-joint* OA of the knees and hips might occur as part of generalized OA or alone. OA of the knees often occurs in the medial and patellofemoral compartments. OA of the hips can be characterized in two subsets, central and superior poles. Central or medial involvement of the hip joint space occurs in the setting of generalized OA, is usually bilateral, and is seen in women more than men. Most hip OA is superior pole, usually unilateral, seen more in men, and occurs without other joint involvement. As many as 40% to 90% of cases of adult hip OA might arise from subtle developmental abnormalities of the hip, including acetabular dysplasia, developmental (formerly "congenital") hip dislocation, Legg-Calvé-Perthes disease, and slipped capital femoral epiphysis (Brandt and Slemenda, 2004).

A rare form of primary OA known as *erosive* OA involves the hand's PIP and DIP joints equally, with significant inflammation. Other joints are often not involved, although 15% of erosive OA cases might subsequently evolve into seropositive RA (Kujala et al., 1995).

Physical Findings

Physical findings of OA typically include joint swelling, tenderness, crepitus, and enlargements at joint margins, causing deformity. The location of pain should be precisely localized as to whether it is truly articular or periarticular; if pain is located in the joint, an inflammatory or infectious cause should be ruled out first. Patients might have reduced ROM or, in severe cases, joint instability, resulting in excess motion or locking because of loose cartilage fragments. Warmth and soft tissue swelling because of joint effusion might be present, but a markedly swollen, hot, erythematous joint suggests a septic or microcrystalline disease rather than OA.

Laboratory Studies

Clinical study criteria for OA classification are helpful as a means to standardize the diagnosis (see eTables 32-2 and 32-3 online). Although the diagnosis of OA can almost always be made by history and physical examination, definitive diagnosis can be helped by synovial fluid analysis, radiography, and normal ESR, ANA, and RF during symptomatic periods. Synovial fluid analysis of large-joint effusions can

be used to exclude other processes. Joint effusions in OA typically show leukocyte counts lower than 1000 WBCs/mm³, predominantly lymphocytes (Table 32-2). Serum tests might be misleading because ESR rises with age and 20% of healthy older adults have positive RF levels. A greatly elevated ESR suggests a process other than OA. Although many have been identified, biochemical markers of OA are not generally useful to the practicing clinician at this time.

Imaging Studies

Radiographs are generally the first-line confirmation of the presence of OA. Treatment should not be based solely on radiographic abnormalities, however, given the frequency of asymptomatic joints demonstrating radiographic OA changes. OA changes include osteophyte formation, asymmetric joint space narrowing (defined as <3 mm on a weight-bearing knee), and subchondral bone sclerosis (Figs. 32-6 and 32-7). Later in the disease process, subchondral cysts with sclerotic walls might develop. Periarticular osteoporosis and marginal erosions suggest RA or some other inflammatory arthritis rather than OA. Patients with OA involving atypical joints (MCP joints, wrists, elbows, shoulders, or ankles) should be evaluated for an underlying disorder such as CPPD or hemochromatosis.

Treatment

Treatment of OA includes pharmacologic therapy, nonpharmacologic therapy, and surgery. Before initiating treatment, a definitive diagnosis of OA must be made by careful history and

physical examination. No currently available treatment has been shown to alter the natural history of the disease. Therefore, the goal of management of OA is primarily to relieve pain, stiffness, and swelling. The physician seeks to reduce limitation of motion and disability without causing iatrogenic side effects. Patients and their families must also be educated about the disease and their treatment options (Box 32-1).

Nonpharmacologic therapy includes rest during pain episodes, exercise, weight control, avoidance of trauma, patient

and family education, and assistive devices. The patient's ability to perform both self-care ADLs and IADLs requiring higher functioning (e.g., shopping, driving, writing) should be assessed. Physical and occupational therapists can provide great benefit by offering an exercise program and assistive devices to maintain independence and minimize symptoms (Fransen et al., 2001). Patients benefit from the use of canes, walkers, bathtub and toilet wall bars, and dressing sticks for socks and from the other methods of joint protection and symptom relief, such as heat massage. Rest is important for patients with acute pain. Otherwise, helpful exercise programs include swimming, other aerobic conditioning, and walking (van Baar et al., 1999). Weight control and weight reduction have also been shown to improve symptoms (Messier et al., 2004).

First-line pharmacologic therapies for symptom control include acetaminophen, up to 1000 mg four times daily in the absence of liver disease, and traditional NSAIDs, beginning with ibuprofen. Because few RCTs studied differences in efficacy of NSAIDs, the initial choice is empiric. Therefore, relative safety, patient adherence, and cost should determine selection. Risk factors for upper GI bleeding with NSAIDs include age over 65, history of peptic ulcer disease or upper GI bleeding, concurrent use of oral corticosteroids and anticoagulants, and possibly smoking and alcohol consumption. Evidence suggests that NSAIDs are superior to acetaminophen for improving knee and hip pain from OA. No significant difference in overall safety was found, although patients taking NSAIDs were more likely to experience an adverse GI event (Towhead et al., 2006). Capsaicin (Zostrix) topical cream four times daily, formerly a first-line agent, now has been shown to have minimal benefit, especially when considering side effects that impair compliance (Mason et al., 2004). Combination therapy (NSAIDs with

(From Resnick D, Yu JS, Sartoris D. *Imaging*. In Kelley WN Harris ED, Ruddy S, et al [eds]. *Textbook of Rheumatology*, 5th ed, vol 1. Philadelphia, Saunders, 1997, pp 626-686.)

Box 32-1 Options in the Management of Patients with Osteoarthritis**Nonpharmacologic Therapy**

Patient education and self-management programs
 Social support through telephone contact
 Physical and occupational therapy
 Range of motion (ROM) and strengthening exercises
 Aerobic conditioning
 Weight loss
 Assistive devices for ambulation and activities of daily living

Pharmacologic Therapy

Oral nonopioid analgesics (e.g., acetaminophen)
 Topical analgesics (e.g., capsaicin cream)
 Nonsteroidal anti-inflammatory drugs (NSAIDs)
 Intra-articular steroid injections
 Opioid analgesics

Surgical Therapy

Closed tidal joint lavage
 Arthroscopic debridement and joint lavage
 Osteotomy
 Total joint arthroplasty

From Hochberg MC. Osteoarthritis: clinical features and treatment. In Klippel JH (ed). *Primer on the Rheumatic Diseases*, 12th ed. Atlanta, Arthritis Foundation, 2001, pp 293-295.

analgesics) may also be helpful. The addition of tramadol (Ultram, 200 mg/day) in patients responding to 1000 mg/day of naproxen has been shown to allow significant reduction (by half) in the naproxen dose needed without compromising pain relief (Schnitzer et al., 1999).

Misoprostol (Cytotec) was the first U.S. Food and Drug Administration (FDA)-approved drug for GI protection when used with NSAIDs, although higher doses of famotidine (Pepcid), nizatidine (Axid), and omeprazole (Prilosec) also decrease the risk of NSAID-induced gastric ulcers. Currently, NSAIDs plus a PPI such as omeprazole remains the treatment of choice for prevention of NSAID-induced gastric ulcers. Opioid analgesics and limited intra-articular corticosteroid injections (up to 4 injections per joint per year) are the remaining traditional choices. Opiates should generally be avoided for long-term use but might be helpful for acute exacerbations. It is unclear whether the risks of long-term NSAID use outweigh the addiction potential of chronic opiate use.

Intra-articular glucocorticoids are often used and are particularly useful in patients with contraindications or continued pain despite NSAIDs. This modality is postulated to work by decreasing cartilage catabolism and osteophyte formation. A meta-analysis found that patients receiving intra-articular steroid injections for OA of the knee were twice as likely to have short-term improvement as controls (Arroll et al., 2004). Data on injection of the hip and knee joint show the most promise, but efficacy at other sites is less certain. Aseptic technique should be used to prevent iatrogenic complications of infection. Patients should be counseled on postinjection complications such as bleeding, infection, skin hypopigmentation, fat necrosis, and steroid flare.

Because OA is a common incurable disease that causes pain, many other treatments, including dietary supplements and other alternative therapies, have been tried for centuries. Balanced hormone therapy, copper bracelets, bee venom, vitamins, herbs, homeopathic remedies, and certain types of foods are promoted as effective treatments or cures for OA. Family physicians should be aware of proven and unproven remedies used by their patients. One therapy shown to be efficacious is glucosamine sulfate.

Glucosamine and chondroitin sulfates both stimulate the production of proteoglycan in cartilage and inhibit its breakdown. Over-the-counter formulations vary in the amount of glucosamine (made from crab shells) and chondroitin (processed from cow cartilage). Research has shown that patients have moderately benefited from glucosamine and chondroitin supplements over 3 years with less knee joint space narrowing on radiography, significant reduction of symptoms, and no adverse effects (Richy et al., 2003). The major studies of glucosamine used two different formulations of the supplement, which yielded different results, the Rotta brand and non-Rotta formulations. A 2005 Cochrane review found that a non-Rotta preparation failed to show benefit in pain and function, whereas the Rotta preparation showed that glucosamine was superior to placebo in the treatment of pain and functional impairment resulting from symptomatic OA. Studies for chondroitin are less convincing, with no consistent improvement in pain or functional status (AAFP, 2006). The safest daily intake is 1500 mg/day of glucosamine and 1200 mg/day of chondroitin. Most capsules containing both minerals are also formulated with manganese, theorized to assist in proteoglycan metabolism but not studied (Richy et al., 2003).

A meta-analysis of 11 studies found that S-adenosylmethionine (SAMe) was as effective as NSAIDs at reducing pain and functional limitations, with a somewhat better adverse effect profile (Soeken et al., 2002).

A Cochrane review of herbal therapies for OA found two studies demonstrating that avocado-soybean unsaponifiables showed beneficial effects on function, pain, intake of NSAIDs, and global evaluation (Little et al., 2004). Another beneficial intervention is transcutaneous electrical nerve stimulation (TENS) for OA of the knee; electrical stimulation has been shown to improve knee OA moderately by 25% and cervical OA by 12% (Osiri et al., 2004).

Studies comparing acupuncture with a sham control found greater improvement in those receiving the actual treatment (Berman et al., 2004; Ezzo et al., 2001; Vas et al., 2004). A meta-analysis found that acupuncture was more effective than placebo in pain reduction in peripheral OA (Kwon et al., 2006). Two studies found that therapeutic touch, an energy modality, showed benefit in OA (Gordon et al., 1998). Although previously cited as beneficial for OA secondary to antioxidants, the literature reports an increased risk of cardiovascular disease with vitamins C and E (Alkhenizan and Palda, 2003).

Other, less traditional therapies have received much media attention but not shown effectiveness. Cycles of three or more weekly intra-articular injections of hyaluronic acid (viscous substance in synovial fluid that lubricates and protects joints) have been used, with partial success (Abramowicz, 1998a). Hyaluronate sodium (Hyalgan) and hylan G-F 20 (Synvisc) are FDA approved for OA of the knee. Onset of pain relief can take several weeks and can last for 6 months

or longer. Meta-analyses of hyaluronic acid have shown minimal effectiveness versus placebo. The cost/benefit ratio favors therapies other than joint injection (Lo et al., 2003).

Other largely unproven therapies include doxycycline, diathermy (deep heat using ultrasound), iontophoresis with dexamethasone, and intra-articular therapeutic gene therapy before joint replacement. Although diathermy and iontophoresis are widely used and have widespread anecdotal reports of subjective relief of pain, there is no definitive proof of benefit.

KEY TREATMENT

Treatment of osteoarthritis begins with nonpharmacologic modalities, including weight loss (Messier et al., 2004), physical therapy (Fransen et al., 2001), exercise (van Baar et al., 1999), and orthotics if needed (SOR: A).

Acetaminophen and NSAIDs are both first-line pharmacotherapy for pain associated with OA, although NSAIDs appear to be more effective (Towhead et al., 2006) (SOR: A).

Intra-articular glucocorticoids show short-term improvement in pain associated with OA of the hip and knee (Arroll et al., 2004) (SOR: B).

Treatments such as Synvisc (Lo et al., 2003), glucosamine (Richy et al., 2003), and acupuncture (Kwon et al., 2006) are often used for OA relief before surgical measures (SOR: B).

Rheumatoid Arthritis

Key Points

- Rheumatoid arthritis affects women 3:1 over men, with 70% having an insidious onset.
- Symmetric synovitis with morning stiffness longer than 1 hour is the hallmark of RA.
- Constitutional symptoms are common in patients with RA.

Rheumatoid arthritis is a chronic inflammatory systemic disease in which cellular and autoimmune mechanisms result in destruction of tissues, primarily the synovium. Genetic predisposition appears to be important, but a specific inciting infectious agent or other cause has still not been found. RA manifestations vary from very mild, self-limited disease to multiorgan destruction and early death. Increasing knowledge of the modulating factors in disease progression is transforming the treatment of RA. Without treatment, the normally fluctuating disease course results in progressive joint destruction. Patients with active, polyarticular, RF-positive RA have more than a 70% chance of developing joint damage or erosion within 2 years (Fuchs et al., 1989). Because RA is relatively uncommon compared with OA and is now treated quite differently, the family physician must be able to make the correct diagnosis and initiate disease-modifying therapy early, before joint destruction.

Epidemiology

Rheumatoid arthritis affects women more frequently than men (about 3:1 ratio) and occurs in all age groups but has a peak incidence between 20 and 50 years. Prevalence is 1% to 2% of adults, ranging from 0.3% of the population

younger than 35 to about 10% of those older than 65. There is a higher concordance of RA in monozygotic twins than in dizygotic twins because of gender differences and differences in major histocompatibility complex (MHC) class II gene products (HLA-DR). Combinations of different genes most likely predispose patients to the disease. The HLA-DR antigen appears to be triggered by many stimuli. After this inciting event, the synovial lining cells and subsynovial vessels proliferate, forming a pannus. Leukocytes invade, followed by a further inflammatory cascade involving proteases and cytokines. RF produces autoantibodies to IgG Fc fragment, influenced by HLA-DR polymorphism and associated with more severe, extra-articular disease. Again, RF is not specific to RA and can be detected in normal persons.

Diagnosis

Rheumatoid arthritis is a clinical diagnosis made by careful history and physical examination. Laboratory testing can be confirmatory but is also misleading if not interpreted in context. Radiographic evidence of erosions appears only several months to a year after disease onset. The American College of Rheumatology (ACR) published useful criteria in 1987 for the diagnosis of RA (Table 32-3). Symptoms must be present for at least 6 weeks for initial diagnosis.

Symmetric synovitis is the hallmark of RA and can be suggested by joint aspiration of synovial fluid, yielding over 2000 WBCs/mm³ without crystal, or by radiographic evidence of erosions. Because the cause of synovitis cannot be differentiated clinically, extra-articular manifestations can help distinguish RA from other inflammatory conditions.

History

Approximately 70% of patients with RA experience an insidious onset over weeks to months, 10% have an acute abrupt onset, and 20% have an intermediate onset, with increasing symptoms for days to weeks. Morning stiffness occurring for more than 1 hour is suggestive of RA. Morning stiffness results from joint immobilization during sleep and is not related to time of day. As opposed to patients with OA, patients with RA have constitutional symptoms such as fatigue, malaise, weight loss, low-grade fever, and anemia. Small joints in hands and feet (PIP, MCP) are typically involved first, with larger joints involved later. The joints themselves might be warm to the touch but are usually not erythematous. A pannus of inflamed synovium palpable as a rubbery mass of tissue strongly suggests RA.

The presentation of exacerbations of chronic rheumatoid synovitis might differ from those of early acute synovitis. Chronic inflammation causing fibrosis decreases synovial vascularity, reducing the amount of swelling from previous episodes. Although the frank swelling of burned-out RA appears less severe, the amount of pain, morning stiffness, constitutional symptoms (fatigue, malaise), and joint destruction on radiography shows this physical finding to be misleading. These episodes in patients with chronic, long-term RA should therefore not be considered improvement over more visible, earlier episodes of synovitis.

Less common presentations of RA include acute onset (which has the best prognosis) and palindromic RA, which

Table 32-3 American College of Rheumatology Revised Criteria for Classification of Rheumatoid Arthritis (Traditional Format)

| Criterion* | Definition |
|---|--|
| 1. Morning stiffness | Morning stiffness in and around the joints lasting at least 1 hour before maximal improvement. |
| 2. Arthritis of three or more joint areas | At least three joint areas with simultaneous soft tissue swelling or fluid (not bony overgrowth alone) observed by physician. The 14 possible joint areas are right or left PIP, MCP, wrist, elbow, knee, ankle, and MTP joints. |
| 3. Arthritis of hand joints | At least one joint area swollen as above in a wrist, MCP, or PIP joint. |
| 4. Symmetric arthritis | Simultaneous involvement of the same joint areas on both sides of the body; bilateral involvement of PIP, MCP, or MTP joints is acceptable without absolute symmetry. |
| 5. Rheumatoid nodules | Subcutaneous nodules over bony prominences or extensor surfaces or juxta-articular nodules regions, observed by physician. |
| 6. Serum rheumatoid factor | Demonstration of abnormal amounts of serum rheumatoid factor by any method that has been positive in less than 5% of normal control subjects. |
| 7. Radiologic changes | Radiologic changes typical of rheumatoid arthritis on posteroanterior hand and wrist radiographs, which must include erosions or unequivocal bony decalcification localized to, or most marked adjacent to, the involved joints (osteoarthritis changes alone do not qualify). |

From Arnett FC. Revised criteria for the classification of rheumatoid arthritis. *Bull Rheum Dis* 1989;38:1. Used with permission.

*Four or more criteria are needed for the diagnosis of rheumatoid arthritis (RA). Criteria 1 through 4 must be present for 6 weeks or longer. Presence of criteria is not conclusive evidence for the diagnosis of RA. Absence of criteria is not conclusively negative.

MCP, Metacarpophalangeal; MTP, metatarsophalangeal; PIP, proximal interphalangeal.

is characterized by brief episodes of swelling of a large joint such as a knee, wrist, or ankle. Palindromic RA can therefore be easily misdiagnosed as gout.

Approximately 20% of patients with RA have intermittent symptoms. The remainders have progressive disease of varying severity, from slowly to rapidly progressive. In addition to morning stiffness, synovitis, and structural damage, RA exhibits classic manifestations in specific joints. Cervical spine involvement is common, whereas thoracic and lumbar spine involvement is rare. Early symptoms are neck stiffness and decreased motion, which can lead to neurologic complications from C1-C2 instability resulting from tenosynovitis

of the transverse ligament of the first cervical vertebra (C1, which stabilizes odontoid process of C2), as well as disease of the apophyseal joints.

Neck pain without neurologic features tends to be self-limited and usually improves, but neck pain and neurologic symptoms often do not correlate well. A neurologic examination, even in the absence of neck pain, is therefore prudent in patients with RA. Radiographs of the cervical spine in flexion and extension might be needed to detect C1-C2 involvement, which necessitates caution during surgical procedures requiring intubation.

Physical Examination

Upper Extremity

Shoulder RA usually manifests as decreased ROM. Elbow RA is more accessible than shoulder RA for physical examination and joint aspiration. Elbow involvement can manifest with elbow pain and swelling; ulnar compression syndrome (paresthesia and weakness of fourth and fifth digits) can develop from the synovitis. The wrists are affected in most RA patients, in contrast to OA patients; carpal tunnel syndrome is seen frequently. RA usually involves the MCP and PIP joints rather than the DIP joints. Classic late changes such as swan neck and boutonnière deformities and ulnar deviation of the MCP joints caused by ligamentous laxity might occur. The swan neck deformity is characterized by flexion of the DIP and MCP joints and hyperextension of the PIP joint, probably resulting from shortening of the interosseous muscles and tendons and shortening of the dorsal tendon sheath. The boutonnière deformity results from avulsion of the extensor hood of the PIP because of chronic inflammation. This causes the PIP to pop up in flexion while the DIP stays in hyperextension.

Lower Extremity

Hip involvement in RA might be difficult to detect on physical examination and might manifest as only a small decrease in ROM. If pain develops, it can be felt in the buttock, lower back, groin, thigh, or medial aspect of the knee. RA of the knee is usually easily apparent on examination. A *Baker's cyst* (posterior herniation of the joint capsule to the popliteal area) might occur and can be diagnosed by ultrasound. Rupture of a Baker's cyst into the posterior leg might mimic thrombophlebitis. RA might involve the MTP, talonavicular, and ankle joints, causing gait problems. The tarsal tunnel containing the posterior tibial nerve can be compressed by synovitis, causing burning paresthesias on the sole of the foot made worse by weight bearing.

Joint Deformities

The synovitis of RA has many effects on cartilage, bone, muscles, tendons, and ligaments. Cartilage and bone erode, and muscles and tendons shorten in response to chronic inflammation. Ligaments are weakened by collagenases released by inflamed synovium and pannus. Upper extremity joints (shoulder, wrist, elbow) are prone to more severe deformities, as previously noted, than knees and ankles because splinting (avoiding joint motion to minimize pain) is easier in these lower extremity joints. The decreased use of these joints leads to more destruction by tendon shortening and contraction of the articular capsule.

Extra-Articular Manifestations

Systemic constitutional symptoms such as fatigue, malaise, anorexia, weight loss, and fever occur in addition to joint inflammation and destruction in RA. Significant inflammation of almost all organ systems occurs. Patients have an increased incidence of renal, cardiac, pulmonary, and neurologic disorders, serious infections, and hematologic malignancies such as non-Hodgkin's lymphoma. Subcutaneous rheumatoid nodules occur frequently in RA patients, usually in areas subject to pressure such as the elbows and sacrum. Their onset can be abrupt or gradual, and they might also resolve spontaneously. Biopsies are sometimes required to differentiate these from a gouty tophus or xanthoma. Rheumatoid nodules can also occur throughout the body, including (rarely) organs such as the lungs and heart.

Pulmonary involvement can include pleural effusions, interstitial fibrosis, solitary or multiple nodular lung disease, and pleurisy. Asymptomatic pericarditis diagnosed by echocardiography during RA exacerbations is relatively common but rarely results in cardiac-related sequelae. Nodules can occur rarely in the myocardium, heart valves, and aorta. Renal and GI complications are generally secondary to the treatment of RA rather than arising from the disease itself. Eye dryness from keratoconjunctivitis sicca, episcleritis, or scleritis is associated with RA. Hematologic complications of RA include a hypochromic microcytic anemia with a low serum ferritin level and low or normal iron-binding capacity. Because many RA patients are taking NSAIDs, it can be difficult to distinguish anemia associated with their RA from NSAID-induced GI blood loss. *Felty's syndrome* (RA, splenomegaly, leukopenia, leg ulcers, lymphadenopathy, thrombocytopenia, HLA-DR4 haplotype) is most common in patients with severe, nodule-forming RA.

Laboratory Studies

Arthritis panels should not be routinely performed and might only confuse the diagnosis. RF, ESR, uric acid level, ANA, and radiographic abnormalities all increase with age in the general population, even in the absence of disease. Therefore, laboratory studies should be reviewed as confirmatory of the clinical diagnosis made by careful history and physical examination.

Rheumatoid factor, ANA, and ESR are normally the most helpful tests to diagnose RA. RF is present in 80% to 90% of patients with RA. Therefore, 10% to 20% of patients with RA never have a positive RF. Also, up to 4% of normal young persons have low levels of RF. Moreover, RF titers are not helpful in following disease progression; when a patient is discovered to have a positive RF, repeating the test is of no value. Repeating an RF 6 to 12 months later for patients with initially negative RF may be useful when RA is still being strongly considered. RF can be increased in other diseases, mainly chronic infections (Lyme disease, subacute bacterial endocarditis, tuberculosis, syphilis), viral infections (infectious mononucleosis, cytomegalovirus, influenza), parasitic infections, and other chronic inflammatory diseases such as sarcoidosis, pulmonary interstitial disease, and noninfectious hepatitis.

Anti-cyclic citrullinated peptide (anti-CCP) antibody is another laboratory test useful in the diagnosis of RA when the diagnosis is in question or the RF is negative. Anti-CCP is

more specific than rheumatoid factor for RA with 95% specificity and 69% sensitivity. Positive anti-CCP serology has also been linked with more severe radiologic progression of joint erosions from RA (Nishimura et al., 2007). Anti-CCP can also be positive in patients with active tuberculosis or other autoimmune diseases.

Other serum tests include ANA titers, complement, ESR, and CBC. Abnormal ANA titers indicate SLE, Sjögren's syndrome, and scleroderma, but up to 30% of RA patients also have abnormal ANAs. Complements (CH50, C3, and C4) are decreased in SLE but are normal or increased in RA. The ESR, a nonspecific marker of inflammation, might help differentiate RA from other noninflammatory diseases. C-reactive protein (CRP), an acute-phase reactant, is also nonspecific but increases more rapidly than the ESR in early inflammation. A CBC showing a mild normochromic, normocytic anemia and a normal WBC count suggests RA. Thrombocytosis might also mimic disease activity as another acute-phase reactant, and eosinophilia might be seen.

Synovial fluid analysis in RA shows a yellow-white, turbid, but sterile fluid without crystals. WBC counts of synovial fluid in RA are typically 10,000 to 20,000 cells/mm³ but are at least higher than 2000/mm³, with more than 75% PMNs. Synovial CH50 is lower than serum levels, and the serum and synovial glucose difference is usually higher than 30 mg/dL.

Imaging Studies

Radiography is indicated early when infection or fracture must be ruled out, the patient has a history of malignancy, the physical examination fails to localize the source of pain, or pain persists despite conservative treatment. Early RA might show only soft tissue swelling. Advanced destruction on radiographs should not be required to initiate disease-modifying therapy if a diagnosis of RA is strongly suspected clinically. In late-stage disease, radiographs might show marginal bony erosions, periarticular osteoporosis, and joint space narrowing, especially in the hands and feet (Figs. 32-8 and 32-9).

Course

Almost 90% of joints ultimately affected in a given patient are involved during the first year of the disease, allowing the family physician to alert the patient with chronic RA about which joints will ultimately be affected (Anderson, 2004). Rate of spontaneous remission is extremely low, usually occurring within 2 years of disease onset. The presence of RF, nodules, extra-articular manifestations, and HLA-DR4 haplotype is associated with a more severe course. Mortality rates for patients with severe RA are higher secondary to infections; cardiovascular, pulmonary, and renal disease; GI bleeding; and excess malignancy. The strongest predictors of survival appear to be extra-articular manifestations of the disease and comorbidities (Gabriel et al., 2003).

Treatment

Initiation of early aggressive treatment of RA is essential to achieve the best prognosis in an individual patient. An integrated approach using up-to-date pharmacotherapy, patient

Figure 32-8 Rheumatoid arthritis marginal erosions and joint space narrowing. (From Resnick D, Yu JS, Sartoris D. *Imaging*. In Kelley WN, Harris ED, Ruddy S, et al [eds]. *Textbook of Rheumatology*, 5th ed, vol 1. Philadelphia, Saunders, 1997, pp 626-686.)

education, physical and occupational therapy, and surgery is optimal. The family physician's role in early diagnosis of RA and subsequent initiation of DMARDs gives patients the best chance for minimizing joint destruction. The early aggressive treatment of RA begins with initial sign and symptom onset through the first 1 to 2 years of the disease. Considering symptomatology such as the patient's overall function, fatigue, inflammation and erosion of joints, and extra-articular symptoms can lead to an early diagnosis.

Although long used as the mainstay of pharmacologic therapy, NSAIDs provide only symptomatic relief without improving prognosis. Therefore, almost all patients should start taking a DMARD as soon as the diagnosis of RA has been made (Fig. 32-10). Many DMARDs are no more toxic than high-dose NSAIDs. Treatment options include DMARDs (hydroxychloroquine, sulfasalazine, and methotrexate) and minocycline. After 1 to 2 years of this therapy, the disease will have progressed to established RA. For moderate signs and symptoms, single and combination therapy is applicable, with options such as methotrexate, anti-TNF (tumor necrosis factor), anti-K-1, leflunomide, azathioprine, gold, cyclosporine, and other medications for mild RA (Osiri et al., 2003; Wells et al., 2004). The disease progresses to severe rheumatoid arthritis if the treatment options for established rheumatoid arthritis have failed. Therapy such as cyclophosphamide (Cytoxan), a different DMARD selection, pulse steroids, and Prosurba Column (protein A) could then be considered. Along with prescribing the DMARD, the family physician must educate the patient and family about the importance of DMARD compliance. Physical and occupational therapy are important for joint protection during exacerbations, as is exercise to improve function and ROM. Early consultation with a rheumatologist is generally recommended.

Figure 32-9 Classic forefoot deformities of rheumatoid arthritis. (From Resnick D, Niwayama G. *Diagnosis of Bone and Joint Disorders*. Philadelphia, Saunders, 1988.)

Disease-Modifying Antirheumatic Drugs

Although traditional first-line therapy has included aspirin and NSAIDs, DMARDs are now used more frequently in early RA (Table 32-4). Because of the potential for toxicity, it is important to differentiate RA from other causes of synovitis as well as from OA. The 2008 ACR recommendations identified four adverse prognostic factors that would encourage use of DMARDs: functional limitation, extra-articular disease, RF positivity or presence of anti-CCP antibodies, and bony erosions documented on radiographs. Hydroxychloroquine appears to be the least toxic of the DMARDs, followed (in order) by sulfasalazine (Azulfidine), methotrexate (Rheumatrex), intramuscular (IM) gold sodium thiomalate (Myochrysin), and aurothioglucose (Solganal). Hydroxychloroquine is dosed at 200 mg orally once or twice daily; however, patients need ophthalmologic follow-up in 6 months (Carmichael et al., 2002; Wassenberg and Rau, 2003). Hydroxychloroquine is generally only used for patients with milder RA symptoms. Significant improvement was seen in patients with mild RA taking hydroxychloroquine compared with those taking placebo (Davis et al., 1991).

Sulfasalazine is given at 2 to 3 g/day in two divided doses (Suarez-Almazor et al., 2000a). Before prescribing sulfasalazine, a sulfa drug, the physician must be aware of potential allergy and check CBC and liver function tests (LFTs) weekly for 1 month, then every 4 to 6 weeks. Using sulfasalazine use as the sole DMARD for treatment should be limited to those patients lacking the poor prognostic factors noted earlier or those with contraindications to methotrexate. A meta-analysis of 15 trials showed that sulfasalazine was effective for treatment of RA (Weinblatt et al., 1999b). Oral gold, or auranofin (Ridaura), is not as effective as IM preparations and should be used only for early mild RA or in combination with other DMARDs (Suarez-Almazor et al., 2004a). Gold is given as 3 mg twice daily, and CBC must be done every 4 to 6 weeks. Diarrhea is a frequent side effect. The onset of action of most DMARDs is at least several months, so adequate

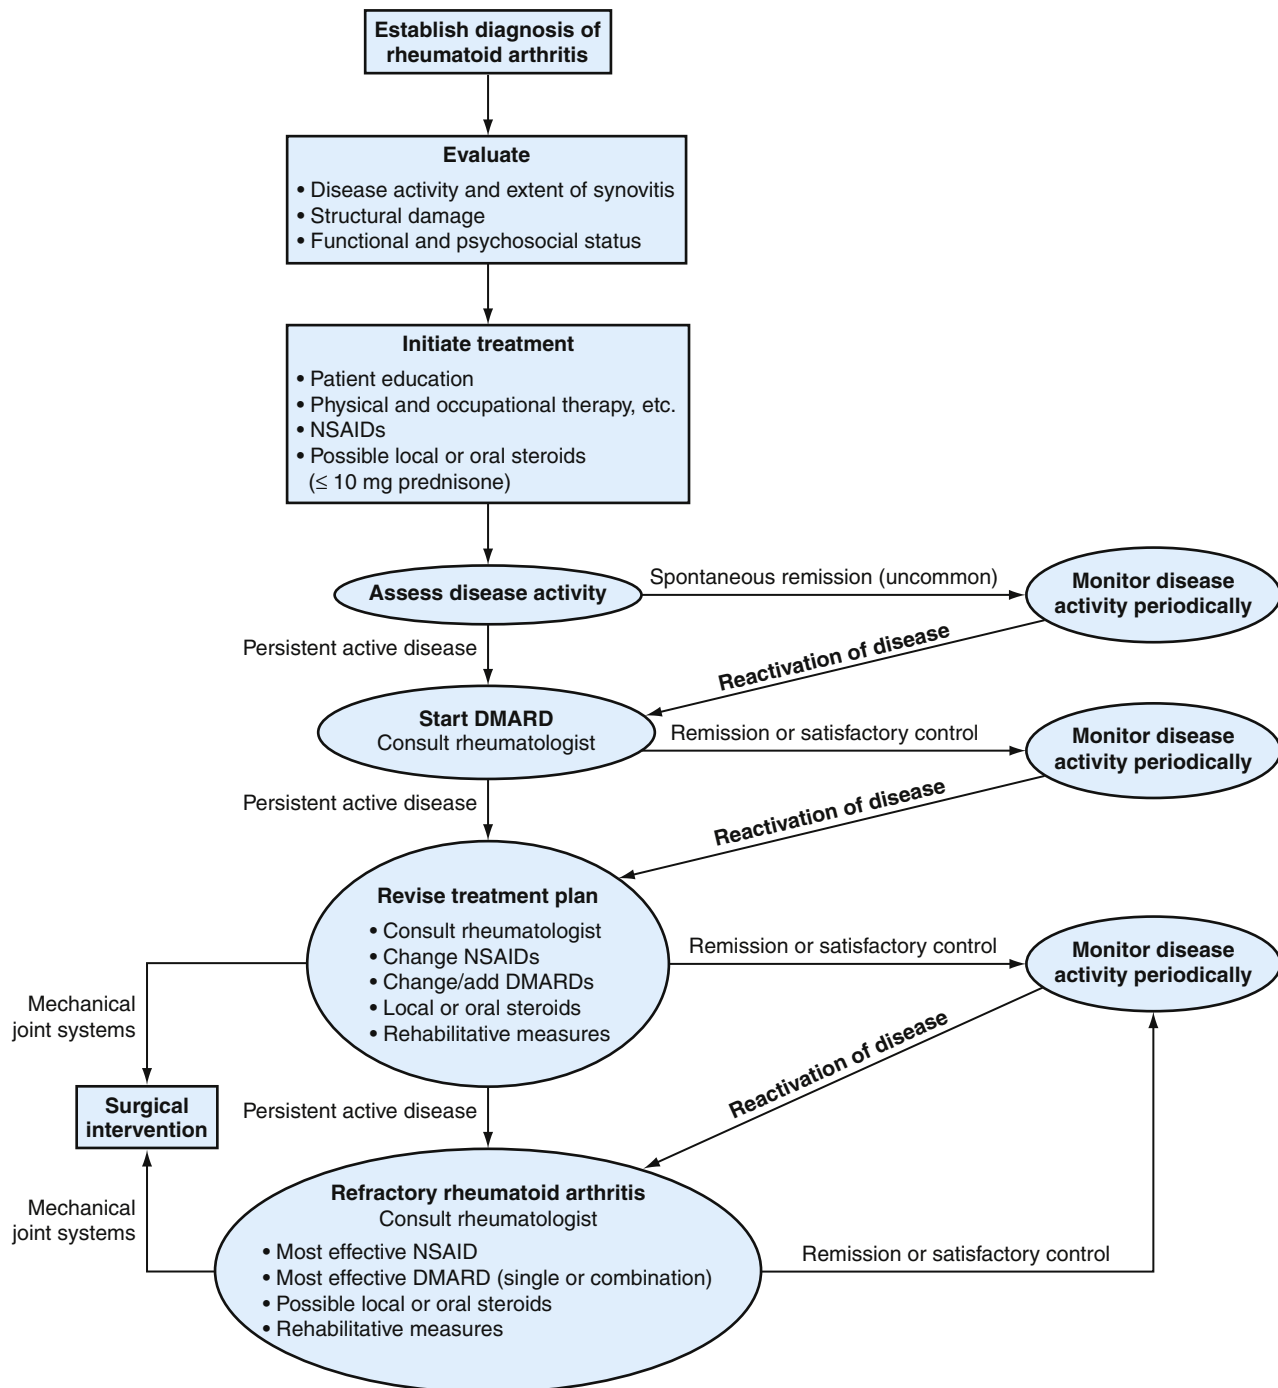

Figure 32-10 Algorithm for management of rheumatoid arthritis. *DMARD*, Disease-modifying antirheumatic drug; *NSAID*, nonsteroidal anti-inflammatory drug. (From American College of Rheumatology Ad Hoc Committee on Clinical Guidelines. Guidelines for the initial evaluation of the adult patient with acute musculoskeletal symptoms. *Arthritis Rheum* 1996;39:1.)

pain control with analgesics should be given and the patient counseled about realistic expectations.

Methotrexate

Many rheumatologists consider methotrexate to be the DMARD of first choice; it is the most frequently used DMARD in the United States. Methotrexate inhibits folic acid synthesis and is the primary choice for moderate to severe RA, showing significant short-term benefit but adverse effects on abrupt withdrawal (Suarez-Almazor et al., 2004a; Ortiz

et al., 2000). Folic acid (1 mg/day) reduces methotrexate-induced mouth sores without decreasing the drug's efficacy. Patients cannot drink alcohol and must have LFTs every 4 to 6 weeks. Increasing the dose up to 25 mg/week and using the subcutaneous or IM route might enhance efficacy. Liver biopsies are no longer recommended during therapy unless abnormal alanine transaminase (ALT) or albumin levels persist (Kremer et al., 1994). Methotrexate toxicities include hepatotoxicity, bone marrow suppression, rare development of B-cell non-Hodgkin's lymphoma, subcutaneous nodules

Table 32-4 Selected Disease-Modifying Antirheumatic Drugs

| Class/Drug (Brand) | Recommended Dosage | Toxic Effects | Recommended Monitoring |
|---------------------------------------|---|--|---|
| Gold Compounds | | | |
| Gold sodium thiomalate (Myochrysine) | IM: 10 mg followed by 25 mg 1 wk later, then 25-50 mg weekly until there is toxicity, major clinical improvement, or cumulative dose of 1 g. If effective, interval between doses is increased. | Pruritus, dermatitis (frequent in one third of patients), stomatitis, nephrotoxicity, blood dyscrasias, "nitritoid" reaction: flushing, weakness, nausea, dizziness 30 min after injection | CBC, platelet count before every other injection U/A before each dose |
| Auranofin (Ridaura) | Oral: 3 mg bid or 6 mg qd; may increase to 3 mg tid after 6 mo | Loose stools, diarrhea (up to 50%), dermatitis | Baseline CBC, platelet count, U/A, renal, liver function at onset, then CBC with platelet count, U/A at 9 mo |
| Antimalarial | | | |
| Hydroxychloroquine (Plaquenil) | Oral: 400-600 mg qd for 4-12 wk, then 200-400 mg qd | Retinopathy, dermatitis, muscle weakness, hypoactive DTRs, CNS | Ophthalmologic examination every 3 mo (visual acuity, slit lamp funduscopic, visual field tests) neuromuscular examination |
| Penicillamine (Cuprimine) | Oral: 125-250 mg qd, then increasing doses by 125-250 mg at monthly intervals to max 750-1000 mg | Pruritus, rash, or mouth ulcers; bone marrow depression; proteinuria, hematuria, hypogeusia myasthenia, myositis, GI distress, pulmonary toxicity, teratogenic | CBC every 2 wk until dose stable, then every month U/A weekly until dose stable, then every 9 mo hCG as needed |
| Methotrexate (Rheumatrex) | Oral: 7.5-20 mg weekly | Pulmonary toxicity, ulcerative stomatitis, leukopenia, thrombocytopenia, GI distress, malaise, fatigue, chills, fever, CNS, elevated LFTs or liver disease, lymphoma, infection | CBC with platelet count LFTs weekly for 6 wk, then monthly U/A periodically hCG as needed |
| Azathioprine (Imuran) | Oral: 50-100 mg qd, increase at 4-wk intervals by 0.5 mg/kg/day, up to 2.5 mg/kg/day | Leukopenia, thrombocytopenia, GI, neoplastic if previous therapy with alkylating agents | CBC with platelet count, weekly for 1 mo, twice monthly for 2 mo, then monthly hCG as needed |
| Sulfasalazine (Azulfidine) | Oral: 500 mg daily, then increase, up to 3 g daily | GI, skin rash, pruritus, blood dyscrasias, oligospermia | CBC, U/A every 2 wk for 3 mo, then monthly for 9 mo, then every 6 mo |
| Alkylating Agents | | | |
| Cyclophosphamide (Cytoxan) | Oral: 50-100 mg daily, up to 2.5 mg/kg/day | Leukopenia, thrombocytopenia, hematuria, GI, alopecia, rash, bladder cancer, non-Hodgkin's lymphoma, infection | CBC with platelet count, regularly hCG as needed |
| Chlorambucil (Leukeran) | Oral: 0.1-0.2 mg/kg/day | Bone marrow suppression, GI, CNS, infection | CBC with platelet count every wk WBC 3-4 days after each CBC during first 3-6 wk at therapy hCG as needed |
| Cyclosporine (Sandimmune) | Oral: 2.5-5 mg/kg/day | Nephrotoxicity, tremor, hirsutism, hypertension, gum hyperplasia. | Renal function, liver function |
| Pyrimidine Synthesis Inhibitor | | | |
| Leflunomide (Arava) | Loading dose: 100 mg/day for 3 days Maintenance therapy: 20 mg/day; if not tolerated, 10 mg/day | Hepatotoxicity, carcinogenesis Immunosuppression, long half-life | LFTs every month, drug levels after discontinuation (after 1-mo therapy, remains in blood for 2 yr without cholestyramine) |

Table 32-4 Selected Disease-Modifying Antirheumatic Drugs — cont'd

| Class/Drug (Brand) | Recommended Dosage | Toxic Effects | Recommended Monitoring |
|---|--|---|---|
| Tumor Necrosis Factor (TNF) Inhibitors | | | |
| Etanercept (Enbrel) | 2-5 mg SC twice weekly or 50 mg SC weekly | Sepsis, opportunistic infections, congestive heart failure, injection site pain | PPD, CBC, ALT at baseline monthly until dose is stable; then every 2-3 mo |
| Infliximab (Remicade) | 5 mg/kg IV on weeks 0, 2, 6; then biweekly | Sepsis, opportunistic infections, reactivation of hepatitis B and TB, pancytopenia | PPD, CBC, ALT at baseline monthly until dose is stable; then every 2-3 mo |
| Adalimumab (Humira) | 40 mg SC every 2 wk | Sepsis, opportunistic infections, reactivation of TB | PPD, CBC, ALT at baseline monthly until dose is stable; then every 2-3 mo |
| Extracorporeal* | | | |
| Staphylococcal protein A immunoadsorption | IV weekly for 12 wk | Hypotension (especially with ACE inhibitor), injection site infection, anemia, flulike symptoms, joint pain | CBC routinely |

*Use only in patients whose disease is refractory to disease-modifying antirheumatic drugs (DMARDs).

ACE, Angiotensin-converting enzyme; ALT, alanine transaminase; *bid*, twice daily; CBC, complete blood count; CNS, central nervous system; DTRs, deep tendon reflexes; GI, gastrointestinal; hCG, human chorionic gonadotropin; IM, intramuscular; IV, intravenously; LFTs, liver function tests; PPD, purified protein derivative; *qd*, once daily; SC, subcutaneously; TB, tuberculosis; *tid*, three times daily; U/A, urinalysis; WBC, white blood cell count.

(treated with colchicine), opportunistic infections, and hypersensitivity pneumonitis (treated with corticosteroids). It can be difficult to withdraw methotrexate once it has been started without causing a disease flare.

Other Disease-Modifying Antirheumatic Drugs

Azathioprine (Imuran) is used for moderate and severe RA as a second- or third-line drug after methotrexate, sulfasalazine, gold, and hydroxychloroquine have been tried. It suppresses bone marrow and can lead to infection. After the initial DMARD therapy, azathioprine can be tried in a 2- to 6-week course. No evidence has demonstrated increased effectiveness over other DMARDs (Suarez-Almazor et al., 2000d).

Cyclosporine (Sandimmune, Neoral) is used in combination with methotrexate and is given as a 2.5-mg/kg dose to prevent hypertension and renal disease. It has shown modest efficacy in short-term treatment with progressive RA (Wells et al., 2000). D-Penicillamine (Depen, Cuprimine) has unpredictable toxicity, making it a less attractive choice. The alkylating agents cyclophosphamide and chlorambucil, as well as cyclosporine, are effective but are reserved for refractory severe cases because of their toxicities. All second-line drugs are teratogenic, so a family physician must help the patient establish an effective means of birth control. The risk of toxic effects is an important factor in choice of these agents, and selection is generally best handled in consultation with the rheumatologist.

Leflunomide (Arava) inhibits pyrimidine synthesis, is given orally, and is considered a possible alternative to methotrexate for decreasing erosion and controlling inflammation, but it provides no apparent benefit over methotrexate and is expensive. Leflunomide has been shown not only to reduce symptoms but also to slow disease progression. The routine dosage is 100 mg daily for 3 days, followed by a maintenance dosage of 10 to 20 mg/day. LFTs must be ordered, and as

with methotrexate, leflunomide is better for short-term therapy (Suarez-Almazor et al., 2000a). Research continues into combining DMARDs to lower drug resistance. DMARD combination therapy in early RA has shown minimal benefit (Mottonen et al., 1999).

Anticytokine Therapy

Cytokines such as interleukin-1, tumor necrosis factor alpha (TNF- α), granulocyte-macrophage colony-stimulating factor, interleukin-6, and chemoattractant cytokines (known as chemokines) are derived from macrophages and fibroblasts and appear to be the most important cytokines involved in RA treatment. TNF- α is produced by synovial macrophages and causes many destructive inflammatory actions in the rheumatoid joint. Synovial macrophages proliferate; synoviocytes (fibroblast-like cells lining the joint) produce prostaglandins and cytokines, continuing the inflammatory process. Administering monoclonal antibodies such as infliximab (Remicade) to bind TNF- α and block its activity and giving TNF- α receptors such as etanercept (Enbrel) are two approaches to decrease TNF activity. Patients with a suboptimal response to methotrexate at 25 mg/wk (maximum dose) are the best candidates for etanercept or infliximab. Before starting any anticytokine therapy, CBC and tuberculin test (PPD) are required.

Etanercept, a recombinant p75 TNF- α receptor-Fc fusion protein, is given subcutaneously once to twice weekly. It decreases binding of TNF- α to cellular receptors and avoids downstream inflammation. It is well tolerated and is indicated for use alone or with methotrexate for methotrexate-refractory disease (Blumenauer et al., 2003; Weinblatt, 1999). The most common side effect is injection site erythema, which must be carefully watched in RA patients with diabetes mellitus. Etanercept has significantly reduced disease activity in a dose-related manner over 6 months, with no laboratory abnormalities noted (Moreland et al., 1999).

Infliximab, an anti-TNF- α monoclonal antibody, is given intravenously for refractory disease every 4 to 8 weeks. It is 75% human and 25% mouse antibody to TNF- α . The primary mechanism is halting joint space narrowing, with subsequent decreased erosion. It is FDA approved only in combination with methotrexate. Again, caution is warranted in diabetic patients for skin ulcers. If the patient has a positive PPD, isoniazid and vitamin B₆ therapy must be given for 9 months with the treatment. Fewer appropriate trials exist for infliximab than etanercept; however, the benefit in refractory disease has been demonstrated (Blumenauer et al., 2004).

Adalimumab (Humira), 40 mg subcutaneously every other week, has a greater therapeutic potential when used with methotrexate (OnMedica, 2005). It is a full human anti-TNF- α . Fewer studies exist on its long-term efficacy, but short-term studies show a greater effect than infliximab or etanercept. Risk factors with this regimen include skin infection, malignancy, and demyelination.

Nonsteroidal Anti-Inflammatory Drugs

The NSAIDs improve inflammation and pain but do not alter disease progression. Therefore, most patients with RA should be taking a DMARD. NSAIDs are used for analgesia and to help control symptoms. DMARDs generally have a slow onset of action, necessitating use of other agents to help keep the patient comfortable while awaiting onset of the DMARD's action. NSAID-associated GI bleeding is a widespread problem; one in three RA patients will be hospitalized or will die from a GI bleed at some point. Selection of NSAID is largely empiric (Table 32-5). The least toxic NSAIDs are coated or buffered aspirin, salsalate (Disalcid, Mono-Gesic, Salflex), and ibuprofen (Advil, Motrin, Nuprin, Rufen). The most toxic are indomethacin (Indocin), tolmetin sodium (Tolectin), meclofenamate sodium (Meclomen), and ketoprofen (Orudis, Oruvail). High-toxicity NSAIDs provide no more clinical benefit than lower-toxicity drugs (Fries et al., 1991).

Misoprostol (Cytotec), a synthetic prostaglandin analogue, helps decrease NSAID-induced risk of gastric and duodenal ulceration. Although 30% to 40% of patients receiving 200 mg of misoprostol four times daily experienced diarrhea, lower doses (100 mg two or three times daily) cause less diarrhea, with most GI protection maintained. PPIs such as omeprazole used with the NSAID are better tolerated than misoprostol and are also efficacious. As mentioned, sucralfate and normal doses of H₂ blockers might help dyspepsia but have not prevented ulcer formation from NSAIDs such as PPIs and misoprostol. Patients receiving long-term nonselective NSAIDs should be monitored several times annually for hematocrit abnormalities and should undergo stool guaiac testing and have renal and liver function evaluated. There is no benefit to combining different NSAIDs.

Aspirin and Salicylates

High-dose aspirin (900-1050 mg four times daily) is as effective as much more expensive NSAIDs but is often less well tolerated and less convenient to take.

Glucocorticoids

Glucocorticoid articular injections are often used for temporary localized suppression of RA but are not recommended for use more than three times per joint per year. Common drugs for injection (used with lidocaine to minimize patient

discomfort) include hydrocortisone, triamcinolone (Kenalog, Aristocort), methylprednisolone (Depo-Medrol), dexamethasone (Decadron-LA), and betamethasone (Celestone Soluspan), in ascending order of duration of action.

Systemic corticosteroids are used primarily as bridge therapy for several months when initiating DMARDs and awaiting their onset. Prednisone might be especially useful for constitutional symptoms such as fatigue and malaise. Low-dose prednisone (<7.5 mg daily) in a single morning dose might particularly be useful in older adult patients when other drugs have more potential for toxicity.

Surgery

Surgery is useful in RA patients with more severe disease who, despite optimal medical treatment, develop joint erosions and severe destruction resulting in pain and limitation of function. Surgical procedures range from carpal tunnel release to synovectomy, joint fusion, and arthroplasty. About 90% of older adult patients with severe incapacitating rheumatoid joint disease can expect excellent pain relief and increased ROM after total hip or knee replacement (Harris and Sledge, 1990).

Other Therapies

On the basis of the theory that persistent mycoplasma infection might cause RA, tetracyclines such as minocycline (Minocin) have been used by some physicians for years. Minocycline, 100 mg orally twice daily, has shown modest efficacy but can lead to dizziness and dosing sensitivity in early RA (O'Dell et al., 2001). A small study showed that use of minocycline (100 mg twice daily) in early RA (first 3 months after diagnosis) resulted in more frequent remissions, and the need for DMARD therapy was reduced after follow-up for 4 years (O'Dell et al., 1999). These antibiotics result in mild improvement in RA patients, and other actions may include inhibition of collagenase activity, direct anti-inflammatory effect, and interference with leukocyte function.

Stress management, cognitive-behavioral pain management techniques, relaxation training, biofeedback, and family-oriented behavior therapy have all been shown to improve daily functioning, pain reports, and disease activity in RA patients (Parker et al., 1995). A small RCT showed a 28% decrease in mean disease severity at 4 months using writing therapy (Smyth et al., 1999). Another study showed that 20% of the disability of RA was related to psychosocial factors (Escalante and del Rincon, 1999). Educating patients about methods to cope with their disease can significantly improve quality of life. Interventions shown to improve outcomes include tai chi (Han et al., 2004) and journaling (Smyth et al., 1999). A meta-analysis of psychological interventions (e.g., biofeedback, relaxation, cognitive-behavioral therapy) found significant effects on pain, disability, functional status, and coping, although these might be more effective for patients with RA of shorter duration (Astin et al., 2002). Experimental therapies include total lymphoid irradiation, interferon gamma (IFN- γ), high-dose prednisolone, and oral collagen. Oral collagen has thus far not been shown to cause statistically significant improvement, but better-designed studies might demonstrate a benefit. The theory is that collagen will induce regulatory T cells to be generated in the gut, which will then migrate to

Table 32-5 Selected NSAIDs Used in Rheumatoid Arthritis and Osteoarthritis

| Class/Drug (Brand) | Usual Dosage Range for Arthritis |
|--|-------------------------------------|
| I. Arylcarboxylic acids | |
| A. Salicylic acids | |
| 1. Acetylated | |
| Aspirin, extended release | 1600 mg bid |
| Aspirin, enteric coated | 1000 mg qid |
| 2. Nonacetylated | |
| Diflunisal (Dolobid) | 250-500 mg bid, max 1500 mg/day |
| Choline-magnesium salicylate | 3 g/day in 1-3 doses |
| Salsalate (Disalcid, Salflex) | 3-4 g/day in 2-3 doses |
| B. Anthranilic acid | |
| 1. Meclofenamate sodium | 200-400 mg/day in 3-4 doses |
| II. Arylalkanoic acids | |
| A, Arylacetic acids | |
| 1. Diclofenac (Voltaren) | 150-225 mg/day in 3-4 divided doses |
| 2. Naproxen (Naprosyn) | 250-500 mg bid-tid |
| 3. Naproxen sodium (Anaprox) | 275-550 mg bid |
| B. Arylpropionic acids | |
| 1. Ibuprofen (Advil, Motrin) | 300-800 mg/tid-qid |
| 2. Ketoprofen (Oruvail) | 100-200 mg daily |
| 3. Fenoprofen (Nalfon) | 300-600 mg tid-qid |
| C. Oxazolepropionic acid | |
| 1. Oxaprozin (Daypro) | 600-1800 mg/day in 1-2 doses |
| D. Heteroarylacetic acid | 600-1800 mg/day in 3-4 doses |
| 1. Tolmetin | |
| E. Indoleacetic and indeneacetic acids | |
| 1. Indomethacin (Indocin, Indocin SR) | 25-50 mg tid-qid 75 mg qd-bid |
| 2. Sulindac (Clinoril) | 150-200 mg bid |
| F. Pyranocarboxylic acid | |
| 1. Etodolac (Lodine) | 300-500 mg bid |
| III. Enolic acids-Oxicam | |
| 1. Piroxicam (Feldene) | 20 mg daily |
| IV. Nonacidic agent | |
| 1. Nabumetone (Relafen) | 1000-2000 mg divided qd-bid |
| 2. Meloxicam (Mobic) | 7.5-15 mg qd |
| V. Cyclooxygenase (COX-2) inhibitor | |
| 1. Celecoxib (Celebrex) | 100-200 mg bid |

NSAID, Nonsteroidal anti-inflammatory drug; qd, once daily; bid, twice daily; tid, three times daily; qid, four times daily.

joints where a protein analogous to the orally dosed antigen resides, resulting in immune tolerance and reduced inflammation (Kalden and Sieper, 1998).

Nutritional changes are hypothesized to decrease RA signs and symptoms. A Cochrane review of herbs found that gamma-linolenic acid (GLA) resulted in some improvement in clinical outcomes (Little and Parsons, 2000; Zurier et al., 1996), consistent with other findings on essential fatty acids. Fish oil, high in omega-3 fatty acids, significantly improved the number of tender joints and morning stiffness (Fortin et al., 1995; Volker et al., 2000); the recommended dose would be 3 g/day, and symptom relief might not be evident until 12 weeks of use. Changes in the total diet have been studied as well. Fasting has anecdotal evidence for inducing remission of symptoms. A 7- to 10-day fast followed by a gluten-free vegan diet was found to sustain improvements (Kjeldsen-Kragh et al., 1991; McDougall et al., 2002). Proceeding immediately to a vegan gluten-free diet resulted in RA symptom improvement (Hafstrom et al., 2001). Symptoms were exacerbated with challenges of foods that patients had reacted to on skin-prick test (Karatay et al., 2004). Therefore, a trial of such a diet or an elimination diet would be reasonable options (Box 32-2).

Monitoring Arthritic Activity

Because RA is a chronic disease with significant psychosocial impact, the continuity that the family physician provides is crucial. Frequency of visits depends on disease activity, need for drug toxicity monitoring, and psychosocial functioning of the patient (see eTable 32-4 online). Periodic ESR/CRP levels, radiography, and functional status assessment are important, in addition to serial joint examination. A team approach using the expertise of a rheumatologist and physical and occupational therapists is generally indicated. Patients' ability to perform their job must be considered, and using modified work profiles or absences may be necessary. Osteoporosis resulting from RA should be monitored and prevented. The patient should also be monitored for infection, pulmonary disease, renal disease, or GI bleeding, taking a general health maintenance approach to this systemic disease.

KEY TREATMENT

The NSAIDs are the preferred treatment for pain in rheumatoid arthritis (SOR: C).

Treatment of RA with DMARDs should be started as soon as possible (SOR: C).

Methotrexate has substantial benefit in the treatment of RA and is generally the first-line DMARD (Suarez-Almazor et al., 2000a) (SOR: A).

Sulfasalazine has proven benefits on RA disease activity (Weinblatt et al., 1999) (SOR: A). However, it should be used as sole therapy only in patients with minor symptoms and no poor prognostic signs of RA.

Hydroxychloroquine has been shown to be effective in treatment of RA (Davis et al., 1991) (SOR: B). However, it is generally used with another DMARD or methotrexate in refractory cases when initial treatment fails. Biologic agents such as etanercept and infliximab reduce RA disease activity and are important treatment options in patients with moderate to severe RA who have failed treatment with methotrexate or combination therapy (Blumenauer et al., 2003; Weinblatt, 1999) (SOR: A).

Box 32-2 Elimination Diet: Patient Handout

Special diets called *elimination diets* are sometimes used to discover whether food allergies or sensitivities are related to symptoms you might be having. The goal of an elimination diet is to identify problem foods. The diet is temporary and must be followed very carefully so that a permanent diet to help you feel better can be planned. The steps in an elimination diet follow:

- 1. Decide which foods might be causing problems.** This step involves describing your diet for your doctor and sharing your ideas about what foods might be causing problems. Sometimes, food allergy tests are used to help with the decision.
- 2. Avoid the foods completely for 2 to 4 weeks.** This is the actual elimination step. This step involves the greatest restrictions in your diet.
 - The foods need to be avoided completely for symptoms to be noticeable when the foods are added back.
 - Foods should be avoided both in their whole form and as ingredients in food.
 - Keeping track of how you feel during this step is important. It is useful to keep a written record. You may feel worse before you feel better, but that should last only 1 or 2 days. If you feel worse for longer, please call your doctor.
- 3. Add the foods back one at a time.** This is called the *challenge step*. It allows you to learn which foods, if any, are causing symptoms.
 - Decide with your doctor which food to add back first.
 - Keep track of how you feel throughout this step with a written record.
 - On the day a food is added, eat that food twice. For the next 2 days, do not eat that food again, but continue to follow the elimination diet. You can have a reaction up to 3 days after a food is eaten.
 - Add a new food every 3 days, because you can have a reaction up to 3 days after the challenge food is eaten.
 - If the food does not cause a reaction, that food “passes” and can be added back to your diet when the entire process is over. Do not eat the foods you have added back, even if they “passed,” until you have tested all the foods.
 - After following the elimination diet carefully, you and your doctor will have a better picture of which foods, if any, are causing your problems. Remember that problems with foods can be intermittent, and it is sometimes difficult to tell exactly whether foods are a problem.

From Rake! D: Integrative Medicine. Philadelphia, Saunders, 2002.

Crystal Arthropathies

Gout and pseudogout are conditions caused by deposition of crystals of urate and calcium pyrophosphate dihydrate, respectively, with a resulting inflammatory response. These conditions can be distinguished from each other and from other causes of an acutely swollen joint or joints by synovial fluid examination, looking for crystals using polarized light microscopy.

Gout

Key Points

- Hyperuricemia is present (usually >8 mg/dL) in patients with gout.
- Gout affects more men than women.
- Negative birefringent crystals are seen on fluid analysis in gout.

Gout primarily affects middle-aged men (40-60 years) and postmenopausal women. It typically manifests as an acutely painful monoarticular arthritis, possibly becoming chronic after years of progressively more severe and frequent episodes, interspersed with variable symptom-free periods. *Hyperuricemia* is a marker for gout, but each can exist without the other. Asymptomatic hyperuricemia is not a disease. The risk of gout, however, is proportional to the degree and duration of hyperuricemia. Multiple genetic and environmental factors affect uric acid concentration. Uric acid is derived from ingestion of a diet rich in purines (e.g., typical American diet), as well as from endogenous production of purines. Inborn errors of metabolism, either reduced excretion (90% of patients) or increased production (10%) of uric acid, cause primary hyperuricemia. Secondary hyperuricemia results from diseases or drug therapies that raise uric acid levels.

In addition to attempting to prevent acute flares, the family physician's goal in treating patients predisposed to gout is to minimize the risk of developing other sequelae. These include interstitial nephropathy with renal function impairment; accumulation of urate crystal deposits in joints, soft tissue, cartilage, and bone, called *tophi*; and uric acid calculi in the genitourinary (GU) tract.

Clinical Presentation

The first MTP joint (great toe) is involved in 50% of initial acute gouty attacks (podagra) and is eventually affected in 75% to 90% of gout patients. This joint sustains more micro-trauma and is relatively cool compared with the rest of the body. The heel, ankle, knee, midtarsal joints, and olecranon bursa can all be initially involved but are so less frequently than the first MTP joint. Gout severity ranges from vague aches and pains to severe pain, swelling, redness, and exquisite tenderness. Acute attacks resolve within several days to weeks, even in untreated gout.

In contrast to the typical middle-aged male presentation, gout in women and in older adult patients tends to be polyarticular. Because gout in these patient subgroups tends to involve more than one joint, it can often be misdiagnosed as RA (tophi are mistaken for rheumatoid nodules) or septic joint cellulitis, especially if low-grade fever, leukocytosis, redness, or desquamation is present. Synovial fluid analysis is necessary for definitive diagnosis.

Synovial Fluid Examination

A presumptive diagnosis of gout can be made by clinical signs and symptoms, a negative joint culture, response to NSAIDs or colchicine, and hyperuricemia. However, definitive diagnosis can be made only by finding needle-shaped, negatively birefringent urate crystals on synovial fluid examination or in tophi.

Clinical Stages of Primary Gout

Hyperuricemia is defined as two standard deviations (2 SD) above the individual laboratory's mean based on gender, usually 8 mg/dL in men and 7 mg/dL in women. Hyperuricemia is present in 5% of men, only 5% to 10% of whom develop acute gout. It normally takes at least 20 years of hyperuricemia before a patient has a first episode of gouty arthritis. Lowering the serum uric acid level does not decrease the risk of gouty nephropathy; chronic renal disease is almost always caused by

(From *Visual Aids*, Subcommittee of the Professional Education Committee of the Arthritis Foundation. *Clinical Slide Collection on the Rheumatic Diseases*. New York, Arthritis Foundation, 1972, p 82.)

concurrent diseases such as diabetes or hypertension. Because of expense and potential drug toxicity, treatment of asymptomatic hyperuricemia is therefore generally not recommended.

The two most important factors in the development of acute gouty arthritis are obesity and alcohol (Choi et al., 2005). Ethanol metabolism blocks renal excretion of uric acid, leading to gouty attacks. Studies have shown a 2.5-fold increase in the risk of gout in men who drink 2 or more beers per day. This risk was similar but slightly lower in men who drank the same amount of distilled alcohols. In contrast, two 4-ounce glasses of wine or more per day was not associated with an increased risk of gout (Choi et al., 2004). Other factors include rapid decrease or increase in serum urate level (thus a possible attack at start of allopurinol treatment), emotional stress, infection, and surgery. Dietary excesses of purine-rich foods (e.g., sweetbreads, sardines, anchovies, kidney, liver) have traditionally been mentioned but are in reality rarely responsible for acute gouty attacks. Diuretics, both hydrochlorothiazide and loop, have been associated with increased serum uric acid. Risks, benefits, and cost must be evaluated before deciding to change or stop these medications for hypertension.

After an initial gouty attack, more than half of patients will have a recurrent attack. The timing is highly variable, however, and the recurrent attack can be weeks or years later. As time passes, gouty attacks tend to become more frequent, more severe, and less responsive to therapy and to involve more joints. Between acute attacks, urate crystals can still be aspirated from asymptomatic joints, demonstrating that this so-called intercritical or interval gout represents a progression of disease. Chronic tophaceous gout occurs at least 10 years into the disease and is now seen infrequently because of more aggressive treatment of gout and hyperuricemia. Tophi can occur anywhere but tend to occur in the helix of the ear, on the proximal ulnar surface of the forearm, on the olecranon, on the Achilles tendon, on the prepatellar bursa, or near active joints. Tophi are not seen on plain radiographs unless they are calcified. The classic radiographic finding of chronic gout is sharply marginated erosions proximal to the joint space, with an overlying rim of cortical bone (Fig. 32-11).

Secondary gout is caused by drugs or disease processes affecting uric acid metabolism or excretion. Myeloproliferative and lymphoproliferative diseases, hemolytic anemia, multiple myeloma, and other malignancies result in

overproduction. Renal disease, diuretics, salicylates, alcohol, nicotinic acid, and chronic lead intoxication (saturnine gout) all cause underexcretion. Chemotherapy for hematologic or myeloproliferative disorders can result in gouty nephropathy unless adequate hydration and possibly allopurinol prophylaxis are initiated before therapy.

Treatment of Gouty Arthritis

The NSAIDs are generally used first because of their efficacy and relative lack of toxicity. Indomethacin (Indocin) has been used for years for gouty arthritis attacks, but any NSAID can probably be used with similar efficacy, as long as an initial maximal dose is given. After 2 days of therapy at the maximal dose, the NSAID can be tapered over the next several weeks.

Colchicine decreases inflammation associated with lactic acid production and phagocytosis of urate; it terminates most gouty attacks within 6 to 12 hours but is limited by GI side effects (nausea, vomiting, abdominal cramps, diarrhea). Two 0.5- or 0.6-mg tablets are taken initially, then 1 tablet every hour, until clinical response has been achieved, GI side effects cause discontinuation, or a total of 6 mg has been given (Cox, 2004). Colchicine at 0.5 to 1 mg every 6 hours intravenously, up to 4 mg total, can also be given for a single attack, but the parenteral route is associated with increased bone marrow suppression, renal and hepatic toxicity, and myopathy. No additional colchicine should be given for at least 1 week if the patient is given the full 4-mg total dose.

When NSAIDs and colchicine are ineffective or contraindicated, corticosteroids might be used. Treatment options include oral corticosteroids using prednisone, 0.5 mg/kg, followed by tapering the dose by 5 mg/day. An intra-articular injection can be given using triamcinolone hexacetonide (Aristospan), triamcinolone acetonide, or methylprednisolone (Medrol); typical doses are 10 to 40 mg in large joints and 5 to 20 mg in small joints. Intra-articular injection is preferred for monoarticular episodes. Finally, adrenocorticotropic hormone (ACTH), 40 to 80 mg intravenously or intramuscularly every 8 to 12 hours, has been successful when all other therapies fail, but it is quite expensive.

Prophylaxis of Recurrent Gout

Asymptomatic hyperuricemia need not be treated, but after one episode of acute gouty arthritis or acute nephrolithiasis, patients should be offered the option of prophylaxis. Some choose not to take a daily drug, particularly if their gouty attacks are not severe or are infrequent. For patients with recurrent gouty attacks, renal damage, nephrolithiasis, or uric acid levels higher than 12 mg/dL, or those undergoing cancer chemotherapy, uric acid-lowering therapy should be initiated. Prophylaxis may be discontinued when uric acid levels are brought down to normal levels for 2 months. Patients should be instructed to avoid alcohol, aspirin, diuretics, prolonged fasting, and high-purine foods. Several days before initiating uric acid-lowering therapy, it is prudent to start colchicine, 0.5 mg twice daily, to avoid precipitating an acute attack. This therapy can continue for up to 6 months after the desired uric acid levels have been obtained.

Allopurinol (Zyloprim) is a xanthine oxidase inhibitor that decreases uric acid production but also produces a more soluble metabolite. Allopurinol is therefore effective regardless of the cause of the hyperuricemia. Allopurinol therapy

should never be initiated until an acute attack has subsided. Allopurinol is started at 100 mg/day with food, then increased at weekly intervals by 100 mg/day until the serum uric acid level is lower than 6 mg/dL. The usual effective dose is 200 to 300 mg/day, although some patients require up to 600 mg/day (Perez-Ruiz et al., 1998). Patients should ensure adequate fluid intake to produce more than 2 L of urine output daily. The dose needs to be adjusted for decreased creatinine clearance. If an acute attack occurs when the patient is taking allopurinol, the dose should be maintained and the attack treated as usual (NSAIDs, colchicine, corticosteroids). Allopurinol can cause rash, liver transaminase level elevations, and renal toxicity if used with thiazide diuretics. It might also potentiate the effect of anticoagulants and cause a rash if used with amoxicillin.

The uricosuric drugs probenecid and sulfinpyrazone (Anturane) block renal tubular reabsorption of uric acid. Probenecid is started at 250 mg twice daily for 1 week, then increased to 500 mg twice daily, and then increased by 500 mg/week, up to 3 g/day, until the urate level is normal. Sulfinpyrazone is started at 100 mg twice daily, increasing to 400 mg twice daily. These drugs should also never be started during an acute attack but should be maintained if the patient is already taking them. Urate stone formation risk can be minimized by a high fluid intake and alkalinization of the urine. A 24-hour urine sample for determination of creatinine clearance and uric acid level should be obtained before starting these drugs, because GFR must be higher than 50 mL/min and uric acid excretion less than 800 mg/24 hr.

KEY TREATMENT

Patients with gout who are overweight should be instructed on weight loss (Choi et al., 2005) (SOR: B).
 Patients with gout should limit intake of beer and distilled alcohol (Choi et al., 2005) (SOR: B).
 Colchicine is an effective treatment for acute gout but should be used as second-line therapy when NSAIDs or corticosteroids are ineffective (SOR: C).
 Allopurinol should be started for prophylaxis in patients with frequent severe attacks, nephrolithiasis, or gouty tophi (Perez-Ruiz et al., 1998) (SOR: B).
 Antihyperuricemic therapy should be titrated to a dose that results in a serum urate level less than 6 mg/dL (slowly, <0.6 mg/dL/mo) (SOR: C).
 Before starting allopurinol, colchicine prophylaxis can be used for up to 6 months after desired uric acid level is reached, to prevent acute attacks (SOR: C).

Pseudogout

Key Points

- Knees are the most common source of pain in pseudogout (CPDD).
- Genetic factors are present in calcium pyrophosphate deposition disease.
- Positive birefringent crystals are seen on fluid analysis in CPPD disease.
- Radiographic appearance of CPDD is punctate or linear densities in cartilage.

Figure 32-12 Chondrocalcinosis in calcium pyrophosphate deposition disease. **A**, Anteroposterior radiograph of knee. **B**, Lateral radiograph of knee. **C**, Anteroposterior radiograph of wrist. **D**, Radiograph of pelvis. (From Reginato AJ, Reginato AM. *Diseases associated with deposition of calcium pyrophosphate or hydroxyapatite*. In Kelley WN Harris ED, Ruddy S, et al [eds]. *Textbook of Rheumatology*, 5th ed, vol 2. Philadelphia, Saunders, 1997, pp 1352-1367.)

Calcium pyrophosphate deposition disease (CPDD) is known as pseudogout because of the acute goutlike attacks that CPPD crystals can cause. *Chondrocalcinosis* refers to radiographically detectable densities in cartilage and joint inflammation caused by these calcium-containing crystals. Calcium pyrophosphate (CP) crystals can be deposited not only on articular cartilage but also in ligaments, tendons, soft tissues, and synovium.

This arthritis is caused by genetic factors (autosomal dominant inheritance pattern) secondary to trauma and various metabolic diseases or is sporadic or idiopathic. CPDD is most often associated with aging, and about 4% of the adult U.S. population has articular CP crystal deposits at death (Agudelo and Wise, 2000). CPPD disease can be associated with hyperparathyroidism, hypothyroidism, hypomagnesemia, hypophosphatemia, hemochromatosis, and amyloidosis. Therefore, newly diagnosed CPDD should be followed up with serum measurements of calcium, magnesium, phosphorus, thyroid-stimulating hormone (TSH), ferritin, transferrin, serum iron, and alkaline phosphatase (ALP) levels.

The most common site is the knee, although the first MTP joint is also often affected, resulting in difficulty differentiating CPDD from gout. Any joint can be affected, however. Synovial fluid examination for rhomboid or rod-shaped, weakly positively birefringent crystals is diagnostic. Analysis needs to be done promptly after aspiration because identification of crystal diminishes over time. The crystals are also smaller and more difficult to detect, so careful preparation

of the slide to avoid false-positive results must be taken. Pseudogout can also cause pseudo-RA. CPDD can be misdiagnosed as RA because of its often multiple joint involvement with symmetric distribution, morning stiffness, and elevated ESR, and because 10% of CPDD patients have positive RF tests. CPDD might also be confused with OA because of its knee and hip involvement, but it also often affects the wrists, MCP joints, elbows, and shoulders. An acute attack of CPDD can cause low-grade fever, leukocytosis ($12,000$ – $15,000/\text{mm}^3$), and elevated ESR. The typical radiographic appearance of CPDD is punctate or linear densities in cartilage (chondrocalcinosis) (Fig. 32-12). Definitive diagnosis relies on either the typical radiographic signs or synovial fluid confirmation.

Treatment of acute pseudogout consists of removal of the crystals through joint aspiration, use of NSAIDs or colchicine during the acute inflammatory period, intra-articular joint injection with a glucocorticoid when possible, and a limited period of joint immobilization. No solid data support removal of crystals and prevention of crystal deposition, which are done only for diagnostic purposes and pain relief. If only one or two joints are involved, intra-articular injections may give the most symptomatic relief; if more joints are involved, a NSAID or colchicine is a better option. Because of severe pain associated with acute events, limited weight bearing may be needed for a short period while symptoms improve.

For patients with recurrent episodes of pseudogout, prophylaxis with colchicine, 0.6 mg twice daily, should be considered.

In 10 patients with recurrent attacks, colchicine was associated with a marked decrease in the number of episodes (10) in 1 year compared with the previous year (32 episodes) (Alvarellos and Spilberg, 1986).

KEY TREATMENT

Aspiration of knee joint for symptomatic relief and diagnosis of pseudogout (CPDD) (SOR: C).
 The patient with CPDD receives intra-articular injection of glucocorticoid if septic joint has been ruled out and less than two joints are involved (SOR: C).
 A NSAID or colchicine is prescribed for acute pain of pseudogout (SOR: C).
 For recurrent pseudogout attacks, colchicine can be used for prophylaxis to decrease number of episodes (Alvarellos and Spilberg, 1986) (SOR: B).

Spondyloarthropathies

The spondyloarthropathies are a group of multisystem inflammatory disorders that affect predominantly the spine but also other joints and extra-articular tissues. Most are linked to the HLA-B27 gene, but HLA-B27 by itself does not explain the development of these diseases; pathogenesis of these conditions is still unknown. They include ankylosing spondylitis, reactive arthritis (Reiter's syndrome), psoriatic arthropathy, enteropathic arthropathy, juvenile-onset arthropathy, and undifferentiated spondyloarthropathy. Both genetic and environmental factors probably contribute to the onset and progression of these diseases. Most people with HLA-B27 do not develop these diseases, and these diseases occur in the absence of HLA-B27.

Ankylosing Spondylitis

Key Points

- Back pain and progressive stiffness are primary symptoms of this chronic inflammatory disease of axial skeleton.
- The male predominance for ankylosing spondylitis is 5:1.
- Clinical history, physical exam, and radiologic findings are key to AS diagnosis.

Primary or uncomplicated ankylosing spondylitis (AS) is a systemic inflammatory disorder predominantly affecting the sacroiliac joints and the spine. Patients with secondary AS have inflammatory bowel disease (IBD), psoriasis, or Reiter's syndrome in addition to their arthropathy. Hip and shoulder joints may also be involved in AS. Inflammation occurs at the intervertebral disk's annulus fibrosus-vertebral bone margin. This area is replaced by fibrocartilage and then ossified. Progression of this process results in the classic vertebral fusion known as *bamboo spine*; this ankylosis is a very late finding. Inflammation also occurs at the sites of ligament and tendon attachments (enthesitis) in the spine and pelvis, which become ossified.

Ankylosing spondylitis usually affects men (male/female ratio 5:1) in their 20s and 30s. It often manifests as vague, somewhat diffuse low back pain, felt generally in the buttocks or sacroiliac area but often in the lumbar area. Pain

becomes more persistent and bilateral. Back stiffness after inactivity, such as on awakening, becomes more predominant and is relieved by activity or a hot shower. AS can also disturb sleep, leading to complaints of fatigue, and can be associated with systemic symptoms such as malaise, low-grade fever, and weight loss. Symptoms can be subtle, but AS should be considered if back stiffness or discomfort persists, is relieved by exercise, and occurs in a man younger than 40 years. In juvenile-onset AS, hip and shoulder symptoms might predominate first, whereas in adult AS the back is usually the first affected area. Disease progression is highly variable and can be mild and self-limited or can cause disability.

The two most common techniques to detect AS are palpation of the sacroiliac joints and assessment for spinal mobility. Decreased mobility early on is usually caused by pain and muscle spasm rather than by ankylosis. Flexion, hyperextension, axial rotation, and forward flexion should be assessed. Over time, the spine becomes increasingly stiff at an unpredictable rate, and stiffness might or might not eventually involve the entire spine.

Other extra-articular manifestations of AS include acute uveitis (iritis), aortitis, and neurologic complications resulting from cervical spine fractures from even minor trauma. Diaphragmatic breathing and limited chest excursion can be seen as a result of costovertebral involvement. The earliest radiographic abnormality can usually be seen in the sacroiliac joints, with sacroiliitis progressing to bony erosions and sclerosis (Figs. 32-13 and 32-14). These changes might also be seen at the sites of ligamentous attachments to bones. Bone scans, computed tomography (CT), and MRI should be used only if plain radiography does not confirm clinical suspicion of AS.

From 70% to 80% of AS patients report substantial relief of their symptoms with NSAIDs, the mainstay of AS therapy (Song et al., 2008). Continuous NSAID use may decrease radiographic progression of the disease (Ward, 2005). However, the benefits must be weighed against the risks associated with prolonged NSAID use. Corticosteroids have not been shown to be helpful. Physical therapy focusing on strengthening of back extensor muscles might improve functional status and, at the very least, help maintain an erect position if spinal ossification occurs (Dagfinrud et al., 2004). Patients should be encouraged to walk erectly and to keep the spine erect as much as possible, sleep on a firm mattress with the spine extended, and swim for exercise. Splints and braces do not help.

A home exercise program is better than no intervention for AS patients, and supervised group exercise is better than home exercise. Combined inpatient spa treatment and exercise (group physical exercises, walking, correction therapy, hydrotherapy, sports, sauna), followed by supervised outpatient weekly group physiotherapy, is better than weekly physiotherapy alone (Dagfinrud et al., 2004).

Second-line drug therapies include etanercept, sulfasalazine, and methotrexate, as well as topical or oral steroids for associated uveitis, in consultation with an ophthalmologist. Second-line drugs, however, have shown no clear effect on the progression of decreased spinal mobility (Dagfinrud et al., 2004). A meta-analysis indicated that all three of the anti-TNF agents were similar in efficacy for patients with AS, and that 80% of patients responded to treatment, with improved

Figure 32-13 Ankylosing spondylitis. **A**, Bone erosion of dorsal aspect of thoracic spine. **B**, Classic appearance of bamboo spine. (From Resnick D, Yu JS, Sartoris D: *Imaging*. In Kelley WN Harris ED, Ruddy S, et al [eds]. *Textbook of Rheumatology*, 5th ed, vol 1. Philadelphia, Saunders, 1997, pp 626-686.)

global, pain, and functional assessment and reduced inflammation, based on morning stiffness (MacLeod et al., 2007). Sulfasalazine in general is only used for peripheral AS. Methotrexate, sulfasalazine, and leflunomide are ineffective for axial disease of AS.

KEY TREATMENT

NSAIDs are the recommended initial therapy for ankylosing spondylitis (Song et al., 2008) (SOR: A).
 Patients with AS should initiate an exercise program (Dagfinrud et al., 2004) (SOR: B).
 Systemic glucocorticoids are not recommended for AS therapy (SOR: C).
 For AS patients with axial disease who do not respond to NSAIDs, anti-TNF therapy is recommended (MacLeod et al., 2007) (SOR: A).

Reactive Arthritis (Reiter's Syndrome)

Key Points

- Signs and symptoms of reactive arthritis develop within 1 month after a genitourinary or gastrointestinal infection.
- *Chlamydia* infection or common enteric bacterial infections are the primary cause of Reiter's syndrome.
- Only one third of patients with reactive arthritis will present with the classic triad of urethritis, conjunctivitis, and arthritis.

Reactive arthritis, or Reiter's syndrome, is characterized by asymmetric oligoarticular arthritis with other extra-articular manifestations within 1 month of GU or GI tract

Figure 32-14 Ankylosing spondylitis. Arrows indicate sacroiliitis progressing to bony erosions and sclerosis. (From Resnick D, Yu JS, Sartoris D. *Imaging*. In Kelley WN Harris ED, Ruddy S, et al [eds]. *Textbook of Rheumatology*, 5th ed, vol 1. Philadelphia, Saunders, 1997, pp 626-686.)

(and possibly pulmonary) infection. The arthritis often occurs after the urethritis, uveitis, or gastroenteritis has resolved. The classic triad of nongonococcal urethritis, conjunctivitis, and arthritis is fully present clinically in only one third of patients.

Reactive arthritis occurs secondary to *Chlamydia trachomatis* and possibly *Ureaplasma urealyticum* urethritis. Urethritis is sometimes asymptomatic or, in male patients, might manifest not with a mucopurulent discharge but rather with gross hematuria secondary to a hemorrhagic cystitis. *Neisseria gonorrhoeae* infection does not cause reactive arthritis, but a septic joint, including that from gonococcal infection, must be ruled out. GI infections caused by *Shigella*, *Salmonella*, *Campylobacter*, *Klebsiella*, *Clostridium*, or *Yersinia* can all lead to reactive arthritis. By the time the gastroenteritis has resolved and arthritis has developed, the inciting bacterial agent cannot be cultured from the stool. Pulmonary infections with *Chlamydia pneumoniae* might also cause the disease (Braun et al., 1994). Conjunctivitis occurs at the same time or several days after the arthritis, if it occurs at all. The relationship between Reiter's syndrome and HIV infection is most likely caused by HIV's association with *Chlamydia* and enteric bacterial infections rather than by HIV itself. Two thirds of patients with reactive arthritis are HLA-B27 positive, indicating genetic factors as well as infectious causes.

Reactive arthritis usually affects several joints, most often in the lower extremity (knees, ankles, feet). Common sites are entheses (where ligaments attach to bones), in particular the Achilles tendon attachment, which causes heel pain. Extra-articular manifestations of reactive arthritis include oral ulcers, aortitis, keratoderma blennorrhagicum (a papulosquamous skin rash occurring most commonly on the palms and soles), and balanitis circinata.

Reactive arthritis usually resolves within 1 year. Although there is no cure, the underlying illness should be treated. When *Chlamydia* is suspected, patients might be given doxycycline or an analogue for up to 3 months, but the optimal duration of therapy is unknown (Mandell et al., 2004). Antibiotics might limit recurrences as well as shorten the course after an episode of urethritis; however, antibiotic use following enteric infections has not been shown to affect the course of reactive arthritis. Reactive arthritis is treated with NSAIDs or intra-articular corticosteroid injections acutely and subsequently with sulfasalazine, 1 g two or three times daily, or methotrexate, 7.5 to 25 mg weekly. No specific studies using anti-TNF therapy have been done, but antidotal research indicates it may be helpful. Long-term disability is uncommon but is usually caused by chronic foot or heel pain or vision problems.

KEY TREATMENT

NSAIDs are the mainstay of treatment for symptomatic reactive arthritis but do not alter or shorten its course (SOR: C).
 Intra-articular injections can be helpful and are not contraindicated in Reiter's syndrome (SOR: C).
 When there is unsatisfactory response to NSAIDs or steroid injections, a trial of sulfasalazine is suggested for patients with reactive arthritis (SOR: C).
 For patients with contraindications or intolerance to sulfasalazine, a trial of etanercept can be attempted (SOR: C).

Psoriatic Arthritis

Key Points

- Psoriatic arthritis affects 5% to 7% of psoriasis patients.
- Arthritis can occur before or after psoriatic lesions.
- Obtaining family history for psoriasis is important in those without current diagnosis and active psoriatic lesions.

Psoriatic arthritis is seen in approximately 5% to 7% of psoriasis patients, but it might affect up to 40% of hospitalized patients with extensive psoriatic lesions (Cuellar et al., 1994). The associated inflammatory peripheral arthritis might be monoarticular, asymmetric oligoarticular, or symmetric polyarticular, resembling RA. RF is usually absent. Psoriatic arthritis is associated with multiple HLA genes; environmental factors such as infections and physical trauma likely are also involved.

Psoriatic skin lesions predate arthritis in 70% of patients, occur with arthritis in 15%, and follow arthritis in 15%. Family history of psoriasis is therefore important for diagnosis in patients with an arthritis similar to psoriatic but without a known history. Psoriatic arthritis often manifests initially as an asymmetric monoarticular or oligoarticular arthritis of a large joint, such as a knee, evolving into asymmetric polyarticular arthritis. The distribution of involvement of psoriatic arthritis might resemble RA but involves the DIP joints more often, as well as causing enthesitis. Psoriatic arthritis might also cause spondylitis, sacroiliitis, chest wall pain from enthesitis, arthritis mutilans (destruction of phalanges and metacarpals, causing telescoping of fingers), conjunctivitis, and Achilles tendon and plantar fascia involvement. Radiographic abnormalities include marginal erosions at DIP and PIP joints, with new bone formation.

In addition to treating the psoriatic skin lesions, the arthritis is treated first with NSAIDs, followed by DMARDs for widespread disease and corticosteroid injections if only one or two joints are involved (Cuellar et al., 1994). A Cochrane analysis showed that high-dose methotrexate and sulfasalazine have efficacy in psoriatic arthritis (Jones et al., 2000). Azathioprine, etretinate, low-dose methotrexate, and colchicines all had some effectiveness versus placebo, but more studies are necessary. Anti-TNF medications are also used if patients continue to have symptoms despite DMARD treatment or if axial disease is present and NSAIDs have not worked. A meta-analysis of RCTs showed that anti-TNF drugs are effective against psoriatic arthritis (Saad et al., 2008). When contemplating local steroid joint injection the physician should keep in mind that bacterial colonization of psoriatic skin lesions with streptococcus or staphylococcus is common. Injecting through skin lesions should therefore be avoided.

KEY TREATMENT

NSAIDs are the first line of treatment for psoriatic arthritis (Cuellar et al., 1994) (SOR: B).
 Methotrexate and sulfasalazine have proven efficacy in the treatment of psoriatic arthritis (Jones et al., 2000) (SOR: B); used as second-line agents if inadequate response to NSAIDs.
 Patients with axial disease or who have peripheral disease without improvement to DMARD treatments are candidates for anti-TNF medications, which have proven efficacy (Saad et al., 2008) (SOR: A).

Enteropathic Arthropathy

There seems to be a connection between the gut and spondyloarthropathies. Of patients with inflammatory bowel disease (IBD; ulcerative colitis and Crohn's disease), 10% to 20% have a peripheral arthritis different from other defined arthritides. Migratory arthralgias, especially of the knees, ankles, and feet, often coincide with periods of GI disease flares. Other joints, including the spine and sacroiliac joints, might be involved but are seemingly less coincident with bowel exacerbations. HLA-B27 is found in 50% of patients with IBD-associated spondylitis but is not found in a higher percentage than in the general population for this type of spondylitis. RF and ANA are negative. NSAIDs are normally used but must be taken with caution given the patient's underlying GI disease. As noted earlier, dietary factors might increase the patient's baseline inflammatory state, so a trial of dietary manipulation or the addition of omega-3 fatty acids is reasonable.

Infectious Arthritis

Septic Arthritis

Key Points

- The knee is the most common source of infectious arthritic pain.
- Septic arthritis is a surgical emergency.
- *Staphylococcus aureus* and *Neisseria gonorrhoeae* are the two most common causes.

Acute bacterial arthritis is one of the few rheumatologic emergencies. Failure by the primary care physician to diagnose this entity and to initiate prompt antibiotic therapy results in significant morbidity (functional disability, joint destruction) and at least 5% mortality. Even in patients with known rheumatologic disease, a bacterial infection may cause an acutely inflamed joint. The three mechanisms of a septic joint are (1) hematogenous spread from a distant location, such as a urinary tract infection (UTI) or pneumonia; (2) contiguous spread from a wound infection, abscess, or osteomyelitis; and (3) direct introduction of bacteria through trauma, surgery, or arthrocentesis. Concern about the third mechanism should not prevent the family physician from ruling out bacterial infection by performing synovial fluid analysis in an inflamed joint if the diagnosis is unclear. As for lumbar puncture, if the physician thinks it should, arthrocentesis probably should be done.

From 80% to 90% of acute bacterial articular infections are monoarticular. In adults with nongonococcal bacterial arthritis, the most common sites are the knee (50%), hip (20%), shoulders (8%), ankles (7%), wrists (7%), elbow (6%), other (5%), and more than one joint (usually two; 12%) (Brusch, 2005). In children, the most common sites are the knee (40%), hip (28%), ankle (14%), shoulder (4%), wrist (3%), elbow (11%), other (3%), and more than one joint (7%) (Baker and Schumacher, 1993). About 20% of patients are afebrile. Septic joints are normally painful, swollen, red, and warm. Diabetes mellitus, malignancy, chronic liver disease, and other rheumatic diseases (e.g., RA, SLE) increase the risk of a septic joint and probably its severity. Other risk factors for a septic joint include advanced age, intravenous

drug abuse, HIV infection, and having a prosthetic joint. Almost half of adults with septic arthritis are older than 60 years, and the condition usually affects an arthritic hip, knee, or shoulder. Septic arthritis in older adults causes a fever in only 10% of patients and a marked leukocytosis in only one third, although ESR elevation is usually marked. Joint and blood cultures are usually positive.

Most polyarticular disease is seen in immunosuppressed patients or those with underlying rheumatic disease. The causative organism is usually *Staphylococcus aureus*. The mortality rate in patients with polyarticular septic joints approaches 40% (Youssef and York, 1994).

Most cases of septic arthritis are secondary to hematogenous spread of infection. In drug abusers, the causative organism is usually *S. aureus* or gram-negative organisms and affects predominantly the joints of the axial skeleton (hip, shoulder, vertebrae, symphysis pubis, costochondral, sternoclavicular, sacroiliac). Iatrogenic septic arthritis is usually caused by *S. aureus*, *Staphylococcus epidermidis*, and gram-negative organisms. This complication might be difficult to recognize because the joint is already symptomatic (which prompted the arthroscopy or arthrocentesis) before infection. Bacterial infection after arthroscopy is 0.04% to 4% and after arthrocentesis, 0.01%. Septic arthritis complicating RA is polyarticular in 50% of patients, usually caused by *S. aureus*, and arises from pulmonary or UTIs, infected rheumatoid nodules, or foot infections. Prosthetic infections are from direct inoculation or hematogenous spread; the prosthesis often must be removed.

Septic arthritis in children normally involves the lower extremities (knee, hip, and ankle). An infant or child with a septic joint often presents with not moving the infected joint and being generally irritable. Septic arthritis can complicate otitis media, an umbilical catheter, meningitis, or osteomyelitis. *S. aureus* and group B streptococci are the most common organisms in infants and children, except ages 6 months to 2 years, when *Haemophilus influenzae* and *Kingella kingae* organisms predominate. *H. influenzae* septic arthritis is seen especially in partially immunized children.

The most common form of acute bacterial arthritis is disseminated gonococcal infection, which causes a migratory polyarthritis and tenosynovitis, affecting predominantly the small joints of the hands, wrists, elbow, ankles, and knees. Papules and vesicles are often apparent on the trunk and extremities, including the palms and soles. Patients usually do not have symptoms of urethritis, cervicitis, or pharyngitis. If gonococcal arthritis is suspected, empiric treatment should be initiated immediately while culture results are pending. *Neisseria meningitidis* can cause a similar arthritis-rash syndrome following an illness, ranging from a mild upper respiratory infection to a frank meningitis. In contrast to gonococcal infections, the meningococcus might cause oral mucosal lesions as well as skin lesions.

Acute gonococcal arthritis can be confirmed by Gram stain in only 25% of patients and by culture in 50%; nongonococcal bacterial arthritis can be confirmed in 50% and 90% of patients, respectively. It is therefore important to make a clinical diagnosis rather than rely solely on laboratory studies. Fever is often absent or of low grade. Blood cultures are also positive only approximately half the time but might be positive when synovial fluid cultures fail to identify an organism. Synovial fluid analysis usually shows WBC count over 50,000/mm³, with over 90% PMNs. Crystals can coexist

with bacterial infections, and their presence should not rule out bacterial infection. Plain radiography might detect an osteomyelitis and should be done as a baseline study, because destruction can be seen on radiographs 10 to 14 days later. Air in the joint suggests an anaerobic infection, which accounts for 1% of septic joints.

The duration of appropriate intravenous (IV) antibiotic treatment depends on the presumptive or culture-identified causative organism. Initial therapy depends on the Gram stain result from synovial fluid. If gram-positive cocci are seen, IV vancomycin should be started empirically. If gram-negative bacilli are seen, a third-generation IV cephalosporin should be initiated. If Gram stain is negative, IV vancomycin should be considered. Once sensitivity data return, antibiotic therapy can be narrowed appropriately. Duration varies, but often the patient will receive 2 weeks of IV therapy followed by 2 weeks of oral therapy. Intra-articular antibiotic injections are unnecessary. A joint might need repeated needle aspirations or tidal lavage with arthroscopy to sterilize the joint space (Klippel, 2001).

KEY TREATMENT

Empiric treatment of infectious arthritis with appropriate IV antibiotics is based on Gram stain results; joint and blood culture sensitivities narrow the antibiotic regimen (SOR: C). Joints may need drainage in patients with septic arthritis (SOR: C).

Viral Arthritis

See the discussion online at www.expertconsult.com.

Lyme Arthritis

Key Points

- *Borrelia burgdorferi* is the most common source of Lyme disease.
- Lyme titer is diagnostic but might have a high false-negative ratio.
- False-positive titers can be caused by RA or lupus.
- About 80% of Lyme disease patients have classic erythema migrans rash.

Lyme disease is caused by the *Ixodes* tick-borne spirochete *Borrelia burgdorferi* and was first described in 1975 after an apparent outbreak of juvenile RA in Lyme, Connecticut. The characteristic target rash of erythema migrans (EM) develops within 1 month (mean 1 week) of a tick bite and can be complicated by CNS disease (meningitis, neuritis), cardiac disease (atrioventricular conduction blocks), and arthritis. It occurs most often in northeastern states (New York, Connecticut, Massachusetts, New Jersey, Rhode Island, Pennsylvania) and upper midwestern states (Wisconsin, Minnesota). As with other rheumatologic diseases, Lyme disease is a clinical diagnosis, with laboratory tests used only to clarify the diagnosis.

Although most patients with Lyme disease do not recall an actual tick bite, most (80%) manifest the EM rash, which might be confluent or have central clearing or darkening. This rash may enlarge quickly and may be accompanied by arthralgia, myalgia, fatigue, fever, and chills. Weeks to

months after the EM rash, neurologic involvement can occur. A facial nerve palsy is common, although most facial nerve palsies are not caused by Lyme disease, even in endemic areas. As with neurologic signs, carditis might be the first presenting symptom, often manifesting as a first-, second-, or third-degree atrioventricular block or bundle branch block. Cardiac symptoms normally do not occur for 1 to 2 months after onset of symptoms.

Arthritis can occur in approximately half of untreated Lyme patients but is rare in treated patients. Rheumatic symptoms occurring late in the clinical course include polyarthralgias, a migratory polyarthritis, or an oligoarticular arthritis with few systemic symptoms. In those untreated patients developing an arthritis, some develop a chronic arthritis resistant to antibiotics.

Laboratory Studies

The current recommended approach is a two-tier strategy using a sensitive enzyme-linked immunosorbent assay (ELISA) and, if positive, Western blot. ELISA is associated with a high false-positive rate, so all positive results must be confirmed with a positive Western blot. Western blot can test for both immunoglobulin M (IgM) and IgG antibodies to *B. burgdorferi*. IgM antibodies typically appear within 1 to 2 weeks and IgG in 2 to 6 weeks, after onset of EM rash. Only one third of patients with a single lesion of EM are seropositive at diagnosis (Verdon and Sigal, 1997). The presence of EM is itself enough to make the clinical diagnosis, and testing is not required. Negative serology in a suspected case should be followed by acute- and convalescent-phase samples (2-4 weeks after initial sample). False-positive ELISA test results can occur in RA, juvenile rheumatoid arthritis (JRA), SLE, and infectious mononucleosis. Serologic testing after treatment is not helpful because seroreactivity persists long after successful treatment.

Treatment

Treatment of early Lyme disease in adults includes doxycycline, 100 mg twice daily, or amoxicillin, 500 mg three times daily, for 21 days. Amoxicillin is first-line therapy in children less than 8 years old; cefuroxime axetil or erythromycin is used in cases of doxycycline or amoxicillin allergy (Worsmer et al., 2006). Oral therapy is as effective as IV therapy for patients with either early Lyme disease or Lyme arthritis and is less costly (Eckman et al., 1997). Concern about the risk of late neurologic sequelae should not lead to more aggressive treatment with IV antibiotics for these patients (Wormser et al., 2000). Early treatment prevents recurrent arthritis as well as neurologic and cardiac sequelae. IV therapy with ceftriaxone (Rocephin), cefotaxime (Claforan), or penicillin G is used for early disseminated and late Lyme disease. IV antibiotic therapy is preferable for patients with neurologic symptoms, with the possible exception of those with facial palsy alone (Steere, 1989). Most patients are symptomatically better with 20 days of treatment. Continued symptomatology in patients with treated infection does not respond to further antibiotics (Klippel, 2001). Antibiotic treatment failures can occur but are rare and usually associated with poor absorption. Antibiotic resistance to typically used agents has not been shown.

For preventive measures against Lyme disease, see the online discussion at www.expertconsult.com.

KEY TREATMENT

Adults and children 8 years and older should be treated with oral doxycycline for 21 days for early Lyme disease (Worsmer et al., 2006) (SOR: A).

Pregnant women and children younger than 8 years should be treated with oral amoxicillin or cefuroxime (SOR: C).

Patients with neurologic (excluding isolated facial nerve palsy) or cardiac manifestation are treated with IV antibiotic therapy for Lyme disease (Wormser et al., 2000) (SOR: B).

Other Infectious Arthritides

Although mycobacteria, parasites, and fungi rarely cause arthritis, incidence has increased with increasing numbers of HIV/AIDS and other immunosuppressed patients. *Mycobacterium tuberculosis* arthritis occurs by hematogenous spread from the lung and is diagnosed by synovial fluid culture. The classic tuberculosis infection involves the spine and is known as Pott's disease. Thoracic vertebrae are most often involved, but a monoarticular arthritis can also occur in large, weight-bearing joints. Mild arthritides might also be caused by *Giardia lamblia* infection, histoplasmosis, cryptococcosis, blastomycosis, sporotrichosis, coccidioidomycosis, actinomycetes, and atypical mycobacteria.

Rheumatic Fever

Key Points

- Rheumatic fever is seen 2 to 4 weeks after beta-hemolytic streptococcal pharyngitis.
- Antibiotic treatment for streptococcal infection can help prevent development of rheumatic fever.

The Jones criteria and antistreptolysin O titers are helpful in diagnosis of rheumatic fever.

Rheumatic fever is a systemic inflammatory process initiated by group A beta-hemolytic streptococcal pharyngitis. Often, younger children in particular do not recall antecedent pharyngitis, which usually occurs 2 to 4 weeks before symptom onset. Rheumatic fever appears to be linked only to pharyngitis; group A streptococcal (GAS) impetigo does not seem to be associated with rheumatic fever. Rheumatic fever most often affects children 4 to 9 years of age, and onset is usually characterized by an acute febrile illness that can cause large-joint migratory arthritis, CNS involvement (Sydenham's chorea), characteristic rash, and carditis with inflammation of heart valves and subsequent damage. Antibiotic treatment of GAS pharyngitis greatly reduces development of rheumatic fever. The 1992 revised Jones criteria are useful in the diagnosis of acute rheumatic fever (Table 32-6).

Rheumatic fever-related arthritis is often preceded by arthralgias out of proportion to frank swelling, lasting approximately 1 week. Arthralgias usually migrate to lower extremity joints and then to the upper extremities. Children experience this arthritis less frequently than adolescents and

Table 32-6 Revised Jones Criteria for Diagnosis of Acute Rheumatic Fever*

| Major Manifestations | Minor Manifestations |
|---|---|
| Carditis Polyarthritides Chorea Erythema marginatum Subcutaneous nodules | <i>Clinical:</i> Arthralgia, fever <i>Laboratory:</i> Elevated acute-phase reactants (ESR, CRP) Prolonged PR interval |
| <i>Plus:</i> Supporting evidence of antecedent group A streptococcal infection Positive throat culture or rapid streptococcal antigen test Elevated or rising streptococcal antibody titer | |

From Gibofsky A, Zabriskie JB. Rheumatic fever. In Klippel JH (ed). Primer on the Rheumatic Diseases, 12th ed. Atlanta, Arthritis Foundation, 2001, p 282.

*If supported by evidence of preceding group A streptococcal infection, the presence of two major manifestations or of one major and two minor manifestations indicates a high probability of acute rheumatic fever.

ESR, Erythrocyte sedimentation rate; CRP, C-reactive protein.

adults. The arthritis then resolves spontaneously. Carditis involving the valves, particularly the mitral valve, is the most severe sequela. Rheumatic heart disease is the most common serious sequela and usually occurs 10 to 20 years after the original attack. Patients might also have erythema marginatum, a rash with open or closed ring lesions with sharp outer edges or macular rings with pale centers, or both. The rash spreads centrifugally from the trunk to the extremities with lesions that come and go.

The antistreptolysin O (ASO) titer is the most useful laboratory test, because pharyngeal cultures are often negative by the time rheumatic fever develops. The ASO titer rises 4 to 5 weeks after the onset of GAS pharyngitis, or 2 to 3 weeks after development of rheumatic fever. Because only 80% of patients with rheumatic fever develop an increase in ASO titer, clinically suspicious rheumatic fever with a negative ASO titer should be followed up by testing for antistreptococcal antibody, such as anti-DNase, anti-DNase B, and antihyaluronidase antibody tests.

Aspirin is the drug of choice for acute rheumatic fever and usually results in a dramatic response. The usual dose is 80 to 100 mg/kg/day for children and 4 to 8 g/day for adults. Penicillin should also be given for a 10-day course whether or not pharyngitis is present, and family members and other close contacts should be cultured and treated if necessary. Intramuscular (IM) penicillin is more effective than oral (PO) penicillin in clinical trials. No benefit has been shown from IV immune globulin (IVIG) or corticosteroids for rheumatic fever, but studies continue (Manyemba and Mightosi, 2004).

Patients who have had documented rheumatic fever and who develop subsequent GAS pharyngitis are at high risk for a recurrent rheumatic episode and thus at increased risk for worsening rheumatic heart disease. For this reason, prevention of recurrent episodes requires continuous antimicrobial prophylaxis (Gerber et al., 2009). Before prophylaxis initiation, a full treatment course for GAS pharyngitis should be completed. In the United States,

typical prophylactic therapy is with long-acting IM benzathine penicillin G every 4 weeks until early adulthood (about 18 years of age).

KEY TREATMENT

Patients with acute group A streptococcal pharyngitis should receive antibiotic therapy to help prevent the complication of acute rheumatic fever (Denny et al., 1950) (SOR: B). Patients with acute rheumatic fever should receive appropriate antibiotic therapy to eradicate the GAS infection, regardless of whether pharyngitis is present at diagnosis (SOR: C). Use of aspirin is the treatment of choice for the acute symptoms of acute rheumatic fever (SOR: C). Prevention of recurrent acute rheumatic fever requires prophylactic treatment for GAS pharyngitis with antibiotics (Gerber et al., 2009) (SOR: A).

Systemic Lupus Erythematosus

Key Points

- The 5-year survival rate of SLE patients is 90%.
- The female/male ratio is 2:1 before and 4:1 after puberty.
- Four of 11 criteria are needed for SLE diagnosis.

Systemic lupus erythematosus is a generalized autoimmune disease of unknown cause characterized by the production of antibodies to numerous antigens. The most common antibodies found in SLE are those directed against the cell nucleus (ANAs). These antibodies bind DNA, RNA, nuclear proteins, and protein-DNA or protein-RNA complexes. Antibodies to double-stranded DNA and an RNA-protein complex called Sm are found almost exclusively in SLE. Immune complex deposition results in inflammation and vasculitis, causing multiorgan pathology.

Systemic LE is most common in women of reproductive age (15-40 years), and the female/male ratio is approximately 2:1 before puberty and 4:1 after puberty. However, SLE can be seen in all ages, including infants and older adults; in these two subpopulations, the female/male ratio is only 2:1. SLE affects approximately 1 in 1000 to 2500 in the general population, but disease incidence in African American and Latino women is much higher (up to 1 in 250 in African American women ages 18-65 years). The 5-year survival after diagnosis is 90%.

Systemic LE also shows a strong familial tendency. An association with MHC genes *DR2*, *DR3*, *DR4*, and *DR5* has been found. As with other rheumatologic diseases, SLE appears to result from a genetic abnormality that can be triggered by environmental factors. Some of these hypothesized factors include infections, stress (neuroendocrine changes), exposure to sunlight, diet, and toxins, including drugs. In addition to autoantibody production, SLE involves immune cell (B, T, monocyte) abnormalities. Because of the wide variety of presentations, ACR created a classification system to standardize the diagnosis of SLE (Box 32-3). To confirm a diagnosis of SLE, patients must have at least 4 of 11 criteria present either serially or simultaneously.

Box 32-3 Criteria for Classification of Systemic Lupus Erythematosus*

1. *Malar rash*. Fixed erythema, flat or raised, over the malar eminences, tending to spare the nasolabial folds.
2. *Discoid rash*. Erythematous raised patches with adherent keratotic scaling and follicular plugging; atrophic scarring may occur in older lesions.
3. *Photosensitivity*. Skin rash as a result of unusual reaction to sunlight, by patient history or physician observation.
4. *Oral ulcers*. Oral or nasopharyngeal ulceration, usually painless, observed by a physician.
5. *Arthritis*. Nonerosive arthritis involving two or more peripheral joints, characterized by tenderness, swelling, or effusion.
6. *Serositis*
 - a. Pleuritis—convincing history of pleuritic pain or rub heard by a physician or evidence of pleural effusion *or*
 - b. Pericarditis—documented by electrocardiogram or rub or evidence of pericardial effusion.
7. *Renal disorder*
 - a. Persistent proteinuria higher than 0.5 g/day or higher than 3+ if quantitation not performed *or*
 - b. Cellular casts: may be red cell, hemoglobin, granular, tubular, or mixed.
8. *Neurologic disorder*
 - a. Seizures—in the absence of offending drugs or known metabolic derangements (e.g., uremia, ketoacidosis, electrolyte imbalance) *or*
 - b. Psychosis: in the absence of offending drugs or known metabolic derangements (e.g., uremia, ketoacidosis, electrolyte imbalance).
9. *Hematologic disorder*
 - a. Hemolytic anemia—with reticulocytosis *or*
 - b. Leukopenia—less than 4000/mm³ total on two or more occasions *or*
 - c. Lymphopenia—less than 1500/mm³ on two or more occasions *or*
 - d. Thrombocytopenia—less than 100,000/mm³ in the absence of offending drugs.
10. *Immunologic disorder*
 - a. Positive lupus erythematosus cell preparation *or*
 - b. Anti-DNA: antibody to native DNA in abnormal titer *or*
 - c. Anti-Sm: presence of antibody to Sm nuclear antigen *or*
 - d. False-positive serologic test for syphilis known to be positive for at least 6 months and confirmed by *Treponema pallidum* immobilization or fluorescent treponemal antibody absorption test.
11. *Antinuclear antibody*. An abnormal titer of antinuclear antibody by immunofluorescence or an equivalent assay at any point in time and in the absence of drugs known to be associated with “drug-induced lupus” syndrome.

From Tan EM, Cohen AS, Fries JF, et al. The 1982 revised criteria for the classification of systemic lupus erythematosus (SLE). *Arthritis Rheum* 1982;25:1271-1277, with permission of the American College of Rheumatology.

*The proposed classification is based on 11 criteria. For the purpose of identifying patients in clinical studies, a person is said to have systemic lupus erythematosus if any four or more of the 11 criteria are present, serially or simultaneously, during any interval of observation.

Clinical Features

Constitutional symptoms found in patients with SLE include fatigue, malaise, fever, and weight loss. The family physician therefore has an important role to play in the diagnosis of this multisystem disease, which must be differentiated from infections such as HIV (which often is false positive in SLE)

and subacute bacterial endocarditis; other connective tissue diseases such as vasculitis, RA, and mixed connective tissue disease; and malignancies such as lymphomas. SLE is characterized by specific organ system abnormalities. The disease most often affects the skin, joints, kidneys, CNS, GI tract, and lungs, with a spectrum of disease severity and an unpredictable course. SLE is truly systemic; other asymptomatic organ involvement must be searched for during active periods of disease, regardless of the presenting sign or symptom.

Mucocutaneous Manifestations

More than 90% of SLE patients eventually have a mucocutaneous manifestation. The classic malar butterfly rash gave lupus its name, because it was thought to resemble the bite of the wolf. This rash is present in only one third of patients; when it occurs, it is often after sunlight exposure. One third to two thirds of SLE patients are extremely photosensitive. Sun exposure not only can cause a maculopapular, erythematous rash but also can induce a flare of systemic symptoms. Other lesions can occur, such as bullae or generalized erythema.

Subacute cutaneous lupus erythematosus (SCLE) occurs in sun-exposed areas of the skin, particularly on the upper torso, in two forms—annular or papulosquamous lesions. The former variant might be confused with erythema annulare and the latter with psoriasis or lichen planus. About 70% of patients with photosensitivity have anti-Ro antibodies (Boumpas et al., 1995). SCLE lesions do not result in scarring. Discoid lupus lesions are raised plaques that often occur in the absence of any other systemic manifestations, most often on the face, neck, scalp, and external ears. Unlike SCLE lesions, these erythematous plaques with heavy scales can cause scarring, with a hypopigmented, atrophic central area. Other mucocutaneous manifestations of SLE include alopecia, which resolves when the acute SLE exacerbation ends, unless the alopecia is secondary to discoid scarring. Oral, nasal, and vaginal ulcerations as well as palpable purpura also occur.

Latent lupus refers to the condition of those patients who do not meet the ACR criteria for diagnosis of SLE but have many features consistent with lupus. This form is mild and is treated symptomatically. Many of these patients never develop classic SLE; there are no identifiable prognostic indicators of propensity for progression to frank lupus.

Drug-induced lupus occurs when a patient taking a drug develops clinical and serologically consistent lupus, which then resolves (clinically and then serologically) on discontinuation of the drug. Drugs known or suspected to cause lupus include *antituberculous* drugs (e.g., isoniazid, streptomycin), *antibiotics* (e.g., penicillin, tetracycline, sulfa, griseofulvin), *anticonvulsants* (e.g., phenytoin [Dilantin], ethosuximide [Zarontin], carbamazepine [Tegretol]), *phenothiazines* (e.g., perphenazine [Trilafon], promethazine [Phenergan], thioridazine [Mellaril]), and *antihypertensives* (e.g., hydralazine, methyl dopa, reserpine), as well as oral contraceptives, lithium, propylthiouracil, and procainamide. Symptoms are usually mild and do not involve the CNS or kidneys.

Musculoskeletal Manifestations

Arthralgias and arthritis are the most common initial symptoms of SLE. The typical pattern is symmetric involvement of the hands, wrists, or knees, either migratory or

persisting in an involved joint. There may be subcutaneous nodules similar to those of RA, but SLE usually does not cause RA-like erosions. Subluxations causing swan neck deformities and other deformities in the hands are known as *Jaccoud's arthropathy*, characterized by deformity without erosion of bone and cartilage. SLE patients sometimes experience myalgias but usually not to the degree seen in dermatomyositis.

Musculoskeletal complications of SLE also include osteoporosis and avascular necrosis of bone (osteonecrosis), especially in corticosteroid-treated children with SLE. In one study, 65% of premenopausal women with SLE had abnormal bone mineral density (Petri, 1995). Screening for osteoporosis, even in premenopausal women, and treatment, if indicated, are therefore prudent measures, as is minimizing the use of corticosteroids. Late SLE can cause osteonecrosis, particularly of the hip, independent of active SLE episodes. Major risk factors for osteonecrosis include a prednisone dosage higher than 20 mg/day for 1 month or longer and the presence of Raynaud's disease or vasculitis. Avascular necrosis of the hip is diagnosed early by MRI.

Renal Disease

Called *lupus nephritis*, SLE-induced renal disease is typically asymptomatic until relatively late. More than 50% of all patients and 75% of African American patients with SLE have renal involvement. Immune complex deposition along the glomerular basement membrane leads to the nephrotic syndrome or renal failure, which can be the presenting sign. An elevated serum creatinine level can be found, as well as proteinuria, hematuria, pyuria, and casts in the absence of infection. Definitively diagnosed by renal biopsy, lupus nephritis constitutes a spectrum of severity from mild to more severe that involves mesangial, focal proliferative, diffuse proliferative, and advanced sclerosing forms of glomerulonephritis (Petri, 1998). SLE patients should have an annual urinalysis and renal function test to rule out proteinuria. An elevated creatinine level (>2 mg/dL) is the best predictor of prognosis. Patients with SLE have had successful renal transplants, although lupus nephritis can recur.

Neuropsychiatric Disease

Neuropsychiatric symptoms are common when SLE is active but can occur in isolation. Manifestations include headache, generalized seizures (20% of SLE patients), stroke, cranial and peripheral neuropathies, psychosis, severe depression (40%), cognitive abnormalities, and organic brain syndrome. Cranial neuropathies may manifest as visual defects, tinnitus, vertigo, nystagmus, ptosis, or facial palsies. A migraine-type headache is common and can be intractable. *Neuropsychiatric lupus* is a diagnosis of exclusion, after other causes of the patient's symptoms have been ruled out. Electroencephalographic findings are often abnormal but non-specific. MRI of the head can show diffuse, small focal areas of increased signal density on the cerebral white matter and cortical gray matter that clear with corticosteroid treatment. Cerebrospinal fluid (CSF) studies are important to rule out infectious causes. Even in long-term mild disease, neurocognitive abnormalities affecting memory or causing speech abnormalities often persist. Antiribosomal P antibody presence correlates with cognitive impairment in SLE (Hirohata and Nakanishi, 2001).

Cardiovascular Manifestations

Patients with SLE have an increased risk of premature atherosclerosis from the disease itself as well as from its treatment; up to 40% of SLE patients have been found to have this complication in screening studies. Corticosteroids increase cardiac risk factors such as weight, BP, cholesterol, and homocysteine levels, which the family physician must keep in mind. Primary coronary disease prevention monitoring and patient education plans for the SLE patient are important, because the mortality from myocardial infarction is approximately 10 times that in an age- and gender-matched population (Klippel, 2001). Myocarditis and endocarditis are rare, but pericarditis can occur in up to 45% of SLE patients (25% in most series). Symptoms might be mild or severe, but constrictive pericarditis and cardiac tamponade are rare.

Thrombosis is a major cause of morbidity and mortality in lupus patients. Between 30% and 50% of SLE patients make antiphospholipid autoantibodies to the phospholipid part of the normal cell membrane, although most people with these antibodies do not have lupus. Types of antiphospholipid antibodies include anticardiolipin antibody, β 2-GP-I antibody and lupus anticoagulant. Lupus anticoagulant antibodies might result in prolonged partial thromboplastin time (PTT) and prothrombin time (PT) but paradoxically result in an increased risk of thrombotic events for these patients. This might be caused by an antibody-induced vasculopathy. Anticardiolipin and β 2-GP-I antibodies can be detected using ELISA, but there is no direct testing for the lupus anticoagulant. If the lupus anticoagulant is clinically suspected but activated PTT is normal, more sensitive coagulation tests should be done, including kaolin clotting time (KCT), modified Russell viper venom time (RVVT), and platelet neutralization procedure (PNP) (Petri, 1994).

Antiphospholipid antibody syndrome is defined as the presence of lupus anticoagulant, β 2-GP-I antibody or anticardiolipin antibody with one of these four entities: arterial thrombosis, venous thrombosis, recurrent first-trimester or one late (second- or third-trimester) spontaneous abortion, or thrombocytopenia. This acquired autoimmune hypercoagulability is more common in SLE patients than in the general population.

The incidence of spontaneous abortion, intrauterine death, and prematurity is also increased in women with SLE alone. Studies differ, but currently pregnancy is not thought to exacerbate SLE, as formerly thought. It is recommended that women be flare free for 6 months and do not have serious comorbidities such as renal disease before deciding to become pregnant. Fertility is apparently not affected by SLE. Women with either recurrent first-trimester or late pregnancy loss can reduce their risk of pregnancy loss with heparin and low-dose aspirin therapy.

Other Manifestations

Serositis that causes pericarditis, pleurisy, and peritonitis is common in SLE. Bilateral pleural effusions are usually small and are seen most often in drug-induced lupus patients and in older adult patients. Pleurisy is clinically more common than pericarditis, which rarely becomes severe enough to be constrictive.

Systemic LE can cause multiple GI symptoms such as nausea, vomiting, anorexia, and abdominal pain, often as a result of peritoneal inflammation. Mesenteric vasculitis can

cause lower abdominal pain and rectal bleeding. Hepatomegaly with increases in liver enzyme levels and pancreatitis with amylase level elevations can occur with SLE. In addition to hepatomegaly, splenomegaly and lymphadenopathy can occur with lupus exacerbations.

Lung involvement can include pulmonary hemorrhage, pulmonary hypertension, and pneumonitis. *Lupus pneumonitis* often manifests as a diffuse interstitial disease. *Shrinking lung syndrome*, seen in late SLE, is a restrictive condition with decreased lung volumes resulting from abnormal musculoskeletal respiratory function.

Laboratory Abnormalities

There are no specific tests for lupus. The lupus erythematosus cell, formed when complexes of nuclei and antibodies are phagocytosed by PMNs, is highly specific but of low sensitivity. ANA, anti-double-stranded DNA, and antiphospholipid antibody are all markers for SLE, but antibody test results are misleading if not considered in the clinical context. From 2% to 5% of patients with SLE are ANA negative, whereas 5% of the normal population and up to 20% of healthy young women are ANA positive (Fritzler et al., 1985). Antibodies to an RNA-protein complex called Sm (anti-Smith antibody) and to double-stranded DNA (dsDNA) are almost unique for SLE, both being 95% specific. ESR is normally increased, whereas CRP is normal (Linares et al., 1986).

Autoantibodies in SLE include ANA and anticytoplasmic antibodies (including lipoproteins), antibodies against blood cells, antibodies against various organs and structures (e.g., gastric mucosa, neurons, muscle sarcolemma, thyroglobulin), and antibodies against collagen. Different antibodies against different parts of the cell nucleus appear as the four patterns of ANA staining. These include membranous antibodies against single-stranded DNA, speckled antibodies against extractable ribonucleoproteins, dsDNA antibodies against native dsDNA, nucleolar antibodies against nucleolar antigens and sometimes associated with scleroderma, and homogeneous antibodies against deoxyribonucleoproteins.

In active SLE, serum complement (C3, C4, and often CH50) levels are depressed. ESR is often elevated during active disease but is not a precise indicator of disease activity. DNA autoantibodies also do not correlate well with periods of active disease. A normochromic normocytic anemia, leukopenia (2500-4000 WBCs/mm³), and thrombocytopenia are common because of bone marrow suppression or the autoimmune process, although other causes must be ruled out first. SLE can manifest as immune thrombocytic purpura years before the patient develops other symptoms of lupus.

The confirming tests for lupus (e.g., ANA, anti-DNA titers) are generally not helpful in follow-up. Monitoring for disease or treatment sequelae often involves serial CBC, renal function testing (creatinine), urinalysis, C3 and C4, and laboratory tests monitoring specific drug toxicities, including homocysteine and cholesterol levels for patients taking corticosteroids.

Treatment

The major goal of treatment is to treat the active disease without causing iatrogenic long-term complications and to be supportive of the patient and family. The family physician

has a vital role in educating patients with SLE about signs and symptoms of disease flares. Continued monitoring, even when the disease appears inactive, is also important. General advice includes avoiding sun exposure or using potent sunscreens, early evaluation of unexplained fevers, annual influenza vaccine, adequate rest and exercise, and weight control. Other specific information tailored to the patient's needs is also important, such as SLE and its effect on pregnancy.

Vigilance for severe infections, particularly when corticosteroids are being used, should be continual. Proper monitoring for drug toxicities must include ophthalmologic examination with antimalarials and monitoring for corticosteroid-induced side effects. Treatment approaches for SLE emphasize using a drug combination to minimize corticosteroid use. Corticosteroids increase cardiovascular risk factors, including weight, BP, and cholesterol and homocysteine levels. Too-rapid steroid tapering should also be avoided. Immunosuppressive drugs are also being used more often, requiring careful monitoring.

The NSAIDs are still the drugs of choice for musculoskeletal manifestations, especially mild symptoms. The potential renal and GI toxicity of these drugs being used for a disease that in itself causes renal and GI damage must be kept in mind and monitored. Gastroduodenal cytoprotective therapy should be strongly considered for patients taking NSAIDs.

For minor polyarthritic disease activity, prednisone at 0.5 mg/kg/day in a single dose can be given, but many recommend other agents if the daily maintenance prednisone dose is 10 mg or more. Antimalarials such as hydroxychloroquine (Plaquenil) are often used for lupus arthritis but require ophthalmologic monitoring every 6 to 12 months. For severe arthritis or flare-ups, prednisone at 1.0 mg/kg/day, intra-articular injection with triamcinolone hexacetonide, or IV methylprednisolone sodium succinate (Solu-Medrol), 1000 mg over 90 minutes daily for 3 days, can be used, followed by oral prednisone. Methotrexate, 7.5 mg orally once weekly, along with folic acid supplementation or azathioprine, can also be used to minimize prednisone dosage, although methotrexate cannot be used during pregnancy.

Cutaneous lupus is treated with sunscreen and sun avoidance, topical or intralesional corticosteroids, topical cryotherapy with liquid nitrogen (less often), and antimalarials. The most common antimalarials are hydroxychloroquine, chloroquine (Aralen), and quinacrine. For patients who cannot take antimalarials, dapsone and retinoids such as tretinoin (Tegison) or isotretinoin (Accutane) might be used with appropriate precautions. Fluocinonide cream has greater effect than hydrocortisone for discoid lupus (Jessop et al., 2001). Dapsone should not be used in patients with glucose-6-phosphate dehydrogenase (G6PD) deficiency, and retinoids should be avoided in pregnant patients. Severe cutaneous lupus can be treated with high-dose corticosteroids, but if the daily dose of prednisone exceeds 10 mg, methotrexate or azathioprine should be considered. Finally, thalidomide is effective for discoid lupus, but its use is limited by concerns about neuropathy and teratogenicity.

Lupus nephritis, once diagnosed by renal biopsy, can be treated with high-dose corticosteroids alone or with steroid-sparing drugs such as methotrexate or azathioprine. Cyclophosphamide for rapidly progressive or severe nephritis is effective but has substantial toxicities and is generally best left for the rheumatologist to prescribe. Toxicity can

be minimized somewhat with prehydration and a mesna (Mesnex) injection, a cyclophosphamide metabolite binder, to avoid hemorrhagic cystitis. Later development of hematologic malignancies (rare) and premature ovarian failure (common) can result from cyclophosphamide use. If cyclophosphamide is indicated in a young woman, her family physician should raise options such as egg harvesting to preserve fertility.

Patients with SLE and antiphospholipid antibody syndrome who consequently have venous or arterial thrombosis can be treated with warfarin (Coumadin) to keep the international normalized ratio (INR) between 2 and 3. Although somewhat controversial, therapy should continue for at least 3 to 6 months, and often, lifelong anticoagulation is recommended based on high risk for subsequent events. Severe hemolytic anemia responds to IV methylprednisolone. Leukopenia rarely requires treatment. Severe thrombocytopenia with platelet counts below 50,000/mm³ can be treated with methylprednisolone, danazol (Danocrine), immunosuppressive drugs, and possibly splenectomy.

Arthritis, serositis, and constitutional signs usually respond to 0.5 mg/kg/day of prednisone; nephritis and CNS disease usually require doses of 1 mg/kg/day. Patients who do not respond to high-dose steroids after 7 weeks should be considered for immunosuppressive drugs.

Rarely, plasma exchange is necessary for severe thrombotic thrombocytopenic purpura and pulmonary hemorrhage. Plasmapheresis has not shown long-term benefit for lupus nephritis. End-stage lupus nephropathy is treated with dialysis or kidney transplantation. Other experimental therapies for SLE include immunotherapy with anti-CD4, anti-TNF- α , and interferon- α .

Treatment of SLE has been successful in decreasing morbidity and mortality in what used to be considered a universally progressive, terminal disease. More than 90% of treated patients survive at least 15 years. SLE evolves over time with new manifestations and sometimes vague symptomatology arising unpredictably. Therefore, good communication in an ongoing physician-patient relationship and teamwork between the family physician and the rheumatologist are necessary for optimal care.

KEY TREATMENT

Cutaneous lupus should initially be treated with topical corticosteroids (Jessop et al., 2001) (SOR: B) and avoidance of precipitating factors such as sun exposure (SOR: C).

Patients with persistent cutaneous lesions should be considered for treatment with antimalarials such as hydroxychloroquine (SOR: C).

NSAIDs are the initial treatment for SLE-associated myositis, serositis, and arthritis. Refractory cases can be treated with 0.5 to 1 mg/kg/day of prednisone (SOR: C).

Sjögren's Syndrome

Sjögren's syndrome (SS) is an autoimmune disorder caused most likely by T-cell-mediated exocrine gland destruction characterized by dry eyes (keratoconjunctivitis sicca) and dry mouth (xerostomia). Patients with secondary SS have these symptoms in association with other autoimmune diseases such as RA, SLE, polymyositis, systemic sclerosis, or biliary cirrhosis.

Box 32-4 San Diego Criteria for Sjögren's Syndrome**I. Primary Sjögren's syndrome***

- A. Symptoms and objective signs of ocular dryness
1. Schirmer's test <8 mm wetting per 5 minutes, *and*
 2. Positive rose bengal staining of cornea or conjunctiva to demonstrate keratoconjunctivitis sicca
- B. Symptoms and objective signs of dry mouth
1. Decreased parotid flow rate using a Lashley cup or other method *and*
 2. Abnormal findings from biopsy of minor salivary gland (focus score of ≥ 1 based on average of four evaluable lobules)
- C. Serologic evidence of a systemic autoimmunity
1. Elevated rheumatoid factor >1:320 *or*
 2. Elevated antinuclear antibody <1:320 *or*
 3. Presence of anti-SS-A(Ro) or anti-SS-B(La) antibodies

II. Secondary Sjögren's syndrome

Characteristic signs and symptoms of Sjögren's syndrome (described above), plus clinical features sufficient to allow a diagnosis of rheumatoid arthritis, systemic lupus erythematosus, polymyositis, scleroderma, or biliary cirrhosis

III. Exclusions

Sarcoidosis, preexisting lymphoma, HIV infection, hepatitis virus B or C infection, primary fibromyalgia, and other known causes of autonomic neuropathy, keratitis sicca, or salivary gland enlargement

*Definite Sjögren's syndrome requires objective evidence of dryness of eyes and mouth and autoimmunity, including a characteristic minor salivary gland biopsy (criteria IA, IB, and IC). Probable Sjögren's syndrome does not require a minor salivary gland biopsy but can be diagnosed by demonstrating decreased salivary function (criteria IA, IB-1, and IC).

From Fox RI, Saito I. Criteria for diagnosis of Sjögren's syndrome. *Rheum Dis Clin North Am* 1994;20:391.

A diagnosis of definite SS requires a minor salivary gland biopsy; a probable SS diagnosis can be based on demonstrating decreased salivary function. Exclusions to the diagnosis based on the San Diego Criteria include patients with HIV, primary fibromyalgia, sarcoidosis, preexisting lymphoma, keratitis sicca, hepatitis B or C, or salivary gland enlargement (Box 32-4). Objective evidence of ocular dryness can be obtained by the Schirmer II test, which involves stimulating the nasolacrimal reflex by inserting a cotton swab into the nostril; the increase in tear flow is then measured for both eyes (Tsubota, 1991). Rose bengal staining of the corneal or conjunctiva epithelial layer is another objective test. Serologic evidence of SS includes an elevated RF (>1:320), elevated ANA (>1:320), or presence of anti-SS-A (Ro) or anti-SS-B (La) antibodies.

Salivary secretions can be quantified by asking the patient to suck on a sugarless piece of candy for 3 minutes and then expectorate. If there is very little or no expectorant, a probable diagnosis of SS can be made; a follow-up minor salivary gland biopsy is definitively diagnostic. Patients not fitting these objective criteria can be reassured that their dry eyes or mouth is most likely not caused by an autoimmune disorder. Other manifestations of SS include constitutional symptoms such as fatigue, dry skin, vaginal dryness, upper respiratory tract dryness, and difficulty swallowing (caused by decreased saliva).

SS is not the only entity that can cause enlarged lacrimal and salivary glands and glandular dysfunction. SS needs to be differentiated from infiltrative processes (lymphoma, sarcoidosis, fatty infiltrates, hemochromatosis); infectious diseases (blepharitis, HIV, hepatitis B and C, tuberculosis, syphilis); neuropathic dysfunction of the glands caused by multiple sclerosis or Bell's palsy; autonomic neuropathy; and drug side effects.

Treatment of keratoconjunctivitis sicca consists of the use of artificial tears while monitoring for blepharitis caused by preservatives used in these preparations. Punctal plugs can be used to increase eye moisture, with either collagen plugs that dissolve after 2 days or silicone plugs, which are more durable but can be removed if excessive tearing occurs. If this is helpful, permanent punctal occlusion surgery might be considered. Humidifiers may also be helpful. Cyclosporine ophthalmic preparations are FDA approved for treatment of keratoconjunctivitis sicca, with objective and subjective improvement in dry eyes (Sall et al., 2000).

Dry mouth can be relieved by sugarless mints or gum. Frequent sips of water are also helpful. Those with continued symptoms may be candidates to try artificial saliva solutions (Salivart, Mouth Kote). Meticulous dental care should be encouraged because caries can occur more frequently with reduced salivary flow. Secretagogues such as pilocarpine or cevimeline can be used, but adverse effects such as flushing, increased perspiration, and increased bowel or bladder motility might outweigh their benefits. Topical antifungal troches are useful for low-grade oral infections.

Systemic treatment of SS is similar to that of SLE. NSAIDs and antimalarials, in particular, are useful for concomitant arthralgias and other systemic symptoms, but corticosteroids and immunosuppressants might be needed for refractory severe systemic disease.

KEY TREATMENT

Simple treatments such as the use of humidifiers, artificial tears, sugarless gums, and frequent sips of water are adequate in most patients with keratoconjunctivitis sicca and xerostomia of Sjögren's syndrome (SOR: C).

Vasculitic Syndromes

Vasculitis refers to a broad spectrum of conditions involving inflammation of blood vessels. Although many classification schemes have focused on the size of the vessels involved, this might not be very useful clinically because of the significant amount of overlap between these disorders. Many vasculitides characteristically affect certain age groups for unknown reasons: Kawasaki's disease in children, temporal arteritis in the elderly, and Henoch-Schönlein purpura with a bimodal distribution. Most vasculitic syndromes are of unknown cause. Pathologic findings are usually not diagnostic for a specific syndrome; diagnosis is still made primarily on clinical grounds. Most vasculitides tend to cause sporadic involvement of vessels with skip lesions. That is, they involve only part of the vessel wall for only part of the segmental length of the vessel and do not occur uniformly in other vessels of the same size.

Giant Cell Arteritis

Also known as *temporal arteritis*, giant cell arteritis (GCA) usually occurs in patients older than 50 years. It is most common in whites, particularly in people of northern European ancestry. Giant multinucleated cells are found in vessel walls, most frequently in the temporal arteries but sometimes in the vertebral or carotid arteries. The disease usually begins gradually with constitutional symptoms for weeks or even months, such as fatigue, malaise, fever, weight loss, and *polymyalgia rheumatica* (PMR, a separate entity characterized by proximal muscle pain and stiffness, elevated ESR, and constitutional symptoms). Specific symptoms then develop, such as jaw claudication (masticatory muscle discomfort with chewing); new-type or new-onset headache; scalp tenderness, particularly overlying the temporal arteries; diplopia; and visual loss secondary to retinal ischemia. Patients might also have loss of taste or hearing. About 30% of patients have neurologic symptoms such as peripheral neuropathies and transient ischemic attacks (TIAs). About 10% of patients have respiratory tract symptoms such as sore throat, cough, and hoarseness.

On physical examination, the temporal arteries might be tender, thickened, and erythematous. New carotid artery bruits should also raise suspicion. The aortic arch or its branches might be involved, manifested by reduced BP in one or both arms or arm claudication. Temporal artery biopsies confirm the diagnosis before initiating treatment, although the skip lesion nature of involvement means that a negative temporal artery biopsy does not rule out the diagnosis. The ESR tends to be high in GCA, usually 80 to 100 mm/hr, although in one small study, 25% of all patients with GCA on temporal artery biopsy had a normal ESR (Weyand et al., 2000). ALP and aspartate transaminase (AST) levels are mildly elevated in one third of patients. Serum IL-6 levels parallel inflammatory activity, and CRP may also be used to follow inflammation. The family physician should consider the diagnosis of GCA for any patient older than 50 years presenting with new-onset or new-type headache, elevated ESR, abrupt loss of vision, PMR, and prolonged fever.

The treatment for temporal arteritis or clinically suspected temporal arteritis with a negative biopsy is prednisone, 40 to 60 mg/day for 2 to 4 weeks. One should not wait for the biopsy results if clinical suspicion is high; treatment should start immediately. If symptoms and laboratory values suggest that the disease is under control, the dose is decreased 10 mg every 2 weeks for 1 month and then by 10% of the daily dose every 2 weeks (serum ESR and CRP levels are measured before decreasing the dose). Full courses often last 9 to 12 months. Prednisone often eliminates symptoms within 12 to 48 hours. GCA is usually self-limited, up to 2 years, at which time prednisone can be discontinued in most patients, although some still require small doses of corticosteroids for years to control symptoms. Because thoracic aortic aneurysms and renal artery stenosis are relatively common sequelae, the patient should be evaluated for these.

KEY TREATMENT

Prednisone is the treatment of choice in temporal arteritis (SOR: C).

Polymyalgia Rheumatica

As with GCA, polymyalgia rheumatica usually occurs in whites older than 50 years, especially those of northern European ancestry. Constitutional symptoms such as fever, fatigue, malaise, and weight loss occur early on, followed by neck and proximal upper extremity muscle aches. PMR is sometimes misdiagnosed as a frozen shoulder because of this. PMR later involves the lower extremity proximal muscles of the hips and thighs. Morning stiffness of large joints can make it difficult for the patient to perform ADLs, such as getting out of bed or combing the hair. The only typical physical finding is muscle tenderness, but without other objective signs. A transient mild synovitis of the knees, wrists, and sternoclavicular joints might occur. Diagnosis is made clinically by noting the combination of proximal extremity and truncal muscle pain and stiffness, increased ESR, and response to steroids.

Both PMR and GCA (temporal arteritis) are often seen together. PMR can precede, appear simultaneously with, or follow the onset of GCA symptoms. These two conditions might represent different manifestations of the same pathologic process. The best treatment for PMR is corticosteroids, with the dose determined by patient characteristics as well as by whether GCA is present. The typical dose is 15 to 30 mg/day of prednisolone; the daily dose is reduced by 5 mg/week until the dose is 15 mg/day, at which point the dosage is decreased by 2.5 mg/month.

Treatment can be stopped after 6 to 12 months if the ESR remains normal and the patient remains asymptomatic at a daily dose of 2.5 mg. Serial ESRs should be performed every 2 to 3 weeks, although following the patient's symptoms closely is more important than simply following laboratory values. For recurrences, 15 mg of prednisolone is restarted and gradually tapered. NSAIDs might help relieve symptoms but do not protect against vasculitis.

KEY TREATMENT

Prednisone is the treatment of choice in polymyalgia rheumatica (SOR: C).

Other Vasculitic Conditions

See the discussions of the following online at www.expert-consult.com.

- Takayasu's arteritis
- Polyarteritis nodosa
- Churg-Strauss syndrome
- Wegener's granulomatosis
- Cryoglobulinemia
- Hypersensitivity vasculitis
- Behçet's disease

Inflammatory Myopathies

This heterogeneous group of diseases causes inflammation of skeletal muscle, increases in levels of enzymes derived from muscle, and proximal muscle weakness or myopathy. The two most common myopathies are dermatomyositis and polymyositis. Inflammatory myopathies are classified by patient age at onset or by coexisting diseases, such as myositis associated with neoplasia or myositis associated

with collagen vascular diseases (e.g., systemic sclerosis, SLE, SS). They have a bimodal distribution and are seen most often between age 10 to 15 and 45 to 60 years. Myositis is most common after age 50. The cause of inflammatory myopathies is unknown, but evidence suggests a genetic predisposition (associated with certain HLA markers) combined with an environmental insult, such as viruses, thereby initiating an autoimmune process.

Patients usually experience progressive, symmetric, proximal muscle weakness with fatigue, malaise, and morning stiffness. Muscles often affected are those of the shoulder, neck, and pelvic girdle. Pulmonary (interstitial pneumonitis or fibrosis), cardiac (cardiomyopathy, congestive heart failure, arrhythmias), pharyngeal (dysphagia), and musculoskeletal (myalgias, arthralgias) symptoms might occur, although most patients do not experience synovitis. CK as well as aldolase, alanine transaminase (ALT), AST, and lactate dehydrogenase (LDH) levels might be elevated, although ESR is elevated only half the time. Muscle biopsy can also be helpful in diagnosis. *Dermatomyositis* is characterized by all these manifestations plus a scaly, erythematous, or violaceous rash on the face and neck, upper back (shawl sign), and upper anterior chest and neck (V sign). Other signs include dystrophic cuticles, mechanic's hands (darkened or dirty-appearing horizontal lines across palmar aspect of fingers), and Gottron's papules, seen on dorsal aspects of the PIP, DIP, or MCP joints, elbows, patellae, and medial malleoli (Olsen and Wortmann, 2004). Disease in patients with skin changes but without muscle inflammation is termed *amyopathic dermatomyositis*.

Inflammatory myopathies can result from malignancies. Screening for malignancies common for the patient's gender and age should be undertaken, but further exploration is not indicated. However, ovarian cancer appears to be associated with dermatomyositis, so the family physician should consider evaluation for this.

Before treatment, a thorough motor neurologic examination is done, with muscle enzyme levels (CK, aldolase, ALT, AST, LDH) and cancer screening tests appropriate for patient age and gender. Prednisone, 1 mg/kg/day for up to several months, is the drug of choice; the earlier started in the disease process, the more effective it normally is. If prednisone is not sufficient, methotrexate, azathioprine, or another immunosuppressant is added.

Systemic Sclerosis

Key Points

- CREST syndrome and diffuse cutaneous systemic sclerosis are the primary manifestations of systemic sclerosis.
- Female/male predominance is 8:1 for sclerosis.
- The major ACR criterion for systemic sclerosis is skin thickening proximal to the MCP and MTP joints.

"Scleroderma," or hardening of the skin, is now recognized to be a disorder involving almost every organ system in the body and is therefore more appropriately referred to as *systemic sclerosis*. Systemic sclerosis is characterized by a progressive fibrosis of the skin, blood vessels, lungs, kidneys, heart, and GI tract. The degree of skin involvement (diffuse

or limited) is useful for prognosis. *Diffuse cutaneous systemic sclerosis* (DCSS) involves almost the entire body, including the trunk, face, neck, and extremities. Cardiopulmonary disease is the leading cause of death in DCSS. Limited cutaneous systemic sclerosis has a more benign course and involves the face, neck, and distal extremities below the knee and elbow. CREST syndrome (calcinosis, Raynaud's phenomenon, esophageal dysmotility, sclerodactyly, and telangiectasias) is one of the limited forms of systemic sclerosis, characterized by cutaneous thickening of the distal limbs only. Skin biopsy showing subcutaneous fibrosis is helpful if the diagnosis is in doubt.

Systemic sclerosis affects women up to eight times more often than men; peak incidence is in the 40s and 50s. There is no significant familial connection, but systemic sclerosis patients typically have a family history of autoimmune disease. Many chemicals and toxins have been implicated, most clearly silica exposure in coal miners.

The major ACR classification criterion for systemic sclerosis is skin thickening proximal to the MCP or MTP joints. The three minor ACR criteria are involvement distal to the MCP joints (sclerodactyly), fingertip-pitting scars or loss of subcutaneous tissue, and chronic pulmonary interstitial changes. Patients with the major criterion or two of the three minor criteria are considered to have systemic sclerosis; however, many patients with clear-cut systemic sclerosis do not meet these criteria because their disease might be early or undifferentiated or in an overlap category with other connective tissue diseases. Ninety-five percent of patients have a positive ANA test result, most often nucleolar staining. Various serologic tests, including anti-RNA polymerase, anticentromere antibody, and antifibrillar, can provide prognostic information.

The vast majority (>90%) of systemic sclerosis patients have *Raynaud's phenomenon*, which is the initial complaint in most patients, although some might complain first of puffy hands and fingers and of arthralgias. Raynaud's patients experience cold hands and feet, usually triggered by cold temperature or emotional stress. Vasospasm of the digital arteries and arterioles causes skin pallor, followed by cyanosis. With rewarming, the digits have a hyperemic or red color, thus completing this white, blue, and red phenomenon.

Scleroderma's skin changes result from inflammation and subsequent collagen deposition. The skin feels (and is) thickened, with decreased flexibility. As the skin becomes more fibrotic and thickened, it becomes very dry, causing pruritus. Late-stage skin changes include atrophy. Arthralgias and myalgias progress to muscle atrophy and weakness.

Scleroderma patients can develop two different pulmonary diseases, pulmonary hypertension and pulmonary fibrosis. Pulmonary hypertension (which can occur independently of fibrosis) is associated with a poor prognosis. Gastrointestinal symptoms include dysphagia with heartburn, dry mucosal membranes, esophageal reflux, and dysmotility. Cardiac manifestations are usually late and caused by coronary vasospasm, myocardial fibrosis, and pericardial effusions.

Scleroderma renal crisis is characterized by accelerated hypertension, rapidly progressive renal failure, or both (Steen, 1994). Depression is present in more than 50% of patients with systemic sclerosis and is often amenable to

Figure 32-15 Location of the specific tender points in fibromyalgia. (From Freundlich B, Leventhal L. Diffuse pain syndromes. In Klippel JH [ed]. *Primer on the Rheumatic Diseases*, 11th ed. Atlanta, Arthritis Foundation, 1997, pp 123-127.)

antidepressants. Thyroid fibrosis might lead to hypothyroidism; sicca syndrome can be treated with artificial tears and good dental care.

Treatment

Treatment for systemic sclerosis is difficult. Penicillamine, immunosuppressive drugs, and other agents have been used to treat scleroderma, but none has yielded dramatic results. Localized sclerosis can soften with ultraviolet-A (UVA) light therapy, with dramatic improvement in symptoms seen in two small, non-RCTs (Kreuter et al., 2004; Stege et al., 1997). Other options include high-dose topical corticosteroids and methotrexate. Treatments for calcinosis, including probenecid, colchicine, and warfarin, have not shown improvement. A five-patient study showed that the calcium channel blocker (CCB) diltiazem caused significant regression in calcinosis and clinical improvement (Palmieri et al., 1995); more studies are needed. Raynaud's phenomenon is treated by cold avoidance for the entire body (not only hands), tobacco avoidance, and biofeedback or other stress reduction techniques; pharmacologic therapy includes CCBs, topical nitroglycerin, and prazosin (Pope et al., 2004). A meta-analysis concluded that CCBs are efficacious for reduction in frequency and severity of attacks (Thompson et al., 2005). Skin care consists of avoiding excessive bathing and using moisturizers.

The NSAIDs are used first for musculoskeletal symptoms of systemic sclerosis, but low-dose corticosteroids or narcotic analgesics might be needed. No studies have been performed, but in general, acid-reducing medications such as PPIs or H₂ blockers are used to prevent the development of possible esophageal strictures, given the high rates of esophageal dysmotility in the systemic sclerosis. Delayed

small intestinal tract transit time may lead to bacterial overgrowth, causing GI symptoms; antibiotics might be effective. Angiotensin-converting enzyme (ACE) inhibitors are useful in the treatment of renal crisis manifested by hypertension and renal failure.

For *scleroderma-like disorders*, see the discussion online at www.expertconsult.com.

KEY TREATMENT

Systemic sclerosis is difficult to treat. UVA therapy is the most effective treatment for localized skin sclerosis (Kreuter et al., 2004; Stege et al., 1997) (SOR: B).

Pharmacologic therapy with calcium channel blockers is effective at decreasing the frequency and severity of Raynaud's phenomenon (Thompson et al., 2005) (SOR: B).

Diffuse Fasciitis with Eosinophilia

See the discussion online at www.expertconsult.com.

Fibromyalgia Syndrome

Key Points

- Fibromyalgia syndrome accounts for 20% of visits to the rheumatologist.
- The diagnosis is confirmed by finding 11 of 18 areas of tender points over 3 months.
- The female/male predominance is 9:1 for FMS.

Fibromyalgia syndrome (FMS) is one of the most common rheumatic diseases, affecting up to 20% of patients seen in rheumatology practices (Keefe and Caldwell, 1997). Patients have fatigue, diffuse myalgias, poor sleep, and stiffness; the diagnosis is confirmed by finding at least 11 of 18 specific areas of point tenderness (Fig. 32-15). Pain must be present for more than 3 months to make a diagnosis of FMS. Psychological factors and comorbid conditions might aggravate symptoms. FMS is more common than RA and causes a comparable degree of disability and loss of family income. About 90% of FMS patients are women, and there is evidence of familial aggregation. Fibromyalgia might also be present in patients with autoimmune disorders such as SLE, RA, and AS and should be suspected when symptoms are unresponsive to anti-inflammatory therapies.

Fibromyalgia syndrome is probably caused by central pain mechanism dysfunction, possibly in neurotransmitters. Several studies have found that FMS patients have up to three times higher levels of substance P in CSF than normal controls (Russell et al., 1994). FMS can be initially triggered by trauma or peripheral inflammatory arthritis, but peripheral, ongoing inflammation is not present in this syndrome. Important secondary factors contributing to the patient's pain include nonrestorative sleep, muscle deconditioning secondary to pain, and psychological factors. Pain is most common in the neck, back, shoulders, pelvic girdle areas, and hands. Paresthesias in the extremities are also common, as are tension-type headaches, irritable bowel syndrome, primary dysmenorrhea, chronic fatigue syndrome, restless legs syndrome, temporomandibular joint (TMJ) dysfunction, and regional fibromyalgia (myofascial pain syndrome). Although some FMS patients have depression, most do not. Physical examination reveals tenderness with moderate pressure in 11 out of 18 defined points, although some patients might clinically have incomplete FMS, with fewer sites involved. Care must be taken on examination not to palpate too softly or too firmly. The proper amount of palpation pressure is about the amount of pressure required to blanch the nail of the examining finger when it is pressed against the patient's forehead (Yunus, 1996).

No laboratory tests are available to diagnose FMS. CBC results; tests for ESR, muscle enzyme, electrolyte, and ANA levels; and radiography are all normal in the absence of comorbid disease. Sleep electroencephalograms are often abnormal and should be considered if a history of particular sleep disturbances is suspected (see eTable 32-5 online). Because FMS is often seen in association with other rheumatic diseases, the diagnosis is often missed because FMS symptoms might be mistaken for the comorbid disease. Conversely, patients presenting with FMS should be evaluated for an underlying condition.

The cause of fibromyalgia is unknown. Muscle biopsies reveal no apparent abnormalities. There is great overlap with chronic fatigue syndrome, but there is no evidence that an infection such as chronic Epstein-Barr virus (EBV) is associated with fibromyalgia. About 80% of fibromyalgia patients have sleep disturbances, particularly disrupted non-rapid eye movement (non-REM) sleep (stages 3 and 4, which is deep, restorative sleep). Non-REM sleep deprivation studies have reproduced the signs and symptoms of FMS, which make the sleep disturbance possibly an integral part on the pathogenesis and continuation of fibromyalgia. Patients

with RA and other rheumatic diseases have disrupted sleep with nocturnal awakening and arousals to a lighter stage of sleep throughout the night. Sleep studies reveal that patients often cannot recall these episodes on awakening the next day but do feel fatigued or describe themselves as light sleepers.

Treatment

It is important to educate patients with FMS and to reassure them that FMS is a common disease, that it is not psychiatric, and that there are treatments available.

Tricyclic antidepressants (TCAs), selective serotonin reuptake inhibitors (SSRIs), and serotonin-norepinephrine reuptake inhibitors (SNRIs) help relieve pain associated with fibromyalgia. A meta-analysis (18 RCTs with a variety of antidepressants) concluded there was strong evidence of efficacy for antidepressants for relief of pain, fatigue, mood, sleep disturbance and health-related quality of life (Hauser et al., 2009). The effect size for pain reduction was large for TCAs and small for the SSRIs and SNRIs, although newer studies of SNRIs were not included. Studies of the SNRIs milnacipran (Savella) and duloxetine (Cymbalta) have shown significant reductions in pain, and both have been FDA approved for the treatment of fibromyalgia. Amitriptyline doses are typically 25 to 50 mg at night, much lower than the doses used for the treatment of depression. The addition of amitriptyline to SSRIs or SNRIs showed a trend toward improvement versus medication alone, but results were not statistically significant (Goldenberg et al., 1996).

Cyclobenzaprine has a chemical structure similar to TCAs, and various dosing regimens have been studied in the treatment of fibromyalgia. A meta-analysis found that pain was significantly decreased in patients receiving cyclobenzaprine over placebo at 4 weeks, but not statistically significant at 8 or 12 weeks. Overall, patients treated with cyclobenzaprine were three times more likely to report subjective improvement, and five patients would need to be treated for one patient to experience symptom improvement (Tofferi et al., 2004).

Pregabalin (Lyrica), a second-generation anticonvulsant, was the first medication to be FDA approved for the treatment of fibromyalgia. As with gabapentin, pregabalin has effects on cellular calcium channels and may exert its analgesic effects by blocking various neurotransmitters. Multiple large studies have shown its efficacy for the treatment of pain, fatigue, and improvement in sleep (Mease et al., 2008). Gabapentin has not been FDA approved for this use but is efficacious for reducing pain in fibromyalgia (Arnold et al., 2007).

The NSAIDs and corticosteroids are usually not helpful because no evidence indicates FMS is an inflammatory disease, and NSAIDs are no better than placebo in the treatment of pain. Combination analgesic therapy with acetaminophen and tramadol was found to decrease pain significantly in these patients (Bennet et al., 2003). However, the long-term use of tramadol needs to be carefully considered, and this approach is best employed after other therapies (e.g., antidepressants) have failed.

At least two thirds of FMS patients use some type of complementary method, such as herbal supplements or acupuncture. A meta-analysis of acupuncture suggested benefit, but study quality was generally poor (Berman et al., 1999). Local anesthesia injected into tender points can sometimes relieve pain, and topical capsaicin (Zostrix) cream has

helped some patients. Treatment of underlying depression is also important.

Daily exercise programs, particularly aerobic exercise, and physical therapy might also help FMS patients; it is important that exercise regimens begin at a low intensity and build up slowly. A review of controlled trials for aerobic exercise for fibromyalgia found beneficial effects in overall global function, physical function, and possibly in reduction of pain and tender points (Busch et al., 2008).

Cognitive-behavioral treatment (CBT) is promising for FMS patients, although there have been few controlled studies. There might be even more benefit if CBT is combined with physical exercise. Patients are often resistant to starting exercise programs such as walking or bicycling because they fear exacerbation of pain. CBT programs can overcome negative self-statements that prevent the initiation of exercise or limit the amount of exercise that can be done. An emphatic ongoing relationship with a caring physician is particularly important treatment for patients suffering from FMS. Although musculoskeletal rehabilitation has no effect by itself, physical therapy can help subacute low back pain and other comorbidities. Subacute aerobic exercise is also effective in decreasing symptoms but might need to begin at very low levels (Busch et al., 2004).

KEY TREATMENT

Aerobic exercise programs have positive effects for overall global function, physical function and pain (Busch et al., 2008) (SOR: A). Antidepressant therapy is effective for fibromyalgia patients; TCAs show the greatest improvements (Hauser et al., 2009) (SOR: A). Pregabalin improves pain, fatigue, and sleep in patients with fibromyalgia (Arnold et al., 2007; Mease et al., 2008) (SOR: A). Acetaminophen and tramadol significantly reduce pain associated with fibromyalgia (Bennet et al., 2003) (SOR: B), but prolonged use of tramadol should be considered only after inadequate response to antidepressant therapy (SOR: C).

Temporomandibular Joint Syndrome

See the discussion online at www.expertconsult.com.

Rheumatic Disease in Children

Juvenile Rheumatoid Arthritis

Juvenile rheumatoid arthritis (JRA), formerly known as Still's disease, is a heterogeneous group of diseases clinically distinct from adult RA. Although much less common than RA, JRA is four times more common than sickle cell anemia or cystic fibrosis and 10 times more common than other pediatric diseases, such as hemophilia, muscular dystrophy, acute lymphocytic leukemia, and chronic renal failure (Gortmaker, 1984). Fortunately, most children with JRA have long remissions without loss of function or significant residual deformity.

There are no specific laboratory tests to diagnose JRA. Other causes for arthritis must be excluded, including reactive arthritis from extra-articular infection, septic arthritis, neoplastic disorders, endocrine disorders (thyroid disease, type 1 diabetes mellitus), degenerative or mechanical disorders, and idiopathic pediatric joint pain. Diagnosis of JRA

requires true arthritis (signs of inflammation rather than simply arthralgias) persisting for more than 6 weeks, with onset at or before age 16 years.

The three major subtypes of JRA are pauciarticular (40%-50%), polyarticular (30%), and systemic (5%-10%), all with different clinical presentations and courses; their differentiation determines treatment. *Pauciarticular* JRA involves four or fewer joints, usually large joints asymmetrically. Early-onset pauciarticular JRA affects mostly girls younger than 4 years and has a 30% risk of chronic iridocyclitis and a 10% risk of ocular damage. Late-onset pauciarticular JRA affects mostly boys older than 8 years, many of whom later develop spondyloarthropathies; 10% develop iridocyclitis. Slit-lamp ophthalmic examinations are recommended. *Polyarticular* JRA is defined as arthritis in five or more joints; patients are RF positive or negative. RF-positive patients usually are girls age 8 years or older, have symmetric small-joint arthritis, and have a worse functional prognosis than RF-negative patients. *Systemic-onset* JRA is characterized by high intermittent fevers (>38.8° C; 102° F), rash, hepatosplenomegaly, lymphadenopathy, arthralgias, pericarditis, pleuritis, and growth delay. Anemia, leukocytosis, and thrombocytosis are common laboratory findings. Extra-articular symptoms are usually mild and self-limited. Boys and girls are equally affected. The severity of the arthritis is a harbinger of prognosis.

The NSAIDs are the first-line treatment for JRA, but patience is necessary because clinical improvement might not be seen for up to 1 month. Approximately two thirds of patients need another agent in addition to NSAIDs; methotrexate is often used, particularly for systemic and polyarticular JRA. Corticosteroids are used orally for severe, life-threatening, systemic JRA and intra-articularly for pauciarticular JRA. Eye inflammation is best treated by an ophthalmologist.

Juvenile RA is an excellent example of a disease that significantly affects the entire family. JRA can actually have a greater negative psychological impact on siblings than on the patient (White and Shear, 1992). Most children with JRA require extensive physical as well as psychological support. Encourage families to receive support from social programs and JRA advocacy and support groups. The consulting rheumatologist and physical and occupational therapists are vital, but patients and families also benefit greatly from a continuous, supportive relationship with the family physician. Physical and occupational therapy are important because children often stop using painful joints, adding to disability.

Spondyloarthropathies

Four spondyloarthropathies are seen in children: juvenile AS, psoriatic arthritis, Reiter's syndrome (reactive arthritis), and IBD-associated arthritis. Definitive diagnoses of these conditions are often delayed. JAS patients must have their lumbar spine motion monitored. Plain radiographs often do not show the changes characteristic of adult AS. NSAIDs are used for treatment. Significant arthritis can be seen in 7% to 20% of IBD patients.

Systemic Lupus Erythematosus in Childhood

Systemic LE primarily affects adolescent girls, many of whom do not have the typical malar rash. The small joints of the hands or feet and the kidneys are typically affected; the

Box 32-5 Diagnostic Guidelines for Kawasaki's Syndrome*

Fever lasting >5 days *plus* four of the following five criteria:

1. Polymorphous rash
 2. Bilateral conjunctival infection
 3. One or more of the following mucous membrane changes:
 - Diffuse infection of oral and pharyngeal mucosa
 - Erythema or fissuring of the lips
 - Strawberry tongue
 4. Acute, nonpurulent cervical lymphadenopathy (one lymph node must be >1.5 cm)
 5. One or more of the following extremity changes:
 - Erythema of palms, soles, or both
 - Indurative edema of hands, feet, or both
 - Membranous desquamation of the fingertips
- Other illnesses with similar clinical signs must be excluded.

From Freundlich B, Leventhal L. Diffuse pain syndromes. In Klippel JH (ed). *Primer on the Rheumatic Diseases*, 12th ed. Atlanta, Arthritis Foundation, 2001, p 409.

*Based on the Centers for Disease Control and Prevention case definition.

patient should be monitored for proteinuria and hematuria. Because of steroid side effects, immunosuppressant drugs are often used for severe cases.

Henoch-Schönlein Purpura

Henoch-Schönlein purpura is a small-vessel vasculitis seen mostly in children. Immune complexes are deposited, causing petechiae, nephropathy, or renal disease (40%) and GI bleeding. The purpura is usually in dependent areas such as the buttocks and lower extremities. Affected children often present with abdominal pain after an upper respiratory infection. Symptoms typically resolve spontaneously without treatment within 2 weeks, but serious GI and renal involvement can occur, requiring steroids. NSAIDs might be helpful for arthralgias.

Kawasaki's Syndrome

Kawasaki's syndrome (KS), also known as Kawasaki's disease, is the leading cause of acquired heart disease in children. Prolonged high fever (up to 40° C [104° F]), with an urticaria-like rash and injection of mucous membranes, including a strawberry tongue, is followed by erythema of

the palms and soles and desquamation of the fingertips. Most patients have cervical lymphadenopathy. A myocarditis is present in more than 50% of patients and is manifested by a tachycardia. Many other symptoms might also occur, such as respiratory, neurologic, and GI symptoms (Box 32-5). Because KS symptoms resolve spontaneously, cardiac manifestations might not be diagnosed. A coronary arteritis and even aneurysms might develop, with significant morbidity and mortality. Laboratory studies are not helpful. Serial electrocardiograms are recommended at diagnosis, 2 to 3 weeks into the illness, and 1 month after that.

Although KS's seasonal variation (winter and spring) and epidemics suggest an infectious cause, none has yet been identified. IV fluids, aspirin, and IVIG have been used most frequently for KS. Antibiotics are of no use unless there is a concomitant bacterial infection. Steroids might actually increase the incidence of aneurysms and should be avoided, if possible.

Nonarticular Rheumatism

Any pain and stiffness without true inflammation in the joint and with normal laboratory results in children is termed *nonarticular rheumatism*, or "growing pains." These usually occur at night, last several hours, and often resolve spontaneously or are helped by massage or analgesics. Pain is sometimes felt behind the knees. No further evaluation is indicated unless pain occurs during the day. Overuse or hypermobile joints are two possible explanations; nonarticular rheumatism does not normally cause any reduction in activity.

Rheumatology Information on the Internet

A great deal of information on rheumatic diseases for both physicians and patients can be found on the Internet. This can be a valuable tool for the family physician in this era of active research and new treatment modalities in rheumatology. Patients might receive online support from numerous advocacy and support groups for these conditions, although the Internet can also be a source of misinformation, with charlatans touting arthritis cures. Websites of the ACR, Arthritis Foundation, and Medline Plus are particularly good sources of information (see Web Resources).

Principles of Diagnosis

Dermatologic diagnosis often begins with *pattern recognition*. Experts can look at most lesions and make an immediate and accurate diagnosis through pattern recognition. The basic terms used to describe lesion morphology and patterns provide the vocabulary to describe what is seen. The physician then combines keen observation of the lesions (including type and distribution) with a careful history to create an informed differential diagnosis. If the diagnosis is still not known, the physician can consult a dermatology atlas (online or print), textbook, or expert to complete the diagnosis. In some cases, further testing (scraping, culture, biopsy) may be needed.

Initial Evaluation

Although medical school teaches students to perform the history before doing the physical examination, this is not the most efficient way to approach the diagnosis of a skin condition. When the patient has a skin complaint, immediately look at the skin while asking your questions. Look carefully at the lesions and determine the lesion morphology. [Table 33-1](#) provides definitions for the terms used to describe primary and secondary morphology. A magnifying glass and good lighting help to distinguish the morphology of many skin conditions. Next, touch the lesions, with gloves when appropriate. For some lesions, such as actinic keratosis with

Table 33-1 Primary and Secondary Skin Lesions

| Lesions | Description |
|---------------------------------------|---|
| Primary (Basic) Lesions | |
| Macule | Circumscribed flat discoloration (up to 5 mm) |
| Patch | Flat nonpalpable discoloration (>5 mm) |
| Papule | Elevated solid lesion (up to 5 mm) |
| Plaque | Elevated solid lesion (>5 mm) (often a confluence of papules) |
| Nodule | Palpable solid (round) lesion, deeper than a papule |
| Wheal (hive) | Pink edematous plaque (round or flat), topped and transient |
| Pustule | Elevated collection of pus |
| Vesicle | Circumscribed elevated collection of fluid (up to 5 mm in diameter) |
| Bulla | Circumscribed elevated collection of fluid (>5 mm in diameter) |
| Secondary (Sequential) Lesions | |
| Scale (desquamation) | Excess dead epidermal cells |
| Crusts | Collection of dried serum, blood, or pus |
| Erosion | Superficial loss of epidermis |
| Ulcer | Focal loss of epidermis and dermis |
| Fissure | Linear loss of epidermis and dermis |
| Atrophy | Depression in skin from thinning of epidermis/dermis |
| Excoriation | Erosion caused by scratching |
| Lichenification | Thickened epidermis with prominent skin lines |

scaling or the sandpaper rash of scarlet fever, lightly feeling the skin provides much information. For deeper lesions, such as nodules and cysts, deep palpation is needed. Observe the distribution of the lesions. Try to determine if the primary lesions are arranged in groups, rings, lines, or merely scattered over the skin.

Determine which parts of the skin are affected and which are spared. Be sure to look at the remainder of the skin, nails, hair, and mucous membranes. Patients often show only one small area and appear reluctant to expose the rest of their skin, especially their feet. With many skin conditions, it is essential to look beyond the most affected area because other areas may provide important clues (e.g., nail pitting when considering psoriasis). Patients may have lesions on their back or feet that they have not observed. For example, a patient may have a papular eruption on the hands or arms that represents an autosensitization reaction (*id reaction*) to a fungal infection on the feet; not looking for the fungus on the feet will lead to a missed diagnosis (Figs. 33-1 and 33-2). Some skin diseases have manifestations in the

Figure 33-1 Vesicular tinea pedis leading to autosensitization reaction. (© Richard P. Usatine.)

Figure 33-2 Autosensitization reaction secondary to vesicular tinea pedis (*id reaction*). (© Richard P. Usatine.)

mouth; finding white patches on the buccal mucosa may lead to the correct diagnosis of lichen planus (Fig. 33-3).

Once the physician starts to look at the skin, the patient history will be more focused, directed toward finding the correct diagnosis. The following information assists in making a dermatologic diagnosis and planning treatment:

- Onset and duration of skin lesions: continuous or intermittent?
- Pattern of eruption: Where did it start? How has it changed?
- Any known precipitants, such as exposure to medication (prescription, OTC), foods, plants, sun, topical agents, chemicals (occupation, hobbies)?
- Skin symptoms: itching, pain, paresthesia
- Systemic symptoms: fever, chills, night sweats, fatigue, weakness, weight loss
- Underlying illnesses: diabetes, thyroid disease, human immunodeficiency virus (HIV)
- Family history: acne, atopic dermatitis, psoriasis, skin cancers, dysplastic nevi

The most important in-office examinations of the skin are the following:

Microscopy. To diagnose a fungal infection, scrape some of the scale onto a microscope slide, add 10% potassium

Figure 33-3 Oral lichen planus showing Wickham's striae. (© Richard P. Usatine.)

hydroxide (KOH) (best with dimethyl sulfoxide [DMSO] and fungal stain), and look for the hyphae of dermatophytes or the pseudohyphae of *Candida* or *Pityrosporum* species.

Wood's light examination. This is helpful in diagnosing tinea capitis and erythrasma. Tinea capitis caused by *Microsporum* spp. produces green fluorescence, but *Trichophyton* spp. do not fluoresce. Erythrasma has a coral-red fluorescence.

Wood's lamp also helps distinguish lesions of vitiligo in patients with fair skin.

Surgical biopsy. The biopsy can be used as a diagnostic and treatment tool. Having a reasonable differential diagnosis will help the physician choose shave, punch, or elliptic biopsy.

General Management

Topical Corticosteroids

The choice of a topical steroid involves maximizing benefit and minimizing adverse effects. Many skin conditions benefit greatly from topical steroids. However, local adverse effects of topical steroids are common with regular use over weeks to months. The most common adverse effect of topical steroids is skin *atrophy*, in which the epidermis becomes thin and the superficial capillaries dilate. Epidermal atrophy can be accompanied by hypopigmentation and telangiectasias. If atrophy involves the dermis, striae may occur. Although the epidermal atrophy may be reversible in months, striae are irreversible. When fluorinated steroids (the strongest steroids) are continuously applied to the face, perioral dermatitis, rosacea-like eruptions, and acneiform eruptions can occur.

Systemic adverse effects are rare and occur when large amounts of topical steroids are absorbed systemically. The risk of such absorption increases with stronger steroids, thinner skin, younger patients, longer duration of therapy, and the use of occlusion in therapy. Prescribing the minimum strength needed for the shortest duration required helps prevent adverse effects. In choosing the best topical steroid, consider the following factors:

1. **Skin disorder.** As the severity of the disorder increases, the need for higher-potency steroids increases. Also, thicker lesions (e.g., psoriatic plaques, lichen planus) need higher-potency steroids.

2. **Site.** Use only the weakest-potency steroids on the face, genitals, and intertriginous areas, where skin is thin or moist and skin atrophy and striae occur most rapidly. There are exceptions, however, as when clobetasol is needed to treat certain vulvar disorders. The skin on the palms and soles is so thick that the most potent steroids may be needed.
3. **Age.** Avoid the use of high-potency topical steroids in infants and children because they have greater surface area per body mass than adults and have greater risk and consequences of systemic absorption.
4. **Steroid potency** (strength and concentration). There are more than 50 types and brands of steroids; family physicians should know at least one steroid from each of four basic strengths (Table 33-2). Generic agents can be used from all the potency groups to save on costs.
5. **Vehicle.** The vehicle is the substance in which the steroid is dispersed. The most common vehicles are ointments, creams, gels, solutions, lotions, and foams. The choice of vehicle is determined by the characteristics of the lesion (dry or moist), the site involved, and patient preference. Further, the vehicle affects the potency of the steroid because it determines the rate at which the steroid is absorbed through the skin.

Most skin preparations can be applied two times a day (bid), conveniently in the morning and evening. Try to estimate and prescribe an appropriate amount; many topical products are supplied in 15-g, 30-g, 60-g, and 80-g sizes; 80 g is about the size of a tube of toothpaste. Based on common practice, it is accepted that 2 g of cream is required to cover the face or one hand, 3 g for an arm, 4 g for a leg, and 12 to 30 g for an entire body. To avoid adverse effects of steroid overuse, do not prescribe large quantities for small lesions, and specify duration of use. On the other end of the spectrum, prescribing only 15 g of steroid for a large area of involvement will be frustrating to the patient when the steroid is depleted before completing the prescribed treatment. Generic triamcinolone comes in 1-pound tubs (454 g), extremely helpful for patients with inflammatory conditions covering much of the body.

The duration of therapy is usually the time required for resolution of symptoms or lesions. To avoid adverse effects, the highest-potency steroids should not be used for longer than 2 to 4 weeks continuously. However, these can be used intermittently for chronic conditions such as psoriasis in a pulse-therapy mode (e.g., apply every weekend, with steroid-sparing medication on weekdays). For conditions with dry skin, liberal use of emollients between steroid applications can minimize steroid exposure while maximizing the benefits of therapy.

Management of Pruritus

Often, patients present because of the pruritus associated with a skin condition rather than the skin condition itself. Itching associated with visible lesions often responds to relatively nonspecific antipruritic treatments. If the itching is generalized, patients may obtain temporary relief from cool or tepid baths with the addition of colloidal oatmeal (Aveeno). Soap should be avoided. Oral antihistamines can be given every 6 to 8 hours, especially at bedtime to promote sleep. Diphenhydramine (Benadryl) and hydroxyzine (Atarax, Vistaril) are first-generation antihistamines that are relatively

Table 33-2 Potency of Topical Corticosteroids

| Potency | Generic Drugs | Brand Names |
|-----------------------------------|--|---|
| “Superpotent” (class 1) | Clobetasol, betamethasone dipropionate, halobetasol, fluocinonide | Clobex, Diprolene, Olux, Psorcon, Temovate, Ultravate, Vanos |
| High potency (classes 2 and 3) | Betamethasone dipropionate, mometasone, halcinonide, fluocinonide, desoximetasone, triamcinolone 0.1%, fluticasone, amcinonide | Diprolene, Elocon, Halog, Lidex, Psorcon, Topicort, Aristocort, Cutivate, Cyclocort |
| Midpotency (classes 4 and 5) | Prednicarbate, mometasone, betamethasone valerate, hydrocortisone probutate, fluocinolone, desoximetasone, hydrocortisone valerate, triamcinolone 0.025% | Dermatop, Elocon, Luxiq, Pandel, Synalar, Topicort, Westcort, Cordran, Cutivate, Locoid |
| Low potency (classes 6 and 7) | Alclometasone, desonide, fluocinolone, hydrocortisone | Aclovate, DesOwen, Synalar, Hytone, Desonate |

safe and effective, although caution should be used in older adult patients. Second-generation antihistamines are similarly effective for reducing pruritus in the daytime, and are less sedating for some patients. These include fexofenadine (Allegra), loratadine (Claritin), and cetirizine (Zyrtec). Usually, second-generation antihistamines are given once daily.

Skin Problems Beginning in Childhood

Atopic Dermatitis (Eczema)

Key Points

- Atopic dermatitis is a common inherited childhood disorder that may occur with other atopic conditions such as allergic rhinitis and asthma.
- Topical steroids and emollients are the mainstays of treatment for AD.
- Topical and systemic antibiotics are used for AD secondarily infected with bacteria.

Atopic dermatitis (AD) is a potentially debilitating condition that can compromise quality of life. Its most frequent symptom is pruritus. Pruritus leads to scratching, resulting in secondary skin changes such as lichenification, excoriation, and breakdown of the skin barrier. Consequently, atopic dermatitis has been referred to as “the itch that rashes.”

Atopic dermatitis is a common problem affecting up to 15% of all children. In most cases, AD occurs before 5 years of age, frequently on the face in the first year of life (Fig. 33-4). As children grow, the antecubital and popliteal fossae are often involved (Fig. 33-5). The disease may occur

Figure 33-4 Atopic dermatitis. (© Richard P. Usatine.)

Figure 33-5 Atopic dermatitis in antecubital fossa. (© Richard P. Usatine.)

intermittently between periods of complete remission. By adulthood, the incidence becomes less than 1%. Treatment should be directed at limiting itching, repairing the skin, and decreasing inflammation. Lubricants and topical corticosteroids are the mainstays of therapy. Topical pimecrolimus or tacrolimus are considered steroid-sparing agents and are effective for short-term use or in cases unresponsive to topical corticosteroids. These agents are only approved for second-line treatment in patients over 2 years of age. When required for severe cases, oral corticosteroids can be used. If pruritus does not respond to treatment, other diagnoses, such as bacterial overgrowth or viral infections, should be considered.

Always look for signs of bacterial superinfection, such as weeping of fluid and crusts (Fig. 33-6). Superinfection with *Staphylococcus aureus* may lead to worsening of atopic dermatitis as the bacteria functions as a super antigen. *S. aureus* superinfections are usually sensitive to methicillin, so oral cephalexin is frequently a good choice for treatment. Bleach baths are helpful to cut down on colonization. (Add ½ cup regular bleach per full tub of lukewarm water and soak for 5 to 10 minutes before washing off bleach water.)

Figure 33-6 Impetiginized atopic dermatitis. (©Richard P. Usatine.)

KEY TREATMENT

Topical steroids and emollients are the mainstay of treatment for atopic dermatitis (Hanifin et al., 2004) (SOR: A). Topical and systemic antibiotics are used for AD with secondary bacterial infection; weeping fluid and crusting during an exacerbation should prompt consideration of antibiotic use (Hanifin et al., 2004) (SOR: A). Topical calcineurin inhibitors (immunomodulators such as pimecrolimus and tacrolimus) reduce the rash severity and symptoms of AD in children and adults (Hanifin et al., 2004) (SOR: A). Dietary restriction is useful only for infants with proven egg allergies (Hanifin et al., 2004) (SOR: B). The value of antihistamines in AD is controversial; if used, the sedating agents are most effective and can be given at night (Hanifin et al., 2004) (SOR: B).

Pityriasis Alba

Pityriasis alba is a common hypopigmented dermatitis that may affect nearly one third of school-age children in the United States. The condition is more common in patients with a history of atopic dermatitis. Patients present with numerous hypopigmented macules ranging from 1 to 4 cm in size on the face, neck, and shoulders (Fig. 33-7). The macules are poorly defined and may have fine scales. Occasionally, erythema and pruritus occur before the lesions. Generally, pityriasis alba is self-limited and asymptomatic, so therapy is typically unnecessary. Lesions usually fade by adulthood. Topical steroids, emollients, and phototherapy have limited efficacy. Hydrocortisone 1% cream or ointment may provide some benefit, and if used for no more than 2 weeks, the patients should be relatively safe from adverse effects.

Keratosis Pilaris

Keratosis pilaris is very common and presents as tiny (<1 mm) keratotic follicular papules found on extensor arms and thighs and occasionally the cheeks. The numerous papules give the skin a rough feeling. Often there is a ring of erythema around the follicle. Incidence of keratosis pilaris

Figure 33-7 Pityriasis alba. (©Richard P. Usatine.)

is increased in AD patients. Treatment consists of emollients combined with keratolytic agents; common preparations are 5% or 12% ammonium lactate (AmLactin, Laclotion, Lac-Hydrin) and urea-based creams or lotions. Patient education should stress that keratosis pilaris is genetic and cannot be cured. Any smoothing with topical agents is temporary and will return if the treatment is stopped.

Melanocytic Nevi

Nevi (moles) are benign lesions composed of collections of nevus cells of neuroectodermal origin. They appear in childhood, tend to increase in number throughout the adult years, and then resolve with age. *Pigmented* nevi can be flat, raised, or pedunculated and have impressive variations in size, color, and surface characteristics. Histologically, *junctional* nevi are located in the epidermis, *intradermal* nevi in the dermis, and *compound* nevi in the epidermis and dermis. Junctional nevi are flat and pigmented, intradermal nevi are raised and often not pigmented, and compound nevi may be raised and pigmented (Figs. 33-8 and 33-9).

Unless they become suspicious for melanoma, nevi need not be removed except for cosmetic reasons or because of chronic irritation based on their location. Nevi should be examined frequently, however, for changes in color, shape, or size. These changes may herald the onset of a melanoma in a previously benign nevus and warrant excision with pathologic evaluation of the tissue.

Nevi that are present at birth and are visible shortly thereafter are considered *congenital* nevi. Although these nevi may have a slightly higher risk of developing melanoma than acquired nevi, it is not cost-effective or sensible to recommend the

Figure 33-8 Intradermal nevi. (© Richard P. Usatine.)

Figure 33-10 Dysplastic nevus. (© Richard P. Usatine.)

Figure 33-9 Compound nevus. (© Richard P. Usatine.)

removal of all congenital nevi. It is even controversial with regard to removal of large, “bathing suit” nevi, which have the highest risk of melanoma. Children born with these nevi are at risk for developing melanoma in the central nervous system (CNS) as well as subcutaneous melanoma, which is not visible and requires palpation in order to detect on routine skin examination.

Dysplastic nevi (atypical moles) are markers for increased risk of melanoma somewhere on the body. These nevi have more atypical features but are not at high risk of converting to melanoma (Fig. 33-10). Therefore, removing dysplastic nevi does not provide a survival benefit for patients.

The presence of five or more dysplastic nevi should alert the patient and physician to this higher risk of melanoma, and therefore regular skin examinations should be performed, with sun avoidance and sun protection.

Infantile Hemangioma

A hemangioma is an extremely common type of benign tumor that occurs most frequently in infants and children. It is composed of newly formed blood vessels that result from malformation of angioblastic tissue during fetal life. The two main types are capillary (superficial) and cavernous (deep) hemangiomas (Figs. 33-11 and 33-12).

Hemangiomas undergo a growth phase before resolving spontaneously. Although some regression begins by the end of the first year of life, many hemangiomas do not completely resolve until the child is 10 to 12 years old. Although typically benign, rapidly proliferating hemangiomas can ulcerate. Those on the face may obscure vision and can cause blindness. Hemangiomas of the genital region are also problematic and may indicate other internal malformations. Persistent or obstructive hemangiomas have been successfully treated with propranolol, lasers, excision, systemic corticosteroids, interferon, imiquimod, and cryosurgery.

Acne Vulgaris

Acne is a disorder of the pilosebaceous follicles on the face, chest, and back. Follicular obstruction leads to comedones, and inflammation results in papules, pustules, and nodules. The four most important steps in acne pathogenesis are (1) sebum overproduction related to androgenic hormones and genetics, (2) abnormal desquamation of follicular epithelium (keratin plugging), (3) *Propionibacterium acnes* proliferation, and (4) follicular obstruction, which leads to inflammation and follicular disruption. These steps are stimulated by androgens, and strong genetic factors determine a person’s likelihood of developing acne. Although common, acne can cause physical pain, psychosocial suffering, and scarring. Acne may be associated with fever, arthritis, and other systemic symptoms in acne fulminans (Fig. 33-13).

Topical treatments include retinoids, antibiotics, benzoyl peroxide (BP), azelaic acid, and alpha or beta hydroxyl acid products. Topical retinoids are comedolytic and anti-inflammatory, normalize follicular hyperproliferation and hyperkeratinization, and reduce the numbers of microcomedones, comedones, and inflammatory lesions. The most frequently prescribed topical retinoids include tretinoin (Retin-A), adapalene (Differin), and tazarotene (Tazorac, Avage). Patients are frequently sensitive to topical retinoids and may have skin irritation, peeling, and redness. Mild cleansers and noncomedogenic moisturizers can reduce the inflammation, as does less frequent dosing of the retinoids. Glycolic acid (α -hydroxy acid) or salicylic acid (β -hydroxy acid) come in various products, are used in chemical peels, and are also effective for hyperkeratinization.

Figure 33-11 Strawberry hemangioma. (© Richard P. Usatine.)

Figure 33-12 Cavernous hemangioma. (© Richard P. Usatine.)

Topical antibiotics are effective against *P. acnes* and also act as anti-inflammatories. Erythromycin and clindamycin are frequently used once or twice daily. Topical dapsone (Aczone) was approved in 2008 for acne treatment. Benzoyl peroxide is also effective against *P. acnes* and is available over the counter (OTC) in various preparations. Combination products with antibiotics and BP are a convenient method of delivering synergistic medications in one preparation.

Oral medications used in acne treatment include antibiotics, hormone therapies, and isotretinoin. Isotretinoin is a known teratogen and should not be used in women of childbearing age unless avoidance of pregnancy is ensured. Contraception counseling is mandatory, and two negative pregnancy test results are required before initiation of therapy. The baseline laboratory examination should also include determination of cholesterol, fasting triglycerides, transaminase levels, blood urea nitrogen (BUN)/creatinine, and complete blood count (CBC). Pregnancy tests and laboratory examinations should be repeated monthly during treatment.

KEY TREATMENT

Topical benzoyl peroxide (gel, cream, lotion, wash) has an antimicrobial effect in acne treatment. Higher-percentage products (10%) cause more irritation and are not more effective (Agency for Healthcare Research and Quality, 2001) (SOR: A).

Topical antibiotics such as clindamycin and erythromycin are beneficial treatments (AHRQ, 2001) (SOR: A).

Combination products with antibiotics and BP deliver synergistic medications in one preparation (AHRQ, 2001) (SOR: B).

Topical retinoids (tretinoin, adapalene, tazarotene) are excellent to treat all types of acne and the primary treatment in comedonal acne (AHRQ, 2001) (SOR: A).

Azelaic acid is useful to treat spotty hyperpigmentation and acne (AHRQ, 2001) (SOR: B).

Oral antibiotics with proven benefit in acne include tetracycline, doxycycline, minocycline, and erythromycin and are particularly useful for inflammatory acne and trunk acne (AHRQ, 2001; Strauss et al., 2007) (SOR: A).

Isotretinoin is the most powerful treatment for cystic and scarring acne that has not responded to other therapies (Fig. 33-14) (Strauss et al., 2007) (SOR: A).

Figure 33-13 Acne fulminans. (© Richard P. Usatine.)

Viral Exanthems

Viral causes of rashes include varicella, rubeola, rubella, roseola, and erythema infectiosum (fifth disease). Treatment is aimed at symptoms using acetaminophen or ibuprofen for fever and diphenhydramine for pruritus.

Varicella

Varicella is now much less common with universal varicella vaccination of children. Occasionally the family physician sees a case of breakthrough chickenpox in a vaccinated child. Unvaccinated adults may also present with varicella. Patients with varicella have fever and general malaise as a mild prodrome lasting 1 to 2 days before the rash appears. The rash typically begins on the face, scalp, or trunk and then spreads to the extremities. The lesions appear as erythematous macules and progress to papules with an edematous base. The papules quickly evolve into vesicles, appearing as “dewdrop on a rose petal” (Fig. 33-15). The vesicles evolve into pustules, which become umbilicated and subsequently crust over in the ensuing 8 to 12 hours. A defining characteristic of varicella is that lesions may be present in all stages simultaneously.

Figure 33-14 Acne conglobata. (© Richard P. Usatine.)

Figure 33-15 Chickenpox. (© Richard P. Usatine.)

In children the most common varicella complication is secondary bacterial infection of excoriated lesions. Other complications include cerebellar ataxia, encephalitis, meningitis, transverse myelitis, and rarely Reye's syndrome. Varicella pneumonia and encephalitis can be serious complications in adults. Because of the risk of Reye's syndrome, aspirin use should be avoided in patients with varicella. Acyclovir is recommended for adolescents, adults, and children with varicella who are taking steroids or otherwise immunocompromised.

Measles (Rubeola) and Rubella

Rubeola presents as maculopapular (morbilliform) eruption. It starts on the face and spreads centrifugally. It is associated with cough, coryza, conjunctivitis, fever, and Koplik spots (red-white-blue macules in mouth). As with varicella, rubeola is now uncommon because of vaccinations.

The exanthem of rubeola (measles) begins around the fourth febrile day, with discrete lesions that become confluent as they spread from the hairline downward, sparing the palms and soles. The exanthem typically lasts 4 to 6 days. The lesions fade gradually in order of appearance, leaving a residual yellow-tan coloration or faint desquamation. Rubeola is also distinguished by the presence of Koplik spots in the oral mucosa. These are usually small white or bluish macules with a ring of erythema on the buccal mucosa.

Rubella is similar to rubeola and is caused by a togavirus. It causes less severe symptoms, and its exanthem characteristically has a duration of 2 to 3 days. Rubella is associated with tender cervical lymphadenopathy, most notably in the posterior cervical and occipital areas. Another unique feature is Forchheimer spots, which are pinpoint red macules and petechiae over the soft palate and the uvula.

Hand, Foot, and Mouth Disease

This common childhood illness usually occurs in the summer or early fall and presents as flat-topped vesicles on hands, feet, and mouth, especially on the palms and soles. Every case may not involve all three sites. Hand, foot, and mouth disease is most often caused by coxsackievirus A16.

Erythema Infectiosum (Fifth Disease)

Erythema infectiosum is caused by human parvovirus B19 and primarily affects children 3 to 12 years old. The prodrome may consist of fever, anorexia, sore throat, and abdominal pain. Once the fever resolves, the classic bright-red facial rash (“slapped cheek”) appears. The exanthem progresses to a diffuse, reticular or “lacy” pattern on the extensor extremities that may wax and wane for several weeks.

Roseola Infantum (Sixth Disease, Exanthem Subitum)

Roseola infantum, or exanthema subitum, is caused by human herpesvirus 6. This disease occurs in children younger than 3 years. As in fifth disease, the rash of sixth disease appears after the resolution of several days of high fever. The diffuse morbilliform eruption often spares the face and is of short duration, typically fading within 3 days.

Inflammatory Dermatologic Diseases

Seborrhea

Seborrheic dermatitis is a chronic inflammatory disorder affecting areas of the head (scalp, face) and body where sebaceous glands are prominent. The inflammation is thought to be caused by *Malassezia (Pityrosporum)* species. All age groups may be affected, and seborrhea can be chronic or intermittent. On the scalp, seborrhea can range from mild dandruff to thick, adherent plaques. Seborrhea on the face and body appears as greasy scales in skin folds and along hair margins, with a symmetric distribution bilaterally. On the face, two common locations are around the eyebrows and around the beard and mustache in men (Fig. 33-16 and 33-17)

Treatments are aimed at the inflammation and the *Malassezia* overgrowth and include shampoos containing selenium sulfide, ketoconazole, or pyrithione zinc that target the fungus. Topical antifungal lotions and corticosteroid preparations are also effective. Low-potency corticosteroids used intermittently are safe and effective. In infants, seborrheic dermatitis might only involve the scalp (cradle cap) or can be seen in other areas of skin folds such as the diaper area. If not treated prophylactically, seborrheic dermatitis has a tendency to recur.

KEY TREATMENT

Shampoos containing ketoconazole, selenium sulfide or zinc pyrithione are effective for moderate to severe seborrhea capitis (Danby et al., 1993; Pierard-Franchimont, 2002) (SOR: A). Ketoconazole 2% cream, gel, or emulsion is safe and effective for facial seborrheic dermatitis (Chosidow et al., 2003; Pierard et al., 1991) (SOR: B). Oral terbinafine, 250 mg daily for 4 weeks, is effective for moderate to severe seborrhea (Scaparro, 2001; Vena et al., 2005) (SOR: A). Hydrocortisone 1% cream or lotion can be used twice daily on face, scalp, or other affected area (Firooz et al., 2006) (SOR: B). Desonide 0.05% lotion is safe and effective for short-term treatment of seborrheic dermatitis of the face (Freeman, 2002) (SOR: B). For moderate to severe seborrhea on the scalp, 0.05% fluocinonide solution once daily is affordably priced and beneficial (SOR: C).

Psoriasis

Psoriasis is a common skin disorder that most often appears as inflamed plaques covered with a thickened, silvery-white scale. Psoriasis is divided into the following nine categories, although a patient can have more than one type at the same time:

1. *Plaque* psoriasis accounts for 80% to 90% of patients with psoriasis (Fig. 33-18).
2. *Scalp* psoriasis causes plaques on the scalp (Fig. 33-19).
3. *Guttate* psoriasis appears as small, round plaques that resemble water drops (Fig. 33-20).
4. *Inverse* psoriasis causes inflammation in the intertriginous areas of the axilla, groin, inframammary folds, and intergluteal fold. Inverse psoriasis may not exhibit classic scaly plaques, and the erythema, scaling, or maceration in intertriginous areas is often mistaken for fungal infection (Fig. 33-21).
5. *Palmar-plantar* psoriasis occurs on the plantar aspects of the hands and feet (palms and soles) (Fig. 33-22).

Figure 33-16 Seborrheic dermatitis. (© Richard P. Usatine.)

Figure 33-17 Seborrheic dermatitis around beard and mustache. (© Richard P. Usatine.)

6. *Erythrodermic* psoriasis is widespread erythema and scales.
7. *Pustular* psoriasis can be localized or generalized. In the generalized form, superficial pustules may appear and coalesce to form lakes of pus that dry and desquamate in sheets (Fig. 33-23).
8. *Nail* psoriasis causes the nails to develop pits, onycholysis, and oil spots and to thicken.
9. *Psoriatic* arthritis affects the joints of the hands, feet, and knees but can involve other joints as well.

From 1% to 2% of the U.S. population has plaque psoriasis. Genetic factors are involved; when both parents are affected by psoriasis, the rate of psoriasis may be as high as 50%; with one parent affected, the rate is approximately 16%. Psoriasis can appear at any age, but the two peak age ranges are 16 to 22 and 57 to 60. Guttate psoriasis often occurs after streptococcal pharyngitis or another upper respiratory infection. Pustular psoriasis may be provoked by the withdrawal of systemic steroids in a patient already diagnosed with psoriasis.

The most common areas involved include the elbows, knees, extremities, trunk, scalp, face, ears, hands, feet, genitalia, intertriginous areas, and the nails. In most cases,

Figure 33-18 Psoriatic plaques. (© Richard P. Usatine.)

Figure 33-20 Guttate psoriasis after streptococcal throat infection in child. (© Richard P. Usatine.)

Figure 33-19 Scalp psoriasis. (© Richard P. Usatine.)

Figure 33-21 Inverse psoriasis under breasts. (© Richard P. Usatine.)

diagnosis of psoriasis is based on the clinical appearance. The differential diagnosis list is long, however, and a KOH preparation or skin biopsy may be needed. A biopsy may also be helpful to establish the diagnosis in less common types of psoriasis (pustular, palmar-plantar, inverse). Do not treat psoriasis with oral or systemic steroids; this can precipitate a life-threatening case of generalized pustular psoriasis.

A meta-analysis showed that 68% to 89% of patients treated with clobetasol (ultrahigh-potency steroid) had clear improvement or complete healing (Nast et al., 2007). Comparable efficacy was shown for topical calcipotriene (vitamin D analogue) and tazarotene (retinoid), with a slight increase in adverse effects for tazarotene (Afifi et al., 2005). Combination topical steroids and calcipotriene or tazarotene is the most promising

current topical treatment and seems to have increased efficacy and fewer side effects (Afifi et al., 2005; Nast et al., 2007). Clinical trials suggest that tacrolimus (0.1%) ointment twice daily produces a good response in a majority of patients with facial and intertriginous (inverse) psoriasis (Brune et al., 2007; Lebwohl et al., 2004; Martin et al., 2006). Methotrexate as a weekly oral dose of 5 to 15 mg can be very effective for widespread psoriasis not responding to topical treatments (Saporito and Menter, 2004). Acitretin (Soriatane) is a potent systemic retinoid used for psoriasis that is widespread or palmar-plantar and not responding to topical treatments (Pearce et al., 2006).

Etanercept (Enbrel) is a subcutaneous biologic agent that is especially valuable in patients with psoriatic arthritis, as well as those with moderate to severe cutaneous psoriasis (Nast et al., 2007). Adalimumab (Humira), a subcutaneous biologic agent, and infliximab (Remicade), an intravenous biologic agent, are effective for patients with psoriatic arthritis as well as those with moderate to severe cutaneous psoriasis (Bansback et al., 2009). Ustekinumab (Stelara), the most recently approved subcutaneous biologic agent, significantly reduced signs and symptoms of psoriatic arthritis and diminished skin lesions compared with placebo (Gottlieb et al., 2009).

KEY TREATMENT

Potent topical steroid ointments are a good choice for first-line therapy of psoriasis (Afifi et al., 2005) (SOR: A).
 Clobetasol successfully treated 68% to 89% of patients with psoriasis (Nast et al., 2007) (SOR: A).
 Topical calcipotriene and tazarotene show comparable efficacy as clobetasol for psoriasis (Afifi et al., 2005) (SOR: A).
 Topical steroids and calcipotriene or tazarotene show increased efficacy in psoriasis and fewer side effects (Afifi et al., 2005; Nast et al., 2007) (SOR: A).
 Tacrolimus (0.1 % ointment bid) helps most patients with facial and inverse psoriasis (Brune et al., 2007; Lebwohl et al., 2004; Martin et al., 2006) (SOR: B).
 Narrowband UVB is safer and more effective than broadband UVB for psoriasis (Ibbotson et al., 2004) (SOR: A).
 Methotrexate (5-15 mg/wk) is effective for widespread psoriasis not responding to topical treatments (Saporito and Menter, 2004) (SOR: A).
 Acitretin (Soriatane) is used for unresponsive widespread or palmar-plantar psoriasis (Pearce et al., 2006) (SOR: A).
 Etanercept (Enbrel) is especially valuable in patients with psoriatic arthritis or cutaneous psoriasis (Nast et al., 2007) (SOR: A).

Figure 33-23 Generalized pustular psoriasis presenting as erythroderma. (© Richard P. Usatine.)

Pityriasis Rosea

Pityriasis rosea is a common acute eruption usually affecting children and young adults; the cause is unknown. It is characterized by the formation of an initial herald patch (Fig. 33-24), followed by the development of a diffuse papulo-squamous rash. Pityriasis rosea is difficult to identify until the appearance of characteristic, smaller, secondary lesions that follow Langer's lines in a "Christmas tree" pattern (Fig. 33-25). The rash of pityriasis rosea typically lasts 5 to 8 weeks, with complete resolution in most patients. An important goal of treatment is to control pruritus, which may be

Figure 33-24 Pityriasis rosea with herald patch on neck. (© Richard P. Usatine.)

Figure 33-25 Pityriasis rosea with "Christmas tree" pattern on back. (© Richard P. Usatine and E.J. Mayeaux, Jr. *The Color Atlas of Family Medicine*.)

severe; zinc oxide, calamine lotion, topical steroids, and oral antihistamines are usually helpful. Systemic steroids are generally not recommended.

Ultraviolet (UV) radiation and erythromycin have been used with varying results. Because no bacterial cause has been associated with the disease, the likely effect of erythromycin is a result of its anti-inflammatory properties. Postinflammatory hyperpigmentation may occur with UVB radiation therapy, so some experts recommend against its use. High-dose acyclovir (800 mg qid) may help shorten disease, especially if instituted early in the disease course, but studies are limited.

Patients should be reassured about the self-limited nature of pityriasis rosea. Persistence of the rash or pruritus beyond 12 weeks should prompt reconsideration of the original diagnosis, consideration of biopsy to confirm the diagnosis, and questioning the patient again about use of medications that may cause a rash similar to that of pityriasis rosea.

Rosacea

Rosacea, sometimes called “acne rosacea,” is an inflammatory disease with unknown etiology. Various facial manifestations occur, and symptoms differ from patient to patient. The four types of rosacea are erythematotelangiectatic, papulopustular, phymatous, and ocular. Patients may have overlapping features of more than one type. The predominant manifesting complaints of *erythematotelangiectatic* rosacea are intermittent central facial flushing and erythema. Itching is often absent; however, many patients complain of a stinging pain associated with flushing episodes. Common triggers include exposure to the sun, cold weather, sudden emotion including laughter or embarrassment, hot beverages, spicy foods, and alcohol consumption.

Papulopustular rosacea presents with acnelike papules and sterile pustules and can occur alone or in combination with the erythema and telangiectasias (Fig. 33-26). Intermittent or chronic facial edema may also occur in all forms. Some patients develop *rhinophyma*, a coarse hypertrophy of the connective tissue and sebaceous glands of the nose. This can be extremely disfiguring and even cause nasal airway obstruction. Approximately one third of patients with

rosacea develop ocular symptoms, including eyes that are itchy, burning, or dry; a gritty or foreign body sensation; and erythema and swelling of the eyelid. The ocular changes can become chronic. Corneal neovascularization and keratitis can occur, leading to corneal scarring and perforation. Episcleritis and iritis have also been reported to occur in patients with rosacea.

First-line treatment is avoidance of triggering or exacerbating factors. Although patients have different trigger(s), almost all patients benefit from strict sun avoidance and protection. Acnelike lesions respond well to long-term topical treatment using metronidazole, azelaic acid, erythromycin, and clindamycin. Oral tetracyclines used in antimicrobial (high) doses or anti-inflammatory (low) doses are helpful for moderate to severe rosacea. Oral or topical retinoid therapy may also be effective. Laser treatment is an option for progressive telangiectasia, erythema, or rhinophyma. Ocular symptoms generally require oral tetracyclines. Consultation may be required for the management of rhinophyma, ocular complications, or severe disease.

KEY TREATMENT

Best evidence supports the topical use of metronidazole (0.75% or 1%) and azelaic acid (15% or 20%) for rosacea (van Zuuren et al., 2005) (SOR: A).

If the skin lesions are more extensive, oral antibiotics, such as tetracycline and metronidazole, are recommended for rosacea (van Zuuren et al., 2005) (SOR: C).

Both anti-inflammatory (low-dose) doxycycline (40-mg delayed-release Oracea) and 100-mg doxycycline are equally effective once-daily treatments for moderate to severe rosacea; higher dosage (100 mg) is associated with a higher incidence of adverse effects (mostly GI symptoms) (Del Rosso et al., 2008).

Pulsed-dye laser and intense pulse light result in significant reduction in erythema, telangiectasia, and patient-reported associated symptoms (Neuhaus et al., 2009).

Lichen Planus

Lichen planus is a papular pruritic skin eruption characterized by its violaceous color and polygonal shape. Most frequently, flat-topped papules and plaques are found on the flexor surfaces of the upper extremities, on the genitalia, around the ankles, and on the mucous membranes (Figs. 33-27 and 33-28). Lesions can be intensely pruritic. Because lichen planus is thought to be immune-mediated, it may be

Figure 33-26 Rosacea. (© Richard P. Usatine.)

Figure 33-27 Lichen planus with linear papules. (© Richard P. Usatine.)

Figure 33-28 Lichen planus on lateral ankle. (© Richard P. Usatine.)

Figure 33-29 Lichen simplex chronicus. (© Richard P. Usatine.)

found in conjunction with ulcerative colitis, vitiligo, myasthenia gravis, dermatomyositis, and alopecia areata. Lichen planus is also associated with primary biliary cirrhosis, chronic active hepatitis, and hepatitis C infection.

Patients with lichen planus are usually between 30 and 60 years old, although the disorder may occur at any age. Men and women are equally affected, and there is no racial predisposition. The cutaneous form spontaneously resolves within 6 months in about half of patients, and most forms resolve within 18 months. Mucous membrane lesions may become chronic and persist for years. Mild cases can be treated symptomatically with antihistamines and topical steroids. More severe cases or those involving the mucous membranes can be treated with systemic steroids, oral acitretin, or UV light. Other immunosuppressants, such as mycophenolate mofetil and cyclosporine, have also been used with some success.

KEY TREATMENT

Treatment of lichen planus starts with high-potency topical steroids twice daily to the affected areas (SOR: C). Intralesional triamcinolone (3 mg/mL) is considered for hypertrophic or mucous membrane lichen planus lesions (SOR: C). Systemic treatment with oral steroids, acitretin, mycophenolate mofetil, and cyclosporine can be considered for severe cases of lichen planus that involve mucous membranes (Zakrzewska et al., 2005) (SOR: B).

Lichen Simplex Chronicus

Lichen simplex chronicus (LSC) is a secondary condition that results from repeated mechanical trauma to the skin, usually through rubbing and scratching, which causes lichenification (thickening of epidermis). Skin appears leathery, violaceous to hyperpigmented, and scaly (Fig. 33-29). Involved areas are within the patient's easy reach, such as arms, legs, posterior neck, upper back, buttocks, and scrotum. The cycle of pruritus, which is alleviated by scratching, perpetuates the condition. Pruritus is usually worse during periods of inactivity, usually at bedtime and during the night. Stress also may provoke pruritus, which

is relieved by rubbing and scratching and often becomes an unconscious behavior.

Treatment of LSC is aimed at treating existing lesions, reducing pruritus, providing insight into the itch-scratch cycle, and eliciting behavioral changes. Topical steroids decrease inflammation and pruritus and help "thin down" the hyperkeratosis. Because lesions are by nature chronic, long-term treatment should be stressed. Occlusion can be used to increase potency and enhance delivery of the topical steroid and also provides a barrier to scratching. Flurandrenolide tape (Cordran) is very effective and can be cut to fit each lesion of LSC. Anxiolytics and antihistamines such as diphenhydramine and hydroxyzine may be considered as adjunct treatments. In severe, debilitating cases, oral doxepin and clonazepam may be considered. For secondary infections, a topical or oral antibiotic is appropriate.

Contact Dermatitis

Key Points

- Contact dermatitis is classified as irritant (ICD) or allergic (ACD).
- Clinical findings of ICD and ACD can be identical, and both entities can be present simultaneously.
- Nickel is the most common cause of ACD.
- Avoidance of irritating substances or environments and allergens is key to therapy. Dry-skin care and topical corticosteroids are also helpful.
- Referral for patch testing can help identify the causative agent in ACD.

Contact dermatitis may be classified by cause into two subgroups: *irritant* contact dermatitis (ICD) and *allergic* contact dermatitis (ACD). ICD occurs when the skin is exposed to an environment or substance in a sufficient frequency, quantity, or duration that it overcomes the barrier function of the skin. Therefore, given adequate exposure, anyone may experience ICD. ACD is a delayed-type hypersensitivity (type 4) reaction to a topical agent and requires initial contact with a substance causing a T helper cell type 2 (Th2)-mediated immune response in a predisposed individual. Only with

repeated exposure do the primed T cells cause the clinical response of dermatitis.

Findings of contact dermatitis can include erythema, vesicles, bullae, exudation, and crusting from breaking of blisters, swelling, and scaling. Common areas affected are the hands, neck, eyelids, face, genitalia, and legs. ICD and ACD can look identical and can present on similar body areas. Both may be intensely pruritic, further complicating the diagnosis. In addition, ACD and ICD can be present simultaneously, as with the health care worker allergic to latex who washes the hands repeatedly throughout the day. A careful history and patch testing are often the key to diagnosis.

Each year, millions of patients develop an allergic rash after contact with poison ivy, poison sumac, or poison oak, and contrary to popular belief, the fluid within these vesicles does not cause poison ivy "to spread." Nickel is the most common nonplant cause of ACD and historically more common in women because of costume jewelry and ear piercing (Fig. 33-30). With the increased popularity of jewelry and body piercing, the prevalence is rising in men. The 10 top causes of ACD in North America are nickel, neomycin, balsam of Peru (common fragrance), fragrance mix, thimerosal (preservative no longer used in vaccines but still found in eye preparations), sodium gold thiosulfate, quaternium-15 (preservative), formaldehyde (preservative), bacitracin, and cobalt (metal often in conjunction with nickel in silver-colored jewelry).

In the workplace, ACD is very common. For skin conditions, 90% of workers' compensation claims result from contact dermatitis. Common offenders in specific occupations are rubber or latex in health care workers, hair and clothing dyes in hairdressers, chromates in cement workers, and the Rhus family (poison ivy, oak, and sumac) in agricultural workers. ICD most often develops in response to excessive exposure to soaps, cleansers, hand sanitizers, and water. Therefore the primary treatment is avoidance of these irritating substances, application of a barrier ointment such as petrolatum, and protective equipment such as gloves.

For ACD caused by plants, the skin and clothes with soap and water should be thoroughly washed as soon as possible to minimize exposure to the antigen. Cool, wet soaks for 10 to 15 minutes may be soothing. Superpotent topical steroids, such as clobetasol propionate or betamethasone dipropionate applied twice daily for 1 to 2 weeks, are effective for treating small areas of moderate ACD. Systemic steroids are reserved for severe episodes of and should be continued for at least 2 weeks to prevent rebound dermatitis. In otherwise healthy persons, a tapering dose of prednisone is not required for short courses of systemic therapy. Severe pruritus may respond to antihistamines such as hydroxyzine, diphenhydramine, or a nonsedating H₂ blocker such as loratadine, cetirizine, or fexofenadine.

If ACD is suspected based on history, consultation for patch testing with a dermatologist can be customized to the patient's occupation or hobbies. Once the offending agent is identified, avoidance is crucial. When the offending agent is occupational, a change in jobs may be required. Alternative protective equipment can be sufficient in other cases, such as substituting nitrile gloves for latex. Generalized dry-skin care, topical steroids, or immunomodulators (pimecrolimus, tacrolimus) can help prevent recurrence and treat flares.

Figure 33-30 Contact dermatitis to nickel jewelry in umbilicus. (©Richard P. Usatine.)

Figure 33-31 Dyshidrotic eczema with tapioca vesicles (pompholyx). (©Richard P. Usatine.)

Dyshidrotic Eczema (Pompholyx)

Dyshidrotic eczema is a form of dermatitis characterized by a pruritic vesicular eruption on the fingers, palms, and soles (Figs. 33-31). Patients may be affected at any age, with women affected twice as often as men. The condition may be acute, intermittent, or chronic. Eruptions occur with varying severity and can be mild or debilitating. Before the formation of vesicles, patients describe itching or burning of the hands and feet. Small vesicles appear along the lateral aspects of the fingers or feet, palms, and soles. Lesions may persist for weeks and may be accompanied by erythema of the palms and soles.

Treatment of dyshidrotic eczema includes high-potency topical steroids and cold compresses for symptomatic relief

of the burning sensation. Greasy emollients are helpful to moisturize, protect, and prevent fissures. If fissures do occur, cyanoacrylate ("superglue") can be used to seal small cracks in the skin and decrease pain. Short courses of oral steroids may be used for acute flares.

Stasis Dermatitis

Stasis dermatitis occurs on the lower extremities in patients with chronic venous insufficiency (Fig. 33-32). Impaired function of the venous valves permits backflow of the blood from the deep venous system to the superficial system, causing increased venous hydrostatic pressure and increased permeability of dermal capillaries. The condition typically affects middle-aged and older-adult patients, except for patients with acquired venous insufficiency resulting from surgery, trauma, or thrombosis.

Stasis dermatitis can range from mild to severe. In all stages, reddish brown discoloration is caused by staining from hemosiderin that has leaked out of red blood cells in the overtaxed dermal capillaries. Pedal edema and scaling are also present in various degrees, and one leg can be more affected than the other. ACD is often superimposed on stasis dermatitis and can mislead the physician into suspecting cellulitis because of a sudden reddening, weeping, or induration of the area. Because of the impaired skin barrier and frequent use of OTC products and "home remedies," neomycin, lanolin, iodine, fragrances, and preservatives are common triggers for ACD in these patients.

Long-term treatment focuses first on reducing pedal edema with compression therapy, after assessing the integrity of the arterial circulation to prevent claudication or ischemic necrosis. Compression stockings are best applied early in the morning, before the patient rises from bed, when leg edema is at a minimum. For the pruritus and dermatitis, stasis dermatitis is treated in the same manner as other forms of acute eczematous dermatitis. Dry skin care with mild cleansers (Dove, Cetaphil) and bland emollients (petrolatum, Aquaphor or Absorbase) should be used liberally. Medium-potency topical corticosteroids (e.g., triamcinolone 0.1% ointment) should be used twice daily when inflammation and pruritus are present. If infection is suspected, mupirocin should be used preferentially over other topical antibiotics. For severe cases with exuberant purulent drainage and induration, oral antibiotics with activity against *Staphylococcus* and *Streptococcus* should be used.

Nummular Dermatitis (Nummular Eczema)

Nummular dermatitis consists of well-demarcated, coin-shaped lesions of eczema, typically on the extremities and less often the trunk (Fig. 33-33). Nummular dermatitis tends to worsen in dry, cold weather. Lesions may be mildly to severely pruritic and as a result become excoriated or even lichenified with scratching. Nummular dermatitis can be confused with plaques of psoriasis or tinea corporis but skin scrapings will not reveal hyphae on KOH preparation. Also, lesions lack the typical central sparing of tinea corporis. If necessary, a biopsy can help differentiate nummular eczema from psoriasis.

As with all eczematous dermatitis, general dry skin care is recommended with mild cleansers and bland emollients.

Figure 33-32 Stasis dermatitis. (© Richard P. Usatine.)

Figure 33-33 Nummular eczema. (© Richard P. Usatine.)

An intermediate to potent topical steroid may be applied two to four times daily to the affected areas. Once lesions improve, a lower-potency steroid should be used to minimize skin atrophy. Pruritus may be treated with an antihistamine if needed.

Generalized Exfoliative Dermatitis

Exfoliative dermatitis, also known as *erythroderma*, is an uncommon but serious skin disorder defined as erythema and scale covering over 90% of the body surface area (Fig. 33-34). The four most common causes of erythroderma are psoriasis, AD, cutaneous T-cell lymphoma (CTCL), and drug reactions. More than 60 drugs have been implicated in cases of exfoliative dermatitis; more often allopurinol, beta-lactam antibiotics, antiseizure medications, and sulfa drugs. More than half of patients will have a known underlying skin disease, but in up to 25% an etiology may never be determined and is termed *idiopathic* erythroderma. The majority of patients are adults over age 40.

The long-term prognosis is good in patients with drug-induced exfoliative dermatitis. The course tends to be remitting and relapsing in idiopathic cases. The prognosis of patients with associated malignancy usually depends on the

Figure 33-34 Erythroderma secondary to pustular psoriasis. (© Richard P. Usatine.)

outcome of the malignancy. A skin biopsy can help establish the diagnosis when the underlying skin disease is not known. The approach to treatment should include discontinuation of potentially causative medications and a search for any underlying malignancy. Initial evaluation and treatment usually require hospitalization for fluid and electrolyte replacement, temperature modulation, and prevention and treatment of secondary infection.

Erythema Nodosum

Erythema nodosum is an acute inflammatory process involving the fatty tissue layer underlying the skin (panniculitis). The condition is more frequently seen in women, and although often idiopathic, many cases are associated with streptococcal infections of the upper respiratory tract, drugs such as estrogens/oral contraceptives, sarcoidosis, and inflammatory bowel disease. Other, less frequent bacterial causes include tuberculosis, brucellosis, mycoplasma, and chlamydia. Fungal infections such as blastomycosis and histoplasmosis may also cause erythema nodosum. Rare causes are Behçet's disease, acute myelogenous leukemia, and Hodgkin's disease.

Patients present with tender red nodules, most frequently on the pretibial area or lower legs. The nodules may become fluctuant but do not suppurate or ulcerate. New lesions may continue to appear for several weeks. Additional symptoms may include fever, malaise, and arthralgia. Treatment is aimed at determining any underlying cause. Infectious processes should be evaluated and treated appropriately. Discontinuation of any possible offending agents is also advised. Bed rest, leg elevation, and nonsteroidal anti-inflammatory drugs (NSAIDs) are the mainstays of therapy. Spontaneous

Figure 33-35 Granuloma annulare. (© Richard P. Usatine.)

resolution occurs within 4 to 6 weeks in most patients, but residual leg pain and ankle edema can persist for weeks.

Granuloma Annulare

Granuloma annulare is a benign, self-limited dermatosis characterized by a raised annular distribution (Fig. 33-35). The condition may be localized, generalized, perforating, or subcutaneous. Except for subcutaneous granuloma annulare, the subtypes have similar appearances, but each follows a distinct clinical course. *Subcutaneous* granuloma annulare appears differently, with deep dermal or subcutaneous nodules. Patients with *localized* granuloma annulare present with groups of 1-mm to 2-mm papules in an annular arrangement over the distal extremities, ranging in color from skin tone to erythematous. Lesions most frequently appear on the dorsal surfaces of the hands and feet, fingers, and extensor aspects of the arms and legs. In *generalized* granuloma annulare, patients have a few to thousands of papules and rings that involve many body regions. The rings tend to be distributed symmetrically. Patients with *perforating* granuloma annulare present with up to hundreds of grouped 1-mm to 4-mm papules that may evolve into pustular lesions that drain and umbilicate, leaving atrophic scars. These lesions tend to appear on the extensor surfaces of extremities and the dorsa of the hands and fingers. Granuloma annulare may resolve spontaneously but can take several years. When patients request treatment, steroid injections are most effective.

Infectious Skin Diseases

Bacterial Infections

Key Points

- Most bacterial skin infections are caused by *Streptococcus pyogenes* or *Staphylococcus aureus*.
- Impetigo is the most superficial bacterial skin infection and often appears with honey-crusted lesions.
- Erysipelas is a superficial bacterial skin infection that extends into the cutaneous lymphatics, most often on the face or lower leg.

- Cellulitis is a deeper skin infection that requires oral antibiotics active against *S. pyogenes* and *S. aureus*.
- Abscesses often require incision and drainage to resolve completely.
- Community-acquired methicillin-resistant *S. aureus* is a common cause of abscesses and other bacterial skin infections.

Impetigo

Impetigo is a bacterial infection of the epidermis caused by *Staphylococcus aureus* and group A beta-hemolytic streptococci (GABHS). Both organisms may be present at the same time in the affected site. Community-acquired methicillin-resistant *S. aureus* (CA-MRSA) may cause impetigo. Impetigo is highly infectious and easily transmitted by hand contact. Various types of dermatitis can become secondarily infected with bacteria, and the skin is then called “impetiginized.” About 30% of people are colonized in the anterior nares by *S. aureus*. The bacteria are transmitted from one person to another through hand contact, entering through broken skin created by cutaneous diseases, burns, surgery, trauma, radiation therapy, and insect bites.

Impetigo is a common condition that occurs in all age groups and in both genders equally. The incidence in those younger than 6 years is higher than in adults. Peak incidence occurs during the summer and fall. Most patients recover without complications. Individuals with impetigo from streptococcal infections can develop glomerulonephritis as a rare complication. Impetigo is usually diagnosed clinically based on its characteristic appearance of honey crusts and superficial ulcerations (Figs. 33-36). Exudate from beneath the skin crust should be obtained for culture and sensitivity testing if a community outbreak has occurred, MRSA is suspected, or poststreptococcal glomerulonephritis is present.

Mupirocin ointment is the treatment of choice for small areas of impetigo and is as effective as oral antibiotics, including cases caused by MRSA and GABHS. Mupirocin three times daily for 5 days each month is also recommended intranasally for patients found to be chronic nasal carriers. Oral antibiotics are used in patients with extensive impetigo or with refractory infection. A cephalosporin, semisynthetic

Figure 33-36 Impetigo on back and buttocks of child showing honey crusts. (© Richard P. Usatine.)

penicillin, or beta-lactam–beta-lactamase inhibitor is recommended. If bacterial cultures reveal MRSA, trimethoprim-sulfamethoxazole, doxycycline (over age 10), or clindamycin are appropriate. Gentle debridement of crusts using antibacterial soap and a washcloth is also recommended. Patients should be encouraged to use careful handwashing to prevent further spread of infection.

Erysipelas (St. Anthony’s Fire)

Erysipelas is a superficial bacterial skin infection that extends into the cutaneous lymphatics. Usually, this infection is caused by *Streptococcus pyogenes* and occurs on the face or lower leg. Bacterial inoculation into an area of damaged skin is the initial event in developing erysipelas, although patients may not recall the precipitating event. The source of the bacteria is often from the host’s nasopharynx. A history of recent streptococcal pharyngitis is reported in up to one third of patients.

The most common complaints during the acute infection are pain, fever, chills, and swelling of the skin. Infants, young children, and older adult patients are the groups most often affected, with a peak incidence at age 60 to 80. Erysipelas may become a red, indurated, tense, and shiny plaque with sharply demarcated margins. Local inflammatory signs, such as warmth, edema, and tenderness, are universal. Lymphatic involvement is manifested by a peau d’orange look to the skin, with sharp borders and regional lymphadenopathy. More severe infections may include numerous vesicles or bullae, petechiae, and even skin necrosis. Streptococci cause erysipelas in as many as 80% of cases, with two thirds of those caused by group A and 25% by group G streptococci. *S. aureus* has been implicated in cases of recurrent erysipelas secondary to lymphedema. Atypical forms have been caused by *Streptococcus pneumoniae*, *Klebsiella pneumoniae*, *Yersinia enterocolitica*, and *Moraxella* spp. and should be considered in cases refractory to standard antibiotic therapy.

In cases involving the extremities, elevation and rest of the affected limb are recommended to reduce local swelling and inflammation. Oral or intramuscular (IM) penicillin for 10 to 14 days is sufficient for many cases of erysipelas. A macrolide such as erythromycin or azithromycin may be used if the patient is allergic to penicillin. Hospitalization for close monitoring and intravenous (IV) antibiotics are recommended for severe cases and for infants, older adults, and immunocompromised patients. Facial erysipelas should be treated empirically with a penicillinase-resistant antibiotic such as dicloxacillin to cover for possible *S. aureus*. Predisposing skin lesions, such as tinea pedis and stasis ulcers, should be treated aggressively to prevent superinfection.

Cellulitis

Cellulitis is an acute infection of the skin and soft tissues, usually developing after a break in the skin. The condition is characterized by localized pain, swelling, tenderness, erythema, and warmth (Fig. 33-37). The vast majority of cases are caused by *Streptococcus pyogenes* or *S. aureus*. Other causes include *Vibrio vulnificus* and *Pseudomonas*. Cellulitis is generally localized and nonrecurrent when treated appropriately.

Mortality is extremely rare but may occur when the condition is neglected or caused by a highly virulent organism. Patients typically present with a red, hot, swollen, and tender area of skin. Unlike erysipelas, the borders are neither elevated nor sharply demarcated. Lymphangitis and local lymphadenopathy may be present. Fever is common, and patients with severe cases may develop hypotension. Those with mild cellulitis may be treated as outpatients. Oral antibiotics are usually effective for treatment of cellulitis in immunocompetent hosts. Severe cases or patients with comorbid conditions (e.g., cardiac, renal, or hepatic failure, immunosuppression) should be initially treated with IV antibiotics in the hospital setting. Elevation of affected limbs improves resolution of swelling.

Folliculitis

Folliculitis is caused by infection or irritation of individual hair follicles. Patients with folliculitis present with pustules at the bases of hairs, particularly on the scalp, back, legs, and arms (Fig. 33-38). Folliculitis occurs more often in obese, immunocompromised, or diabetic patients. *S. aureus* is the most common pathogen. A form of folliculitis

Figure 33-37 Cellulitis on foot of child after a break in the skin. (© Richard P. Usatine.)

Figure 33-38 Folliculitis secondary to methicillin-resistant *Staphylococcus aureus* (MRSA). (Courtesy of Alisha N. Plotner, MD, and Robert T. Brodell, MD, with permission from *J Fam Pract* 2008; 57(4):253–255.)

caused by *Pseudomonas*, “hot tub folliculitis,” occurs when patients use poorly maintained hot tubs. The condition may be self-limited, requiring only the use of antibacterial soap, or may persist and require topical or systemic antibiotic therapy. If a pseudomonal infection is suspected and lesions persist for more than 5 days without treatment, an oral fluoroquinolone (e.g., ciprofloxacin) should be considered.

Abscesses: Furuncles and Carbuncles

Furuncles, or “boils,” are small abscesses in the skin. Patients present with a painful, often fluctuant swelling in areas of friction, the nasal area, or the external ear. A *carbuncle* is a collection of furuncles and usually occurs on the back of the neck in middle-aged and older men. Treatment often requires drainage of the lesion. Antibiotic therapy should be considered if the furuncle is not yet fluctuant, there is evidence of surrounding cellulitis or lymphadenitis, or the lesion is on the face. Carbuncles have many interconnecting sinuses and tend to recur despite drainage and antibiotics. Surgical drainage and resection of the lesions are often necessary. Many abscesses are now caused by MRSA, but the primary treatment is still incision and drainage.

Erythrasma

Erythrasma is a superficial skin infection caused by *Corynebacterium*, a normal inhabitant of the skin. The infection typically occurs in intertriginous spaces, especially in obese, hyperhidrotic, or diabetic patients (Fig. 33-39). Moderate itching and discomfort may occur, and the infected skin is often reddish brown and may be slightly raised, with some central clearing. The lesions are largely confluent but may have poorly defined borders. Because of the production of porphyrins by the infecting corynebacteria, Wood’s light demonstrates the lesions as a coral red. However, if the patient has recently washed the affected area, the coral-red fluorescence may be absent. Erythrasma is often confused with a fungal infection. Erythrasma may be treated with oral or topical erythromycin or clindamycin.

Figure 33-39 Erythrasma in groin. (© Richard P. Usatine.)

Fungal Infections

Key Points

- Tinea capitis should be treated with oral antifungal agents.
- Tinea infections may be transmitted from person to person by animals (pets, livestock) and through fomites.
- Over-the-counter topical antifungals are often effective for tinea pedis.
- Tinea versicolor is caused by *Malassezia* and can be treated by topical antidandruff shampoos or oral antifungal (ketoconazole, fluconazole).

Dermatophytosis (Tinea)

Mucocutaneous fungal infections are caused by dermatophytes (*Microsporum*, *Epidermophyton*, and *Trichophyton*) and yeasts. About 40 species in the three dermatophyte genera can cause tinea pedis and manus, tinea capitis, tinea corporis, tinea cruris, and onychomycosis. Yeasts of *Candida* can cause diaper dermatitis, balanitis, vulvovaginitis, and thrush (Fig. 33-40). The yeastlike organism of *Malassezia* (*Pityrosporum*) causes tinea versicolor and contributes to seborrhea. Although tinea versicolor has the name tinea in it, it is not a true dermatophyte.

The most important test for a suspected fungal infection is the KOH prep. Scrape the leading edge of the lesion onto a slide using the side of a #15 scalpel or another slide. Use the coverslip to push the scale into the center of the slide. Add 2 drops of KOH (with or without fungal stain) to the slide, and place coverslip on top. Examine with microscope starting with 10× and low light to look for the cells and hyphae. The fungal stain helps the hyphae to stand out among the epithelial cells. Look for groups of cells that appear to have fungal elements within them; don't be fooled by cell borders that look linear and branching. Switch to 40× to confirm any areas that appear to have fungal elements by looking for true fungal morphology. The fungal stains bring out these characteristics, including cell walls, nuclei, and arthroconidia (Fig. 33-41). KOH test characteristics without fungal stain are sensitivity, 77% to 88%, and specificity, 62% to 95% (Thomas, 2003).

Tinea Corporis

Tinea corporis is a superficial dermatophyte infection of the cornified layers of skin on the trunk and extremities. Lesions are typically annular with central clearing and a scaling border and may be pruritic (Fig. 33-42). Infection may be transmitted from person to person, by animals such as household pets or farm animals, and through fomites. Because the cornified layer of skin is involved, topical therapy is usually sufficient for localized cases. A topical antifungal should be applied to the lesion and proximal surrounding skin twice daily for a minimum of 2 weeks. Various agents have demonstrated effectiveness, including the azoles (miconazole, clotrimazole, ketoconazole, itraconazole) and the allylamines (naftifine, terbinafine). Terbinafine 1% cream (available OTC as Lamisil AF) produced a mycologic cure of 84.2%, versus 23.3% with placebo (Budimulja et al., 2001). In another study, patients with mycologically diagnosed tinea corporis and tinea cruris were randomly allocated

Figure 33-40 Thrush caused by *Candida albicans*. (© Richard P. Usatine.)

to receive either 250 mg of oral terbinafine once daily or 500 mg of griseofulvin once daily for 2 weeks. The cure rates were higher for terbinafine at 6 weeks (Voravutinon, 1993). Patients should be instructed to avoid direct contact with others and avoid sharing towels and clothing to prevent spread of the infection. Oral antifungal agents should be considered for first-line therapy for tinea corporis covering large areas of the body (Fig. 33-43).

KEY TREATMENT

All topical antifungal agents (not nystatin) may be effective, but evidence supports the greater effectiveness of the allylamines (e.g., terbinafine) over the less expensive azoles (e.g., clotrimazole) for tinea pedis and corporis (Crawford, 2000) (SOR: A). Terbinafine 1% cream or solution once daily for 7 days is highly effective for tinea corporis or cruris (Budimulja et al., 2001) (SOR: B). Oral terbinafine, 250 mg once daily, showed higher cure rates for tinea corporis and cruris than griseofulvin (Voravutinon, 1993) (SOR: B).

Tinea Pedis

Tinea pedis is most often caused by *Trichophyton rubrum*. Typically, patients describe pruritic scaly soles, often with painful fissures between the toes. Vesicular or ulcerative lesions may also be present. The most characteristic type of infection is interdigital (Fig. 33-44). Erythema, maceration, and fissuring occur between the toes and are accompanied by intense pruritus. Patients may also have chronic hyperkeratotic tinea pedis, characterized by plantar erythema and hyperkeratosis that may be completely asymptomatic or mildly pruritic. This is described as a moccasin distribution (Fig. 33-45). Inflammatory tinea pedis causes painful vesicles on the foot (see Fig. 33-1).

Figure 33-41 *Trichophyton rubrum* seen after KOH preparation using fungal stain. (© Richard P. Usatine.)

Figure 33-42 Tinea corporis showing concentric circles. (© Richard P. Usatine.)

Tinea pedis is more common in men than in women and rarely occurs in children. Infection can occur through contact with infected scales on bath or pool floors, so wearing protective footwear in shared areas may help decrease the likelihood of infection. Occlusive footwear promotes infection by creating warm, humid, macerating environments; therefore patients should try to minimize foot moisture by limiting the use of occlusive footwear and frequently changing socks.

The treatment of tinea pedis involves application of an antifungal cream to the web spaces and other infected areas. Topical antifungal agents containing allylamines (naftifine, terbinafine, butenafine) or azoles (clotrimazole, miconazole, econazole) all work to treat tinea pedis. Allylamines cure slightly more infections than azoles but are more expensive. No differences in efficacy were found between individual allylamines or individual azoles (Crawford et al., 2000). Infrequently, systemic therapy is used for refractory infections. Twice-daily application of the allylamine terbinafine has resulted in a higher cure rate than twice-daily application of the imidazole clotrimazole (Lotrimin AF), and more rapidly.

Figure 33-44 Tinea pedis between toes. (© Richard P. Usatine.)

Figure 33-45 Tinea pedis in moccasin distribution. (© Richard P. Usatine.)

KEY TREATMENT

With topical antifungals to treat tinea pedis, allylamines cure slightly more infections than azoles but are more expensive (Crawford et al., 2000) (SOR: A).

Consider oral antifungals such as terbinafine, 250 mg daily for 2 weeks, when tinea pedis is severe or does not respond to topical agents (Bell-Syer et al., 2002) (SOR: B).

Oral itraconazole is equal to oral terbinafine in patient outcomes. Itraconazole can be prescribed as two 100-mg tabs daily for 1 week (Bell-Syer et al., 2002; Thomas, 2003) (SOR: B).

Tinea Cruris

Tinea cruris, commonly called “jock itch,” is a dermatophyte infection of the groin. This dermatophytosis is more common in men than women and is frequently associated with tinea pedis. Tinea cruris occurs when ambient temperature and humidity are high. Occlusion from wet or tight-fitting clothing provides an optimal environment for infection. Tinea cruris involves the proximal medial thighs and may extend to the buttocks and lower abdomen (Fig. 33-46). The scrotum tends to be spared. Patients with this dermatophytosis frequently complain of burning and pruritus. Pustules and vesicles at the active edge of the infected area, along with maceration, are present on a background of red scaling lesions with raised borders. Care should be taken to evaluate the feet as a source of infection.

In addition to topical antifungals, treatment can include a low-dose corticosteroid for the first few days to reduce the inflammation of the involved skin. Oral antifungal therapy is needed if the tinea cruris has spread beyond the groin (Fig. 33-47). Inverse psoriasis may be mistaken for tinea cruris and will not respond to antifungal treatment (Fig. 33-48). The fungicidal allylamines naftifine and terbinafine and the allylamine derivative butenafine are more costly topical tinea treatments but allow for a shorter duration of treatment compared with fungistatic azoles (clotrimazole, econazole, ketoconazole, oxiconazole, miconazole, sulconazole) (Nadalo et al., 2006).

KEY TREATMENT

Tinea cruris may be treated with a topical allylamine or a topical azole (Nadalo et al., 2006) (SOR: B).

Fluconazole, 150 mg once weekly for 2 to 4 weeks, appears effective against tinea cruris (Nozickova et al., 1998) (SOR: B).

Tinea Capitis

Tinea capitis, the most common dermatophytosis in children, is an infection of the scalp and hair follicle. Transmission is fostered by poor hygiene and overcrowding and can occur through contaminated hats, brushes, and pillowcases. After being shed, affected hairs can harbor viable organisms for more than 1 year. Tinea capitis is characterized by irregular or well-demarcated alopecia and scaling (Fig. 33-49). Cervical and occipital lymphadenopathy may be prominent. When hairs fracture a few millimeters from the scalp, “black dot” alopecia is produced. Tinea scalp infection also may result in a cell-mediated immune response termed a *kerion*, which is a boggy, sterile, inflammatory scalp mass

Figure 33-46 Tinea cruris in woman. (©Richard P. Usatine.)

Figure 33-47 Tinea cruris that has spread up to umbilicus. (©Richard P. Usatine.)

(Fig. 33-50). A kerion does not require antibiotics or incision and drainage. If a kerion does not respond to oral antifungals alone, an oral steroid may be added for a short course.

Oral griseofulvin daily for 6 to 8 weeks is a proven treatment for tinea capitis, even if it requires a somewhat longer course than the newer antifungal agents (Fleece et al., 2004). It is available in a liquid form for children. Also, consider 4 weeks of oral terbinafine daily; it was as effective as 8 weeks of griseofulvin after 8 weeks, but at week 12 the efficacy of griseofulvin decreased to 44%, whereas the efficacy of terbinafine was 76% (Caceres-Rios et al., 2000). Consider oral fluconazole as an option because it is available in liquid form and appears to be effective and safe, but fewer clinical trials have been done (Foster et al., 2005).

KEY TREATMENT

Give oral griseofulvin daily for 6 to 8 weeks to treat tinea capitis (Fleece et al., 2004) (SOR: B).

Consider 4 weeks of oral terbinafine daily (Caceres-Rios et al., 2000) (SOR: B).

Consider oral fluconazole (available as liquid) as an option to treat tinea capitis (Foster et al., 2005) (SOR: B).

Figure 33-48 Inverse psoriasis that resembles tinea cruris. Note nail pitting of psoriasis. (© Richard P. Usatine.)

Figure 33-49 Tinea capitis with prominent cervical lymphadenopathy. (© Richard P. Usatine.)

Onychomycosis

Onychomycosis is a fungal infection that affects the toenails or fingernails. It may involve any component of the nail unit, including the nail matrix, nail bed, or nail plate. Onychomycosis may be unsightly but is often asymptomatic. In the worst cases, it causes enough discomfort and disfigurement to produce physical and occupational limitations. Use of topical agents should be limited to cases involving less than half the distal nail plate and patients unable to tolerate systemic treatment. Agents include ciclopirox 8% (Penlac), azoles, and allylamines. Topical treatments are poorly effective because of inadequate nail plate penetration. Oral

antifungal agents such as terbinafine and itraconazole have replaced older therapies in the treatment of onychomycosis. Oral antifungals offer shorter treatment regimens, higher cure rates, and fewer adverse effects. Removal of the nail plate should be considered an alternative treatment in patients who cannot tolerate oral therapy and are having symptoms that interfere with their quality of life.

KEY TREATMENT

Terbinafine is more effective than griseofulvin, and terbinafine and itraconazole are more effective than no treatment (Cochrane review; Bell-Syer et al., 2004) (SOR: A).
Two clinical trials of nail infections found no evidence of benefit for topical treatments (did not include ciclopirox) compared with placebo (Cochrane review; Crawford et al., 1999) (SOR: A).

Tinea Versicolor

Tinea versicolor presents with hypopigmented, pink/brown macules and patches on the trunk with fine scale. *Versicolor* means varied colors, and this tinea tends to be white, pink, and brown (Fig. 33-51). Tinea versicolor is found on the back, chest, abdomen, and upper arms, often in a capelike distribution. Tinea versicolor is caused by *Malassezia furfur* (*Pityrosporum*), a lipophilic yeast that can be normal human cutaneous flora. Tinea versicolor is also called *pityriasis versicolor* after the causative organism. *Pityrosporum* is also associated with seborrhea, and thus antidandruff shampoos are effective in treating this tinea. *Pityrosporum* spp. thrive on sebum and moisture and tend to grow on the skin in areas where sebaceous follicles secrete sebum. Topical and oral treatments are effective, but tinea versicolor tends to recur, especially during the warmer months. The diagnosis can usually be made with the clinical examination, and if there is any doubt, a KOH prep can be examined for the typical “spaghetti and meatballs” pattern (Fig. 33-52). The spaghetti or “ziti” is the short mycelial form, and the meatballs are the round yeast of *Pityrosporum ovale*.

Patients may apply selenium sulfide 2.5% lotion or shampoo to the involved areas daily for 1 week. A double-blind study found that selenium sulfide (2.5%) lotion applied daily for 10 minutes for 7 consecutive days was effective in the treatment of tinea versicolor (Sanchez and Torres, 1984). A single oral dose of 400 mg of oral fluconazole or ketoconazole can also be used to treat tinea versicolor. Fluconazole provided the best clinical as well as mycologic cure rate, with no relapse during 12 months of follow-up (Bhogal et al., 2001). Oral itraconazole, 200 mg twice daily for 1 day a month, has been shown to be safe and effective as a prophylactic treatment for tinea versicolor (Faergemann et al., 2002).

KEY TREATMENT

Selenium sulfide 2.5% lotion (or shampoo) daily for 1 week is effective treatment of tinea versicolor (Sanchez and Torres, 1984) (SOR: B).
Ketoconazole 2% shampoo (Nizoral) may be applied daily for 3 days to treat tinea versicolor (Lange et al., 1998) (SOR: B).
Oral fluconazole or ketoconazole (400 mg) also treats tinea versicolor (Bhogal et al., 2001) (SOR: B).
Oral itraconazole (200 mg bid 1 day a month) is effective prophylactic treatment for tinea versicolor (Faergemann et al., 2002) (SOR: B).

Viral Infections

Key Points

- Herpes simplex virus type 1 (HSV-1) is the most common cause of oral herpes infection (80%). HSV-2 is the primary pathogen in genital herpes (70%-90%). Both can cause oral or genital lesions.
- HSV-1 and HSV-2 are characterized by a primary infection, latent periods, asymptomatic shedding, and reactivation.
- Approximately 10% to 20% of the U.S. population develop zoster, but rates are likely to decrease with VZV vaccine for children.
- Corneal involvement should be suspected when herpes zoster involves the tip of the nose and is an ophthalmologic emergency because it can lead to blindness.
- For herpes zoster, antiviral therapy (acyclovir, valacyclovir, famciclovir) should be started within 3 days of onset of symptoms to reduce disease severity and postherpetic neuralgia.
- Human papillomavirus types 6 and 11 are associated with condylomata acuminata (genital warts); HPV types 16 and 18 are associated with carcinoma. The quadrivalent HPV vaccine is active against HPV types 6, 11, 16, and 18.
- Molluscum contagiosum is a common, self-limited viral infection most often affecting children. It is considered sexually transmitted in adults.
- Lesions of molluscum usually resolve spontaneously over months to years; with or without treatment, lesions can leave pitted scars.

Herpes Simplex

Herpes simplex virus types 1 and 2 (HSV-1 and HSV-2) are very common pathogens that cause orolabial and genital blisters or erosions. Seroprevalence of HSV-1 is estimated at 80% to 90% worldwide and is the most common cause of oral herpes infection (80%). HSV-2 is the primary pathogen in genital herpes (70%-90%) and is one of the most common sexually transmitted diseases (STDs). Approximately 50 million Americans have genital herpes, and an estimated 1 million new cases occur each year.

Herpes simplex infection can be characterized by an initial infection, episodes of latency, asymptomatic viral shedding,

and recurrent activation. Spread of HSV-1 is primarily through direct contact with contaminated saliva or other secretions. Symptoms of primary orolabial herpes usually occur 3 to 7 days after exposure and include a prodrome of fever, sore throat, and lymphadenopathy. Localized pain, tingling, tenderness, or burning can occur before the eruption of the vesicles, which are usually grouped on a background of erythema and edema (Fig. 33-53). The lesions coalesce, ulcerate, and heal within 2 to 3 weeks.

Herpes simplex type 2 usually is transmitted through genital contact and must involve mucous membranes or open or damaged skin. Primary HSV-2 occurs up to 3 weeks after exposure to the virus and has more severe clinical manifestations. Systemic symptoms include fever, malaise, edema, inguinal lymphadenopathy, dysuria, and vaginal or penile discharge. These are more common in women. In men, painful vesicles and erosions usually occur on the penis but can also appear on the buttocks or perineum (Fig. 33-54). In women, lesions occur primarily on the labia but may also appear on the cervix, buttocks, or perineum. Symptoms of the primary episode typically last 2 to 3 weeks. Risk factors for genital herpes include age 15 to 30 (age of greatest sexually activity), increased number of sexual partners, black or Hispanic race, lower income levels and education, female gender, homosexuality, and HIV.

In both serotypes, HSV may be latent for months to years following the primary infection. During latency, the virus resides in the sensory nerve root ganglia. Recurrent outbreaks are often preceded by a prodrome of pain, itching, tingling, burning, or paresthesias and are usually less severe than the primary outbreak.

The diagnosis of herpes simplex is conveniently done with a direct fluorescent antibody test (DFA), and results may be obtained within hours. A viral culture can be performed, but results take 2 to 5 days. Serologic testing is also available and approved by the U.S. Food and Drug Administration (FDA) to establish serostatus, but this is not helpful for acute disease.

The treatment of HSV depends on whether the infection is a first episode or a recurrence. Many different dosing schedules are available with oral antivirals, including acyclovir

Figure 33-54 Herpes simplex type 2 (HSV-2) recurrence on penis with cluster of vesicles. (Courtesy Jack Rezneck, Sr., and *The Color Atlas of Family Medicine*.)

(Zovirax), valacyclovir (Valtrex), and famciclovir (Famvir). Suppressive therapy may be considered in patients with recurrent genital herpes. Women who are pregnant or contemplating pregnancy should receive information regarding neonatal transmission and possible cesarean delivery if active lesions are present at the onset of labor. The risk of transmission is highest for women with a primary infection during the third trimester of pregnancy. Neonatal herpes infection can cause long-term CNS morbidity, such as mental retardation, chorioretinitis, seizures, and even death.

Herpes Zoster (Shingles)

Zoster is caused by the reactivation of the varicella-zoster virus (VZV, human herpesvirus 3, HHV-3, chickenpox). After the primary infection, VZV lies dormant in the dorsal root ganglia. The time between the onset of primary chickenpox and reactivation can be any time but usually decades later. Approximately 10% to 20% of the U.S. population eventually develop one or more cases of zoster in their lifetime. The incidence is much higher in immunocompromised patients and older adults. These rates are likely to decrease over time now that a VZV vaccine is given as part of the routine immunization schedule in children.

Patients typically experience pain and paresthesias, followed by the appearance of small groups of vesicles on an erythematous base in a dermatomal distribution (Fig. 33-55). The rash rarely crosses the midline of the body and is usually confined to a single dermatome. The eruption may be accompanied by a fever, headache, and malaise. Lesions usually resolve in 2 to 3 weeks. Pain can be severe and may persist long after skin lesions heal in a condition known as

Figure 33-55 Herpes zoster in dermatomal pattern. (© Richard P. Usatine.)

postherpetic neuralgia. Corneal involvement should be suspected when lesions appear on the tip of the nose or in the distribution of cranial nerve VI and should prompt an emergency ophthalmology consultation because this can cause permanent blindness (Fig. 33-56).

Antiviral therapy such as acyclovir, valacyclovir, and famciclovir should be started within the first 3 days of onset of symptoms, to reduce the severity and duration of symptoms and skin lesions. Early treatment may also reduce the incidence and severity of postherpetic neuralgia. However, benefits can be seen even if started up to 7 days after onset of symptoms. Analgesics such as acetaminophen and even narcotics are sometimes required to control the pain caused by zoster. Cool compresses may also help soothe during the acute phase. Postherpetic neuralgia occurs in up to 40% of adult patients over age 60 but in less than 10% of patients less than 60. In 2006 the FDA approved a live, attenuated vaccine (Zostavax) for adults over 60 years who are immunocompetent and have not already had zoster. The vaccine decreased the burden of illness by 61% and decreased the incidence of postherpetic neuralgia by 67% in large clinical trials (Oxman et al., 2005).

Verruca (Warts)

Warts are common growths of skin and mucosa caused by the human papillomavirus (HPV). Currently, more than 100 types of HPV have been identified. Specific HPV types often correlate to the lesion location, morphology, or oncogenic potential. Although most are benign, warts can be disfiguring or can cause significant psychological distress, and some cause cancer.

Verruca vulgaris (common warts) are dome-shaped keratotic papules that usually develop on the dorsal hands, fingers, or other sites on the extremities (Fig. 33-57). *Palmoplantar* warts are on the palms or soles and are surrounded by hyperkeratotic calluslike skin. These can be painful when occurring on weight-bearing surfaces. Multiple plantar warts may combine to become a large mosaic wart. Both common

Figure 33-56 Herpes zoster on face with herpes ophthalmicus. (© Richard P. Usatine.)

Figure 33-58 Flat warts on forehead. (© Richard P. Usatine.)

Figure 33-57 Kissing warts on fingers. (© Richard P. Usatine.)

warts and palmoplantar warts have characteristic punctuate black dots, mistakenly leading to the common term “seed warts,” whereas these black dots actually represent thrombosed capillaries. *Filiform* warts have fingerlike projections and often appear on the face. *Verruca plana* (flat warts) are smooth, small (1-4 mm) flesh-colored papules, often occurring on the face or legs and often spread by scratching or shaving (Fig. 33-58). Although inconspicuous at first, flat warts propagate rapidly, often into the hundreds.

Condylomata acuminata (genital warts) occur on the external genitalia, perineum, perianal, or adjacent intertriginous regions but can also be found on the oral mucosa. These lesions are generally considered sexually transmitted, but it is usually impossible determine when the inoculation

occurred. The lesions begin as small papules, which often become whitish with maceration and take on a cauliflower-like appearance as they grow (Fig. 33-59). Condylomata are associated with cervical carcinoma and penile cancer. Among the many subtypes of HPV, types 6 and 11 are most often associated with condylomata, whereas types 16 and 18 are most often associated with the development of carcinoma.

There is no standard treatment for warts. Most warts spontaneously regress over many months to years. Local treatments include cryotherapy, salicylic acid, imiquimod, podophyllin, 5-fluorouracil (5-FU), cantharidin, and duct tape. For physician-applied treatments such as cryotherapy or podophyllotoxin, patients should be seen every 3 to 4 weeks for repeat treatment as needed. For home treatments with salicylic acid, podofilox (Condylox), or imiquimod (Aldara), most are applied daily, and patients should be advised that treatment can take months of extreme persistence for resolution. Office and home treatment modalities can also be combined to hasten resolution, but studies are lacking.

Women with condylomata should have annual Papanicolaou tests to evaluate for cervical neoplasia. For both men and women, it is advisable to refrain from sexual activity while genital lesions are present, to prevent transmission. In 2006 the FDA approved an HPV vaccine (Gardasil), recommended for females age 11 to 26 regardless of abnormal Pap history, positive HPV status, or genital warts. It is active against HPV types 6, 11, 16, and 18. In clinical trials, Gardasil decreased the incidence of cervical intraepithelial neoplasia (CIN), cervical cancer, and anogenital warts by 90% (Villa et al., 2006).

Molluscum Contagiosum

Molluscum contagiosum is a common, self-limited viral infection seen most frequently in children and can occur anywhere on the body; most often on the trunk, face, and extremities. In adults, mollusca are considered sexually transmitted and occur in the genital region or lower abdomen. Infection occurs through direct skin-to-skin contact or indirect contact with fomites. The typical molluscum lesion is a pink to flesh-colored, firm, smooth, dome-shaped papule with central umbilication (Fig. 33-60). A white material

Figure 33-59 A, Condyloma acuminata on penis. B, Condyloma acuminata on vulva. (© Richard P. Usatine.)

Figure 33-60 Molluscum contagiosum on penis as sexually transmitted disease. (© Richard P. Usatine.)

can sometimes be visualized in the umbilication and can be easily expressed. This caseous material is teeming with viral particles. Lesions are usually 2 to 5 mm in diameter and number less than 30, but can number in the hundreds. Particularly in immunocompromised patients, the infection may be much more extensive, may fail to resolve spontaneously, and may be resistant to treatment. Over months to years, lesions of molluscum normally resolve spontaneously.

Some patients or parents desire treatment, and cryotherapy, cantharidin, trichloroacetic acid (TCA), tretinoin (Retin-A), or imiquimod may be effective. Cantharidin is most easily given to young children because its application is painless.

Cryotherapy is another good option, but many young children will not willingly submit to this therapy, which is painful. Often it is best to reassure parents that molluscum is not harmful and will eventually resolve, although with or without treatment, lesions can leave pitted scars.

Infestations

Key Points

- Scabies is a pruritic rash involving interdigital spaces, wrists, ankles, waist, groin, and axillae.
- The three types of human lice infest the hair of the head, the body, or the pubic hair.

Scabies

Scabies is caused by the mite *Sarcoptes scabiei*, an obligate human parasite. Patients present with a pruritic rash that is often worse in the night. Skin findings include papules, nodules, burrows, and vesiculopustules (Fig. 33-61). The distribution includes the interdigital spaces, wrists, ankles, waist, groin, and axillae. Pruritic nodules around the axillae, umbilicus, or on the penis and scrotum are highly suggestive of scabies. In children the head can also be involved. Look for burrows because these are pathognomonic of scabies and will be the best site to find mites.

For the most part, scabies is a clinical diagnosis based on the typical rash and the history. It is often helpful if other family members have pruritus and a similar rash. In cases in which the diagnosis is in question or there appears to

Figure 33-61 Scabies with visible burrow (arrow). (© Richard P. Usatine.)

Figure 33-62 Scabies mite (40×). (© Richard P. Usatine.)

be multiple recurrences, the scraping is worthwhile to confirm the clinical impression. A dermatoscope or magnifying lens can be used to look for the small arrowhead-appearing mite at the end of a burrow. Scraping of active lesions can yield the identification of mites, eggs, or feces under the microscope (KOH or mineral oil can be used on the slide) (Fig. 33-62).

Crusted (Norwegian) scabies is a highly contagious form with a propensity for older adults and immunocompromised or physically debilitated patients (Fig. 33-63). Widespread, crusted lesions appear with thick, hyperkeratotic scales over the elbows, knees, palms, and soles. Infections may occur with thousands of mites at a time and can be especially problematic in nursing homes or assisted-living environments. Ivermectin is an oral treatment for resistant or crusted scabies with demonstrated safety and efficacy. Most studies used a single dose of ivermectin at 200 µg/kg (Strong and Johnstone, 2007).

Figure 33-63 Crusted scabies on hands of 2-year-old child. (© Richard P. Usatine.)

Permethrin cream is applied from the neck down (include the head when involved) and rinsed off 8 to 14 hours later. Usually this is done overnight. Repeating the treatment in 1 to 2 weeks may increase the cure rate. Unfortunately, scabies resistance to permethrin is increasing. Antihistamines and midpotency steroid creams can be used for symptomatic relief of itching. It is important to note that pruritus may persist for 1 to 2 weeks after successful treatment because the dead mites and eggs still have antigenic qualities that may cause persistent inflammation. Environmental decontamination is a standard component of all therapies. Clothing, bed linens, and towels should be machine-washed in hot water. Clothing or other items (e.g., stuffed animals) that cannot be washed may be dry-cleaned or stored in bags for 1 week. All household or family members living in the infested home should be treated. Failure to treat all involved individuals often results in recurrences within the family.

KEY TREATMENT

- Begin treatment of scabies with permethrin 5% cream (Strong and Johnstone, 2007) (SOR: A).
- Oral ivermectin (200 µg/kg) is used to treat resistant or crusted scabies. (Strong and Johnstone, 2007) (SOR: A).
- Antihistamines and steroid creams can be used for symptomatic relief of itching (SOR: C).
- Environmental decontamination is a standard component of all scabies therapy (SOR: C).
- All those living in the infested home should be treated to prevent recurrences (SOR: C).

Pediculosis Capitis (Head Lice)

Lice are obligate human parasites transmitted by person-to-person contact. Infestations are increasing in frequency because of the development of resistance to current treatments. The infestation is usually detected because of intense itching and the presence of eggs or nits adherent to the hair shaft (Fig. 33-64). Once the nit is attached to the hair shaft, the head louse develops over 3 to 4 days. Within 12 days of hatching, the nymph becomes a sexually mature adult

capable of reproducing. After a single fertilization, each female lays up to 10 eggs a day during her 30-day life span. Typically, infestation occurs over a 2-week period, resulting in an allergic reaction to the louse saliva, causing the pruritus. Without frequent blood meals from the host, lice survive only 15 to 20 hours.

Detection of a single live louse is sufficient for diagnosis of infestation. Nits should be examined for viable embryo, which will show some movement under magnification. Because of the route of transmission, outbreaks are often seen in daycare centers, classrooms, and homeless shelters.

Effective eradication of pediculosis often requires two treatments given 7 to 10 days apart. Several OTC preparations are available, including 4% piperonyl butoxide with 0.33% pyrethrins (RID, Pronto, A-200) and permethrin (Nix). Malathion is available by prescription for treatment of resistant strains but should not be used in infants or children younger than 6 years. Instructions for use must be followed carefully, including treatment of all household contacts. Removal of all nits is not necessary following eradication but can be done with a fine-toothed comb, if desired. Schools often require no visible nits before permitting children to return to classes. Use of a 50% vinegar and water rinse after shampooing may help reduce adherence of nits to the hair shaft.

Bedding and clothing should be washed in the hottest water possible or dry-cleaned. Combs, barrettes, and hair ornaments may be soaked in hot water for 10 minutes. Items that cannot be otherwise cleaned, such as stuffed animals or decorative pillows, can be sealed in plastic bags for 2 weeks.

KEY TREATMENT

Pediculicides effective in the treatment of head lice include 1% permethrin cream rinse, pyrethrins with piperonyl butoxide shampoo and malathion cream; no evidence shows one is better than another (Cochrane review; Dodd, 2006) (SOR: A).

Figure 33-64 Pearly nits of head lice. (© Richard P. Usatine.)

Pediculosis Corporis (Body Lice)

Body lice are most frequently seen in patients who live in environments that prevent regular changing of clothing and bedding, such as the homeless. Diagnosis should be suspected in patients with generalized itching and excoriations and poor hygiene. Body lice are more likely to be found in the seams of clothing than on the patient (Fig. 33-65). Initial treatment of body lice entails washing the entire body surface and wearing clean clothing. In severe infestations, topical use of permethrin, pyrethrin, or malathion may be indicated. Again, clothing and bedding should be washed in hot water or dry-cleaned. As an alternative to topical treatment, ivermectin may be given orally.

Phthirus Pubis (Pubic Lice, Crab Lice)

Pubic lice are sexually transmitted and may be transmitted through clothing and towels. Treatment is the same as for head lice and should include any sexual contacts. Additionally, the presence of pubic lice should prompt consideration of other STDs.

Hypersensitivity Reactions and Other Eruptions

Key Points

- Morbilliform drug reactions occur 1 to 2 weeks after initial exposure but occur much quicker (1-3 days) on repeat exposure.
- Urticaria can be acute or chronic and is triggered by drugs, infections, arthropods, autoimmune disease, food, and even emotional stress.
- The mainstay of therapy for urticaria is avoidance of known triggers and antihistamines.
- Oral corticosteroids for urticaria should be limited to short-term therapy of severe episodes.

Figure 33-65 Body lice on seams of clothing. (© Richard P. Usatine.)

- Erythema multiforme is a reaction pattern secondary to a variety of etiologic agents and characterized by distinctive target lesions.
- Half of EM cases are caused by HSV; drugs and other infections are also common causes.
- Stevens-Johnson syndrome and toxic epidermal necrolysis typically occur 7 to 21 days after starting NSAIDs, antibiotics, or antiepileptics.

“Morbilloform” (Maculopapular, Exanthemlike) Reaction

Morbilloform eruption is by far the most common type of drug eruption, reported in response to almost every drug. Small, pink to red papules and macules usually start on the face or upper chest and can extend to limbs; resembling measles (Fig. 33-66). The rash may be relatively asymptomatic or extremely pruritic. The typical course begins 7 to 14 days after drug initiation if the first exposure. On reexposure to the same medicine, the eruption will occur much more quickly, within 1 to 3 days. Maculopapular reaction is not generally life threatening and does not proceed to anaphylaxis; therefore, when no alternative drug is available, the offending agent can be continued. The eruption can be treated symptomatically with antihistamines and midpotency topical corticosteroids.

Urticaria

Urticaria, commonly known as “hives,” can be acute or chronic, and the numerous triggers include drugs, food, infections, arthropods, autoimmune disease, and stress. The wheals consist of circumscribed areas of raised erythematous plaques that are often annular and very pruritic (Fig. 33-67).

These wheals can occur on any skin area and are transient and migratory. The acute form of urticaria lasts less than 4 to 6 weeks, and the chronic form lasts more than 6 weeks. When there is an obvious new drug causing the eruption, the causation is easy to determine.

For patients on multiple medications and no evidence of infection or illness, diagnosis can be very difficult. Skin prick testing or radioallergosorbent assay testing (RAST) testing, typically done through an allergy specialist, may help determine the cause but may be elusive. Patients with chronic urticaria unresponsive to antihistamines require an extensive workup. In more than 50% cases of chronic urticaria, no etiology is found, and it is considered idiopathic or chronic “autoimmune” urticaria.

The mainstay of therapy for urticaria is avoidance of known triggering agents and antihistamines. Classic antihistamines are effective (diphenhydramine, hydroxyzine, doxepin), but sedation limits their use to primarily nighttime dosing. Second-generation and third-generation antihistamines are helpful for daytime use (cetirizine, loratadine, fexofenadine, desloratadine, levocetirizine). Oral corticosteroids are useful but should be limited to short-term therapy of severe acute urticaria. H₂-receptor antagonists (cimetidine, ranitidine, famotidine) and leukotriene antagonists are sometimes helpful as adjunctive therapy.

Erythema Multiforme

Erythema multiforme (EM) is a reaction pattern secondary to a variety of etiologic agents characterized by distinctive target lesions. About 90% of cases of EM are caused by infections, most often HSV (50%) and *Mycoplasma pneumoniae* (Fig. 33-68). The other 10% are caused by drugs, most often

Figure 33-66 A, Amoxicillin drug eruption in young woman with mononucleosis. B, Amoxicillin rash in child with otitis media. (© Richard P. Usatine.)

Figure 33-68 Erythema multiforme secondary to recurrent genital herpes simplex. (© Richard P. Usatine.)

NSAIDs, sulfonamides or other antibiotics, antiepileptics, and barbiturates.

Lesions begin as dull-red macules or urticarial plaques on the palms, soles, or extensor surfaces of the extremities and tend to expand in size. A small papule, vesicle, or bulla develops in the center with concentric rings forming around the blister. The center of the lesion becomes dusky or violaceous from necrosis of the epidermis. Most EM cases spontaneously subside within 3 weeks without sequelae.

Identification of the cause should be made, if possible. Patient should be queried for prescription and OTC medications and history of HSV. A thorough examination should

be performed, looking for oral or genital ulcers with Tzanck prep or DFA test for HSV. Cultures of the skin, nose, throat, and conjunctiva are indicated to evaluate for infections and treated appropriately.

Stevens-Johnson Syndrome and Toxic Epidermal Necrolysis

Both Stevens-Johnson syndrome (SJS) and toxic epidermal necrolysis (TEN) are rare, severe, life-threatening reactions that are almost always drug related. The most common offending medications are NSAIDs, antibiotics, and antiepileptic medications. SJS or TEN typically occurs 7 to 21 days after the start of the medication.

Stevens-Johnson syndrome often presents with a prodrome of fever, painful swallowing, stinging eyes, and *painful* skin. Two or more mucosal surfaces eventually become involved (conjunctiva, oral mucosa, genitalia) with vesicles, bullae, erosions or hemorrhagic crusts. Skin lesions usually begin as dusky purpuric macules that progress to bullae or erosions on the trunk and spread centrifugally. *Targetoid lesions*, similar to EM, may also be present. By definition, less than 10% body surface area (BSA) is involved in SJS. A similar presentation occurs in TEN, but the bullae and erosions involve greater than 30% BSA. Also, the skin that initially appears normal may easily slide off with gentle tangential pressure (Nikolsky's sign), leaving more denuded skin. When skin and mucosal involvement is 10% to 30% BSA, it is considered SJS/TEN overlap.

Both SJS and TEN can be fatal; mortality is 1% to 5% for SJS and 25% to 35% for TEN, but may be even higher in elderly patients or those with comorbidities. Above all, removal of the offending agent is paramount. Most patients are treated in a burn unit because the skin is necrotic and no longer functioning as a barrier. Care is supportive and aimed at regulation of fluids, electrolytes, protein, temperature, and prevention of infection. Neither systemic steroids nor intravenous immune globulin (IVIG) demonstrate consistent clinical efficacy in clinical studies, which are limited because of the rarity of SJS and TEN.

Skin Signs of Systemic Disease

Lupus Erythematosus

Key Points

- Lupus erythematosus is an autoimmune disease of connective tissue that may be limited to the skin (cutaneous lupus), or the skin findings may indicate systemic disease.
- All LE variants are photosensitive, and primary treatment should include education in sun protection and avoidance.

Lupus erythematosus (LE) is an autoimmune disease of connective tissue that has frequent dermatologic manifestations. LE may be limited to the skin, or the skin findings may indicate systemic disease. For dermatologic purposes, there are three main variants:

Acute cutaneous (ACLE): exemplified by the malar rash, usually associated with systemic disease and positive antinuclear antibodies (Fig. 33-69).

Figure 33-69 Systemic lupus erythematosus and with malar rash. (© Richard P. Usatine.)

Figure 33-70 Subacute cutaneous lupus erythematosus in sun-exposed areas. (© Richard P. Usatine.)

Subacute cutaneous (SCLE): characteristic photosensitive papulosquamous annular lesions of the trunk and arms, associated with anti-Ro antibodies (70%); 10% to 15% will have systemic involvement (Fig. 33-70).

Discoid (DLE): inflammation involves deeper adnexal structures, with predilection for head and neck; results in scarring; less than 10% have systemic involvement (Fig. 33-71).

Acute cutaneous LE presents as the classic “butterfly rash” and tends to follow sun exposure. Erythema and edema may be mild to severe. The presence of *poikiloderma* (patches of hypopigmentation, hyperpigmentation, telangiectasias, and epidermal atrophy) may help to differentiate the malar rash of lupus from other skin diseases of the midface, such as rosacea

Figure 33-71 Discoid lupus with hyperpigmentation atrophy and scarring. (© Richard P. Usatine.)

or seborrheic dermatitis, which are not poikilodermatous. There is sparing of the nasolabial folds and the skin under the nose and upper lip, areas that are shaded from the sun.

Lesions of SCLE are very photosensitive and appear as annular, scaly, erythematous patches or papulosquamous rings with central clearing. These usually affect the lateral face (instead of central face), upper chest, arms, and shoulders, areas that are sun exposed. Discoid lesions are somewhat photosensitive but also found on nonexposed skin and mucosal surfaces. Most often these present on the ears, face, and neck and appear as scaly, brightly erythematous to violaceous plaques. Because of the deeper involvement of inflammation, as DLE lesions resolve, they often leave behind hyper- or hypopigmentation, even depigmentation. Severe scarring and disfigurement may also occur. ACLE, or systemic lupus erythematosus (SLE), is more common in women, especially of childbearing age (female/male ratio 6-10:1), suggesting a hormonal factor in susceptibility. The female/male ratio for patients with only cutaneous forms of lupus is much lower (3-4:1 for SCLE; 2:1 for DLE). The prevalence of ACLE/SLE is also fourfold higher in African American women than Caucasian American women, and DLE is slightly more common in African Americans. However, SCLE is more prominent in Caucasians (80%).

Occasionally, drugs can induce ACLE or SCLE. Procainamide, hydralazine, isoniazid, quinidine, and phenytoin are most frequently reported for ACLE, whereas hydrochlorothiazide, calcium channel blockers (diltiazem), angiotensin-converting enzyme (ACE) inhibitors, terbinafine, NSAIDs, griseofulvin, and tumor necrosis factor (TNF) antagonists are most frequently reported for SCLE. Drug-induced ACLE usually fades once the drug is discontinued but may take

many months. Drug-induced SCLÉ may or may not clear with cessation of the drug.

For skin lesions of lupus, sun protection and sun avoidance are crucial because all types are photosensitive. Although discoid lesions are not as photosensitive as the other variants, some patients with ACLE, SLE, or SCLÉ can even be triggered by indoor light. Topical corticosteroids and calcineurin inhibitors (pimecrolimus, tacrolimus) are the mainstay in treatment of skin lesions. If oral medications are required to control skin disease, antimalarials (most often hydroxychloroquine) are first-line therapy.

Dermatomyositis

Key Points

- Dermatomyositis, presumably an autoimmune disease, is triggered by malignancy, drugs, or infection.
- High-dose corticosteroids with a slow taper over 2 to 4 years are the primary treatment, and muscle disease usually responds more rapidly than skin disease.

Dermatomyositis is presumably an autoimmune disease that is triggered by an outside factor. Antinuclear antibodies or anticytoplasmic antibodies (antisynthetase) are found in up to 95% of patients. Clinically, dermatomyositis is characterized by a symmetric proximal inflammatory myopathy and distinct skin lesions. Proximal muscle weakness may precede the skin findings, may follow them, or may be absent (“dermatomyositis sine myositis”). Classic cutaneous lesions include the *heliotrope rash*, pink to lilac, poikilodermatous or edematous patches of the periocular skin (Fig. 33-72). The *shawl sign* consists of poikiloderma of the upper chest, shoulders, and upper back. Gottron’s papules are erythematous, scaly or lichenified papules or plaques over the knuckles. Similar plaques may be seen on the elbows, mimicking psoriasis. Other common cutaneous findings are periungual telangiectasias (visible dilated capillary loops) and ragged cuticles (cuticular dystrophy).

Although the etiology of dermatomyositis is unknown, triggers may include malignancy, drugs, and infection. In

adults with dermatomyositis, studies report a wide range of association with internal malignancy (10%-50%). Common malignancies include genitourinary, ovarian, colon, breast, lung, pancreatic, and lymphoma. The same association is not found in juvenile cases of dermatomyositis. Therefore, any adult with a new diagnosis of dermatomyositis should be screened with a chest-abdominal-pelvic CT scan with close surveillance for 2 to 3 years.

Double-blind, placebo-controlled trials are lacking for this rare disease, but the mainstay of treatment for dermatomyositis is high-dose corticosteroids with slow taper over 2 to 4 years. Other immunosuppressants used include methotrexate, azathioprine, cyclophosphamide, and cyclosporine. In general, the myopathy responds more rapidly and easily than the skin lesions, and severe pruritus can persist long after muscle disease is controlled. For skin lesions, sun protections, topical corticosteroids, or antimalarials may help.

Sarcoidosis

Sarcoidosis is a systemic granulomatous disease of unknown etiology that most often involves the lungs (90%). The skin is involved in about one third of patients with systemic sarcoidosis. In the United States, women and African Americans are more frequently affected. As with syphilis, sarcoidosis is considered a “great imitator” because it has widely variable presentations and may involve almost any organ system.

Classic skin lesions of sarcoidosis are red-brown, nonscaly papules and plaques appearing on the face, especially around the nose or mouth (Fig. 33-73). Color can vary significantly from yellow to red to brown, and lesions also occur on the trunk or extremities and tend to be symmetric. Lesions on the alar rim of the nose, also known as *lupus pernio*, are highly

Figure 33-72 Heliotrope rash of dermatomyositis. (© Richard P. Usatine.)

Figure 33-73 Cutaneous sarcoidosis. (© Richard P. Usatine.)

associated with granulomatous infiltration of the upper airway. Patients with cutaneous sarcoidosis should have a complete evaluation for systemic disease, including history and physical examination, renal and hepatic function testing, chest radiograph, pulmonary function tests, electrocardiography, and ophthalmologic evaluation.

Lesions of cutaneous sarcoidosis are difficult to treat and tend to recur. The most effective therapy is intralesional injection of corticosteroids repeated at 2- to 4-week intervals. Topical corticosteroids are often ineffective because they do not penetrate the skin lesions adequately. Systemic corticosteroids are effective in treating lesions that are widespread or impairing function. In especially difficult cases, agents such as hydroxychloroquine or methotrexate may be used.

Benign Growths

Key Points

- The most important reason to be able to recognize benign skin growths is to differentiate them from skin cancers.
- Seborrheic keratoses, epidermal cysts, and dermatofibromas can be surgically excised if they are suspicious for cancer or causing symptoms.
- Pyogenic granulomas bleed easily and should be excised and sent for pathology to rule out amelanotic melanoma.
- Seborrheic keratoses and dermatofibromas have characteristic patterns with dermoscopy that can help guide the need for a biopsy.

Seborrheic Keratosis

Seborrheic keratoses (SKs) are hyperkeratotic lesions of the epidermis that often appear to be stuck on the surface of the skin (Fig. 33-74). SKs usually have a discrete border and vary in color from white or tan to dark brown and even black. Most lesions have a rough surface and usually range from 2 mm to 3 cm in diameter, but can be larger. Seborrheic keratosis may start as a hyperpigmented macule and progress to the characteristic plaque. The trunk is the most common site, but the lesions can be found on the extremities, face, and scalp.

The incidence of seborrheic keratosis increases with age in men and women. *Stucco keratoses*, a variant of seborrheic keratosis, are many skin-colored or white, dry scaly lesions often seen on the arms and legs. *Dermatosis papulosa nigra* is another type of seborrheic keratosis consisting of many small, brown or black papules on the faces of patients with highly pigmented skin.

Differentiating between seborrheic keratosis and melanomas can be a challenge, especially in patients with numerous lesions. Both have varying dark colors, the potential for large size, and irregularity. SKs have a rough surface, and the keratin can have horn cysts or look cerebriform. The best way to differentiate a seborrheic keratosis from a melanoma is with a dermatoscope. This special magnifying light can distinguish specific characteristics of the keratosis with higher specificity than with the naked eye. These characteristics are comedo-like openings and milia-like cysts (Fig. 33-74).

Some patients want their SKs treated for cosmetic reasons or to decrease irritation from abrasion on clothing.

Cryosurgery, curettage, and shave excision are the most frequently used methods of removal. Cryotherapy with liquid nitrogen is effective for most SKs, except for extremely thick lesions. Repeat treatments may be necessary. Curettage can be performed with or without electrocautery after administration of local anesthesia. Excisional biopsy should be used to remove lesions suspicious for melanoma.

Pyogenic Granuloma

Pyogenic granulomas (lobulated capillary hemangiomas) are benign vascular lesions that occur most often in young adults and children (Fig. 33-75). These rapidly growing hemangiomas may start at sites of trauma. Treatment is surgical removal. Pyogenic granulomas do not have malignant

Figure 33-74 Seborrheic keratosis with horn cysts (comedo-like openings). (© Richard P. Usatine.)

Figure 33-75 Pyogenic granuloma. (© Richard P. Usatine.)

potential, but it is important to send the tissue for pathology to rule out an amelanotic melanoma. Lesions most commonly occur on the fingers, head, neck, extremities, and on mucous membranes. Pyogenic granulomas frequently occur on the gingiva during pregnancy and regress spontaneously after childbirth. Patients usually are acutely concerned that the lesion has grown quickly and bleeds easily with little or no trauma.

Removal can be accomplished with shave excision and then curettage and electrodesiccation of the base to reduce chances of recurrence. Alternatively, the whole lesion can be cut out down to subcutaneous fat. Pyogenic granulomas will recur if any residual tissue remains after excision.

Epidermal Inclusion Cysts

Epidermal inclusion cysts, also known as *sebaceous cysts*, are filled with keratin and lined with stratified squamous epithelium. Epidermal cysts usually occur on the back, face, and chest and open to the skin through a small, central punctum or keratin-filled plug. On the back, these may be deep and barely palpable, whereas on the scalp an epidermal cyst (pilar cyst) can be elevated and freely movable. The cysts may remain small for years or may grow rapidly. Rupture of the cyst wall into the dermis initiates an inflammatory response.

Acutely inflamed, fluctuant cysts should be incised and drained. Destruction of the cyst wall at incision decreases the risk of cyst recurrence. Alternately, the cyst may be removed intact by excision and blunt dissection. Complete drainage is enhanced with gauze packing, changed frequently during wound healing. The use of antibiotics is unnecessary unless a concurrent cellulitis exists. If a patient requests removal of an epidermal cyst before an acute inflammatory event, the cyst wall can be more easily shelled out, minimizing risk of recurrence.

Dermatofibroma

Dermatofibromas (benign fibrous histiocytomas) are most likely fibrous reactions to minor trauma, insect bites, viral infections, ruptured cysts, or folliculitis. The nodules can be found anywhere on the body, but most often appear on the legs and arms. Dermatofibromas are firm, raised papules, plaques, or nodules that vary from 3 to 10 mm in diameter (Fig. 33-76). Dermatofibromas have a central fibrous scar and often have a hyperpigmented or pink halo around the central hypopigmented area. This has a characteristic pattern on dermoscopy.

Dermatofibromas dimple downward when compressed laterally, caused by tethering of the overlying epidermis to the underlying nodule (Fig. 33-77). Dermatofibromas are usually asymptomatic but may be tender or pruritic. Dermatofibromas can be confused with melanomas, and if growing rapidly, they could be a malignancy called a "dermatofibrosarcoma protuberans." An excisional biopsy can be used to determine the diagnosis. Because of the dermal location of the nodules, excision is superior to shave biopsy to ensure clear histology and complete removal. A punch biopsy can be used for smaller lesions. Dermatofibromas that are stable in size and asymptomatic can be left alone without treatment.

Premalignant and Malignant Skin Lesions

Key Points

- Actinic keratosis is a scaly macule on sun-damaged skin and often easier to feel than to see.
- Topical 5-FU therapy is used for patients with multiple AKs rather than treating each lesion with cryotherapy.
- Bowen's disease (squamous cell carcinoma in situ) and superficial basal cell carcinoma look more like patches of dermatitis than tumors.
- The typical nodular basal cell carcinoma presents as a pearly-colored papule with overlying telangiectasias and a central depression or ulcer.
- Left untreated, local destruction from BCC can be extensive.
- Most SCCs arise from AKs, radiation dermatitis, leukoplakia or erythroplakia, and burn scars or chronic ulcers.
- Organ transplant recipients have a 5% to 10% greater risk of developing BCC and a 40 to 250 times greater risk of developing SCC.
- Risk factors for melanoma include fair skin, red or blond hair, no tan/easily burns, freckles, excessive childhood sun exposure, blistering childhood sunburns (>3), moles (nevi) or dysplastic nevi, family or personal history of melanoma, immunosuppression, and older age.
- One third of melanomas arise in a preexisting nevus.
- Depth of tumor invasion is the most important prognostic indicator for melanoma; most patients with thin tumors (<1 mm) have over 90% 10-year survival.

Actinic Keratosis

Actinic keratoses (AKs) are also known as "solar keratoses" because of their relationship to chronic sun exposure. These lesions are most common on the dorsal surfaces of the hands and arms, neck, ears, bald scalp, and face, areas that are not covered by clothing on a daily basis (Fig. 33-78). AKs are usually scaly, pink to flesh-colored macules or papules and are often easier to feel than see. They have a rough texture as

Figure 33-77 Dermatofibroma undergoing pinch test, in which lesion dimples downward. (© Richard P. Usatine.)

Figure 33-78 Extensive actinic keratoses on forearms and dorsum of hands. (© Richard P. Usatine.)

a bare finger slides over the skin. The lesions have malignant potential and can transform into squamous cell carcinoma at a rate of about 0.1% per lesion per year.

Cryotherapy with liquid nitrogen is the most effective and practical method for treating AKs when a limited number of lesions are present. For more extensive lesions, topical 5-FU (Efudex 5%, Carac 0.5%), diclofenac (Solaraze), or imiquimod (Aldara) is recommended. This treatment can be temporarily disfiguring with erythema, crusting, or ulcerations, but if the skin is kept lubricated with petroleum jelly during treatment, the process usually looks worse than it feels. Both 5-FU and diclofenac are applied daily for 4 weeks. Patients often will not tolerate the 4-week duration, but if erythema or crusting is achieved in 2 to 3 weeks, treatment may still be successful. Lesions will take another 2 to 4 weeks to heal. Treatment with imiquimod is once daily for 3 to 5 days of

the week (depending on irritation) and is continued for 12 to 16 weeks. Imiquimod is supplied in small, expensive packets, so it is less practical for treating larger surface areas. Lesions that are hyperkeratotic should be biopsied because they often recur with cryotherapy and may not be penetrated by topical therapies.

Treating AKs with liquid nitrogen using a 1-mm halo freeze demonstrated complete response of 39% for freeze times less than 5 seconds, 69% for times over 5 seconds, and 83% for more than 20 seconds (Thai et al., 2004). More hypopigmentation is caused by 20 seconds of freeze time. The physician should base duration of freeze time on the size and thickness of the lesion, using sufficient time for clearance while attempting to avoid hypopigmentation and scarring.

All patients with actinic keratosis or skin cancer should be educated on daily sun protection and sun avoidance. This includes sunscreen with a sun protection factor (SPF) of 30 or greater, wide-brimmed hats, long sleeves and pants, and avoiding peak hours of sunlight (10 AM to 4 PM).

KEY TREATMENT

Sunscreen twice daily for 7 months may protect against development of actinic dermatoses (de Berker et al., 2007) (SOR: A).
 Treating AKs with liquid nitrogen showed complete response of up to 83% for freeze times greater than 20 seconds (Thai et al., 2004) (SOR: A).
 Treat multiple AKs of the face, scalp, forearms, and hands topically with 5-FU, imiquimod, or diclofenac (de Berker et al., 2007) (SOR: A).
 Average complete clearance of AKs using 5-FU was 52% ($\pm 18\%$) and for imiquimod, 70% ($\pm 12\%$) (Gupta et al., 2006) (SOR: A).

Bowen's Disease and Erythroplasia of Queyrat

Bowen's disease (BD) is squamous cell carcinoma (SCC) in situ most often caused by chronic solar damage. Therefore, lesions are found most often on the dorsal hands and forearms, neck, ears, bald scalp, and face. HPV also has been documented as a cause of BD, especially HPV-16. Inorganic arsenic ingestion, radiation dermatitis (x-ray damage), immunosuppression or HIV, burn scars, and chronic ulcers are also associated with BD.

Bowen's disease often presents with an asymptomatic, slowly enlarging, erythematous, scaly patch on the skin that mimics an eczematous dermatitis (Fig. 33-79). The head and neck are most frequently affected, followed by the extremities. As they enlarge, lesions may become hyperkeratotic, crusted, fissured, or ulcerated. When BD occurs on mucous membranes, it is a white, red, or erosive patch. SCC in situ on the penis is referred to as *penile intraepithelial neoplasia* (erythroplasia of Queyrat).

Treatment of BD depends on the location, size, number of lesions, clinician's expertise, patient factors (age, immune status, concomitant medication, comorbidities, compliance), cosmetic outcome, and patient preference. For the trunk or extremities, electrodesiccation and curettage (ED&C) is practical. Cryotherapy is also an option but often results in poorer wound healing. One prospective study suggests a superiority of ED&C over cryotherapy in treating BD, especially for lesions on the lower leg. Curettage was associated with a significantly shorter healing time, less pain, fewer complications, and a lower recurrence rate (Ahmed et al., 2000).

Figure 33-79 Bowen's disease (squamous cell carcinoma in situ) on arm. (© Richard P. Usatine.)

For larger or poorly defined lesions, topical therapy with 5-FU or imiquimod can be used, working best when the patient can see and reach the lesion. In a randomized, double-blind, placebo-controlled trial of imiquimod daily for 16 weeks, 9 of 12 patients (75%) in the imiquimod group and none in the placebo group had complete clearance of BD, with no recurrence in the 9-month follow-up (Patel et al., 2006). Lesions can also be excised with 4-mm margins or referred for Mohs micrographic surgery when tissue sparing is crucial. Mohs surgery is recommended for BD at sites such as digits or penis, where it is important to limit removal of unaffected skin. It is also useful for poorly defined or recurrent head and neck BD (Cox et al., 2007). Excision should be an effective treatment with low recurrence rates, but the limited evidence cannot address specific lesion sites (Cox et al., 2007).

The overall risk of progression of BD to invasive cancer is about 3% to 5%. However, risk is greater for patients with oral and genital lesions (about 10%), as well as those with a history of arsenic exposure or lesions located in a chronic scar or ulcer.

KEY TREATMENT

Curettage and electrodesiccation may be superior to cryotherapy in treating Bowen's disease, especially for lesions on the lower leg (Ahmed et al., 2000) (SOR: A).

Use of 5-FU is more practical than surgery for large BD lesions, especially at potentially poor healing sites (Cox et al., 2007) (SOR: B).

Imiquimod effectively clears BD lesions in most patients (Patel et al., 2006) (SOR: B).

Mohs surgery is recommended for BD at the digits or penis and is useful for poorly defined or recurrent head and neck BD (Cox et al., 2007) (SOR: B).

Basal Cell Carcinoma

Basal cell carcinoma (BCC) is the most common human malignancy. In the United States, BCC affects almost 1 million people per year, and this estimate is likely low because no national registry exists for nonmelanoma skin cancers.

Figure 33-80 Nodular basal cell carcinoma on nasal ala. (© Richard P. Usatine.)

BCC typically appears in areas of sun-exposed skin, is usually slow growing, and rarely metastasizes. Prognosis is excellent with proper therapy, but BCC can cause significant local destruction and disfigurement if neglected. The estimated lifetime risk in Caucasians approximately is 1 in 5 but increases to 1 in 3 in those over age 65 living in southern latitudes. The incidence is extremely low in those with highly pigmented skin. Organ transplant recipients have a 5 to 10 times greater risk of BCC.

Patients often present with a nonhealing sore on the face, ears, scalp, neck, or upper trunk. The most common type of BCC is *nodular*, which is usually a pink papule or nodule, with a central depression or ulceration and pearly, rolled borders with overlying telangiectasias (Fig. 33-80). *Superficial* BCC is the second most common type (Fig. 33-81). *Sclerosing* (morpheaform, infiltrating) BCC is the least common (Fig. 33-82). It is not unusual to see pigment in a nodular BCC (Fig. 33-83). A shave biopsy is usually adequate to confirm the diagnosis.

Superficial BCC can be treated with ED&C or topically with 5-FU or imiquimod. Imiquimod 5% cream once daily five times weekly for 6 weeks for superficial BBC produced an initial clearance rate of 90%, with 80% of subjects clinically clear at 2 years (Gollnick et al., 2005). In another study, superficial BBC lesions on the trunk or limbs were treated with 5-FU cream twice daily for up to 12 weeks. The histologic cure rate was 90%, and mean time to clinical cure was 10.5 weeks. 5-FU was generally well tolerated, with a good cosmetic outcome; most patients had no pain or scarring and only mild erythema (Gross et al., 2007).

Nodular BCC can be excised with 3 to 5-mm margins or treated with ED&C, depending on location and patient comorbidities and preference. Cryotherapy is another option but is infrequently performed due to poor wound healing. Tumors that are more aggressive by histologic pattern (sclerosing, morpheaform, or infiltrating) or those occurring near vital or cosmetically sensitive structures are best treated with Mohs micrographic surgery (MMS). This tissue-sparing method also allows for examination of almost 100% of the

Figure 33-81 Superficial basal cell carcinoma on back. (© Richard P. Usatine.)

tissue margins. MMS is the removal of tumor by scalpel in sequential horizontal layers, in which each tissue sample is frozen, stained, and microscopically examined. This is repeated until all the margins are clear. MMS is the treatment of choice for BCCs greater than 2 cm, with poorly defined margins, with aggressive histology, involving areas of cosmetic or functional importance (mouth, ears, nose, eyelids), or recurrent lesions (Thissen et al., 1999).

Patients diagnosed with BCC have an approximately 30% higher risk than the general population of being diagnosed with another BCC unrelated to the previous lesion. Because BCC can recur, patients should have frequent full-body skin examinations at least twice yearly for the first 2 years, then yearly if no new lesions occur. As with all sun-related malignancies and precancerous lesions, patients must be instructed on sun protection and sun avoidance.

KEY TREATMENT

Mohs surgery (3 studies, $n = 2660$) is the “gold standard” but is not needed for all basal cell carcinomas. Recurrence rate was 0.8 to 1.1. Systematic review also showed the following (Thissen et al., 1999) (SOR: A):

Surgical excision (3 studies, $n = 1303$): recurrence rate was 2 to 8. Mean cumulative 5-year rate was 5.3. Recommended margins are 4 to 5 mm.

Curettage and desiccation (6 studies, $n = 4212$): recurrence rate was 4.3 to 18.1. Cumulative 5-year rate was 5.7 to 18.8. Three cycles of curettage and desiccation can produce higher cure rates than one cycle.

Cryosurgery (4 studies, $n = 796$): recurrence rate was 3.0 to 4.3. Cumulative 5-year rate (3 studies) was 0 to 16.5.

Superficial BCC is effectively treated with imiquimod 5% cream (Gollnick et al., 2005) or 5-FU cream (Gross et al. 2007) (SOR: B).

Figure 33-82 Sclerosing basal cell carcinoma. (© Richard P. Usatine and The Skin Cancer Foundation)

Figure 33-83 Pigmented nodular basal cell carcinoma. (© Richard P. Usatine.)

Squamous Cell Carcinoma

Cutaneous squamous cell carcinoma is the second most common form of skin cancer, also arising primarily on sun-exposed skin of middle-aged and older adults. Most SCCs arise from sun-induced precancerous lesions (actinic keratoses). As in BD, there is a higher risk of SCC in patients with radiation dermatitis (x-ray damage), leukoplakia or erythroplakia (in oral or genital mucosa), burn scars, and chronic skin ulcers. It is important to note that organ transplant recipients have a 40 to 250 times greater risk of developing SCC, purportedly from interaction of HPV and immunosuppression.

Lesions are typically pink to flesh-colored papules or nodules, often with crusting or ulceration (Fig. 33-84). They may also be keratotic or may develop a cutaneous horn. The most common locations include the face, scalp, lips, ears, neck, dorsal arms and hands, and genitalia (Fig. 33-85). Although many SCCs are asymptomatic, symptoms such as bleeding, pain, and tenderness, may be noted. SCC has an overall *metastasis* rate of 2% to 3%, but it is highly variable based on location, size, depth, invasion, and immunosuppression;

Figure 33-84 Squamous cell carcinoma under ear. (© Richard P. Usatine.)

Figure 33-85 Squamous cell carcinoma on lip. (© Richard P. Usatine.)

rates can be as high as 30% to 40%. High-risk areas for metastasis include the ear, lip, genitalia, and areas of chronic inflammation (burns, scars, ulcers). A biopsy is required for diagnosis, which can be done with the shave or punch technique. Treatment of superficial SCC is covered under Bowen's disease.

Many SCCs can be excised with 4-mm to 5-mm margins. Smaller lesions may be amenable to ED&C. Several series report excellent cure rates with ED&C, and experience suggests that small (<1 cm), well-differentiated, primary slow-growing tumors arising on sun-exposed sites can be removed by experienced physicians with curettage (Motley et al., 2003). As with BCC, tumors of SCC that are large, invasive, recurrent, or near vital or cosmetically sensitive structures are best treated with Mohs surgery. Surgical resection with 4-mm margins should be adequate for well-defined low-risk tumors less than 2 cm in diameter. Such margins are expected to remove the primary tumor mass completely in 95% of cases. MMS should therefore be considered as first-line treatment of high-risk SCC, particularly at sites where wide surgical margins may be difficult to achieve without functional impairment (Motley et al., 2003). A prospective, multicenter case series of 1263 patients with SCC who

underwent MMS, recurrence after MMS was diagnosed in 15 of the 381 patients (3.9%) who completed the 5-year follow-up: 2.6% in patients with primary SCC, and 5.9% in patients with previously recurrent SCC (Leibovitch et al., 2005).

KEY TREATMENT

Surgical resection with 4-mm margins should remove small cell carcinoma (low risk, <2 cm) completely in 95% of patients (Motley et al., 2003) (SOR: A).
Mohs surgery (MMS) is considered first-line treatment of high-risk SCC (Motley et al., 2003) (SOR: B).
Experienced physicians can remove small (<1 cm) slow-growing SCC tumors on sun-exposed sites with curettage (Motley et al., 2003) (SOR: B).

Melanoma

Melanoma is the most lethal of the cutaneous malignancies, causing more than 77% of skin cancer deaths. In the United States, more than 62,000 new cases of invasive melanoma and almost 50,000 new cases of melanoma in situ were diagnosed in 2008. Melanoma arises from the pigment-producing cells (melanocytes) located predominantly in the skin, but it also found in the eyes, ears, GI tract, leptomeninges, and oral and genital mucous membranes. Early detection and treatment of melanoma are the best means of reducing mortality.

The development of melanoma is not completely understood and is not as directly linked to chronic sun exposure as is BCC or SCC. Risk factors include fair complexion, red or blond hair, inability to tan or predisposed to burn, freckles, excessive childhood sun exposure, more than three blistering childhood sunburns, an increased number of moles (nevi) or dysplastic nevi, family history of melanoma, personal history of melanoma, immunosuppression, and older age.

One third of melanomas arise in a preexisting nevus. A changing or newly acquired nevus in a person over age 20 is the most common warning sign for melanoma. Increase in size, change in color, asymmetry of borders, and variegated pigmentation are signs that warrant a biopsy. The mnemonic ABCDE (*asymmetry, border irregularity, color, diameter, evolving*) is helpful to assess lesions that may be melanocytic (Table 33-3). Symptoms such as bleeding, itching, ulceration, and pain in a pigmented lesion are less common but also warrant further evaluation.

The subtypes of melanoma include superficial spreading melanoma (60%-70%), nodular melanoma (15%-30%), lentigo malignant melanoma (5%-15%), and acral lentiginous melanoma (5%-10%). These are essentially histologic subtypes but do tend to favor certain areas or populations. Superficial spreading, the most common type usually occurs on the trunk or legs (Fig. 33-86). Lentigo maligna melanoma is an in-situ variant and usually found on the face in elderly persons (Fig. 33-87). Nodular melanomas often have a solid-black color, and their thickness predicts a worse prognosis (Fig. 33-88). Acral lentiginous melanoma is most often found on the great toe or thumb and is the most common type to occur in African Americans (Fig. 33-89).

Excisional biopsy, including 1 to 2 mm of normal skin surrounding the pigmented lesion, is optimal to provide

Table 33-3 Mnemonic for Signs and Symptoms of Melanoma

| ABCDE | Description |
|---------------------|--|
| Asymmetry | Half the mole does not match the other half. |
| Border irregularity | Edges of mole are ragged, blurred, or notched. |
| Color | Color over mole is not homogeneous; may be varying shades of tan, brown, or black; patches of red, blue, or white in some cases. |
| Diameter | Mole is larger than 6 mm. |
| Evolution | Previously stable mole that is changing (evolving) in color, size, or other signs or symptoms. |

**Figure 33-86** Superficial spreading melanoma on back. (© Richard P. Usatine.)**Figure 33-87** Lentigo maligna melanoma on the face. (© The Skin Cancer Foundation.)**Figure 33-88** Nodular melanoma with 22-mm Breslow depth. (© Richard P. Usatine.)**Figure 33-89** Acral lentiginous melanoma on heel of African American woman. (© Richard P. Usatine.)

accurate diagnosis and histologic staging. Referral for biopsy may be appropriate based on the location and size of the lesion. “Scoop shave” biopsies can be performed as long as the depth of the specimen obtained is greater than 1 to 2 mm. This is important because the depth of tumor invasion (Breslow depth) is the most important prognostic indicator and used in staging. Melanomas are also staged based on presence of ulceration (histologically), lymph node involvement, and location of metastasis. Diagnosing melanoma early is critical to a good prognosis. Most thin tumors (Breslow depth <1 mm) have a greater than 90% 10-year survival rate.

Treatment for melanoma is primarily surgical and depends on the depth of the tumor. Lesions with Breslow thickness less than 1 mm can be excised with 1-cm margins. Lesions with Breslow thickness of 1 mm or greater should be referred for sentinel lymph node biopsy to provide accurate staging. There is limited adjuvant therapy for melanoma that has spread to the lymph nodes, and at this time there is no standard chemotherapy for metastatic melanoma. Clinical

trials are an option for patients with advanced-stage disease. Patients with advanced melanoma should be referred to a medical oncologist to consider adjuvant therapy with interferon- α . This may offer a small benefit in terms of recurrence-free and overall survival (Garbe and Eigentler, 2006).

For 2 to 3 years after any diagnosis of melanoma, patients should be seen every 3 to 6 months because most metastases occur in the first few years. If no new tumors are found, annual full-body skin examinations should be performed for life because of the higher risk of subsequent primary melanomas. Strict sun protection and sun avoidance should also be followed.

KEY TREATMENT

World Health Organization recommendations for excision margins are 5 mm for melanoma in situ lesions, 1 cm for lesions less than 1 mm, and 2 cm for melanomas 2 to 4 mm in thickness (Lens et al., 2002) (SOR: A).

Sentinel lymph node biopsies are recommended for melanomas 1 mm or greater in depth, although it is unclear whether this improves survival (Tanis et al., 2008) (SOR: B).

Interferon- α may offer some benefit in recurrence-free and overall survival of melanoma patients (Garbe and Eigentler, 2006) (SOR: B).

Definition and Pathogenesis

Diabetes mellitus is currently defined as a group of metabolic disorders characterized by hyperglycemia that result from defects in the secretion and action of insulin. Normally, plasma glucose, the primary substrate for brain function, is tightly regulated within a narrow fasting range of 60 to 100 mg/dL by insulin secreted from the beta cells of the pancreatic islets. Daily mean glucose values which exceed 100 mg/dL have been associated with the progression of diabetic complication. Over the long term, diabetic patients often develop complications such as retinopathy, neuropathy, nephropathy, and accelerated aging of the cardiovascular system.

Although elevated fasting glucose remains the earliest and most readily detectable sign of the onset of diabetes

mellitus (DM), the metabolic errors of diabetes are likely disordering the utilization of all substrates long before hyperglycemia becomes apparent. Both glucose and fatty acids are energy substrates oxidized by muscles, including the myocardium, for adenosine triphosphate (ATP) generation. The relative lack of insulin in DM leads to lipolysis or the release of fatty acids stored in adipose tissue, resulting in increased free fatty acid (FFA) levels. FFAs then compete with glucose for oxidative disposal or storage in muscles. This substrate competition further promotes hyperglycemia. During conditions of marked insulin deficiency, a massive efflux of FFAs from adipose tissue can precipitate diabetic ketoacidosis because of the incompletely oxidized FFA degradation products β -hydroxybutyrate and acetoacetic acid. Defects in FFA removal from lipoproteins account for the

dyslipidemias implicated in the acceleration of atherogenesis in the diabetic state. When fatty acids packaged into triglycerides are not properly degraded in tissues, their intracellular accumulation causes lipotoxicity, which in turn impairs cellular function, including the beta cell of the pancreatic islets.

Insulin is also important in maintaining the integrity of proteins, whose amino acids become substrates for hepatic gluconeogenesis when cortisol and glucagon's actions are unopposed by insulin. Insulin insufficiency of diabetic disorders has ubiquitous adverse effects on metabolism of all energy substrates, which contributes to the diverse complications challenging diabetic patients in their activities of daily living.

Classification and Diagnosis

Key Point

- Fasting serum glucose values of 100 to 125 mg/dL are considered to be *prediabetes* to indicate that these values have an increased risk of progressing to diabetes by various pathophysiologic processes.

Diabetes mellitus has been subdivided into four groups: type 1, type 2, other specific types, and *gestational diabetes mellitus* (GDM). The diagnosis of DM is made by finding any one of the following criteria subsequently confirmed on another day by any of the criteria:

1. Typical symptoms of hyperglycemia, such as weight loss, polyuria, and polydipsia, associated with a casually found serum glucose value greater than 200 mg/dL.
2. Fasting serum (blood) glucose (FSG, FBG) value of 126 mg/dL or greater.
3. An FSG value of 200 mg/dL or greater obtained 2 hours after a 75-g glucose challenge (after 72 hours of eating 300 g of carbohydrate daily).

The diagnosis of GDM is made during pregnancy using specific criteria discussed later.

Glucose circulating in the blood enters red blood cells (RBCs) and reacts with the amino acid sequence of hemoglobin (Hb), resulting in a glycosylated product called hemoglobin A_{1c}. The HbA_{1c} value reflects the average FSG value of the prior 3 months that hemoglobin circulated in RBCs (given that RBCs have a mean half-life of 90 days). The HbA_{1c} value has become extraordinarily useful in gauging the level of glycemic control, and values of 6.5% or greater are now being considered a level diagnostic of DM. However, the test has limitations as the result can be lowered by anemia, renal disease, and other disorders that shorten RBC survival (e.g., chronic disease, hemoglobinopathy). Some forms of hemoglobinopathy can also increase the HbA_{1c} test despite near-normal glycemic control. The fructosamine test measures the glycosylation of albumin, which has a shorter circulating half life than hemoglobin, and may be used to resolve inconsistencies between average glucose values and HbA_{1c} level, although this is related to the albumin concentration. Insulin and C-peptide levels are readily affected by the toxic effects of glucose and fatty acids on beta cells, making low levels difficult to interpret.

Fasting glucose values of 100 to 125 mg/dL are consistent with prediabetes and increase the risk of progressing

to diabetes through various pathophysiologic processes. Finding these values allows the family physician to initiate prospective and preventive interventions. Participants in the Diabetes Prevention Program had impaired glucose tolerance, and those randomized to metformin or intensive lifestyle modification had reduced incidence of diabetes compared to those randomized to placebo (Knowler et al., 2002). Predictors of prediabetes changing to normal glucose regulation over 3-year follow-up included lower baseline fasting and 2-hour glucose levels, younger age, intensive lifestyle modification, and greater weight loss (Perreault et al., 2009).

Epidemiology

Prevalence

Prevalence of diabetes has increased worldwide. In 1990 the prevalence of self-reported diabetes was 2.9% in the United States, increasing to almost 8% in the first decade of the 21st century. Because self-report misses persons with undiagnosed diabetes, the Centers for Disease Control and Prevention (CDC) estimates total prevalence of diabetes in adults 20 or older approaches 11% of the U.S. population, and those with impaired fasting glucose (prediabetes), about 26% (2003–2006).

In both men and women the prevalence of diabetes increases with age; the rate now is almost 1 in 4 for those 60 years and older. In those over 20, American Indians and Alaskan Natives have high prevalence rates (16.5%). Blacks (11.8%) and Hispanics/Latinos (10.4%) also have rates greater than whites (6.6%). Education is inversely proportional, with the highest prevalence among those not finishing high school. Perhaps because of its effect on weight, smoking reduces the prevalence of diabetes, although ex-smokers have an even higher prevalence. The Southeast has a much higher prevalence than other parts of the United States. Regional differences are probably explained by differences in the populations cited, as well as cultural factors.

The lifetime risk of acquiring diabetes is high and is climbing. More than one third of those born in the year 2000 will eventually become diabetic; risk for men is 32.8%, and risk for women is 38.5% and higher risk at all ages. The lifetime risk for Hispanics is about 50% (45.4% for men, 52.5% for women); for black women, 49.0%; and for black men, 40.2%.

Types

Patients with type 1 diabetes make up only 5% to 10% of the diabetic population; the remaining 90% to 95% have type 2. Usually, type 1 diabetic patients first manifest their illness in childhood or adolescence, with about 1 in 4000 children having DM; this includes a few young people with the increasingly prevalent *maturity-onset diabetes of the young* (MODY), although this form may not manifest until adulthood. MODY is classified under "other specific types," which include a heterogeneous group of conditions (specific genetic conditions, surgery, drugs, malnutrition, infections) that result in diabetic manifestations and symptomatology (Table 34-1). These other types are found in 1% to 5% of the diabetic population. GDM is by definition temporal and is categorized separately; 3% to 6% of all pregnant women

Table 34-1 Other Specific Types of Diabetes

| Cause or Category | Examples |
|---|---|
| Genetic defects of beta-cell function | Maturity-onset diabetes of the young (MODY) |
| Genetic defects in insulin action | Lipoatrophic diabetes |
| Diseases of exocrine pancreas | Pancreatitis, cystic fibrosis |
| Endocrinopathies | Acromegaly, Cushing's syndrome, hyperthyroidism |
| Drug or chemical induced | Nicotinic acid, thiazides |
| Infections | Congenital rubella, cytomegalovirus |
| Uncommon forms of immune-mediated diabetes | Antibody against insulin receptor |
| Other genetic syndromes occasionally associated with diabetes | Down, Klinefelter's, Turner's |

From Report of the Expert Committee on the Diagnosis and Classification of Diabetes Mellitus. *Diabetes Care* 2003;26(suppl 1):4-20.

develop GDM, and 40% to 60% of women with GDM develop diabetes, usually type 2, within a decade of the pregnancy.

Genetics

The exact nature of how diabetes or at least the risk of diabetes is transmitted is still not well understood. It is known that those with HLA DR3 and DR4 (human lymphocytic antigens that are cell surface markers) have a fourfold increased risk of developing type 1 diabetes. If a person has both antigens, the risk increases to 12 times normal. There is a very strong familial transmission, with concordance of type 2 in 90% of identical twins older than 40, compared with 50% in type 1 diabetes. Certain genetic types (e.g., MODY) may have different responses to medications than other types.

Complications

Mortality in diabetic adults with heart disease is two to four times higher than in nondiabetic persons, and strokes occur two to four times more often in diabetic patients. Approximately three quarters of diabetic adults have high blood pressure. Diabetic retinopathy is now the leading cause of blindness in adults, and DM is also the leading cause of end-stage renal disease (44% of all cases). About two thirds of diabetic patients have some form of neural damage (e.g., peripheral neuropathy, gastroparesis, carpal tunnel syndrome, erectile dysfunction). Younger diabetic adults are twice as likely to have periodontal disease, and all those with poorly controlled diabetes are three times more likely to have gum disease. GDM poorly controlled in the first trimester can cause major birth defects (5%-10% of pregnancies) and spontaneous abortions (15%-20%).

The total direct costs (costs of medical care and services) and indirect costs (disability, work loss, premature

mortality) of diabetes in 2007 were an estimated \$174 billion (\$116 billion for direct, \$58 billion for indirect).

Prevention

When diabetes is controlled, the risk of complications decreases. For example, for every 1% decrease in HbA_{1c} there is a corresponding 40% decrease in the risk of microvascular complications. Similarly, for every 10-mm Hg drop in blood pressure, there is a 12% reduced risk of cardiovascular and microvascular complications; controlling LDL cholesterol reduces risks of large-vessel disease even further (20%-50%). Appropriate eye and foot programs (e.g., laser therapy, podiatry monitoring) can reduce the risk of loss of vision or amputation by 50% or more.

Pathophysiology

Common Mechanisms

The pathogenic mechanisms resulting in DM are generally divided into (1) primary defects in beta-cell function, causing variable insulin deficiency (type 1 diabetes), and (2) defects in the peripheral action of insulin associated with a slowly evolving loss of the beta cells' ability to compensate (type 2 diabetes). The failure of beta cells in type 1 is most likely caused by autoimmunity, comparable to other disorders affecting endocrine gland function (e.g., Hashimoto's thyroiditis, Addison's disease). Anti-islet cell antibodies are markers of the ongoing process resulting in type 1 diabetes. Beta-cell failure of type 2 diabetes is thought to result from primary genetic defects or acquired dysfunction, as in mitochondrial metabolism that reduces the oxidation of glucose and fatty acids needed for insulin synthesis and secretion. Such defects in mitochondrial function may also account for the peripheral insulin resistance in skeletal muscle, liver, and adipose tissue at the onset of type 2 diabetes. The insulin secretory function of beta cells and muscle energy metabolism can be significantly improved by any intervention that reduces hyperglycemia and hyperfatty acidemia. These observations are the basis of reversible glucotoxicity and lipotoxicity. Thus any diabetic patient with type 1 or 2 diabetes may have similar mechanisms of both insulin deficiency and insulin resistance.

The clinical characteristics of type 1 and 2 diabetes are shown in Table 34-2. However, diabetic classification and nomenclature have required frequent revisions over the years as the pathogenesis of DM is better understood and changes in culture and human behavior continue to alter its clinical expression. The finding of hyperglycemia on routine examinations of apparently healthy individuals has resulted in a new DM subclass that does not lend itself to easy classification. The finding of anti-islet cell antibodies designates this group as *latent autoimmune diabetes of adults* (LADA). This group mostly consists of young adults who have a prolonged subclinical development of DM. The diabetes may remain indolent or more rapidly deteriorate into classic insulin-dependent type 1 diabetes, or it may continue to evolve into insulin resistance and dependency coincident with weight gain. In this case, LADA patients are clinically

Table 34-2 Characteristics of Types 1 and 2 Diabetes Mellitus

| Sign | Type 1 | Type 2 |
|--------------------------------------|---|---|
| Age of onset | Usually childhood and adolescence | About 40 years, increasing with age; adolescence with childhood obesity |
| Family history, concordance in twins | Uncommon; 50% before age 40 | Common, 95% after age 40 |
| Diagnostic markers | Anti-GAD, undetectable C peptide | C peptide variable: high with insulin resistance; low values improve with glycemic control. |
| Other associated disorders | Primary hypothyroidism, celiac disease, other autoimmune endocrine disorders | Metabolic syndrome |
| Glycemic control, ketosis | Marked brittleness, ketosis prone with hyperglycemia | Stable hyperglycemia without ketosis |
| Treatment requirement | Absolute need for insulin; coincident genetic insulin resistance that might respond to oral drugs | Therapeutic lifestyle changes with and without oral agents; insulin is required when other measures fail. |

GAD, Glutamic acid decarboxylase.

indistinguishable from type 2 patients but have continuing risk of deteriorating to insulin dependency. Thus a patient recognized to have DM may have diverse etiopathogenic mechanisms causing insulin dependency and resistance resulting in hyperglycemia.

Adolescents with significant obesity who develop type 2 diabetes are younger at presentation than usual, so age of onset of type 2 now overlaps with type 1 diabetes. Because their obesity is often intractable, their marked state of insulin resistance at DM onset eventually becomes a state of insulin deficiency. When DM patients develop marked hyperglycemia and dyslipidemia, the resulting glucotoxicity and lipotoxicity cause systemic cellular dehydration along with triglyceride accumulation in skeletal muscle. These acquired defects further accentuate defects in beta-cell insulin secretion and muscle insulin sensitivity. Pathogenic mechanisms may differ (Fig. 34-1), but the resulting glucotoxicity and lipotoxicity so impair insulin secretion and effectiveness that diabetes from any mechanism may lead to similar metabolic crises: diabetic ketoacidosis with or without hyperosmolality.

Mechanisms Underlying Other Specific Types of Diabetes

A diverse array of genetic defects or acquired clinical disorders can impair beta-cell function or insulin sensitivity, resulting in hyperglycemia and the diagnosis of diabetes mellitus (see Table 34-1). These patients generally appear to have type 2 diabetes at presentation and manifest varying

degrees of diabetic severity during the course of their primary disorder.

Maturity-Onset Diabetes of Young

Genetic defects of beta-cell function involve genes coding for hepatic transcription factors and glucokinase. In the MODY variant, hyperglycemia is observed during childhood or adolescence and is caused by a diminution in beta-cell secretion without impairment in insulin action. The genetic disorders are autosomal dominant, and the glucokinase defect impairs the conversion of glucose to glucose-6-phosphate, which is involved in insulin secretion. This glucokinase dysfunction causes a loss of the beta-cell “glucose sensor.” The resulting diabetes is generally not prone to ketosis. Many patients with milder forms of diabetes treated as type 1 eventually are found to have similar genetic defects.

Genetic Disorders of Insulin Resistance

These genetic defects may cause diabetes varying from mild to severe. Marked hyperinsulinemia activates epidermal growth factor receptors in skin, resulting in *acanthosis nigricans*, a darkening of skin folds at the nape of the neck or in the axilla. Marked hyperinsulinemia stimulates ovarian steroidogenesis, which can result in enlarged ovaries and a virilizing syndrome. This condition provided insight into the connection of insulin resistance to polycystic ovarian syndrome, which is now routinely treated with metformin to attenuate hirsutism and stimulate ovulation. The genetic defects in patients with generalized lipodystrophy have not been fully defined, but these patients are extremely insulin resistant because energy substrates can be stored only in liver and muscle. Impairment in fatty acid storage compromises muscle uptake and glucose oxidation.

Disorders of Exocrine Pancreas

Hemochromatosis, chronic pancreatitis, cystic fibrosis, and fibrocalculous pancreatopathy (observed in tropical countries) all cause decreased insulin release to varying degrees.

Other Endocrinopathies

Production of excessive counterregulatory hormones requires an increased insulin output. When increased insulin secretion cannot be maintained and hyperglycemia results, the physician can infer preexisting beta-cell abnormalities in insulin production and secretion.

Infectious Etiologies

Type 1 diabetes may result from viral destruction of beta cells, as in congenital rubella, mumps, cytomegalovirus, or coxsackievirus.

Other Syndromes

Syndromes involving chromosomes (Down, Klinefelter's), fat and muscle metabolism (Prader-Willi, myotonic dystrophy), and autoimmune mechanisms (stiff man syndrome) can affect insulin secretion or sensitivity.

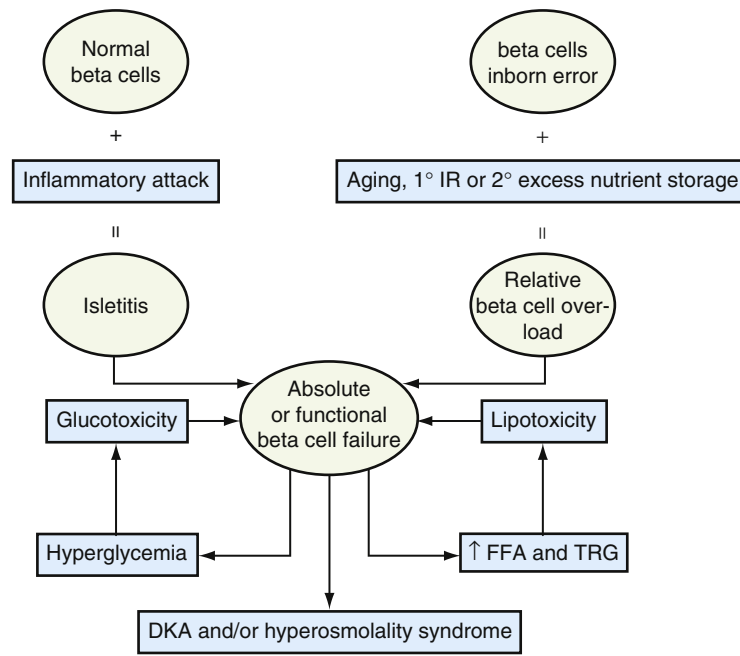

Figure 34-1 How normal or genetically impaired beta cells can be affected by inflammation and overnutrition, resulting in absolute or relative loss of insulin secretory reserve and the activation of the common mechanism leading to diabetic crisis. 1° IR, Primary insulin resistance; 2° IR, secondary insulin resistance; DKA, diabetic ketoacidosis; FFA, free fatty acids; TRG, triglycerides.

Presentation

Key Points

- Fasting glucose values of at least 200 mg/dL usually indicate significant beta-cell failure comparable to type 1 diabetes. Beta-cell loss in type 2 may still be reversible, however, even after long periods, if gluco/lipotoxicity is successfully treated.
- Hyperglycemia (even at prediabetes levels), dyslipidemia, and hypertension associated with increased abdominal girth are the cardinal signs of metabolic syndrome.
- Somatic symptoms and signs of type 2 diabetes usually take years to develop; the prolonged “latent” phase depends on the severity of hyperglycemia.

Type 1 Diabetes

The symptoms of type 1 diabetes may be indolent or precipitous, depending on the rate of decrease in insulin secretion. *Indolent* asymptomatic diabetes can decompensate as a result of a coincident illness. The resulting hyperglycemia causes polydipsia and polyuria from the osmotic effects of glycosuria. Weight loss, blurred vision, and fatigue occur as energy metabolism is disordered. Most patients become aware of a problem at this point, and the diagnosis is easily recognized if the patient seeks help.

If the insulin deficiency is allowed to become profound, the disorder in FFA metabolism results in *ketonuria*, which accentuates the osmotic diuresis. The stress of illness can increase counterregulatory hormones (epinephrine, cortisol, growth hormone) that antagonize the effects of already-reduced insulin. The result is increasing hyperglycemia and further osmotic diuresis. Progressive hyperglycemia causes intravascular and intracellular dehydration, which reduces beta-cell

function and insulin delivery to the periphery. Gastric dysfunction can occur under these conditions, further compromising fluid intake. The result is a “glucotoxic” state in which dehydration compromises the kidney’s ability to excrete ketones, whose production is accelerated by insulin’s failure to regulate FFA oxidation. Acidemia as a result of marked ketonemia causes hyperventilation and subsequent dyspnea. The increasing hyperglycemic state with dehydration causes brain *hyperosmolality*, producing lethargy, stupor, and if uninterrupted with insulin therapy, coma. This sequence is the description of the descent into diabetic ketoacidosis.

Diabetes mellitus may be discovered incidentally in an asymptomatic child or adult when hyperglycemia is noted on a comprehensive metabolic profile or glycosuria on routine urinalysis. Presuming that a lean child, adolescent, or adult has an autoimmune process leading to type 1 diabetes would be strongly supported by the finding of anti-islet cell antibodies. Asymptomatic patients with mild hyperglycemia thought to have an autoimmune pathogenesis require glucose monitoring to determine when therapeutic intervention is needed. Although these patients are likely to respond early to a variety of oral agents like any type 2 patient, no interventions have been effective thus far in slowing their progression to clinically overt type 1 requiring insulin. Prudent lifestyle measures, including exercise, dietary discretion, glucose monitoring, and oral therapies designed to reduce insulin secretion, may be efficacious over a surprisingly long period in deferring insulin therapy.

Type 2 Diabetes

The typical indolent course of type 2 diabetes can be further extended by a therapeutic lifestyle. However, this does not mean it is any less serious than type 1 as a state of accelerated vascular aging. Unfortunately, treating middle-aged and

older patients with long-term type 2 diabetes with aggressive pharmacologic methods to correct hyperglycemia has failed to improve cardiovascular outcomes (ACCORD, 2008; VADT, 2009). Improved glycemic control in type 2 diabetes, as in type 1, has been shown to preclude progression of small-vessel disease and nerve function disorder to diabetic retinopathy, nephropathy, and neuropathy (UKPDS, 1998a).

Dyslipidemia, Hypertension, and Atherosclerosis

The unexpectedly negative outcomes of diabetic studies targeting hyperglycemia as a cardinal risk factor for progression of atherosclerosis emphasize the need to correct dyslipidemia and hypertension typical of the type 2 diabetic state. Dyslipidemia occurs chiefly when beta cells are unable to maintain the high insulin levels required to inhibit lipolysis from adipose cells. The resulting free fatty acidemia associated with high insulin levels causes the liver to repackage these energy substrates into more triglyceride-rich lipoproteins.

Hyperinsulinemia has also been associated with hypertension, changes in vascular responsiveness (endothelial dysfunction), and appearance of inflammatory proteins, especially C-reactive protein. The precise causal factor in these relationships and relative importance of these changes are not well understood.

Overt Type 2 Diabetes

Remarkably, only 20% to 25% of individuals with hyperinsulinemia and insulin resistance progress to overt type 2 diabetes. This progression begins when FSG becomes 100 mg/dL or greater, the threshold for the diagnosis of prediabetes. Type 2 diabetes may be diagnosed at this phase if a casual postprandial glucose of 200 mg/dL or higher is detected.

Most patients diagnosed with type 2 diabetes may not note the typical hyperglycemic symptoms described for type 1 diabetes. The difference may be that type 2 diabetes evolves over years below the symptomatic threshold because sufficient insulin is present to prevent the marked lipolysis and ketonemia more typical of type 1 diabetes, with its obligatory water and electrolyte losses. Most patients with type 2 diabetes are discovered incidentally, such as during routine risk factor assessment for cardiovascular disease or other work-up for various symptoms, including peripheral sensorimotor neuropathy, Bell's palsy, erectile dysfunction, visual changes, and gastrointestinal complaints, which may lead to finding an elevated FSG and the diagnosis of type 2 diabetes.

Management

Behavioral Therapy

Key Point

- Self-management is the essence of behavioral therapy for DM, consisting of daily glucose monitoring, diet, exercise, and insulin adjustment.

The diagnosis of diabetes mellitus requires lifestyle adjustments and enduring major inconveniences and sacrifices to

deal successfully with the disorder. Behavioral adjustments reduce the difficulty of controlling type 1 diabetes, but their impact in a type 2 patient can be so powerful as to alter the course of the disorder. All patients receive rational treatment regimens, but those who consciously monitor their diet and glucose variations learn how to make daily adjustments to achieve near-normalization of glucose values. Positive daily outcomes usually stimulate a continuing self-managing effort. Thus the goal of diabetic treatment is to promote this "winning attitude" toward the disorder.

KEY TREATMENT

Risk management: A therapeutic lifestyle based on achieving weight control and maintaining physical fitness can delay the onset of diabetes mellitus in persons in the high-risk groups (ADA, 2009; Knowler et al., 2002; Tuomeilehto et al., 2001) (SOR: A).
Global risk management: All patients should be advised not to smoke. Patients with blood pressure greater than 130/80 mm Hg should receive pharmacologic therapy in addition to lifestyle therapy. Even in patients without overt cardiovascular disease, the primary goal is LDL level less than 100 mg/dL (ADA, 2009; Haffner, 1998; Haire-Joshu et al., 1999; Hanson et al., 1998; UKPDS, 1998b; Vaccaro et al., 2004) (SOR: A).

Glucose Monitoring

Monitoring behavior is itself therapeutic because it warns of the risk of hypoglycemia or a shift to a hyperglycemic state caused by dietary indiscretion or a smoldering stress. Glucometers are now available that require less than 1 μ L of blood (taken up by capillary action). A sample may be taken from a fingertip, earlobe, forearm, or thigh, with the result available in 5 to 15 seconds. Arm or thigh values are derived from interstitial glucose concentration and may be approximately 15 minutes "out of phase" with blood values if the patient is not in a fasting steady state. Average monitored values over 14 to 30 days correlate with HbA_{1c} values. Monitored glucose data are also the basis of formulating therapeutic targets. For a young girl with diabetes, the fasting target may be 150 mg/dL to avoid early-morning hypoglycemia. As she matures, the target becomes the current American Diabetes Association (ADA) goal of less than 120 mg/dL fasting and before meals. In elderly diabetic patients, glycemic targets again can be liberalized to preclude hypoglycemic risks.

Although costs of monitoring must be considered, frequent glucose monitoring usually indicates the patient is well motivated and is attempting to make the necessary adjustments that will improve their mean glucose value and impact favorably on the HbA_{1c}. In an informed patient with stable type 2 diabetes, there is less evidence that daily is any more effective than weekly testing.

KEY TREATMENT

Insulin treatment of type 1 and monotherapy or combination therapy of type 2 diabetic patients, when guided by self-glucose monitoring, can accomplish tight glycemic control to HbA_{1c} less than 7%, which reduces the occurrence and progression of the microangiopathic complications of DM (ADA, 2009; DCCT, 1993; UKPDS, 1998a) (SOR: A).

Nutrition and Diet

Key Points

- Intentional weight loss can help reverse hyperglycemia, dyslipidemia, hypertension, and other risk factors in patients with type 2 diabetic pathoetiologies.
- Caloric restriction without an accompanying exercise program is much less likely to succeed, although increased eating in compensation for exercise is a potential pitfall.

Dietary consistency will also ease the difficulties of living with diabetes. As with a regular exercise program, a stable diet will simplify insulin treatment schedules in type 1 patients but will not produce the marked effects observed in type 2 patients. Therefore, dietary manipulation should be directed toward ensuring content regularity rather than weight loss in type 1 patients.

Dietary Principles and Weight Loss

In terms of *medical nutrition therapy*, there is no longer a specific diabetic diet; all recommendations are individualized as part of a comprehensive plan that includes exercise and appropriate medical therapies. A meal plan that includes a variety of usual foods is recommended as long as the plan is healthy, with conscious control of carbohydrate intake. Weight loss will improve blood pressure control and, along with decreasing fat intake and increasing physical activity, will reduce fasting lipid levels.

It is not necessary to attempt weight loss before instituting medical therapy, especially since weight loss alone may not provide any glycemic control in highly insulin-deficient patients. However, a multifaceted approach with education, reduced energy, and fat-calorie intake, increased regular physical activity, and other lifestyle changes can produce long-term weight loss and glycemic improvement. Less need for calories in elderly patients leads to obvious dietary changes. Of note, patients should not avoid breads and other starches; in fact, complex carbohydrates are an important part of the modern approach to diabetes.

Dietary Details

The current dietary principles recommended by ADA are the same as those of the American Heart Association (AHA). The caloric content should be that which will permit a patient with type 2 diabetes to attain a body mass index (BMI) of 25 kg/m². With gender, height, weight, and age known, the basal daily caloric requirement and the desired weight can be obtained from standard online calculators. A simpler method, for patients with routine and not intensely physical activities, is to estimate the daily caloric expenditure by multiplying the ideal weight in kilograms by 30 calories/kg. Weight loss can be safely achieved if the patient is taught how to reduce caloric intake by 100 calories per day for each 10 pounds of desired weight loss over 1 year. National Institutes of Health guidelines advocate that weight changes be methodically accomplished over long periods. This will preclude acute energy shifts that could cause gallstones, gout, and depression and have 95% likelihood of recidivism. The guidelines suggest a weight loss goal of 7%, usually rounded

to 10%, per year until the patient attains ideal BMI. For example, for a patient with type 2 diabetes weighing 200 pounds, the advice should be to lose 20 pounds in 1 year by reducing dietary caloric intake by 200 calories per day and/or increasing energy expenditure by that amount.

If a new and reduced weight set point is achieved in the central nervous system, longitudinal studies have shown a reduction in the progression of prediabetes, which confirms widespread clinical experience that the weight loss has a reversal effect on type 2 diabetes.

Dietary Recommendations

The 2008 ADA guidelines considered the risk and advisable intake of carbohydrates, fats, proteins, and other food ingredients. Monitoring carbohydrate by counting, exchanges, or experience-based estimation remains a key strategy in achieving glycemic control. Saturated fat should be less than 7% of calories, and there should be minimal *trans* fat. Total cholesterol should be less than 200 mg daily. Higher fiber intake may improve glycemic control; thus fiber intake should be at least 14 g/1000 calories daily. Sugar, alcohols, and nonnutritive sweeteners are safe when consumed within daily levels established by the Food and Drug Administration (FDA). Usual dietary protein of 15% to 20% of calories is appropriate in diabetes in the absence of significant renal insufficiency. Reduction of protein intake to 0.8 to 1.0 g/kg/day in diabetic individuals with early stages of chronic kidney disease, and to less than 0.8 g/kg/day in later stages, may improve renal function. High-protein diets (>20% of calories) are not recommended for weight loss because the long-term effects on renal function are unknown. A reduced sodium intake of 2300 mg/day, with a diet high in fruits, vegetables, and low-fat dairy products, is prudent. For patients with diabetes and symptomatic heart failure, dietary sodium intake of less than 2000 mg/day may reduce symptoms.

Alcohol

The general consensus is that alcohol in moderation is appropriate for diabetic patients, if only for its protective cardiac effects. "Moderate drinking" means a glass of red wine daily, depending on body mass. Also, for accurate carbohydrate counting, the patient must include the amount in alcohol.

Exercise

Key Points

- Exercise is the single best broad-spectrum therapeutic activity to offset the age-related decline of lean body mass and the consequent loss of insulin sensitivity.
- Exercise does not always promote glucose utilization.
- Clinical prudence requires that cardiac risk be evaluated before a patient engages in a rigorous exercise regimen.
- A prudent guideline is to instruct a nonactive patient to stay within a pulse rate 60% of maximum heart rate for age, before progressing to 75% to 85%.

In addition to dietary guidelines, the U.S. Department of Agriculture (USDA, 2005) also recommends daily exercise

activities for weight loss and health maintenance. The difference in these objectives is related to the duration and the intensity of exercise. The advocacy of exercise, as with dieting and food choices, has become an American industry. Exercise is an essential intervention in the diabetic lifestyle. Studies show that exercise activities even without weight loss result in consistently beneficial and safe outcomes. In type 2 diabetic patients with HbA_{1c} of less than 9%, exercise can lower this indicator by 1%. A similar effect in type 1 diabetes has not been demonstrated, despite improved insulin sensitivity. However, both type 1 and 2 patients show improved serum lipid profile and increased fibrinolytic proteins after exercise. Based on its effects in improving athletic performance, exercise in a diabetic patient encourages good cardiac function with increased circulation to muscles and the periphery.

Risks

Hypoglycemia

As with other effective antidiabetic treatments, exercise has risks, especially in patients who maintain good glycemic control. These risks can be reduced, however, by applying increased care in exercising and its timing. Patients who engage in rigorous activities such as team sports can experience a dramatic hypoglycemic reaction either at the time of the activity or later that night. This risk can be prevented by anticipating and monitoring glucose during exercise. The hypoglycemia is a result of energy expended as oxidized glucose and fatty acids and the latent effects of exercise, which improve muscle blood flow and insulin sensitivity for hours, further facilitating glucose uptake. All these phenomena accelerate plasma glucose clearance, which may require decreasing antidiabetic therapies, especially insulin dosages, to prevent a late, insidious decline in glucose. Understanding all the effects of a particular exercise allows adjustments in treatment and nutrient supplementation.

Hyperglycemia

Rigorous exercise undertaken when insulin levels are insufficient and glycemic control is unsatisfactory will stimulate a stress reaction in which epinephrine activates glycogenolysis. If insulin is insufficient to signal muscle utilization of this hepatic outpouring of glucose, marked hyperglycemia results. Ketosis may also occur as lipolysis, stimulated by the sympathetic nervous system, is unregulated. To avoid this diametrically opposed reaction, rigorous exercises should be initiated only when the blood sugar is known to be under control. The more intense the activity, the more monitoring and nutritional supplementation are necessary. However, overeating in response to exercise is not appropriate.

Complications Associated with Heart and Microvasculature

There are also organ-specific risks of exercise in diabetes. Many cardiac patients are found to be unaware of their type 2 diabetes; almost all long-term patients with diabetes have cardiac dysfunction, often "silent ischemia."

Retinopathy and Neuropathy

Rigorous exercise that elevates blood pressure can exacerbate exudative and proliferative retinopathy. These findings may limit exercise to low-intensity activities such as walking,

which is safe and effective, even in patients with reduced cardiac function.

Walking

Walking improves peripheral perfusion and diverts blood volume to the lower extremities, where muscles have greater capacitance. Blood pressure and cardiac afterload are reduced. Regular walking can even overcome intermittent claudication by stimulating collateralization. With sufficient effort and duration, and even if done in short but repeated patterns as part of the activities of daily living, walking can facilitate weight loss. Postprandial walking may be more effective than preprandial walking (Colberg et al., 2009).

Walking can become hazardous, however, when the foot is affected by marked sensorimotor peripheral neuropathy. Exercise involving the feet requires that the patient is aware of risks and understands how to avoid them. Dry, thin skin lacking the cooling and lubricating effects of sweating is very susceptible to blistering when walking causes rubbing of the foot within the shoe. Prior foot injuries resulting from neuropathic trauma or the microfractures of diabetic osteonecrosis often cause foot deformities and uneven distribution of weight over the surface of the foot. The hyposensitive skin beneath bony deformities is at risk for ulceration. Prophylactic treatment requires orthotic devices, daily foot lubrication, and footwear that is soft with room to expand. Rather than contraindicating exercise of the foot and lower leg, advanced diabetic foot problems benefit from the increased perfusion accompanying non-weight-bearing exercise. Safe, effective exercise activities helpful in this situation use devices that "lock" the feet into the pedals of a stationary bicycle or an elliptical cyclist.

Exercise Prescription

The type, duration, and intensity of exercise as therapy for diabetes is often decided by patient preference and common sense based on the patient's age and abilities and the previous considerations. As noted with walking, modest but periodic low-intensity efforts such as stationary cycling, arm conditioning with light weights, and dancing for 30 to 45 minutes with brief rest period, as often as daily, but at least three times per week, will achieve measurable improvement in HbA_{1c} and lipid levels, indicative of the overall physiologic benefit.

For patients under age 40, the maximum heart rate (HR) is calculated simply by subtracting the patient's age from 220; for a 35-year-old patient, maximum HR would be 220 - 35, or 185 beats/min. Within a 30-minute exercise regimen, after a 5-minute warm-up, there should be 20 minutes of exercise in the pulse range of 111 to 124 beats/min (60%-67% of 185), followed by another 5 minutes of a cool-down phase. With more conditioning, the patient should aim to exercise in the range of 75% to 85% (139-157 beats/min). For patients over 40, the formula for maximum HR is 208 - (0.7 × age); for a 45-year-old patient, 208 - (0.7 × 45) = 208 - 32 = 176 beats/min, with the calculated HR guideposts of 106 (60%), 118 (67%), 132 (75%), and 150 (85%) beats/min.

Pharmacologic Therapies

Key Points

- The ongoing UKPDS combines oral agents and insulin to confirm that better glycemic control lessens microangiopathic complications in type 2 diabetes, independent of the agents used.
- Lowering blood glucose at any time will augment the action of oral medications, which are intended to take over control once the hyperglycemia is overcome.

Glycemic Targets

Since the publication of the Diabetes Control and Complication Trial (DCCT) in 1993, which demonstrated that improved glycemic control meant less neuropathy, retinopathy, and nephropathy in patients with type 1 diabetes, development of antidiabetic agents has accelerated. These include the α -glucosidase inhibitors, metformin, meglitinides, thiazolidinediones (also called glitazones), designer insulins, synthetic analogs of pancreatic peptides called amylin, and incretins, as well as antagonists of incretin degradation called dipeptidyl peptidase inhibitors. How intensely these agents should be used to limit the macrovascular complications of diabetes (coronary heart disease, peripheral vascular disease, stroke) requires continuing study.

Although the efficacy of attaining HbA_{1c} values in the low 7% range resulted in reduced microangiopathic complications, the DCCT and U.K. Prospective Diabetic Study (UKPDS) did not provide conclusive evidence of protection from macrovascular complications. In contrast, UKPDS demonstrated the efficacy of antihypertensive therapy given primarily as a beta blocker or angiotensin-converting enzyme (ACE) inhibitor in slowing the progression of proteinuria and reducing cerebrovascular and cardiac events. Other clinical trials of the statins showed that diabetic patients experience better cardiovascular outcomes with relatively brief treatment. Controlling other major cardiovascular risk factors in DM has a more readily apparent effect on improving diabetic macrovascular outcomes than correction of hyperglycemia.

Similar data from other large trials indicate that the difference in intensive efforts to lower HbA_{1c} to values below 6% versus conventional treatment was not associated with reduced cardiovascular events in middle-aged type 2 diabetic patients (ACCORD, 2008; VADT, 2009). This may have resulted from unawareness of hypoglycemia common in patients with HbA_{1c} values approaching 6%. Recurrent hypoglycemia may downregulate appropriate physiologic response to the stress of cardiac ischemia, which may be clinically silent in diabetic patients.

Considering these data, professional societies recommend that glycemic targets be applied with clinical judgment based on the patient's age and life expectancy, which would relate to the patient's risk of developing microangiopathic complications. Thus an HbA_{1c} target of about 6.5% is appropriate for a young diabetic patient with type 1 but inappropriate for a 75-year-old woman with type 2 and cardiovascular disease. Hemoglobin A_{1c} values of less than 8% in type 2 patients are readily attainable and would likely slow the progression of retinopathy, neuropathy, and subtle renal loss while preventing an acute metabolic decompensation associated

with rapid onset of infection. Glycemic targets of 7% or less are ideal if attained without the risk of hypoglycemia unawareness.

Table 34-3 lists the classes of antidiabetic drugs, mode and duration of action, effectiveness, and side effects. The introduction of the newer agents now allows the clinician to consider drugs that address a specific etiopathogenic mechanism. If the patient is thought to have a type 1 presentation, insulin at the onset is the logical and safest treatment, as discussed later. Oral medications, at least in the short term, should be advised for type 2 diabetic presentations. Behavioral therapies can produce dramatic improvement even at higher HbA_{1c} values, but a FSG over 200 mg/dL indicates marked insulin insufficiency, and some form of drug therapy (including insulin) is necessary to reduce such values expeditiously. Instituting drug therapy should not deemphasize behavioral therapies; as noted, once the inertia of gluco/lipotoxicity is overcome with drugs, effective behavioral therapies could control DM indefinitely.

KEY TREATMENT

Management of either type 1 or type 2 diabetes should be continually modified to find the optimal therapeutic regimen yielding HbA_{1c} of less than 7% while avoiding the risk of hypoglycemia (ADA, 2009; DCCT, 1993; UKPDS 1998) (SOR: A).

Oral Agents

Metformin

With various oral medications available, the physician can choose different therapeutic protocols according to clinical factors. For an overweight patient with a FSG value in the mid-100 mg/dL range, current consensus recommends metformin as the first-line drug (ADA and European Association for the Study of Diabetes, 2009). Metformin blocks glucose production by the liver, which reduces insulin resistance. Metformin is available in generic form and generally does not cause further weight gain. The contraindication is renal insufficiency or the risk of renal impairment secondary to low renal perfusion from dehydration or heart failure. Lactic acidosis can occur if metformin is given in renal failure. Procedures with a risk of nephrotoxicity (e.g., x-ray contrast studies) may necessitate holding the metformin therapy, usually for 24 hours before and after the procedure.

Sulfonylureas and Meglitinides

The sulfonylureas are the oldest class of drugs and were found to be as safe and effective as insulin in the UKPDS. They shut down membrane potassium ion (K⁺) channels, allowing membrane calcium (Ca⁺⁺) channels to open, thereby establishing a calcium gradient that stimulates insulin secretion. In the initial phase of treatment, insulin levels are higher than the previous state following the drug's stimulatory effects. As insulin resistance factors are improved by controlling hyperglycemia, insulin levels fall into a normal range. Treatment is usually effective for 5 to 10 years, depending on the efficacy of behavior treatment and the underlying diabetic progression. The therapeutic duration of sulfonylureas

Table 34-3 Classification of Noninsulin Antidiabetic Agents

| Category/Drug | Action | Onset; Duration | Dosage | Clearance; Side Effects |
|---|--|--|--|--|
| Metformin (Glucophage) | Limits hepatic glucose output | 1 hr; 4-6 hr | 0.5-1 g bid 850 mg tid | Renal clearance GI upset, diarrhea (10%) |
| Sulfonylureas | | | | |
| Glyburide (Micronase, Diabeta) | Increase insulin secretion | 1 hr; 24 hr | 5-20 mg/day | Hepatorenal clearance Hypoglycemia |
| Glipizide (Glucotrol) | | 1 hr; 12 hr | 10-40 mg/day | |
| Glipizide, extended release (Glucotrol XL) | | 2 hr; 24 hr | 5-20 mg/day | |
| Glimepiride (Amaryl) | | 2 hr; 24 hr | 1-8 mg/day | |
| Nonsulfonylurea secretagogues | | | | |
| Repaglinide (Prandin) | Increase insulin secretion | ½ hr; 3 hr | 0.5-4 mg* | Hepatic clearance Hypoglycemia |
| Nateglinide (Starlix) | | ½ hr; 3 hr | 60 mg* | |
| Thiazolidinediones (Glitazones) | | | | |
| Pioglitazone (Actos) | Express transcription factors promoting insulin sensitivity, secretion | 3-6 hr; 24 hr | 15-45 mg/day | Hepatic clearance Weight gain, edema, CHF |
| Rosiglitazone (Avandia) | | 3-6 hr; 24 hr | 1-8 mg/day | |
| α-Glucosidase inhibitor | | | | |
| Acarbose (Precose) | Inhibits intestinal digestion of disaccharides, slowing glucose absorption | ½ hr; 2-4 hr | 50-100 mg* | Intestinal clearance Flatulence, abdominal discomfort, diarrhea |
| Incretin (GLP) agonist | | | | |
| Exenatide (Byetta) Liraglutide (Victoza) | Enhances postprandial insulin secretion Enhances postprandial insulin secretion | ¼ hr 2-3 hr Max effect at 10-12 hr, up to 24 hr | 5 or 10 µg SC bid* 0.6 to 1.8 µg SC/day | Hepatic clearance Nausea, sense of non-well-being |
| Dipeptidyl peptidase (DPP) inhibitor (Gliptin) | | | | |
| Sitagliptin (Januvia) | Enhances postprandial insulin secretion | ½ hr; 12-24 hr | | |

*At mealtime.

GI, Gastrointestinal; bid, twice daily; tid, three times daily; CHF, congestive heart failure; SC, subcutaneously; GLP, glucagon-like peptide.

can be prolonged if an overnight insulin preparation is added to control FSG level.

Sulfonylureas are insulin secretagogues that can be used as first-line drugs or in combination with any of the oral medications. An important advantage is their low cost. However, diabetic patients who do not demonstrate fasting hyperglycemia have an increased risk of hypoglycemia if HbA_{1c} is being maintained below 7%. Another hypoglycemic risk is renal disease, which reduces gluconeogenesis and permits typical sulfonylureas such as glyburide and glipizide to accumulate. Glimepiride and the meglitinides may be used in mild azotemia because of their greater hepatic excretion. The meglitinides are nonsulfonylurea secretagogues that activate a different K⁺ channel. The meglitinides are theoretically safer in elderly patients because of their short half-life, although treatment is required before all meals. Their disadvantage is that generic preparations are not yet available. Failure to respond to metformin is an indication for adding an insulin

secretagogue and titrating the dosage to attain near normalization of HbA_{1c}.

Alpha-Glucosidase Inhibitors

The α-glucosidase inhibitors have been the least utilized of the oral medications available in the United States because of their side effects, not because of their lack of efficacy. The agents interfere with intestinal digestion of complex carbohydrates, slowing the absorption of glucose and limiting the beta-cell insulin response, thus lowering insulin levels. Their disadvantage is that they require administration with meals and often cause postprandial abdominal discomfort and flatulence. Patients who can tolerate these agents can experience HbA_{1c} reductions comparable to other oral agents. However, most patients eventually request a change in medication. These drugs may be better tolerated at the onset of diabetes and prediabetic phase of diagnosis.

Thiazolidinediones (Glitazones)

Thiazolidinediones (TZDs) were developed as transcription factors that stimulate the induction of many cellular proteins facilitating insulin action in the cytosol and mitochondria. TZDs were frequently used as first-line treatment either alone or in combination with metformin because these glitazones can be dramatically effective, especially in overweight patients. Insulin resistance may be significantly improved. However, glitazones can cause unpredictable weight gain and development of peripheral edema, and some patients experience no response. In the presence of renal insufficiency and diastolic dysfunction, glitazones can cause an acute pulmonary edema or subtle congestive heart failure. In fact, a controversial meta-analysis indicated that rosiglitazone increased coronary events, but this was not confirmed in several other series, when patients receiving glitazones were carefully selected. However, these TZDs demonstrating efficacy in slowing the progression of diabetes have been associated with greater fracture risk. For these reasons and high cost, treatment with glitazones is now recommended only after careful deliberation in patients not achieving therapeutic glycemic targets with other agents; the patient and family must be fully informed about the risks before initiating therapy.

Dipeptidyl Peptidase Inhibitors (Gliptins)

The naturally occurring *incretins*, glucagon-like peptide (GLP) and glucoinsulinotropic peptide (GIP), enhance beta-cell insulin secretion after glucose ingestion. The *incretin effect* is the increase in insulin secretion after gastrointestinal (GI) absorption of glucose compared to the amount of insulin secreted in response to glucose infused intravenously. The augmentation of insulin secretion is secondary to a stimulatory effect of GLP and GIP on beta cells. The metabolic clearance of these hormones is governed by dipeptidyl peptidase (DPP), which enzymatically inactivates the incretins. Thus, inhibition of DPP by drugs known as *gliptins* causes a more sustained postprandial insulin secretion.

The prototype DPP inhibitor is sitagliptin, which is safe and generally very effective in the treatment of patients with HbA_{1c} values less than 8%. As with metformin, sitagliptin is not associated with weight gain. It maintains control in patients treated with metformin and sulfonylureas who are slipping out of control. Sitagliptin is rarely efficacious for patients with HbA_{1c} above 8%. Its safety makes sitagliptin a good choice for use alone or in combination with metformin in patients who have insulin secretion, but cost should relegate it to a tertiary role behind more potent sulfonylureas. Other DPP inhibitors are currently in development, and saxagliptin was recently approved as a once-daily tablet to treat type 2 diabetes in adults. Sitagliptin requires dose adjustments for renal failure.

Incretin Agonist (Exenatide)

The prototype GLP agonist is exenatide, which is structurally similar to GLP and was initially approved for use as the therapeutic effects of metformin and sulfonylurea diminished. Exenatide is given subcutaneously by fixed dosages of 5 or 10 µg, twice daily before meals. Its major side effect is nausea and a sense of non-well-being, which limits appetite and

food intake. About 50% of patients are intolerant of treatment in the short term, although many adjust to the side effects, which lessen over time. Overweight patients who are able to take exenatide lose more than 10 pounds (4.5 kg) in the first year. Weight losses can be dramatic, with marked improvement in HbA_{1c} values. Significant weight loss without HbA_{1c} improvement in suggests that the patient has minimal insulin secretory reserve. Exenatide is a therapeutic consideration in overweight patients no longer or not responding to oral agents. Although experience combining exenatide with insulin is sparse, some clinicians report the combination of basal insulin to control fasting glucose with exenatide to be efficacious.

Amylin (Pramlintide)

Amylin is a peptide secreted normally from the pancreas in equimolar amounts with insulin after a meal. It is thought to regulate gastric motility and the release of carbohydrates into the absorptive surfaces of the gut. Pramlintide is an amylin mimetic injected subcutaneously with meals, initially approved to be given with insulin in type 1 diabetic patients. The effect is usually modest to negligible, but anecdotal experience indicates that an occasional brittle diabetic patient may experience dramatic improvement. Pramlintide is now also used in type 2 patients with or without insulin because of its mild effect in limiting food intake and causing weight loss. Pramlintide is therefore used as a tertiary agent when other, more widely used drugs are not fully efficacious.

Developing Therapies

New extended-release incretin agonists will be available soon in addition to other DPP inhibitors. Novel concepts in therapy include the dopamine agonist bromocriptine, shown to reduce FFA levels and improve glucose metabolism. The FDA has recently approved a new formulation of bromocriptine for antidiabetic therapy. Another novel class, the sodium glucose-linked transporter protein (SGLT) inhibitors, interfere with renal reabsorption of filtered glucose in the kidney. The prototype SGLT inhibitor is dapagliflozin, and investigational studies show favorably improved glucose control with modest weight loss.

Insulins

Key Points

- Thresholds for beginning supplemental insulin in type 2 diabetic patients vary depending on whether microangiopathic complications are likely to develop if glucose is not controlled over the patient's lifetime; the better the prognosis, the lower the threshold.
- For elderly patients, keeping fasting serum glucose (FSG) less than 150 mg/dL or HbA_{1c} less than 8% will attenuate the risk of dehydration and metabolic decompensation in the face of stress.
- Appropriate and frequent insulin is the essential therapy of type 1 diabetes and should be used more often in type 2 diabetes if the patient fails to achieve the glycemic goal.

The discovery of insulin by the Toronto group in 1921 has saved the lives of millions of type 1 diabetic patients who

would have succumbed to diabetic ketoacidosis. The remarkable efficacy of insulin despite its nonphysiologic route of administration has stimulated the development of insulins with pharmacokinetic effects mimicking the beta-cell secretion pattern, from short-acting and long-acting beef, pork, and fish extracts, to genetically synthesized human insulins introduced in the 1980s, to biochemically designed insulins with more predictable onset and duration of action (Table 34-4).

Initiating Insulin for Type 2 Diabetes

The classic setting for the use of insulin is in a newly diagnosed type 1 diabetic patient. However, insulin is more frequently used in the treatment of type 2 diabetes to compensate for the secretory defect that often progresses to a profound loss of insulin secretory reserve. This is suggested when FSG or HbA_{1c} continue to rise despite the patient's best behavioral efforts and multiple oral drugs. A patient with type 2 diabetes can also present late in its course with marked hyperglycemia and even ketosis. In these patients, insulin treatment protocols used in type 1 diabetes are appropriate until the type 2 pattern of glucose homeostasis is recognized. In most patients, convenience insulins such as human or synthetic 70/30 or 75/25 combinations can be used for several days until the effects of behavioral measures and oral agents "kick in." Dosage is usually from 0.2 to 0.5

units (U)/kg body weight/day (in elderly patients, consider 0.1 U/kg/day). The initial dosage selected is a probe of insulin sensitivity and responsiveness, which will be informative in advising further adjustments in therapy. The dosage can be given before meals to offset postprandial hyperglycemia and at bedtime to control inappropriate overnight hepatic glucose production.

The oral drugs frequently used with insulin are the insulin-stimulating agents and metformin. With multiple therapies, the duration and peak actions of long-acting insulin preparations must be considered to avoid an overlapping effect and precipitous decline in glucose. This phenomenon may occur if multiple doses of insulin are necessary. Once FSG falls below 200 mg/dL, insulin therapy should be decremented to determine if oral drugs are effective and beta-cell functioning is recovering; continued indefinite insulin therapy may be indicated. In this case, basal bolus insulin regimens as described later may be required as ineffective oral drugs are discontinued.

KEY TREATMENT

Early initiation of insulin therapy in type 2 diabetes is indicated when behavioral therapy and combined oral agents are not achieving near-normalization of HbA_{1c} and FSG levels (ADA, 2009; Mayfield and White, 2004; UKPDS, 1998) (SOR: A).

Table 34-4 Common Insulin Preparations

| Category/Preparation | Onset; Duration | Common Schedule | Advantage; Disadvantage |
|--|----------------------------------|--|---|
| Short-Acting human insulin | | | |
| Human insulin (rDNA) (Humulin R, Novolin R) | 1-2 hr; 6-8 hr; dose dependent | At mealtime | Less expensive Late action can cause nocturnal hypoglycemia. |
| Rapid-Acting synthetic insulins | | | |
| Insulin lispro (Humalog) Insulin aspart (rDNA) (Novolog) Insulin glulisine (rDNA) (Apidra) | ½ hr; 2-4 hr; dose dependent | At mealtime, before or after meal, with 24-hr basal preparation coverage | Controls 2-hr postprandial glucose Cost |
| Intermediate-Acting human insulin | | | |
| Isophane human insulin (Humulin N, Novolin N) | 2-3 hr; 10-14 hr; dose dependent | Overnight to limit hepatic glucose production or 12-hr basal action | Less expensive Hypoglycemic risk, especially nocturnal |
| Combination insulins | | | |
| Isophane human insulin (70/30) Humulin [N/R], Novolin 70/30) | 1-2 hr; 10-14 hr | At breakfast and dinner | Convenience Nighttime hypoglycemia |
| 70/30 Insulin aspart protamine, insulin aspart (NovoLog Mix 70/30) | ½ hr; 8-10 hr | At breakfast and dinner | Convenience Nighttime hypoglycemia |
| 75/25 Insulin lispro protamine, insulin lispro (Humalog Mix 75/25) | ½ hr; 8-10 hr | At breakfast and dinner | Convenience Nighttime hypoglycemia |
| Long-Acting synthetic insulins | | | |
| Insulin glargine (Lantus) | 2-3 hr; 24 hr | Basal coverage overnight or 24 hr | Less nocturnal hypoglycemic risk, convenience; cost |
| Insulin detemir (Levemir) | 2-3 hr; 24 hr | | |

Subacute Presentation of Type 1 Diabetes

The management of type 1 diabetes will depend on the patient's age and the acuity of the diabetes at presentation. Since there is usually no family history of diabetes, or diabetic experience at home, and given the fragility of the new-onset diabetic state, many children or adolescents presenting with type 1 diabetes require hospitalization to initiate and teach glucose monitoring techniques and to begin insulin treatment. The indication for hospitalizing a newly diagnosed child who is not drifting into ketosis depends on the availability of outpatient educational resources and the clinical judgment that the patient can be closely monitored and the family appropriately advised while developing the capabilities of diabetic self-management.

Basal Bolus Insulin

Synthetic insulin preparations designed to achieve either a prolonged steady effect or an acute action, mimicking physiologic insulin secretion, have allowed patients to develop personal and flexible injection schedules. This is known as the basal bolus regimen and is indicated in the treatment of type 1 diabetes. It provides rapidly acting or bolus insulin to cover carbohydrate ingestion in meals and snacks, and basal insulins are usually given at bedtime to achieve a steady state at breakfast, with an ideal FSG target of 120 mg/dL or less. To a large extent, control of the important fasting blood (serum) glucose will depend on attaining an ideal bedtime value of 120 to 140 mg/dL, which is based on rapidly active insulin given at dinner. The authors' experience indicates that basal insulin is most predictable in patients who demonstrate overnight glucose production and have controlled glucose values at bedtime. However, an occasional patient will experience hypoglycemia at 4 AM, and therefore nighttime monitoring is necessary when increasing dosage. Hypoglycemia can also be seen before lunch with overnight basal insulinization.

The starting dosage of insulin as previously discussed is often a conservative approximation. In general, a type 1 diabetic patient requires approximately 0.5 U/kg, half of which is given as basal insulin and the other half in divided boluses before a meal. Experience and clinical judgment may suggest a lower starting dosage if the diabetes is mild, especially with children and elderly patients, who may receive a starting dose of 0.1 or 0.2 U/kg/day. However, hyperglycemia may have resulted in secondary insulin resistance caused by cellular dysfunction, and higher dosages may quickly become necessary. If the patient is not at risk of ketoacidosis, cautiously increasing the dosage from 0.5 U/kg/day is prudent (usually by 10% per day).

The effectiveness of a specific dose of most insulin preparations depends on local factors at the injection site related to capillary perfusion. Insulin uptake is enhanced when hydration is adequate and a patient is vasodilated after exercise or a warm shower (or has a fever). The effectiveness of short-acting preparation is also related to the carbohydrate load about to be consumed. Preprandial hyperglycemia may adversely affect the action of insulin and should be considered as well in deciding proper insulin dosage.

Patients using basal bolus regimens may be taught how to adjust dosage based on the preprandial glucose value, carbohydrate content of anticipated meal, and physical activ-

ity. If glucose monitoring indicates prebreakfast dosage is achieving postprandial glucose of 160 mg/dL or less, and subsequent premeal values are 120 mg/dL or less, the short-acting insulin dosage and the long-acting steady-state dosages are in perfect harmony with the patient's diet and lifestyle.

A long-acting insulin analog (e.g., glargine, detemir) can be used to provide the basal insulin, but in a dynamic situation, intermediate-duration insulin preparations such as N (formerly known as NPH) provides more short-term flexibility and "kick" in the first 12 to 24 hours (see Table 34-4). The short-acting insulin preparations available include R (formerly known as Regular), lispro, aspart, and glulisine. The latter three are synthetic insulins and are ideal for limiting postprandial glucose elevations. R insulin does not have a sharply defined absorption and may remain active for 4 to 6 hours. A patient with slow GI absorption may find the slower onset of action of insulin R more efficacious. However, R can have a delayed effect, putting a tightly controlled patient at hypoglycemic risk, especially if N insulins are also used, with their potential for peak action.

As with 70/30 human N/R insulin, lispro and aspart have been formulated as mixtures of 75/25 and 70/30, respectively, with acute and intermediate duration of action. These might be used to introduce insulin in a subacute presentation of type 1 diabetes to avoid deterioration to ketoacidosis, but these are not as safe and lack the fine-tuning potential of basal bolus regimens. Insulin combinations may promote hypoglycemia if insulin needs to be administered at intervals of less than 12 hours. The treatment of type 1 patients during illness or daily living requires insulins that minimize the risk of hypoglycemia and are therefore safe enough for multiple daily injections.

When glucose values of less than 200 mg/dL are achieved at bedtime, the patient is ready to begin long-acting basal insulin analogs to preclude early-morning hypoglycemia, more often seen with intermediate insulin. Basal insulin analogs are given either at a dosage of 80% of the total daily N requirement or at the calculated basal dosage of 0.25 U/kg/day. Clinical judgment and instinct may modify this recommendation because this dosage should be further titrated based on the agreed fasting glucose target level. Usually, daily bedtime insulin increments of 10% or 2 to 4 U are safe.

Estimating the correct insulin schedule provides goals for the patient. Unless the family physician is proficient and available, nutritionists who are certified diabetic educators should instruct patients on carbohydrate content of meals and insulin dosing. Motivated patients given proper diabetic education will eventually determine their ideal, safe insulin/carbohydrate ratios and corrections for other factors such as activity. Only patients capable of this self-management can successfully use the insulin pump (discussed later).

Supportive Care for Children and Adolescents Requiring Insulin

As subacute diabetes is stabilized, the patient and family require extensive formal diabetic education, support, and empathy to ease the anxieties associated with a new diagnosis of a long-term disorder. A maladjustment in the needed insulin therapy could adversely affect the patient's success in living with diabetes. Instruction in dietary principles includes carbohydrate counting and insulin coverage, correction and adjustment of the insulin dosages based on glucose variability and physical activities, and the standards of care to limit

acute and long-term risks of diabetes, as detailed next. Following clinical stabilization, the family physician can further consider the etiology and alternative treatments according to ongoing diabetic manifestations.

Insulin Rebound

A diabetic complication that family physicians routinely manage is caused by nighttime or very-early-morning hypoglycemia, which leads to fasting hyperglycemia and sometimes ketosis, especially in children (Somogyi effect). If the patient and physician are not careful, they can get caught in a spiral of ever-increasing insulin doses in response to rebounding glucose values. When confronting persisting morning hyperglycemia, the first step is for the patient to monitor 3 AM glucose levels. If low, reduced dosage or timing change in evening insulin administration is necessary.

The Difficult Patient

Some patients cannot self-manage insulin therapy because of personality factors, family issues, or other difficulties of daily living, which can promote and exacerbate both type 1 and type 2 diabetes mellitus. Counseling is indicated for these patients, and insulin regimens may need to be simplified to ensure adherence. At the same time, these more fixed regimens indicate an increased need for a constant, regular diet and predictable behavior and activities. Difficulty achieving this means such patients often have marked glucose fluctuation and elevated HbA_{1c} values. Many patients will eventually benefit from their repeated attempts and the physician's efforts, as their therapeutic behavior synergizes with newer therapies.

Insulin Pump Therapy

Motivated type 1 diabetic patients who are frequently monitoring and self-managing insulin dosages but have not attained their glycemic targets should be considered for an insulin pump protocol. Ideally in these patients, the target should be HbA_{1c} less than 7%, with fluctuations in monitored FSG limited to ± 50 mg/dL. A key requisite for pump therapy is the patient's willingness to monitor frequently (up to 6-8 times daily) to ensure a safe transition from the flexible insulin regimen and learn to adjust basal and bolus infusion rates.

Use of the insulin pump in type 2 diabetic patients who fail to achieve therapeutic targets is less clear-cut. Often, insulin resistance accounts for failed outcomes rather than beta-cell insufficiency in these patients. If planning to use the pump, patients need to maintain high daily basal rates of 3 to 5 units per hour, which would mean frequent reloading of the insulin reservoir. On a physiologic basis, pump therapy may or may not overcome insulin resistance. Also, subjective factors such as "winning" expectations and renewed motivation are associated with pump use. The resulting behavior changes along with pumping effects can alter the frustrating course of DM.

Using the insulin pump requires more detailed diabetic education, but starting principles are simple. A basal rate is programmed based on 50% of the day's daily insulin requirement. The other 50% is used as reactive therapy to cover meals or make corrections. This can be given as an acute bolus infusion or over 2 to 3 hours. Once patients become

proficient in safely covering their ingested carbohydrates and determining their optimal basal rates, they require less professional guidance, and if stable with well-controlled HbA_{1c} levels, they can revisit every 4 to 6 months for periodic organ monitoring and patient reeducation.

The insulin pump is not free of risk. Some patients never master self-monitoring and continue to experience marked swings in blood glucose. Although once thought to result from physiological factors (e.g., unpredictability of diabetic gastroparesis), essentially all patients can develop strategies to overcome such physiologic problems. Most patients have functional problems or some family, school, work, or other environmental issue causing their difficulty adjusting to DM. In these patients and tightly controlled patients, hypoglycemia will remain an ever-present risk until advances in real-time glucose monitoring provide early warning. At a minimum, the family physician should be alerted that issues outside diabetes management need to be addressed.

The other risk is pump failure or *catheter dissociation*, which halts insulin delivery. If the patient was tightly controlled and the insulin effect was countered by high levels of counter-regulatory hormone, a sudden drop in insulin could provoke a rebound in lipolysis leading rapidly to ketogenesis. If the patient is unaware of the pump failure (e.g., because of infrequent monitoring schedule), a rapid deterioration to diabetic ketoacidosis may occur in less than 24 hours. Another complication is localized infection at the injection site of the 3-day indwelling needle. These complications require local therapy but may become severe enough to require incision, drainage, and antibiotics. Family physicians should be able to treat such problems, but consultation is always an option.

Surgery as Therapy

The increasing prevalence of type 2 diabetes coincides with the epidemic of obesity in western and developing societies. As noted earlier, obesity has been an intractable medical problem (see also Chapter 36). One response has been a concomitant increase in gastric bypass surgery. In morbidly obese patients (BMI ≥ 40), diabetes may go into complete remission after successful surgery. Diversion of nutrients from absorptive surfaces may promote the secretion of antidiabetic factors as efficacious as caloric deprivation in counteracting type 2 diabetes. Less invasive techniques are making surgery an option in the treatment of type 2 diabetes. However, complication rates and calcium metabolism problems require that patients make individualized decisions with their physician about surgical risks and benefits.

Diabetic Ketoacidosis

Key Points

- Presentation in diabetic ketoacidosis always requires hospitalization for fluid resuscitation and insulinization.
- Fluid resuscitation is a critical part of treating DKA. Intravenous solutions replace extravascular and intravascular fluids and electrolyte losses.
- Protracted symptoms suggest hypokalemia and total-body potassium depletion.

- If diagnosis of DKA is made immediately by history, physical examination, or fingertip glucose determination, and confirmed with tests demonstrating metabolic acidosis, specific treatment should not be delayed by pending laboratory results.
- Sodium bicarbonate is safely delivered isotonicity as 100 mEq or 100 mL added to 1 L of 0.45% normal saline.
- In a previously known diabetic patient, an episode of ketoacidosis results from the patient's inability to recognize deterioration in glucose control and react promptly with insulin.
- When transitioning to subcutaneous insulin from continuous infusion, basal SC insulin dose should precede cessation of insulin infusion by 4 to 6 hours to prevent recurrent ketosis.

In only a few emergencies in medicine has an understanding of the pathophysiology reduced mortality from 100% to less than 1% in less than 50 years. One example is the discovery and rapid clinical deployment of insulin in 1921 as the major intervention shutting down the diabetic ketogenic state and preventing profound acidosis with cerebral dehydration and edema. With the introduction of low-dose insulin infusion protocols in the early 1970s, the residual mortality of 6% to 8% associated with potassium and water shifts common with overaggressive insulin treatment was reduced to 1%. Cerebral edema and hypokalemic deaths from ketoacidosis in adults are now rare.

Pathogenesis and Presentation

Diabetic ketoacidosis (DKA) results when an absolute or relative lack of insulin allows hyperglycemia to become dehydrating and lipolysis to become ketosis. This progression occurs over several days in patients who are usually unaware of their DM diagnosis. As dehydration becomes more severe, the brain begins to experience an increase in osmolality. Altered mental status begins with lethargy and coincident metabolic acidosis. The patient may become dependent on others to secure medical care; if care is further delayed, lethargy becomes stupor and eventually coma. The pH falls to 7.00 or lower. The crisis has been defined.

Occasionally, acidosis rather than dehydration is the chief presenting system. Such patients are usually known diabetics who are alert, but with dyspnea stimulated by their acidosis. This could occur when a tightly controlled patient fails to take several scheduled insulin doses or after insulin pump failure or the stimulatory phase of overconsumption of alcohol. These circumstances result in a marked outpouring of counterregulatory hormones with their lipolytic and gluconeogenic actions.

Fasting serum (blood) glucose in DKA is usually greater than 450 mg/dL, but this is a function of dehydration, which will further elevate FSG. Awareness of the onset of acidosis might prompt the patient with lower glucose values to seek medical attention. If the development of acidosis is slow, the patient may not be seen until glucose approaches 1000 mg/dL. The severity of the symptomatology is also related to the patient's prior experience with DKA. Repeat offenders are patients who have problems with self-management, typically because of functional issues such as depression, alcohol, or other drug problems, rather than a physiologic disorder. These patients may have pH of less than 7.00 relatively asymptotically. A patient who is aware of the diagnosis should be prepared to intervene quickly to block the descent to DKA and know when to seek professional help.

After the introduction of home glucose monitoring in the 1980s and the emphasis on self-management in the 1990s, DKA has become very uncommon among responsible patients. The occurrence of DKA in a patient known to be responsible indicates some failure in insulin administration or an occult or apparent stress, such as urinary tract infection, acute gastroenteritis, pneumonia, other viremia, or worse, a bacteremia.

The classic presentation of DKA is a child or adolescent who has become increasingly weaker over 3 to 5 days with dyspnea and lethargy. Vomiting and abdominal pain can result from gastric distention caused by marked hyperglycemia. Profound acidosis can cause Kussmaul's respirations, with retractions and lifting of the clavicle, to expand the chest fully for maximal hyperventilation and elimination of carbon dioxide (CO₂). Rarely, the odor of acetone may be perceived. The pulse rate may be rapid, with low blood pressure indicative of hypovolemia. Elevation of the temperature is not unusual, caused by a precipitating infection or the mechanical work of heavy breathing, because dehydration prevents normal sweating and cooling.

Laboratory Findings

The family physician should expect the hematocrit and hemoglobin to be elevated in these patients as a result of hemoconcentration. A low value with dehydration indicates a source of blood loss, such as a stress ulcer in the stomach. A white blood cell (WBC) count as high as 20,000 cells/mm³ without other evidence of infection is not unusual but should trigger a thorough evaluation, especially of the chest, where the signs of pneumonia may be confounded by the dehydration. A reduction in oxygen partial pressure (P_{O₂}) with marked hyperventilation is an ominous sign of lung compromise. Antibiotic coverage after appropriate cultures is indicated until the clinical situation is better defined.

The diagnostic hyperglycemia associated with reduced bicarbonate (HCO₃⁻, usually designated "CO₂" on a basic metabolic profile [BMP]) is accompanied by hyperkalemia in approximately 30% of patients, normokalemia in 50%, and hypokalemia in 15% to 20%. To some extent, serum potassium depends on the severity of the acidosis and duration of the polyuria or vomiting. Hypokalemia is the most dangerous clinical scenario because insulin treatment can cause a precipitous decline in potassium, which may weaken the hyperventilatory effort, causing more profound acidosis and cardiopulmonary arrest. The finding of hypokalemia (and probably even normokalemia) on BMP or electrocardiogram (ECG) with good urine output indicates immediate potassium replacement. In general, hypokalemia on the initial BMP indicates a potassium deficit greater than 400 mEq. Hyperkalemia at the onset of DKA indicates a loss of about 200 mEq of potassium before presentation.

Serum sodium and chloride may also be affected by the extent of water depletion or urine losses caused by the osmotic diuresis or sodium bound to the ketonic anions. Thus, serum sodium of 145 mEq/L would indicate a predominant water deficiency, whereas 129 mEq/L suggests more significant sodium losses. In either case, water is always deficient despite dilutional changes in serum sodium caused by hyperglycemia, and patients require water and salt repletion therapies. Importantly, the anion gap indicates the severity of the

acidosis. Values in the high 30s suggest tissue hypoxia and possible lactate production in addition to the ketonic anions. This could be a dangerous sign if no improvement is noted after fluid resuscitation and insulinization. Lactic acidosis accompanying DKA is rare unless there is an underlying serious diagnosis such as sepsis or a myocardial infarction. However, a patient who is near death before presenting may have perfusion failure initiating lactate production.

Other abnormalities in DKA include prerenal azotemia, although the serum creatinine can be elevated artifactually by ketones in the blood. If so, creatinine promptly normalizes as ketones are cleared with treatment. Phosphate may shift the same as potassium in metabolic acidosis. Total-body phosphate is depleted, but repletion is usually deferred to the subacute phase of treatment, unless extreme weakness does not improve and extremely low serum phosphates are found. If drawn, amylase may be elevated without specific signs of pancreatitis.

Initial Treatment

Insulin and Potassium

Management of DKA involves administration of insulin, water, and electrolytes safely to prevent marked fluid shifts into the brain and a precipitous drop in potassium, which would impair compensatory hyperventilation. Insulinization promptly blocks further lipolysis and shuts down ketogenesis. R insulin is given as an intravenous (IV) bolus of 0.1 U/kg with the start of saline administration. Some suggest the initial bolus should be as much as 20 U. The bolus infusion is followed by a continuous infusion of 0.1 U/kg/hr, with hourly adjustments based on decline in serum glucose and reversal of acidosis. Low-dose insulin infusions are safe if the potassium value is monitored, and improving metabolic parameters should be apparent in 1 or 2 hours. Some patients may be remarkably resistant, and a significant bolus adjustment of up to 20 units may be necessary in 1 hour, with modification of the infusion concentration. The objective is not to decrease glucose precipitously but to turn off ketosis. Rapid glucose reductions with more aggressive insulinization protocols have resulted in fluid shifts, especially in children, which may account for the most serious complication, cerebral edema.

The serum potassium value on presentation can be estimated by reviewing the ECG. Peaking of the T wave with P-wave flattening or worse, QRS widening, means that the full protocol should be instituted at once with continued ECG monitoring to prevent a hyperkalemic cardiac crisis. If there is no evidence of hyperkalemia, and certainly if there is flattening of the T wave with a U wave, indicating the opposite risk of hypokalemia, then potassium chloride or phosphate should be given as long as urine flow is apparent. This situation requires caution with fluid and insulin administration to avert a drop in potassium caused by a rapid intracellular glucose shift. Cardiac monitoring should be continued and renal function ascertained immediately by BMP or urine flow to assess the amount and speed of potassium replacement.

Water and Salt

Intravenous fluids are initiated to maintain and restore capillary perfusion. The first 1 to 2 L should be normal saline (NS), which is the best crystalloid volume expander. The rate

of infusion depends on the patient's age and size. An otherwise healthy adolescent or young adult can tolerate 1 L/hr for 2 hours, but this will require clinical evaluation and judgment based on severity of presentation and patient response. A prompt urinary response to the first liter of NS ensures the safety of replacing potassium from the onset. Simply administering water and electrolytes will not turn off DKA but will help reverse the hyperosmolar state.

Crisis and Sodium Bicarbonate

Insulinization with saline infusion for 2 hours is usually sufficient to halt ketosis and gluconeogenesis and begin reversing metabolic acidosis. Rarely, life-threatening acidosis exists with pH below 6.90. Blood pressure and cardiac output may be compromised. The anion gap may be approaching 40 mEq/dL, suggesting a coexisting component of lactic acidosis. These are the extreme conditions that justify consideration of sodium bicarbonate (NaHCO₃) infusion. The concern involves the serum potassium, which could shift intracellularly with a rapid rise in pH. If present, hyperkalemia would be an overall benefit, but if the ECG is indeterminate or hypokalemia already exists, a further decline in serum potassium would be disastrous. Thus, administration of sodium bicarbonate should be done slowly with caution. Bolus therapy with 100 mEq NaHCO₃ can also cause a transient hyperosmolality, with a potentially deleterious water shift in the brain. Sodium bicarbonate is more safely delivered isotonicity as 100 mEq or 100 mL added to 1 L of 0.45% NS. The addition of the sodium would make this almost an isotonic solution, and delivery of bicarbonate ions in the large volume would preclude any sudden pH shifts.

Further Treatment of the Acutely Ill Patient

After the first 2 L of NS, the patient is transitioned to 0.45% saline, delivered at 250 to 500 mL/hr with a continuous insulin infusion. FSG will usually begin to approach 200 mg/dL in about 4 hours, depending on the initial value. A safe rate of decline in glucose is approximately 150 ±50 mg/dL/hr. This may require hourly adjustments in the insulin infusion rates or repeated low-dose insulin boluses for refractoriness. Once the glucose level is approximately 200 mg/dL, the insulin infusion may need to be adjusted to 0.05 U/kg/hr and 5% dextrose with 0.45% saline administered. Insulin will promote glucose oxidation, generating CO₂, which becomes plasma bicarbonate and further normalizes the pH. In some cases, as the anion gap is close to normal, a hyperchloremic acidosis occurs with decreased CO₂. This should be of no concern because chloride given in saline replaced the ketonic anions before enough bicarbonate could be regenerated. Hyperchloremia will spontaneously improve as the patient advances to oral fluids.

Transitioning

When clinically appropriate, usually at 6 to 12 hours, the patient should be offered oral fluids to determine GI function. When the diet is advanced to solid food, the patient should be started on subcutaneous (SC) insulin, basal and reactive therapy, while still maintaining the insulin infusion. A common error at this phase is discontinuation of the insulin infusion before SC insulin achieves an adequate steady

state to prevent recurrent ketosis. This takes 4 to 6 hours if the correct basal insulin dosage is given. Rebound hyperglycemia and ketosis are more likely with uncontrolled underlying infection.

Once oral fluid intake is adequate, the patient should be appropriately educated about self-management of insulin before being discharged. Even if previously trained to do this, the patient should receive a refresher on this important skill. Appropriate professional guidance can prevent progression of ketosis if obtained before the symptomatology becomes too profound. If patients are educated to avail themselves of this help in a timely manner, they will never again have to endure this potentially life-threatening emergency.

Nonketotic Hyperosmolality Syndrome

See the discussion online at www.expertconsult.com.

Diabetes and Pregnancy

Key Points

- Outcome of diabetic pregnancy depends on the mother's glucose levels, duration of DM before pregnancy, diabetic complications (nephropathy, retinopathy, vascular disease), and age at conception.
- Because of the increasing prevalence of DM, all pregnant women, except those in low-risk groups, should be screened for diabetes.
- Screening for gestational diabetes is performed at 24 to 28 weeks' gestation with 50-g oral glucose load and blood glucose measured 1 hour later (abnormal: >130 mg/dL).
- Diagnosis of GDM is confirmed by an oral glucose tolerance test. Glucose values are determined fasting and at 1, 2, and 3 hours (normal: <95, <180, <155, and <140 mg/dL, respectively; two higher values make diagnosis).
- The patient with GDM is advised of lifetime risk of diabetes and preventive effects of diet and exercise.

Diabetic pregnancies include gestational diabetes mellitus, which is the development of hyperglycemia during pregnancy, and pregnancy in women with prior history of type 1 or type 2 diabetes.

Gestational Diabetes Mellitus

In about 50% of women, GDM is reversible after pregnancy and does not inevitably evolve to type 2 diabetes. Asymptomatic type 1 or 2 diabetes or LADA existing before pregnancy may become clinical and irreversible. Women with no prior evidence of diabetes may demonstrate their type 2 diabetic gene during pregnancy and either remain diabetic postpartum or experience a long, normal latent period before the gene is expressed again. The expected conversion rate of women with GDM to type 2 diabetes after pregnancy can be reduced with therapeutic lifestyle changes.

Screening

Screening for GDM also identifies the woman at risk of having a macrosomic baby, the result of excessive glucose crossing the placenta. Non-low-risk pregnant women are

routinely screened, usually before the mid-second trimester, with a 50-g glucose challenge test given under random conditions—not necessarily fasting. The “low-risk group” is defined as nonminority women younger than 25 years old with no suggestion of insulin resistance, that is, no prior history of glucose intolerance, obesity, hypertension, or family history of DM. A glucose value of 140 mg/dL after ingestion is positive and leads to a formal glucose tolerance test (GTT).

To prepare for GTT, the patient is asked to increase carbohydrate intake to about 300 g for 3 days. Although this is a diabetogenic stimulus, restricting carbohydrates can also downregulate the beta-cell response and result in a false-positive study. The fasting patient drinks 100 g of a glucose solution. Glucose values are determined fasting and at 1, 2, and 3 hours. Normal values are less than 95, 180, 155, and 140 mg/dL, respectively; two higher values make the diagnosis of GDM. However, GTT does not consider the woman's preconception weight. Small women, whose total daily carbohydrate intake may never exceed 250 g, may demonstrate positive results despite their fasting and postprandial glucose values during pregnancy (or later on their regular diet) remaining within normal range. The standard GTT using 75 g has now been standardized for pregnancy but is subject to the same criticism as the 100-g test.

Treatment

Many women who are diagnosed with GDM can be maintained within fasting and postprandial glycemic goals with dietary adjustments and exercise. When glycemic goals are not achieved with behavioral therapies, insulin has traditionally been given in increasing dosages. Although high concentrations of insulin overcome the characteristic insulin resistance of the second half of pregnancy, the result is often marked weight gain. This has been a dilemma. Also, human and lispro insulin are the only antidiabetic agents approved for treatment in pregnancy. Although there are no reports of risk to the fetus from any short- or long-acting synthetic insulin preparations, many experts have been reluctant to use long-acting synthetic basal insulin preparations, which mimic basal insulin secretion and limit weight gain, until more outcome data are available. Thus the role of oral agents in pregnancy has been reconsidered.

Comparable to insulin, *glyburide* is effective in treating GDM and increasingly used because of tight plasma protein binding with minimal transplacental transfer, although some glyburide crosses into the fetus. Theoretically, this might result in islet cell hyperplasia in the fetus, causing hypoglycemia in utero or in the neonatal period. *Metformin* is also known to cross the placenta, but metformin limits insulin secretion. Metformin and insulin treatment for GDM show comparable favorable outcomes. The long-term safety of glyburide and metformin has not been ascertained despite over 10 years of experience, and women should be counseled before receiving these oral agents.

Glitazones might be effective in overcoming the insulin resistance of pregnancy but are contraindicated. Their mechanism of action as transcription factors is a theoretic risk for teratogenesis.

Postpartum Gestational Diabetes

Some authorities recommend GTT at 3 months postpartum to detect evidence of persisting DM if fasting values have normalized. This nonpregnant GTT merely measures the 2-hour value after a 75-g glucose challenge. Values of 200 mg/dL or greater confirm type 2 diabetes; values of 160 to 200 mg/dL and higher indicate impaired tolerance consistent with insulin resistance.

Finding normal glucose values at 3 months does not preclude the onset of type 2 diabetes later, when further changes in body composition occur with aging. Thus a woman with a history of GDM should periodically self-monitor fasting and postprandial values to assess her inherent diabetic risk and demonstrate her motivation to suppress it indefinitely.

Type 1 Diabetic Pregnancy

Key Point

- Newborns of diabetic mothers always require intensive monitoring for hypoglycemia, even following ideal pregnancies.

In anticipation of pregnancy in a type 1 diabetic patient, insulin dosage schedules may need to be modified to flexible, intensive regimens. As mentioned, controversy surrounds continuing effective basal bolus regimens with synthetic insulins during pregnancy. If an insulin pump is being used, adjustments need to be made frequently to attain target HbA_{1c} values of less than 7%. The risk of diabetic embryopathy resulting in congenital anomalies has been directly related to the HbA_{1c} value in the first trimester. Unless the family physician has a particular interest and experience, maternal fetal medicine physicians and endocrinologist should provide counseling and insulinization schedules for type 1 diabetic women preparing for pregnancy.

Type 2 Diabetic Pregnancy

With type 2 diabetes being diagnosed at a younger age, more women will be diabetic and untreated at conception. However, they still require counseling on the risk of embryopathy, dietary considerations, and effects of their oral drugs in the first trimester and later. Some nutritionists argue that limiting calories rather than supplementing in patients with marked obesity will reduce the risk of exacerbating diabetes during pregnancy. Insulin treatment might still become necessary to maintain blood glucose within the acceptable postprandial range.

Hospital Care of Diabetic Patients

Achieving diabetic control under normal ambulatory conditions is difficult enough in most patients. When illness prevents a patient from utilizing diabetic survival skills, however, and the stress of illness overcomes the patient's available insulin, care of the patient becomes a professional challenge. In the past, lack of data often resulted in less-than-optimal diabetic care in favor of managing the primary illness. Recent observations, however, demonstrate the efficacy of glycemic control in critically ill surgical patients. As a result, intensive glucose management

protocols with continuous insulin infusion are now being widely applied. Good glucose control in known diabetic patients and those with marked hyperglycemia and critical illness shortens intensive care unit (ICU) and respirator time and reduces associated polymyopathy while generally improving all outcome parameters. Many post-cardiothoracic surgery units have adopted these protocols to improve myocardial "energetics," limit infection, and discharge the patient sooner.

Similar studies of glycemic control have not been definitive in critically ill patients with sepsis to GI bleeding, although these varying diagnoses may have created methodologic issues. Thus, professional societies are recommending that critically ill patients be maintained with glucose levels less than 140 mg/dL (ADA, 2009). These therapeutic goals seem reasonable, until therapeutic methodology improves to limit hypoglycemia, which adversely affects outcomes associated with intensive insulin treatment protocols.

Preoperative Clearance and Treatment

In all types of procedures, the appropriate preparations begin weeks before surgery, when the family physician clears the patient for surgery. The physician ensures not only that the diabetes is under good control, but also that the patient has no asymptomatic cardiac or renal disease. Immediately before surgery, oral drugs as well as short-acting and intermediate-acting insulin are discontinued in favor of basal insulin coverage along with glucose to provide energy (75-100 mL/hr of dextrose 5%) and potassium (usually 10-20 mEq/L), assuming normal renal function and preoperative testing. If the glucose swings out of control (>200 mg/dL) perioperatively, IV insulin infused at a few units per hour will be more effective than the SC sliding-scale schedule, which can lead to erratic results. Although the ideal, IV insulin requires frequent monitoring by anesthesia and nursing. Alternatively, if this degree of monitoring is not available, no insulin is given or a conservative SC bolus provided, and appropriate adjustments are made immediately postoperatively.

Postoperative Care

Intensive insulinization should be maintained in the postoperative ICU, especially in patients with increased risk of ketoacidosis. Problems can occur when ICU patients transfer to step-down units, where tight control to achieve 120 to 180 mg/dL values depends on SC insulin delivery, which is inherently more unstable. The principles of adequate basal coverage and reactive bolus insulin apply, although frequent adjustments remain necessary because of altered insulin pharmacokinetics associated with bed rest and decreased peripheral perfusion. Sick or postoperative patients also have dietary instability from tests, missed meals, and insulin therapy. Basal and bolus dosages must be flexible and reconsidered daily. Bolus dosages may need to be given immediately after a meal, when the nurse is certain the patient has eaten.

No definite rules can be made, but several generalizations may apply. Basal insulinization can be provided once in 24 hours or 2 or 3 doses of intermediate insulin. Glargine and detemir dosages provide good control 12 hours later, but intermediate insulin dosages could overlap, causing hypoglycemic risk. Shorter-acting synthetic insulins are more safely used in the evening.

Appropriate Antidiabetic Protocols

The family physician must determine if it is appropriate to continue the outpatient treatment schedule in the hospitalized diabetic patient, depending mainly on the reason for hospitalization. If the patient can eat, the regular outpatient treatment (oral agents and/or insulin) should be continued with appropriate adjustments. Supplementing this with basal/bolus insulin may be appropriate if significant hyperglycemia (>200 mg/dL) occurs associated with the stress of illness and hospitalization. The outpatient regimen should not be discontinued in favor of a fixed sliding-scale insulin schedule, which will take days to titrate to the patient's needs and may result in erratic hyper- and hypoglycemic intervals. If the patient cannot be fed and glucose values are drifting above the 150- to 180-mg/dL range because of stress-mediated gluconeogenesis, treatment to prevent further hyperglycemia is appropriate.

Basal insulin can be given to fasting patients at starting dosages of 0.25 U/kg/day and further adjusted as the glycemic pattern becomes apparent. Periodic corrections in bolus insulin dosage may be necessary until titrated to levels achieving glucose values in the mid-100-mg/dL range. Once a safe basal dosage is determined, it should not be withheld if the patient is to be kept fasting for a procedure. Basal insulin will somewhat block hyperglycemic surges after catecholamine release in response to procedure stress. Patients with any remaining risk of hypoglycemia are given dextrose 5% at 75 to 100 mL/hr with continued basal insulin, which also blocks lipolysis from fasting, promoting gluconeogenesis and peripheral insulin resistance. After illness, diabetic patients not previously treated with insulin may require weeks before they can be titrated to their prior oral agents. This partly depends on regaining their lean body mass and state of fitness, which improves sensitivity to their endogenous insulin reserve. In some patients, insulin dependency becomes necessary indefinitely.

KEY TREATMENT

Diabetic care is best individualized for children, pregnant women, elderly patients, and hospitalized and seriously ill patients (ADA, 2009).

Children with type 1 diabetes are prone to hypoglycemia, which can cause apprehensive stress and result in maladjustment to diabetic treatment. Clinicians need to consider options as diverse as intensive insulin pump therapy to deferring tight glycemic goals until the child attains the maturity to participate in care (SOR: C).

In women with preconception diabetes, to lessen the risk of diabetic embryopathy, glycemic goals are to tighten HbA_{1c} within 1% of normal. Planning pregnancy appropriately motivates patients, and the goal can be attained with frequent glucose monitoring (Goldman et al., 1986; Kitzmiller et al., 1991) (SOR: B).

In patients older than 65, glycemic control has not been shown to reduce the risk of micro- and macroangiopathy. Clinical judgment suggests that geriatric patients with short-term life expectancy (<10 years) should be treated to a relaxed HbA_{1c} range of about 7.5% to 8.5%, which provides some reserve in preventing acute hyperglycemia and delaying dehydration associated with acute illness, while limiting the risk of hypoglycemia (Brown et al., 2003) (SOR: B).

In critically ill surgical patients, glucose level generally should be kept below 140 mg/dL to ensure better outcomes (Furnary et al., 2003; van den Berghe, 2001) (SOR: A).

Diabetic Complications

Key Points

- Normalization of glucose control as far as can be accomplished safely has become the objective of all diabetic therapy.
- Physical therapies should promote blood flow into the foot and nerve function and stimulate the patient's psyche.
- Examination of the retina is critical to determine changes requiring immediate attention.
- Angiotensin-converting enzyme (ACE) inhibitors and angiotensin receptor blockers (ARBs) are effective in reducing and reversing microalbuminuria and slowing the onset of diabetic nephropathy, independent of blood pressure (BP) control.
- Systolic BP should be less than 130 and diastolic less than 80 mm Hg, with HbA_{1c} as close to normal as possible considering the risk of hypoglycemia.
- Coronary heart disease is so problematic among diabetic patients that the National Cholesterol Education Panel (NCEP), in recommending guidelines for the treatment of hypercholesterolemia, considers DM equal to prior evidence of coronary artery disease.
- The more risk factors and signs of diabetes (dyslipidemia, microalbuminuria, erectile dysfunction), the more aggressively the patient should be monitored for occult heart disease.

The "Triopathy"

Before the landmark DCCT results in 1993, no definitive evidence showed that better control of type 1 diabetes slowed the progression of the common somatic complications of DM: neuropathy, retinopathy, and nephropathy. The DCCT showed that in 7 years, the average difference in HbA_{1c} between the conventionally treated diabetic patients and the intensive study cohort of 9.0% versus 7.0%, respectively, resulted in reductions of over 50% for each microangiopathic component of the "triopathy." In fact, the investigators discontinued their trial 2 years early to report these remarkable benefits. The UKPDS confirmed the preventive effects of intensive control on reducing diabetic microangiopathic complications in 1998 in patients with type 2 diabetes treated for as long as 15 years. Trials repeatedly reaffirmed that control of hyperglycemia can limit progression of the triopathy in both type 1 and type 2 diabetic patients.

How hyperglycemia causes microangiopathy is complex and not fully understood. Hyperglycemia is known to be associated with increased thickness of capillary basement membranes, and glycosylation is better defined because diabetic blood contains high levels of HbA_{1c}. Advanced glycosylated end products are present in diabetic tissues, and collagen in diabetic patients becomes glycosylated. This accounts for the thickened skin sometimes observed in fingers and hands of diabetic patients and the fibrosis of hand tendons causing Dupuytren's contractures. Albumin and circulating lipoproteins are also altered by hyperglycemia.

Paradoxically, the thickened capillary basement membranes of diabetic patients are known to be "leaky," which may explain capillary rupture or leakage in the retina initiating the beginning of diabetic retinopathy. The onset of

nephropathy may be a similar leakage of plasma proteins and albumin into the glomerulus. Capillary thickening leads to closure of the blood vessel supplying the nerves in diabetic neuropathy. The pathoetiology of each of these common complications is complex; in short, hyperglycemia results in damage to the infrastructure of organ systems by altering the protein matrix and its function and by other mechanisms adversely affecting cellular function.

Diabetic Neuropathy

All components of the peripheral nervous system are susceptible, but nerves in the feet are often the first structures to signal the impact of DM. Typically, onset of symptoms occurs in the evening or at night, suggesting nerve dysfunction because capillary peripheral perfusion diminishes with reclining or sleeping. Paresthesias are perceived as numbness, burning, or “pins and needles” in the toes or the bottom of the foot. Massaging the foot, pushing against a bed board, or walking may help as the microcirculation improves. Remarkably, some patients demonstrate these classic symptoms of diabetic neuropathy even before hyperglycemia occurs in the blood.

Polymotor-Sensory Neuropathy

In the early phase of diabetic neuropathy, physical examination may be uninformative. Assessing the adequacy of perfusion is critical and easily accomplished by inspecting the toenails for capillary perfusion and palpating the tibialis posterior and dorsalis pedis arteries. As noted, a dry, cool foot with thickened or thin subcutaneous tissue and nonelastic skin is demonstrating microangiopathy, despite a palpable dorsalis pedis, indicating a likely positive result in decreased deep tendon reflexes at the ankle, vibratory sensation, position sense, hot-cold discrimination, or fine touch with monofilament test. Inability to perceive the monofilament indicates advanced neuropathy that would endanger the foot if injured. Peripheral neuropathic symptoms may also result from hyperglycemia-mediated nerve injury with no clinical evidence of loss of capillary density. Over time, paresthesias and burning pains usually improve, unless functional factors (endogenous or related to narcotic therapy) prolong or confound the symptomatology.

Loss of the ankle reflex with sensory abnormalities indicates that the classic diabetic polyneuropathy is fully defined, with probable coexisting microangiopathy in the foot. Preventive foot care needs to be practiced to prevent skin breakdown. Patients should never walk barefooted because sharp objects penetrating the diabetic foot are often not perceived, leading to foot-threatening infections. The patient may require professional advice on footwear, orthotic devices, and toenail care. For symptomatic relief of nocturnal paresthesias, including “charley horses,” increasing doses of gabapentin or amitriptyline, with acetaminophen, or low-dose nonsteroidal anti-inflammatory drugs (NSAIDs) often provide some relief. The nutritional supplement α -lipoic acid also can reduce neuropathic pain. New drugs such as duloxetine and pregabalin are approved for specific treatment of *diabetic neuritis*. Patients with these dyskinesias may require benzodiazepines or oxycodone,

although the use of drugs associated with dependency can lead to more difficulties.

KEY TREATMENT

Because the high-risk diabetic foot demonstrates deformities, loss of monofilament sensation, vascular impairment, and prior ulcer or amputations, foot care may require podiatric, orthopedic, and vascular consultation, in addition to optimal glycemic control, to attenuate the progression of diabetic neuropathy (Umpierrez et al., 2002) (SOR: A).

Mononeuropathies

An individual nerve may be affected, such as the peroneal, resulting in footdrop, the seventh cranial nerve causing Bell's palsy, or the extraocular nerves causing strabismus and diplopia. Similar to other causes of Bell's palsy, the pathogenesis of these large-nerve injuries is thought to result from vascular injury; the paralysis is usually self-limiting and spontaneously improves over several months. In general, all these neuropathies have become less common as average HbA_{1c} levels have fallen from above the 9% range over the last 10 years.

Occasionally, a diabetic mononeuritis with a localized region of pain can be misdiagnosed clinically as a mechanically mediated neuritis, such as a herniated intravertebral disk. If the appropriate imaging studies fail to demonstrate a mechanical etiology, a presumptive diagnosis of diabetes neuritis should be made and treatment aimed at glycemic control with physical therapy. On the other hand, diabetic neuritis of this type with constant pain may be initiated by mechanical factors. For example, a diabetic patient may acutely injure spinal nerves with a lifting maneuver, but this “neuromuscular pain” may become a continuing neuropathic pain as diabetic nerve fibers fail to heal in the presence of marked hyperglycemia. With no other etiologies evident, these patients eventually improve with more effective diabetic management.

Autonomic Neuropathies

See the discussion online at www.expertconsult.com.

Diabetic Retinopathy

Limiting the disability of diabetes mellitus has been greatly advanced with laser control of retinal disease. The onset of retinopathy is the appearance of *microaneurysms* indicative of diabetic angiopathy. Microaneurysms represent the beginning of a progression from background to proliferative retinopathy with neovascularization. Advanced retinopathy is caused by continuing capillary failure with leakage, hemorrhage, and closure, producing zones of retinal ischemia. The resulting compensatory capillary proliferation in the ischemic parts of the retina is prone to leak and rupture, causing gross hemorrhage. A reabsorbing hemorrhage in the vitreous can exert a pull on the retina resulting in retinal detachment with onset of blindness. Capillary hemorrhage can be detected by inspection or imaging modalities. Treatment by

laser application decreases angiogenesis and further hemorrhagic risks. Vitreous hemorrhage can be removed, restoring vision and eliminating the risk of retinal detachment.

All type 1 diabetic patients should begin to have periodic dilated retinal examinations about 5 years after diagnosis. Because of the long asymptomatic latent period of type 2 diabetes, these formal eye evaluations should begin at the onset of type 2 diabetic management. In patients maintaining near normal HbA_{1c} of 7% or less, some authorities believe that formal dilated eye examinations can be deferred longer than 12 months.

Measures to prevent diabetic retinopathy include maintenance of glycemic control with avoidance of the stress of hypoglycemic reactions and control of blood pressure (BP). Aspirin therapy does not exacerbate or predispose to bleeding. However, intensive physical activity (exercise, sexual intercourse) can promote ocular bleeding.

KEY TREATMENT

Tight diabetic and optimal BP control reduces risks and progression of retinopathy (ADA, 2005, 2009; DCCT, 1993; UKPDS, 1998) (SOR: A).

Type 1 and 2 diabetic patients should be examined for retinopathy annually (Klein, 2003; Vijan et al., 2000) (SOR: B).

Preferably, a retinologist should follow patients with any degree of retinopathy, including marked nonproliferative change, proliferative change, or macular edema, because laser therapy reduces the risk of vision loss for these conditions (ETDRS, 1991) (SOR: A).

Diabetic Nephropathy, Diabetic Glomerulopathy, Renal Interstitial Syndromes

Before the DCCT, a patient with type 1 diabetes had a 30% to 40% likelihood of developing macroproteinuria (>300 mg/day), which would quickly progress to renal insufficiency and the need for renal dialysis. This process begins with proteinuria and increasing BP as early as 10-15 years after diagnosis of type 1 diabetes. In the early 1970s, when repeated studies showed that lowering of BP reduced cardiovascular events, diabetologists began to observe that good BP control, including use of diuretics, prolonged the interval from the onset of proteinuria to renal failure. The first studies of the angiotension-converting enzyme (ACE) inhibitor captopril suggested that treatment reduced macroproteinuria in patients with moderate renal insufficiency. Subsequent work in the 1990s indicated that reduced proteinuria impaired nephron loss and preserved renal function. The protein leak into the glomerular space may contribute to the mesangial proliferative reaction, starting a process that may end with nodular glomerulosclerosis.

Microalbuminuria

The introduction of the microalbuminuria assay lowered the threshold for the diagnosis of diabetic nephropathy to 20 to 200 µg/min, or 30 to 300 mg/day. Unlike smaller proteins that normally appear in the urine after exercise or fever, albumin does not appear in the urine without significant glomerular capillary leakage. Microalbuminuria can be

detected before clinical signs of diabetic retinopathy; as a quantitative measure, it is the target of treatment protocols.

Although ACE inhibitors may exert a specific protective effect by relaxing transglomerular hydraulic pressure, the UKPDS observed that the use of atenolol achieved similar results in slowing proteinuria and renal loss. In fact, in longitudinal BP trials comparing multiple agents in diabetic patients, even diuretic therapy was as efficacious as newer drugs, without affecting mortality.

Renal protection afforded by BP-lowering drugs might be the consequence of decreasing renal perfusion. Patients with nephropathy and unilateral renal artery stenosis do not develop histologic evidence of diabetic glomerulosclerosis in the stenotic kidney. In contrast, hyperperfusion is deleterious to the diabetic kidney. Type 1 diabetic patients with the highest glomerular filtration rate (GFR) are most likely to develop proteinuria, possibly because of higher blood glucose causing an osmotic diuresis. Moreover, poorly controlled diabetic patients also have high levels of amino acids, some of which mediate renovasodilation and enhance GFR. Before the DCCT results, short-term studies confirmed that correction of glucose control with intensive insulin treatment reversed microalbuminuria.

Renal Protection

Renal protection, achieved with BP and glucose control, is a primary objective in diabetic care. The urine should be checked for microalbuminuria yearly. Finding marginal elevations indicates that control should be tightened and an ACE inhibitor or angiotensin receptor blocker (ARB) prescribed or increased. However, if BP is normal, pharmacotherapy can be difficult because of potential orthostasis. Another measure that could affect microalbuminuria is weight, which relates to the total-body water and the nitrogenous load the kidney must excrete. An appropriate weight reduction will decrease renal perfusion and microalbuminuria. If microalbuminuria increases, more aggressive BP drugs should be used. The onset of edema indicates advanced albumin losses or underlying renal or cardiac dysfunction. Diuretic management can significantly reduce micro- or macroalbuminuria, even though its effect on renal perfusion may cause a rise in serum creatinine (usually reversible when diuretic discontinued). Thus, diuretic therapy may need to be cyclic, depending on edema accumulation and renal function.

Screening for microalbuminuria is controversial because it fails traditional tests of acceptability, including agreement on diagnostic criteria (e.g., measurement of albumin/creatinine ratio in spot collection; 24-hour creatinine collection, with simultaneous measurement of creatinine clearance; time collection of 4-8 hours) and confusing rationale for ongoing testing when the patient is already taking an ACE inhibitor.

The development of significant *macroalbuminuria* above 300 mg/day despite treatment indicates significant glomerular changes with risk of progression to nephritic syndrome or renal failure. Evidence of the nephrotic syndrome may become apparent with hyperlipidemia and more hypertension. The objective of therapy at this point is to attenuate the slope of renal decline and prevent congestive symptoms associated with coincident cardiac dysfunction. Treatment is based on BP and volume control. Dietary limitation of salt, potassium, protein, and fluid intake will be helpful. We believe exposure

to nephrotoxic agents can cause a quantum leap in the decline of the diabetic kidney at any stage of the pathophysiologic process. Unfortunately, nephrotoxicity is frequently the result of radiocontrast agents used repeatedly to detect and treat coronary artery disease or overexposure to antibiotics.

Diabetic Renal Interstitial Syndromes

KEY TREATMENT

To reduce the occurrence and slow the progression of renal disease that begins with microalbuminuria, attain tight glucose and blood pressure control (ADA, 2004, 2005; DCCT, 1995; Lewis et al., 1993; Reichard et al., 1993) (SOR: A).

ACE inhibitors and ARBs have the most favorable outcome data in patients with albuminuria (ADA, 2009; Lewis et al., 1993, 2001; Remuzzi et al., 2006) (SOR: A). In general, ACE inhibitors delay progression of nephropathy in type 1 with hypertension and any degree of albuminuria, and ARBs, in type 2 with renal insufficiency and macroalbuminuria. Both ACE inhibitors and ARBs have shown similar efficacy in type 2 patients with microalbuminuria (Andersen et al., 2000; Brenner et al., 2001; Lindholm et al., 2002; Molitch et al., 2003) (SOR: A).

Diabetic Macroangiopathy: Accelerated Atherosclerosis

Premature development of coronary heart disease (CHD) is the leading cause of morbidity among diabetic patients. Type 1 diabetic patients who are not troubled with diabetic nephropathy will likely experience CHD as early as their third or fourth decade, depending on the duration of their diabetes. The onset of renal disease in type 1 patients will further accelerate this timetable. Premenopausal status does not protect diabetic women from CHD.

The mechanisms causing accelerated atherosclerosis in DM are linked to the lipid and inflammatory pathogenic paradigms. Lipid abnormalities are not as common in type 1 patients, but long-term follow-up of the DCCT cohorts found thickening of large blood vessels related to their history of diabetic control. The disturbances in fatty acid metabolism in type 2 patients result in common dyslipidemias implicated in development of atherosclerotic plaque. Insulin resistance is associated with lipoprotein and coagulation abnormalities, hypertension, and evidence of endothelial dysfunction, all of which contribute to atherogenesis, even before the onset of hyperglycemia. These associations suggest that type 2 diabetes occurring as insulin levels decline is only one component of a larger pathophysiologic process.

KEY TREATMENT

ACE inhibitors reduce cardiovascular events in patients with known cardiovascular disease (ADA, 2009; HOPE, 2000) (SOR: A). Beta-adrenergic blockers reduce mortality in patients with prior myocardial infarction or other heart disease and those with cardiovascular risks undergoing major surgery (Foody et al., 2002) (SOR: A). No diabetic patients should smoke (Haire-Joshu et al., 1999) (SOR: A).

Hypertension

In recent years there has been a growing consensus that the control of high BP in diabetic patients may be more important than the control of hyperglycemia in terms of macroangiopathy. In UKPDS, captopril and atenolol were efficacious in preventing stroke and heart attacks despite less control of blood sugar. These agents were also equal to glycemic control in preventing proteinuria and nephropathy. Given these results, ACE inhibitors have often been recommended as first-line therapy for patients with high BP and diabetes. However, large hypertension trials such as ALLHAT continue to find that diuretics, β -blockers, as well as ACE inhibitors have similar effectiveness in this population and any of these can be used as first-line therapy. Outcomes are also equivalent with ARBs and calcium channel blockers, although these are usually not recommended for initial anti-hypertensive therapy. As noted above, the current recommendation is for lower blood pressure targets in diabetic patients, specifically less than 130/80.

KEY TREATMENT

Blood pressure of 130 to 139 mm Hg systolic or 80 to 89 mm Hg diastolic following therapeutic lifestyle efforts must be lowered with drug therapy (ADA, 2009; UKPDS, 1998) (SOR: A). Pharmacologic therapy for patients with diabetes and hypertension should include an ACE inhibitor or ARB or thiazide diuretic (GFR >30 mL/min). (Loop diuretics are much weaker antihypertensives and should be reserved for patients requiring a diuretic and with estimated GFR <30.) ACE inhibitors, ARBs, beta and calcium channel blockers, and thiazide diuretics have all been shown to reduce cardiovascular events (ALLHAT, 2002; JNC-7, 2003) (SOR: C).

Coronary Artery Disease

Diabetic atherosclerosis in the coronary arteries is most deadly, but the same disease process is ongoing in the vessels of the central nervous system, lower extremities, and abdominal organs. The question is when to search for these problems in an asymptomatic diabetic patient; the recurring nightmare of a diabetologist is having sudden death as a patient's presenting symptom of diabetic heart disease. The cardiac risk of patients with long-term diabetes or middle-age onset of type 2 should be periodically considered.

The cholesterol threshold for using statins in diabetic patients has been lowered to low-density lipoprotein (LDL) cholesterol greater than 100 mg/dL, with a therapeutic target of 70 mg/dL. A large statin trial has shown that patients who demonstrate elevated C-reactive protein (CRP) with normal LDL cholesterol values will benefit from statin therapy (Ridker et al., 2008). Many patients had metabolic syndrome with elevated triglycerides, which raises non-high-density lipoprotein (n-HDL) cholesterol, a risk lowered by statin therapy and more pathologic than LDL cholesterol. Aspirin may not be efficacious in all patients because of genetic factors. However, considering the relative safety of low-dose aspirin, many clinicians think the potential benefits outweigh a possible lack of efficacy. As noted, UKPDS showed that beta blockers and ACE inhibitors were equally effective in protecting the heart, brain, and kidney. Beta blockers are known to protect the previously injured heart but have adverse effects on erectile

dysfunction. Cardiac stress studies are indicated for multiple risk factors, new symptoms, and changes of ischemia on periodic ECG or echocardiogram. Once triple-vessel disease is excluded, repeat coronary angiography in asymptomatic patients to consider prophylactic stent placements is controversial. Stenting appears to be effective in improving angina and cardiac function, but no data yet demonstrate it prevents myocardial infarctions, probably because MIs are more likely to result from rupture of nonobstructing plaques. In 2009 the BARI 2D trial showed that in patients with type 2 diabetes, and stable coronary artery disease, there was no difference in mortality or major cardiovascular events based on randomization to prompt revascularization or medical therapy.

KEY TREATMENT

Reducing lipids is critical in attenuating diabetic macroangiopathy (ADA, 2009; Heart Protection Study, 2003; Pyorala et al., 1997) (SOR: A).

Therapeutic lifestyle changes focusing on reducing saturated fat and cholesterol intake, losing weight, and increasing physical activity will improve lipid profiles (ADA 2004, 2005; NCEP [ATP-III], 2002) (SOR: A). Regardless of LDL level, statin therapy should be added to lifestyle therapy in diabetic patients with overt cerebrovascular disease (CVD), or without CVD who are over 40 and have one or more CVD risk factors (ADA, 2009; Grundy et al., 2004b) (SOR: A).

Patients without overt CVD and diabetes should be treated to an LDL cholesterol of value < 100mg/dL. ADA Diabetes Care Supplements, January 2009 (NCEP [ATP-III], 2002) (SOR: A).

For antiprocoagulant therapy, aspirin (81-162 mg/day) should be used in patients with known CVD (Colwill, 1997; Hayden et al., 2002) (SOR: A).

Cerebral and Peripheral Vascular Disease

The diagnostic and therapeutic considerations discussed earlier apply to the carotid and peripheral vessels with other generalizations and exceptions. Beta-blocker therapy causing bradycardia could provoke neurologic and peripheral symptoms distal to a stenotic lesion. BP control appears to be more important than glycemic control in preventing cerebrovascular accidents (CVAs, strokes). Patients with claudication-like stable angina might respond to exercise. Vascular surgery is indicated for patients with nonhealing ulcers and pain at rest. Insulinization promotes vasodilation and improves perfusion and WBC function in patients treated for a nonhealing wound or foot ulcer.

Extrarenal Macrovascular Disease

The kidney is also susceptible to the accelerated atherogenic process affecting the blood vessels. Acute onset of hypertension or loss of BP control in a known hypertensive patient should suggest a vascular etiology. Accumulation or rupture of an atherosclerotic plaque in a renal artery may cause renal ischemia and secondary hyperaldosteronism through the renin response. Rarely, diffuse atherogenesis in the diabetic aorta can result in cholesterol emboli traveling into the renal microvasculature. The urine sediment can become active, indicative of glomerulonephritis.

The diagnosis of extrarenal macrovascular disease is also evident clinically by the appearance of distal microinfarcts

in the toes. The renal arteries can be examined for stenosis using Doppler ultrasound. Magnetic resonance angiography (MRA) can provide high-resolution imaging of stenotic plaques and quality of the great vessels without the risks of contrast agents. Advances in endovascular surgery with stent placements have simplified renal artery repair and stabilized the aorta in the face of aneurysmal dilation and threatening rupture, which might be signaled by release of cholesterol-laden plaques. Early treatment with statins is thought to stabilize plaques and preclude devastating vascular complications.

Diabetic Dermopathy

See online discussion of dermopathy as an indicator of neuropathy and vascular impairment.

The Metabolic Syndrome

The Adult Treatment Panel (ATP), in recommending guidelines for the treatment of hypercholesterolemia, defined the components of metabolic syndrome as any three of the following (NCEP [ATP-III], 2002; Grundy et al., 2004a, 2004b):

1. Fasting serum glucose greater than 110 mg/dL, a prediabetic value but consistent with insulin resistance. The CDC (2005) recommends that prediabetes be defined by a serum glucose value of 100 mg/dL or greater and less than 126 mg/dL.
2. Systolic BP of 130 mm Hg or greater, or diastolic BP of 85 mm Hg or greater.
3. Fasting serum triglycerides greater than 150 mg/dL.
4. HDL cholesterol less than 40 mg/dL in men and less than 50 mg/dL in women.
5. Waist circumference of 102 cm (40 inches) or greater for men and 88 cm (35 inches) or greater for women.

Ruderman and colleagues (1981) defined the concept of metabolic obesity in type 2 diabetes by noting the association of diabetes with hypertriglyceridemia, low HDL, and hypertension, in patients who were not overtly obese. Prevalence of obesity associated with diabetes has greatly increased in the last 30 years, and obesity is now evident in at least 80% of patients with type 2 diabetes. Others noted the connection of high insulin levels with impaired glucose tolerance leading to type 2 diabetes, disordered fatty acid metabolism, hypertension, and increased abdominal fat deposition indicative of visceral obesity (Reaven, 2003). The linkage of these risk factors with insulin has become known as the *metabolic syndrome*, which is now considered the leading cause of atherosclerosis (Grundy et al., 2004a).

Besides lipoproteins, patients with metabolic syndrome may have high levels of plasminogen activator inhibitor 2, which results in impaired fibrinolysis. Other abnormalities promoting vascular injury in these patients include endothelial dysfunction and inflammatory proteins.

The Friedenwald equation is used to calculate the value of LDL cholesterol from the measured values of total and HDL cholesterol and triglycerides in the serum, as follows:

$$\text{LDL cholesterol} = (\text{Total cholesterol} - \text{HDL cholesterol}) - (\text{Triglycerides} / 5)$$

Because high triglycerides would lower the calculated LDL cholesterol value, the ATP recommends treatment for non-HDL cholesterol (total cholesterol – HDL cholesterol) to a target of 130 mg/dL or less. However, the diabetic, hypertensive, and coagulopathic disturbances of patients with metabolic syndrome also require intervention. Many drugs are needed to address these multiple risk factors, but restoring fitness through exercise redistributes abdominal fat stores, lowers insulin levels, and reverses to some extent several of the described abnormalities.

Office Management to Improve Diabetic Outcomes: Activating the Patient

Key Point

- A mainstay of modern diabetes management is the “activated” patient, who is educated and prepared and involved in care.

Over the last several years, there has been increasing evidence of the effectiveness of the “chronic care model” as developed by Wagner (1998). The essential elements of the model are divided into the *community* (resources and policies), *health system* (self-management support, delivery system design, decision support, clinical information systems), an *informed activated patient*, and a *prepared proactive practice team* (Fig. 34-2). Of note, community programs and organizations are often acknowledged but may not be used in a busy practice. Self-management support involves not only providing instructions but also facilitating the patient’s acceptance of control over DM. The delivery system design means clarifying roles and responsibilities, as well as ensuring that the right care is delivered, with up-to-date information about the patient and appropriate follow-up. Currently, decisions need

to be supported by evidence-based medicine and guidelines, and patients monitored for ongoing care and response. This approach should lead to a patient who is the true locus of control and a practice in which all the professionals and staff provide current and responsive care to their patients. The essential skills needed by the family physician are working in teams and facilitating teamwork in the office setting.

A 2004 Cochrane review found that a multifaceted approach can enhance management of patients with diabetes, such as regular prompted recall and review of patients and patient-oriented interventions, along with proactive, involved nursing. Other models, such as stages of readiness for change, have led to more effective counseling and intervention strategies. Studies have shown that without an organized approach, using the current system of care will not succeed in adequately controlling diabetes, and that simply introducing diabetic flow sheets or the concept of nonphysician personnel interacting with diabetic patients is not enough to change outcomes. Following guidelines, measuring performance, and working to improve the clinical practice are hallmarks of the modern family physician’s approach to diabetes management (see Web Resources; Physician Consortium).

Diet, exercise, medications, foot care, and self-testing are under the patient’s direct control (“locus of control”), as well as keeping appointments, seeing consultants (e.g., ophthalmologist), and participating in daily medical decision making. Self-help manuals and websites can assist the activated patient in self-care. In addition, psychosocial issues, ranging from developmental effects of adolescence to severe psychopathology or aberrant family interactions, can have serious consequences for diabetic control. For example, a well-controlled adolescent may not take her insulin or follow an appropriate diet. However, the effectiveness of treatments for adolescent diabetic patients still varies widely, even within a similar culture, possibly because of underlying

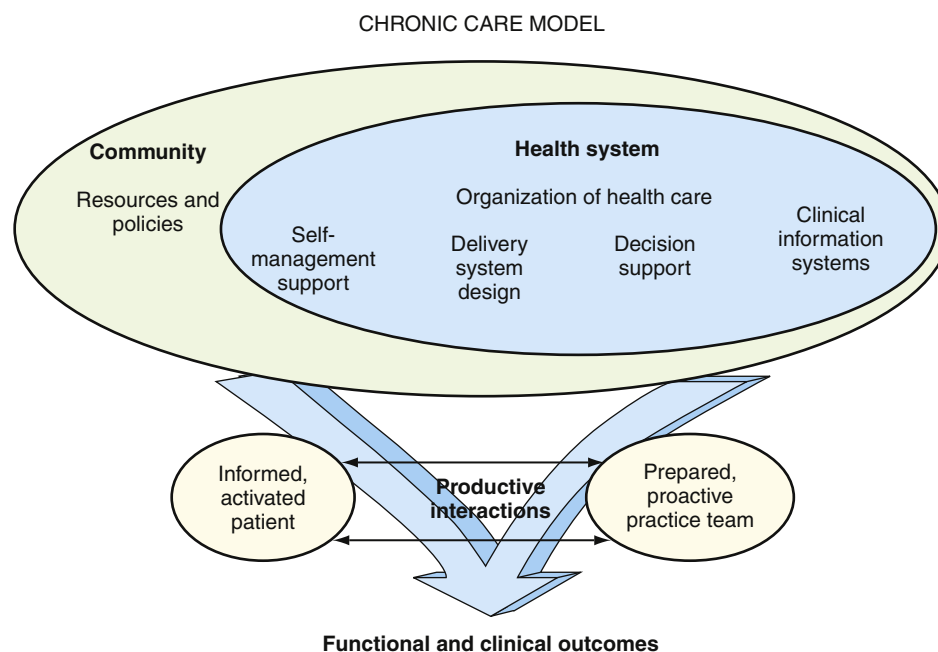

Figure 34-2 Model for improvement of chronic illness care. (From Wagner EH. *Chronic disease management: what will it take to improve care for chronic illness?* *Eff Clin Pract* 1998;1:2-4.)

psychopathology. At the extreme, eating disorders or severe depression can cause marked variations in the intake of essential nutrients, leading to either the dangers of hypoglycemia or the initiation of DKA. This is true among adults with diabetes as well as adolescents. Not surprisingly, therefore, diabetes has been associated with depression, at least in a Caucasian population, and as expected, those with such “dual diagnoses” tend to have more emergency room visits and inpatient hospitalizations.

Parents of a child with diabetes are less depressed or distressed than parents of a child diagnosed with cancer. Over time, however, parents of diabetic children can become more distressed, including their sense of control, self-esteem, and disease-related fears. If a family cannot be appropriately supportive, regardless of the patient’s psychological state, the locus of control may need to be switched from the patient-family to the patient-physician relationship.

A major social issue is inequitable care for diabetic patients depending on their socioeconomic background. Thus, it is widely accepted that minority populations bear a disproportionate burden of diabetes, as do those with less education and lower earnings. Stereotyping and bias have long been part of the U.S. health care system, and the Institute of Medicine report *Unequal Treatment: Confronting Racial and Ethnic Disparities in Health Care* demonstrates that much needs to be done before resolving these issues. It is not only that minority patients have a higher prevalence of diabetes, or that these patients have more severe disease, more

cardiovascular complications, and higher mortality, but also that these patients struggle with multiple barriers to adequate care. *Access* to any care is a perennial problem in many populations, so that for a chronic disease such as diabetes, which requires multiple visits and interventions, the automatic disparity in access leads to significant differences in outcome. In addition, cultural belief systems that lead to the use of alternative healers, distrust of traditional medicines, and misunderstanding of the disease process also serve as barriers to care. Given the complex interchange among culture, diet, body image, illness behavior, and the dynamics of race and gender, a family physician caring for a patient with diabetes must overcome not only the pathophysiology of the disorder but also these diverse barriers to care. The task is difficult, but diabetes control can be achieved when an “activated” patient and the physician confront these challenges together.

KEY TREATMENT

Both disease management and case management of diabetes improve the health and socioeconomic outcomes of patients. These approaches employ an organized, multimethod, responsive approach to delivering health care to diabetic patients (Systematic review; Task Force on Community Preventive Services, 2002) (SOR: A).

Pituitary Disorders

Key Points

- The hypothalamic-pituitary axis orchestrates the hormonal secretions of the other endocrine glands.
- The pituitary is composed of the adenohypophysis (anterior lobe) and neurohypophysis (posterior lobe).
- The hormonal secretions of the anterior pituitary are regulated by hypothalamic releasing hormones and inhibitory molecules.
- The posterior pituitary lobe is where nerve endings, originating in the paraventricular and supraoptic nuclei, project as the supraopticohypophyseal tract.

Hypothalamic-Pituitary Axis

The hypothalamus affects several nonendocrine functions, including appetite, sleep, body temperature, and activity of the autonomic nervous system. In addition, the hypothalamus modulates the pituitary hormone secretions. The

pituitary gland is often referred to as the “master gland” in recognition of its role in orchestrating the hormonal secretions of the other endocrine glands (Mooradian and Korenman, 2007; Mooradian and Morley, 1988). The pituitary gland is located in the anterior fossa, in the sella turcica, close to the optic chiasm. The pituitary is composed of the adenohypophysis, or anterior lobe, and the neurohypophysis, or posterior lobe, and is connected to the hypothalamus by the pituitary stalk.

The hormonal secretions of the anterior pituitary (the adenohypophysis) are regulated by a number of hypothalamic releasing hormones and inhibitory molecules. These factors reach the pituitary through the portal circulation and, on interaction with specific receptors, either stimulate or inhibit the secretion of the anterior pituitary hormones. The main releasing hormones include thyrotropin-releasing hormone (TRH), gonadotropin-releasing hormone (GnRH), corticotropin-releasing hormone (CRH), and growth hormone-releasing hormone (GHRH). The two major inhibitory factors are *dopamine*, which principally inhibits prolactin release, and *somatostatin*, a potent inhibitor of growth

hormone (GH), and to a lesser extent, thyrotropin (TSH). Other factors have an important regulatory effect on anterior pituitary function. The kisspeptin hormones are a family of peptides encoded by the *KISS-1* gene and are thought to play a critical role in reproduction. Kisspeptin receptors stimulate GnRH release and activation of the mammalian reproductive axis. Mutations in kisspeptin receptor GPR-54 cause idiopathic hypogonadotropic hypogonadism, characterized by delayed or absent puberty (Jayasena and Dhillon, 2009).

The portal circulation also allows pituitary hormones to flow backward to the hypothalamus and provide feedback on their own releasing hormones to create a short-loop regulatory system. The control of the pituitary hormonal secretion is the result of interplay between the effects of hypothalamic releasing hormones and the long-loop negative feedback on the pituitary and hypothalamus by hormones secreted by endocrine glands in the periphery. For example, a rise in plasma thyroid hormone level “feeds back” and suppresses pituitary TSH and hypothalamic TRH secretion.

The posterior lobe (pars nervosa) of the pituitary is essentially an extension of the hypothalamus where the nerve endings, originating in the paraventricular and supraoptic nuclei, project as the supraopticohypophyseal tract. The posterior pituitary hormones *vasopressin* and *oxytocin* are directly controlled by neural impulses and are released into the inferior hypophyseal veins and then into the systemic circulation (Mooradian and Morley, 1988).

Approach to Pituitary Disease

Key Points

- Pituitary disease may manifest with pituitary hormone excess or deficiency or symptoms of mass expansion, including headaches and visual disturbances.
- Pituitary adenoma is the most common cause of pituitary dysfunction in adults.
- Hypothalamic-pituitary axis function should be assessed in patients with a mass in the sella turcica.
- Evaluation of pituitary dysfunction involves serum measurements (prolactin, GH, IGF-1, FT₄, TSH), free cortisol or dexamethasone suppression test, and imaging.

The most common cause of pituitary disease is the development of benign tumors. Adenomas can cause symptoms because of excessive production of hormones such as prolactin, GH, or adrenocorticotrophic hormone (ACTH), or can cause pituitary hormone insufficiency secondary to tissue destruction. The pituitary hormones that can be lost early during the gradual destruction of pituitary tissue include GH and GnRH, followed by TSH and lastly ACTH. Occasionally, however, the autoimmune destruction of the pituitary can be cell specific and cause selective pituitary hormone deficiency.

Pituitary tumors can expand into the optic chiasm and hypothalamus and cause visual field defects and symptoms of hypothalamic disease, respectively. The classic symptom of optic chiasm compression is *bitemporal hemianopsia* (inability to see either side). Early manifestations of optic chiasm impingement can be subtle and include seeing images that float apart or seeing one half of the face higher than the other half (Picasso effect, or hemifield slide phenomenon). These

symptoms emerge when the patient is tired or anxious and are the result of failure to fuse the images from both eyes because of the lack of nasal fields. Expansion of tumors into the hypothalamus can cause disturbances in sleep, appetite, temperature regulation, sweating, water balance, and memory (Mooradian and Morley, 1988).

In children, pituitary adenomas are less common, and hypothalamic pituitary dysfunction is typically the result of hypothalamic tumors, notably craniopharyngiomas.

When microadenoma (<10 mm) is discovered incidentally, the initial evaluation should seek hormone hypersecretion by measuring levels of serum prolactin, insulin-like growth factor type 1 (IGF-1), TSH, and free thyroxine (FT₄) levels and 24-hour urine free cortisol or a 1-mg overnight dexamethasone suppression test (Mooradian and Korenman, 2007). More extensive workup is required for pituitary masses larger than 10 mm (macroadenoma), regardless of symptoms. Overall workup and management of pituitary disease should include identifying and treating hormonal deficiency and excess as well as diagnosing and managing mass effects of the tumors.

Hypopituitarism

Key Points

- Hypopituitarism refers to total or partial deficiency of one or more pituitary hormones.
- Hypopituitarism can result from a genetic disorder or releasing factor deficiency but more often results from pituitary tissue destruction secondary to mass expansion, infiltrative process, autoimmune or infectious disease, vascular accidents, radiation injury, or trauma.
- Pituitary apoplexy may result in life-threatening hypocortisolism.
- Lymphocytic hypophysitis is a rare autoimmune pituitary disease occurring in women in late pregnancy or postpartum that may mimic pituitary tumor but does not require resection.
- Kallmann syndrome is characterized by an isolated defect in GnRH secretion.
- Approximately 10% of patients with empty sella syndrome have clinically apparent hypopituitarism, and some may have pituitary adenomas.
- Systemic disease, including end-stage liver disease or chronic renal failure, is associated with variable degrees of hypopituitarism without significant histopathologic changes in the pituitary.

Hypopituitarism refers to total or partial deficiency of one or more pituitary hormones resulting in end-organ changes or reduced hormonal secretion of target endocrine glands (Toogood and Stewart, 2008). The deficiencies could be the result of primary disease of the pituitary or could be secondary to failure of hypothalamic hormone synthesis or transport. There are no good estimates of the incidence of hypopituitarism because the disease is often subclinical.

Causes

Hypopituitarism may result from a genetic disorder or deficiency in hypothalamic releasing factor but more often is the result of pituitary tissue destruction secondary to mass

expansion, infiltrative process, autoimmune or infectious disease, vascular accidents, radiation injury, or trauma. In some patients the etiology of hypopituitarism cannot be identified and is considered *idiopathic*. Most idiopathic cases are sporadic, although there are well-described familial causes of hypopituitarism.

The most common cause of hypopituitarism in the adult population is *intrasellar pituitary tumors*. Occasionally, hypopituitarism is resolved with surgical or medical treatment of the pituitary mass. Parasellar masses that cause hypopituitarism include craniopharyngiomas, meningiomas, optic nerve gliomas, teratomas, germinomas, chordomas, metastatic cancers, and lymphomas.

The second most common cause of hypopituitarism is *postpartum pituitary necrosis* (Sheehan's syndrome). The portal system of the anterior pituitary vascular supply, increased oxygen demand of an enlarged pituitary gland during pregnancy, excessive blood loss, and possibly increased intravascular coagulation combine to cause ischemic pituitary injury. Other ischemic causes of pituitary necrosis can occur in systemic vascular diseases such as diabetes mellitus, temporal arteritis, and sickle cell disease. These diseases can also result in hemorrhagic infarction (*apoplexy*) of the pituitary, with acute onset of severe headache, visual impairment, altered mental status, and hypopituitarism. The sudden decline in ACTH and thus hypocortisolism may be the most life-threatening consequence of hypopituitarism, requiring emergency treatment with corticosteroids. Although pituitary adenomas are the most common cause of pituitary apoplexy, it may often be related to complications of diabetes, radiotherapy, or open heart surgery (Toogood and Stewart, 2008).

Rarely, infectious diseases can lead to hypopituitarism. Examples include meningitis, intracranial abscess, septic shock, fungal infections of the central nervous system (CNS), tuberculosis (TB), malaria, and syphilis.

Infiltrative diseases of the pituitary, and more frequently of the hypothalamus, can cause hypopituitarism. Sarcoidosis can present with hypopituitarism along with polydipsia and polyuria. Histiocytosis X may present as a suprasellar tumor. Lipid storage diseases and hemochromatosis can cause hypopituitarism, often with hypogonadotropin deficiency.

Lymphocytic hypophysitis is a rare autoimmune disease of the pituitary occurring in women during late pregnancy or in the postpartum period. Lymphocytes and plasma cells infiltrate the pituitary gland, which results in the destruction of anterior pituitary cells. This disease may mimic pituitary tumor but does not require resection, making the correct diagnosis especially important. Lymphocytic hypophysitis cannot be distinguished from tumor except by biopsy. The diagnosis is suspected in women who develop hypopituitarism during or immediately after pregnancy, in the absence of a history of hemorrhage during delivery or previous history of infertility or menstrual disorders.

Mutations in the genes coding for specific anterior pituitary hormones have also been described, the most common being isolated GH deficiencies manifesting as short stature, beginning in infancy or childhood. *Kallmann syndrome* is characterized by an isolated defect in GnRH secretion. Young men develop a eunuchoid appearance and testosterone deficiency, and women have amenorrhea or oligomenorrhea. The syndrome may also be associated with hyposmia or anosmia (Oliveira et al., 2001). Mutations in the *PROP-1* gene

are the most common causes of congenital hypopituitarism and present as deficiencies of GH, prolactin, TSH, luteinizing hormone (LH), and follicle-stimulating hormone (FSH). Older adults with *PROP-1* gene mutations may present with ACTH deficiency (Wu et al., 1988). Iatrogenic causes of hypopituitarism include surgical ablation and radiotherapy. Hypothalamic and pituitary deficiency may occur after several years, with GH and gonadotropin deficiencies the most common. Prolactin level may be mildly elevated.

Approximately 10% of patients with *empty sella syndrome* have clinically apparent hypopituitarism, and some may have pituitary adenomas (Mooradian and Morley, 1988). The empty sella syndrome occurs when a defect in the sellar diaphragm allows the subarachnoid space to herniate into the pituitary fossa. It is a relatively common disorder found in 5% to 8% of autopsies.

Systemic disease, including end-stage liver disease and chronic renal failure, is associated with variable degrees of hypopituitarism without significant histopathologic changes in the pituitary (Mooradian, 2001; Nowak and Mooradian, 2007).

Clinical Manifestations

Key Points

- Progressive loss of hormones occurs in pituitary injury, starting with loss of GH and gonadotropin and followed by TSH and ACTH deficiency.
- ACTH deficiency results in cortisol deficiency, leading to hypotension, shock, and cardiovascular collapse.
- TSH deficiency results in signs and symptoms of hypothyroidism.
- Gonadotropin deficiency results in the signs and symptoms of hypogonadism.
- GH deficiency causes short stature in children and may be asymptomatic in adults.

The clinical manifestations of hypopituitarism are highly variable and depend on age and gender of the patient as well as on the etiology of the pituitary disease (Toogood and Stewart, 2008). Patients can be completely asymptomatic for many years or present with dramatic symptoms of nausea, vomiting, headache, and vascular collapse. Symptoms are more common in pituitary apoplexy, when the sudden withdrawal of ACTH and ensuing adrenal insufficiency cause hemodynamic instability. It is believed that at least 75% of the glandular tissue must be destroyed before an individual becomes clinically symptomatic. If the etiology is a space-occupying lesion, such as expanding adenoma or carotid aneurysm, the clinical manifestations will include headache and visual field defects, which are classically bitemporal hemianopsia. Other, subtle changes in vision involve color perception, patchy scotomas, and difficulty in passing a thread through the eye of a needle (Mooradian and Morley, 1988).

Failure to lactate may be the first clinical sign of Sheehan's syndrome (postpartum pituitary necrosis). Lethargy, anorexia, and weight loss; failure to resume normal menstrual periods; and loss of sexual hair may also be present later in the postpartum period. On the other hand, symptoms

and signs of pituitary infarction may be subtle and not recognized for years.

Patients with *panhypopituitarism* (Simmonds' syndrome) are usually pale and lethargic, have dry skin and low blood pressure, and rarely may look cachectic (Toogood and Stewart, 2008). These patients have lost all the anterior pituitary hormones, and the clinical manifestations are caused by a mixture of hypogonadism, hypothyroidism, adrenal insufficiency, and GH deficiency. The clinical manifestations depend on whether the deficiency is partial or complete. Individual signs and symptoms reflect the biologic actions of various hormones secreted by the pituitary.

Growth hormone deficiency manifests as growth retardation in children. The body proportion and primary teeth are normal, but secondary tooth eruption is delayed. In up to 10% of children with GH deficiency, symptomatic hypoglycemia may occur. In adults, GH deficiency may be asymptomatic. Subtle changes may occur in insulin sensitivity, manifested by reduced insulin requirements in diabetic patients, decreased muscle and bone mass and increased adiposity, delayed wound healing, and fasting hypoglycemia, and may contribute to anemia of hypopituitarism. Additional adverse effects associated with GH deficiency in adults include increased low-density lipoprotein (LDL) and decreased high-density lipoprotein (HDL) cholesterol, decreased cardiovascular function and increased risk of cardiovascular events, and a diminished sense of well-being. Life expectancy is reduced in these patients compared with age-matched controls (Svensson et al., 2004).

Gonadotropin deficiency will result in *hypogonadotropic hypogonadism* (HH) or secondary hypogonadism. In prepubertal children, HH manifests as failure to achieve pubertal changes along with lack of pubertal growth spurt. Girls will have primary amenorrhea and lack of breast development or widening of the pelvis. In boys, testicular size will remain small, scrotal skin will not thicken, and penile growth, muscle development, and hoarseness of voice will not appear. In adults, HH presents as infertility, loss of libido, decreased facial hair and muscular mass in men and amenorrhea, and decreased breast size and atrophic vaginal mucosa in women. If left untreated, men and women with HH will develop osteoporosis.

A deficiency in TSH will cause secondary hypothyroidism unless the patient has concomitant Graves' disease or an autonomously functioning thyroid nodule. The classic clinical manifestations of hypothyroidism include lethargy, easy fatigability, dry skin, cold intolerance, constipation, fine silky hair, slow mentation, and slow relaxation phase of deep tendon reflexes. Other features include anemia and hyponatremia secondary to increased antidiuretic hormone (ADH) secretion. In general, these symptoms are less severe in patients with TSH deficiency compared with patients with primary thyroid failure, and other findings, such as hypercholesterolemia, hypercarotenemia, myxedema and effusions in body cavities, may occur less frequently (Toogood and Stewart, 2008).

A deficiency in ACTH will result in deficiency of cortisol secretion and is referred to as *secondary adrenal insufficiency*. The clinical features resemble primary adrenal disease, such as Addison's disease. In both entities, anorexia, lethargy, nausea, vomiting, abdominal pain, postural hypotension, and vascular collapse may occur. Hyponatremia is more

common in ACTH deficiency, whereas hyperkalemia is seen only in primary adrenal insufficiency and loss of aldosterone secretion, primarily regulated by the renin-angiotensin system and serum potassium/sodium concentrations. Hyperpigmentation of the skin and vitiligo are features of primary adrenal insufficiency, whereas patients with ACTH deficiency have difficulty tanning on exposure to sunlight. Mild ACTH deficiency may be asymptomatic and may go undiagnosed for a long time.

Diagnosis

Key Points

- If one pituitary hormone insufficiency is documented, the other pituitary hormones should be tested.
- An 8 AM plasma cortisol level less than 5 µg/dL strongly suggests hypocortisolism; a level greater than 18 µg/dL excludes ACTH deficiency.
- Serum free T₄ must be used with serum TSH concentration in assessing thyroid function.
- Normal or subnormal LH level in menopausal or amenorrheic women, in the presence of a low estradiol level, indicates secondary hypogonadism (in men, low testosterone level).
- Diagnosis of GH deficiency requires provocative testing.

Since the presenting complaints can be subtle, clinicians should have a high index of suspicion to diagnose hypopituitarism (Toogood and Stewart, 2008). If the clinical manifestations fit hypogonadism, hypothyroidism, or adrenal insufficiency, those hormonal tests should be ordered to confirm the diagnosis. If one pituitary hormone insufficiency is documented, every attempt should be made to test the status of the other pituitary hormones as well. The underlying etiology of the disease should be determined by computed tomography (CT) or magnetic resonance imaging (MRI) of the hypothalamic-pituitary area. Occasionally, angiography is needed when carotid artery aneurysm is suspected, or to define the blood supply of the tumor. Formal ophthalmologic examination with visual field evaluation should be ordered if the patient is symptomatic or has a pituitary mass lesion.

Pituitary hormone secretion is episodic, and in general, dynamic testing is more valuable than single, baseline hormone measurements. For practical reasons, however, the screening can be done with pituitary hormone and target hormone measurements simultaneously. For evaluating suspected hypopituitarism, tests include thyroid function, LH, serum testosterone in men and estradiol in women, IGF-1 (because GH has a short half-life in blood), prolactin, and morning cortisol. Provocative testing for GH and ACTH reserve may be required as well. Patients with known pituitary disease and deficiency of ACTH, TSH, or gonadotropins have a 95% chance of a subnormal provocative stimulus for GH. Also, patients with known pituitary disease and a serum IGF-1 concentration lower than normal can be presumed to have GH deficiency (Gharib et al., 2003). Provocative tests for GH are either physiologic (sleep or exercise) or pharmacologic such as insulin-induced hypoglycemia, GHRH with arginine, and levodopa with arginine tests (Biller et al.,

2002). GH deficiency is diagnosed when GH does not rise above 5 ng/mL in response to two or more stimuli.

A plasma cortisol level less than 5 µg/dL at 8 AM on two occasions in the patient with a disorder known to cause hypopituitarism strongly suggests hypocortisolism, and in the presence of normal or low serum ACTH concentration, it establishes the diagnosis of secondary adrenal insufficiency. Conversely, a cortisol level of 18 µg/dL or greater virtually excludes the diagnosis of ACTH deficiency.

To evaluate ACTH reserve, insulin hypoglycemia test (0.1–0.15 U/kg IV) should be done. A normal cortisol response to adequate hypoglycemic stimulus (blood glucose <50 mg/dL) is either an incremental level of 6 to 10 µg/dL or an absolute level greater than 20 µg/dL. The test allows for concomitant evaluation of GH reserve; however, it is contraindicated in elderly patients and those with coronary artery disease or epilepsy (Nowak and Mooradian, 2007). An alternative is the metyrapone test, 750 mg orally every 4 hours for six doses, which assesses the sensitivity of the pituitary to the negative inhibition by cortisol. Metyrapone blocks 11β-hydroxylase, an enzyme that catalyzes the final step in cortisol biosynthesis. The decrease in cortisol secretion after metyrapone is given should result in a compensatory increase in the ACTH level. The level of the precursor steroid 11-deoxycortisol should also increase. A normal response is an increase in serum 11-deoxycortisol level greater than 10 µg/dL, when serum cortisol level is reduced to less than 8 µg/dL, indicating adequate suppression of glucocorticoid synthesis. In the more convenient overnight test, metyrapone, 30 mg/kg orally, is administered at midnight. An increase in the 8 AM serum 11-deoxycortisol level to more than 7 µg/dL is found in healthy persons. If symptomatic postural hypotension occurs after metyrapone administration, hydrocortisone should be administered exogenously.

Cosyntropin, 250 µg intramuscularly (IM) or intravenously (IV), should result in an increase in the serum cortisol level of 18 µg/dL or greater at 60 minutes in normal subjects. The test may not reliably determine the ACTH reserve, especially in those with recent ACTH deficiency, in whom the adrenal glands may not be sufficiently atrophied. Some controversy surrounds whether the 1-µg cosyntropin stimulation test (IV only) may be more sensitive for the diagnosis of subtle secondary adrenal insufficiency.

Thyrotropin (TSH) deficiency is diagnosed when low baseline free T₄ and low or normal TSH is documented on more than one measurement. Gonadotropin deficiency in men is tested with measurements of baseline LH, FSH, and total testosterone. Serum samples are drawn between 8 and 10 AM, and low concentrations should be confirmed with a second serum sample. The 8 to 10 AM serum testosterone concentration generally should be 300 to 1000 ng/dL. A low testosterone value (<200 ng/dL) with low or normal LH is indicative of hypogonadotropic hypogonadism. For serum total testosterone levels between 200 and 400 ng/dL, free testosterone level should also be ordered (Mooradian and Korenman, 2006). The presence of amenorrhea in premenopausal women, along with low estrogen level (<30 pg/mL), establishes the diagnosis of HH. In menopausal women the absence of elevated FSH and LH is sufficient for the diagnosis.

Elevated serum prolactin level in a hypogonadal patient suggests a pituitary adenoma. Prolactin deficiency often indicates severe intrinsic pituitary disease and is uncommon

without concomitant deficiencies of other anterior pituitary hormones.

Conditions known to mimic hypopituitarism should be excluded when evaluating patients, including anorexia nervosa, protein-calorie malnutrition, systemic illness, chronic renal failure, and liver cirrhosis.

Treatment

Key Points

- Hydrocortisone is given to ACTH-deficient adults at 20 to 30 mg/day and increased twofold to threefold during times of illness and other stresses.
- The goal of thyroid replacement is to achieve a normal serum free thyroxine concentration and clinical euthyroidism.
- Thyroid replacement will increase the clearance of cortisol, so ACTH status is assessed; if deficient or uncertain, glucocorticoid replacement is indicated before replacing thyroid hormone.
- Treatment of secondary hypogonadism depends on gender and whether fertility is desired.
- Serum IGF-1 concentration and growth rate in children are used for monitoring the effectiveness of GH replacement.

The treatment of hypopituitarism depends on the etiology and the particular hormonal deficiency. Surgical and medical interventions may be necessary for treatment of pituitary masses, infiltrative diseases, and carotid aneurysms.

Growth hormone deficiency is treated with recombinant human GH (somatotropin) preparations (Gharib et al., 2003). The recommended GH dose in children with GH deficiency is 0.04 mg/kg/day. In adults, recombinant human GH is administered subcutaneously (SC) at 0.001 to 0.008 mg/kg/day. The usual starting dose is 0.1 to 0.3 mg/day for a 70-kg man, with a typical maintenance dose of 0.3 to 0.6 mg/day. In general, women require higher doses than men because estrogen increases GH resistance. Serum IGF-1 concentration should be monitored to maintain it at the mid-normal range. Side effects that should be monitored include edema, carpal tunnel syndrome, arrhythmias, paresthesias, and glucose intolerance.

Levothyroxine (L-thyroxine) is the hormone of choice for the treatment of patients with TSH-deficient hypothyroidism (Oiknine and Mooradian, 2006). A typical replacement dose in adults is approximately 1.6 µg/kg/day. The daily requirements should be individually determined based on clinical and biochemical evaluations. The free T₄ level should be in the middle to upper third of the normal range. Since thyroid replacement will increase the clearance of cortisol and uncover a subclinical adrenal insufficiency, the ACTH status should be assessed, and if deficient or uncertain, glucocorticoid replacement is indicated before thyroid hormone is replaced.

Treatment of secondary hypogonadism depends on the patient's gender and whether or not fertility is desired. Estradiol and progesterone replacement is the treatment of choice for secondary hypogonadism in premenopausal women who have an intact uterus and do not desire fertility. These hormones can be given cyclically or daily in fixed-dose combinations. In women with hysterectomy, estrogen replacement is sufficient, to maintain vulvar and vaginal lubrication,

relieve symptoms of vasomotor instability, and reduce bone loss. Women wanting to restore fertility should be referred to specialized centers for pharmacologic induction of ovulation with exogenous pulsatile GnRH and exogenous FSH and LH treatment. GnRH can be used to restore fertility when hypothalamic disease and tertiary hypogonadism are present. Women over age 50 with secondary hypogonadism should be treated as menopausal, taking into consideration the risk/benefit ratio of estrogen replacement therapy in this age group.

Secondary hypogonadism in men is treated with testosterone replacement. Fertility can be restored in men with pituitary disease using gonadotropin replacement or human chorionic gonadotropin (hCG) therapy. GnRH can be used when hypothalamic disease is the cause of hypogonadism.

Many preparations are available for testosterone replacement. Traditional oral androgens, including 17 α -methyltestosterone, fluoxymesterone, and other 17 α -alkylated steroids, may cause hepatic toxicity and should be avoided. The current injectable testosterone esters, such as testosterone enanthate or testosterone cypionate, act similarly. The usual replacement dose is 200 mg IM every 2 weeks. In older men, it may be prudent to start at 50 to 75 mg weekly. Testosterone undecanoate is available as an oral preparation that does not have hepatotoxicity; because of its short half-life, however, it must be taken three times daily. Transdermal preparations can be given as patches or gels. Some androgen skin patches are associated with a high incidence of skin reactions. The commercially available transdermal gel preparations (Andro-gel 1% , Testim 1%) are applied over the trunk daily. Sublingual and buccal preparations of testosterone (e.g., Striant) are also available for replacement therapy (Mooradian and Korenman, 2006).

Side effects of testosterone replacement should be monitored carefully. Digital rectal examination (DRE), hematocrit (Hct), and prostate-specific antigen (PSA) should be measured at 3, 6, and 12 months follow-up, then annually or semiannually. Bone density measurements should be obtained at baseline and if low, at 2-year intervals to monitor improvement. In addition to monitoring clinical response, serum testosterone levels should be measured with the goal of achieving a midnormal range at 7 days after injection of testosterone enanthate or cypionate, at 3 to 10 hours after application of a testosterone patch, or at any time after application of a testosterone gel.

Absolute contraindications to testosterone therapy are prostate or breast cancer, Hct of 55% or more, or sensitivity to ingredients of the testosterone preparation (Mooradian and Korenman, 2006). Relative contraindications include obstructive sleep apnea, congestive heart failure, obstructive symptoms of prostatic hyperplasia, and Hct of 52% or greater. However, there are no data to suggest that testosterone replacement aggravates subclinical prostate cancer.

Patients with ACTH deficiency should be treated with glucocorticoids, preferably hydrocortisone, which the adrenals produce. Hydrocortisone replacement should be given orally as 20 to 30 mg/day divided into two doses, with two thirds of the daily dose given in the morning and one third given in the early afternoon or evening (Coursin and Wood, 2002; Toogood and Stewart, 2008). Alternatively, prednisone is given at a total daily dosage of 5 to 7.5 mg/m²/day in one to two doses. Clinical evaluation is the primary modality to

assess the adequacy of cortisol replacement. It is important to increase the dose of hydrocortisone twofold to threefold during illness and other stresses. All patients should carry medical alert tags or cards to identify the need for high-dose glucocorticoids in an emergency. Those with secondary adrenal insufficiency usually do not require mineralocorticoid replacement because ACTH is not essential for aldosterone secretion.

Hyperfunctioning Pituitary Adenomas

Key Points

- Pituitary adenomas may present with visual impairment, headache, or hormonal abnormalities.
- Prolactinomas are the most common type of functioning pituitary adenoma and manifest with galactorrhea and hypogonadism.
- Nonpathologic causes of hyperprolactinemia are sought, and primary hypothyroidism is excluded.
- MRI is the imaging modality of choice for the anatomic evaluation of the hypothalamus and pituitary gland.
- Prolactin level over 150 ng/mL and pituitary adenoma not identified on imaging suggest macroprolactinemia.
- A dopamine agonist (bromocriptine or cabergoline) is first-line treatment of prolactinomas.

Pituitary adenomas can arise from any cell type and can be functioning or nonfunctioning. The precise pathogenesis of these adenomas is not known but mutations found in several genes can play a role in the development of many adenomas. With prolactinomas the most common type, other functioning pituitary adenomas include gonadotropic, thyrotropic, somatotropic, and corticotropic adenomas.

Hyperprolactinemia and Prolactinomas

Diagnosis

Prolactin is a polypeptide secreted from the lactotrophs of the anterior pituitary (Leung and Pacaud, 2004; Mancini et al., 2008). The main function of prolactin is the development of breast tissue in preparation for milk production and maintenance of lactation postpartum. Unlike other pituitary hormone regulation, prolactin release is predominantly under inhibitory control. Dopamine is the principal inhibitor, and prolactin stimulators such as TRH and estrogen have minor roles.

Hypersecretion of prolactin may be physiologic or pathologic in origin. Physiologic stimulators include exercise, pain, breast stimulation, sexual intercourse, general anesthesia, and pregnancy. Pathologic causes of hyperprolactinemia include prolactinomas, decreased dopaminergic inhibition of prolactin secretion through pharmacologic agents, and decreased clearance of prolactin. Early manifestation of prolactin hypersecretion is galactorrhea and menstrual irregularities, notably amenorrhea, in women and erectile dysfunction or loss of libido in men. Rarely, galactorrhea with gynecomastia can occur in men. These patients are at risk of developing osteoporosis secondary to hypogonadism as well as a result of the direct inhibitory effect of prolactin on bone formation. Galactorrhea is rarely found in postmenopausal women with hyperprolactinemia, in whom mass effect of prolactinomas may cause the principal

presenting symptom, such as headache or visual disturbance (Mancini et al., 2008). Similarly, the diagnosis of prolactinomas in men is often delayed because the clinical signs and symptoms of hyperprolactinemia are less obvious.

Clinical evaluation of patients with suspected prolactinomas should include a thorough evaluation of medication history and presence of comorbidities. Many drugs are known to cause hyperprolactinemia, including phenothiazines, haloperidol, metoclopramide, H₂ antagonists, imipramines, selective serotonin reuptake inhibitors (SSRIs), calcium channel blockers, and hormones. The physical examination may reveal galactorrhea and visual field defects. Women may have mild hirsutism and men decreased facial hair growth.

Laboratory tests include serum prolactin and thyroid function. Primary hypothyroidism is associated with hyperprolactinemia secondary to elevated TRH that induces prolactin secretion. Testing should also seek systemic illnesses with increased prolactin levels, such as liver or renal failure. MRI is the imaging modality of choice for the anatomic evaluation of the hypothalamus and pituitary gland. Complete pituitary hormone evaluation should be performed when an adenomatous mass is noted in the region of the pituitary.

Features to distinguish hyperprolactinemia associated with pituitary tumors include (1) prolactin levels greater than 150 ng/mL, (2) loss of normal sleep-associated increases in prolactin levels, and (3) failure of prolactin levels to rise in response to exogenous TRH. No test is absolute, and diagnosis of prolactinoma depends on radiologic studies.

Clinicians should be aware of two prolactin assay-related conditions that may cause diagnostic confusion. In *macroprolactinemia*, large-molecular-weight prolactin, aggregated with globulins, is recorded as elevated levels of prolactin in the absence of any physiologic or pathologic cause of hyperprolactinemia (Mancini et al., 2008). Macroprolactinemia is suspected in the patient with very high prolactin level and no galactorrhea or tumor on pituitary MRI. The second area of confusion occurs when extremely high concentrations of serum prolactin overwhelm the assay reagents such that the measurements underestimate the true concentration of prolactin. This is referred to as the "hook effect."

Treatment

The treatment of hyperprolactinemia depends on the etiology, presence or absence of mass effects (e.g., visual changes), presence of bothersome galactorrhea or associated pituitary hormone deficiencies, and whether fertility is desired (Leung and Pacaud, 2004; Mancini et al., 2008). If possible, drugs known to cause prolactin elevation should be discontinued and serum prolactin concentration remeasured. Persistent hyperprolactinemia requires pituitary-hypothalamus imaging.

Treatment of prolactinomas includes dopamine agonists as first-line treatment. In select subgroups, surgical excision is recommended, usually through the transsphenoidal approach. Rare patients with large, residual tumor mass after surgery not responsive to medical therapy may be offered radiation therapy. Associated hormone deficiency should also be targeted. Often, as the prolactin levels are normalized, symptoms of hypogonadism can be reversed.

Bromocriptine and cabergoline are U.S. Food and Drug Administration (FDA)-approved dopamine agonists used to treat hyperprolactinemia. Cabergoline has greater tolerability than bromocriptine and is more effective in achieving

normalization of prolactin levels in 90% of patients with prolactinomas. Because of long-standing experience, however, bromocriptine is the preferred agent in women who want to become pregnant. Bromocriptine should be discontinued once pregnancy has been confirmed, even though the risk of teratogenicity is small. Pregnant women with prolactinomas should be warned to report any visual disturbances or headaches, because up to 10% of microprolactinomas and 30% of macroprolactinomas increase in size sufficient to cause symptoms. During pregnancy, prolactin levels should be monitored periodically, but interpretation of the results may be difficult. Pregnant women with macroadenomas should receive similar advice and have serial visual field testing.

Pergolide is an alternative but non-FDA-approved medication for hyperprolactinemia. Caution should be exercised with all these ergot derivatives because of rare case reports of valvular heart damage in patients taking the drug at very high doses for prolonged periods.

Withdrawal of the drug may lead to recurrent prolactin hypersecretion and adenoma growth, although the microadenomas have resolved after a few years of treatment in some patients. The dosage of the dopamine agonist may be reduced when prolactin levels have been normalized for 1 year and tumor size has been significantly reduced. Medication withdrawal may be considered after 2 years in those with normal prolactin levels and an MRI scan showing no tumor, or tumor reduction more than 50% and more than 5 mm from the optic chiasm, with no invasion of the cavernous sinus. Pituitary MRI and serum prolactin levels should be monitored closely thereafter.

Indications for transsphenoidal surgery in patients with prolactinomas include medical treatment failure or medication intolerance, very large tumors threatening visual pathways, or hemorrhagic infarcts (apoplexy). Approximately 30% of macroadenomas can be successfully removed surgically.

Acromegaly and Gigantism

See the discussion online at www.expertconsult.com.

Cushing's Disease

Key Points

- Cushing's syndrome is categorized into ACTH-dependent or ACTH-independent cases. Pituitary ACTH-dependent Cushing's syndrome is Cushing's disease.
- The diagnosis is established when the clinical findings of Cushing's syndrome are associated with laboratory documentation of excess cortisol production.
- Measurement of 24-hour urinary cortisol excretion is a good screening tool.
- Comparison of serum ACTH concentration with serum cortisol level can help determine the cause of hypercortisolism.
- Treatment of Cushing's syndrome is directed at the cause of hypercortisolism. The treatment of choice for Cushing's disease is selective transsphenoidal resection.

Hypercortisolemia (also hypercortisolism, hyperadrenocorticism), caused by either exogenous administration of cortisol or other synthetic glucocorticoids or endogenous

overproduction of cortisol, leads to a constellation of clinical and biochemical findings referred to as *Cushing's syndrome* (Arnaldi et al., 2003; Findling and Raff, 2005). The multiple causes include pituitary adenomas, excess production of CRH leading to hyperplasia of corticotropes in the pituitary, ectopic production of ACTH and CRH, and adrenocortical adenomas and carcinomas. The term *Cushing's disease* specifically refers to pituitary-dependent cortisol hypersecretion (Biller et al., 2008). Pituitary, ACTH-dependent Cushing's disease accounts for at least 70% of endogenous cases, while the most common cause of ACTH-independent Cushing's syndrome is prolonged glucocorticoid therapy.

Patients who have undergone bilateral adrenalectomy for hypothalamic-pituitary-dependent Cushing's syndrome may develop pituitary tumors associated with marked skin pigmentation. This condition is known as *Nelson's syndrome*. The skin hyperpigmentation occurs because of excess production of melanocyte-stimulating hormone (MSH), a product of the gene that also encodes ACTH and beta endorphin.

Diagnosis

A high index of suspicion is required to make the diagnosis of Cushing's syndrome because manifestations of the disease are insidious and develop over months.

The clinical features include weight gain with centralized obesity distributed in the face, neck, trunk, and abdomen with facial rounding and plethora. The thinning of the skin and loss of subcutaneous tissue result in easy bruisability and violaceous abdominal striae. Patients with ectopic ACTH-dependent Cushing's syndrome have extreme ACTH increases that cause rapid hyperpigmentation and are more likely to demonstrate features of mineralocorticoid excess, such as hypokalemia and metabolic alkalosis. Gonadal dysfunction is associated with decreased testosterone levels in men and decreased serum estradiol levels and menstrual disorders, notably amenorrhea, in women. Virilization and androgen excess are more common in patients with Cushing's syndrome caused by adrenal carcinomas.

Glucocorticoid excess also interferes with calcium and bone metabolism and leads to osteoporosis. Catabolic effects of excess glucocorticoid on muscles cause proximal muscle weakness. Glucose intolerance is found in 30% to 60% of those with hypercortisolism. Other complications of hypercortisolism include risk of opportunistic infections, including *Pneumocystis jiroveci* (formerly *carinii*) pneumonia, hypercoagulable state, and thromboembolic events secondary to increased plasma concentration of clotting factors and neuropsychiatric changes (Arnaldi et al., 2003; Findling and Raff, 2005).

Establishing the Cause

The diagnosis is established when the clinical findings of Cushing's disease are associated with laboratory documentation of excess cortisol production, loss of diurnal variation of plasma cortisol level, and more than 50% suppression of plasma and urine cortisol after administration of 2 mg of dexamethasone every 6 hours (high-dose dexamethasone suppression test). Measurement of 24-hour urinary cortisol excretion is a good screening tool. Alternatively, impaired suppression of cortisol after an overnight 1-mg dexamethasone suppression test can be used as a screen in nonobese individuals. Plasma ACTH concentration less than 5 pg/mL

and serum cortisol concentration greater than 15 µg/dL suggest an ACTH-independent cause. Plasma ACTH concentration greater than 15 pg/mL in a patient with hypercortisolism likely indicates ACTH-dependent Cushing's syndrome (Arnaldi et al., 2003; Findling and Raff, 2005).

The vast majority of ACTH-dependent Cushing's syndrome patients have a pituitary adenoma as the cause. The few patients who have an ectopic source of ACTH must be identified with high-resolution CT scanning of chest, abdomen, and pelvis.

Suppression of urinary cortisol excretion, after administration of high-dose dexamethasone, is consistent with the diagnosis of Cushing's disease, whereas urinary cortisol excretion in cases of ectopic ACTH syndrome is usually not suppressible. When the high-dose dexamethasone suppression test fails to differentiate an ectopic source from a pituitary source of ACTH, and radiographic imaging is not conclusive, further CRH testing and petrosal sinus sampling of ACTH are indicated to localize the tumor to the pituitary.

Treatment

The treatment of choice for Cushing's disease is selective transsphenoidal resection of the pituitary adenoma. The cure rate for this procedure is 70% to 80% for microadenomas at experienced centers. In some patients, total hypophysectomy is considered when the disease recurs after transsphenoidal resection. Many postsurgical patients require low-dose cortisol replacement for up to 12 months, until their endogenous adrenal function recovers.

Bilateral adrenalectomy with or without pituitary irradiation is offered to patients who have recurrence of hypercortisolemia or severe disease. For poor surgical candidates, adjunctive medical therapy is offered and includes metyrapone (blocker of 11β-hydroxylase), mitotane (O'PDDD), and cyproheptadine. These treatment options have variable efficacy.

Craniopharyngiomas; Thyrotropin-Secreting Pituitary Adenomas; Gonadotropic and Other Adenomas

See the discussions of these pituitary tumors online at www.expertconsult.com.

Posterior Pituitary Disorders

Arginine vasopressin (AVP) and oxytocin are the principal hormones secreted from the posterior pituitary. The two major stimuli of oxytocin secretion are suckling during lactation and dilation of the cervix during labor. Although not essential for initiation of labor, oxytocin can be used pharmacologically to initiate labor or control postpartum hemorrhage and uterine atony. Rarely, it has been used to induce milk ejection. The physiologic role of oxytocin in males is not known. AVP differs from oxytocin by only one amino acid. AVP is found in all mammals except pigs and related species, in which lysine vasopressin replaces AVP. In humans and many mammals, AVP and oxytocin are associated with two neurophysins, the exact roles of which are not known, except as carrier proteins in storage and transport of posterior pituitary hormones (Mooradian and Morley, 1988).

Antidiuretic hormone (vasopressin) is synthesized in the hypothalamus and migrates down into the posterior lobe

of the pituitary to be stored and later secreted. Some ADH is secreted directly into the cerebrospinal fluid (CSF) rather than the posterior pituitary. Thus, pathologic lesions affecting the hypothalamus below the median eminence may preserve some functional ADH that migrates from the CSF into the systemic circulation. The half-life of AVP in circulation is only 20 minutes because of its susceptibility to peptidases. Loss of the terminal amino group in position 1 makes this peptide resistant to degradation, whereas substitution of the *levo* analog of arginine for dextroarginine in position 8 reduces presser effect without altering its antidiuretic properties. The resultant peptide deamino-8-D-arginine vasopressin (DDAVP) is currently the treatment of choice for central diabetes insipidus.

The biologic effects of AVP are initiated at two receptors, V1 and V2. The V1 receptors are located in the vascular system, and their stimulation results in vasoconstriction. The V2 receptors are located in the kidneys, and their stimulation results in free-water reabsorption (Korbonits and Carlsen, 2009). Plasma osmolality, blood volume, and blood pressure are the most important physiologic stimuli of AVP secretion. Other factors that modulate AVP secretion include pain, stress, nausea, hypoglycemia, hypercapnea, angiotensin II, atrial natriuretic hormone, and drugs. Many stimuli of AVP release also promote thirst. Thirst is less sensitive than AVP release in response to these stimuli and therefore is a second-line defense against dehydration.

Central Diabetes Insipidus

Key Points

- Diabetes insipidus is characterized by excessive dilute urine with thirst and polydipsia and results from decreased ADH secretion.
- Differential diagnosis of hypotonic polyuria includes neurogenic DI (vasopressin sensitive), nephrogenic DI (vasopressin resistant), and primary polydipsia.
- The water restriction test assists in diagnosis.
- Desmopressin is the primary treatment for central DI.

Clinical Features

Diabetes insipidus (DI) is characterized by the production of excessive dilute urine with secondary thirst and polydipsia. *Polyuria* is defined as 3 L or more of urine daily in adults and 2 L or more in children. Central DI may be familial or sporadic and is caused by head trauma, neurosurgery, neoplasms, granulomas, infections, inflammation, chemical toxins, vascular disorders, congenital malformations, and genetic disorders. Other causes include hypoxic encephalopathy; infiltrative disorders, notably *histiocytosis X* (Hand-Schuller-Christian disease); anorexia nervosa; acute fatty liver of pregnancy; and Wolfram syndrome (central DI, diabetes mellitus, optic atrophy, and deafness) (Reddy and Mooradian, 2009). An autoimmune process is probably the cause of idiopathic DI and accounts for 30% to 50% of cases of central DI (de Bellis et al., 1999).

Thickening or enlargement of the posterior pituitary on MRI may represent lymphocytic infiltration and inflammation. Classically, DI after head trauma or neurosurgery has three phases: polyuria in the first 1 to 2 days after surgery, oliguria for

3 to 4 days, and culminating in a polyuric phase. These phases reflect the early paralysis of vasopressin-producing cells, followed by neuronal degeneration and massive ADH release, with subsequent permanent loss of vasopressin production.

Vasopressin-resistant DI is usually a familial disorder, although sporadic causes are recognized, as in chronic medullary kidney disease associated with sickle cell disease, multiple myeloma, amyloidosis, Sjögren's syndrome, and renal medullary cystic disease. In addition, prolonged primary polydipsia can wash out the normal medullary concentration gradient and may mimic ADH-resistant nephrogenic DI.

Diagnosis

Although a variety of diseases may present as polyuria and polydipsia, thorough history and routine laboratory evaluation can narrow the differential diagnosis of hypotonic polyuria to three possibilities: neurogenic DI (vasopressin sensitive), nephrogenic DI (vasopressin resistant), or primary polydipsia (Mooradian and Morley, 1988).

Serum sodium concentrations less than 137 mEq/L and polyuria are usually manifestations of primary polydipsia. Patients with serum sodium concentration less than 143 mEq/L should have a water deprivation test after an overnight fast, with hourly measurement of body weight, urine volume, and osmolality. In severe cases the dehydration test can be started at 6 AM. When the urine osmolality remains constant during three consecutive measurements, or if the patient loses more than 5% total body weight, plasma osmolality, ADH, and sodium concentrations are determined, and aqueous vasopressin (0.1 U/kg SC) or 10 µg of nasal desmopressin is administered and the response evaluated. An increase in urine osmolality of 150 mOsm/kg above baseline will exclude nephrogenic DI. In central DI, 10 µg of nasal desmopressin will result in increases in urine osmolality of as much as 800%. The response to desmopressin in partial central DI may result in urine osmolality increases of 15% to 50%. Patients with nephrogenic DI continue to have urine osmolality levels that remain below isosmotic. Primary polydipsia responds to the water deprivation test with urine concentration to 500 mOsmol/kg or higher, compared with urine osmolality increasing to 800 mOsmol/kg or higher in normal subjects. Administration of exogenous vasopressin produces no further concentration in cases of primary polydipsia.

When the water suppression test yields equivocal results, the serum AVP concentration at baseline and after the water restriction test should be measured. However, the results of these tests may still be misleading because primary polydipsia will result in submaximal secretion of AVP, mimicking the pattern of AVP secretion in partial central DI.

Treatment

The treatment of choice for central DI is desmopressin. DDAVP can be administered IV, SC, nasally, or orally. An initial nasal inhalation of 5 µg is given at bedtime and increased by 5-µg increments until nocturia is resolved, when a morning dose is given. The total daily dosage of nasal desmopressin is 5 to 20 µg daily. Oral desmopressin should be given on an empty stomach; absorption can be reduced by up to 50% when taken with food. A 0.1-mg tablet is equivalent to 2.5 to 5.0 µg of nasal spray (de Bellis et al., 1999).

Patients with partial DI will benefit from oral agents that potentiate AVP action or stimulate the release of AVP. These

agents include chlorpropamide, carbamazepine, and clofibrate. In such cases, desmopressin requirements may be lower than available preparations can provide. Patients with nephrogenic DI benefit from thiazide diuretics or indomethacin. Patients with DI should wear a medical alert bracelet. When the ability to drink fluids is impaired, intravenous hydration will be required to avoid dehydration and hyponatremia.

Syndrome of Inappropriate Secretion of Antidiuretic Hormone

Key Points

- Laboratory evaluation of plasma osmolality, urine osmolality, and urine sodium concentration assist in determining the cause of hyponatremia.
- Water restriction and salt replacement are the most important treatments in hyponatremia. The underlying cause should be identified and treated, when possible.
- Vasopressin antagonists are currently indicated for the treatment of euvolemic and hypervolemic hyponatremia.

Syndrome of inappropriate secretion of antidiuretic hormone (SIADH) is associated with plasma ADH concentrations that

are inappropriately high for the plasma osmolality. Laboratory and clinical features of SIADH include (1) euvolemic hyponatremia; (2) decreased measured plasma osmolality (<275 mOsm/kg); (3) urine osmolality >100 mOsm/kg; (4) urine sodium usually >40 mEq/L; (5) normal acid-base and potassium balance; (6) blood urea nitrogen (BUN) <10 mg/dL; (7) hypouricemia <4 mg/dL; (8) normal thyroid and adrenal function; and (9) absence of advanced cardiac, renal, or liver disease (Reddy and Mooradian, 2009). Conditions or factors associated with SIADH include CNS trauma and infections, tumors, drugs, major surgery, pulmonary disease (e.g., TB), hormone administration, human immunodeficiency virus (HIV) infection, hereditary SIADH, idiopathic causes, and cerebral salt wasting (Box 35-1).

In some cases it is difficult to differentiate SIADH from mild to moderate depletion hyponatremia. The response of urinary and plasma sodium concentration to an infusion of 1 to 2 L of 0.9% (isotonic) saline may help in the differential diagnosis. In the patient with SIADH who is at equilibrium, the saline will be excreted, and therefore urinary sodium will increase while plasma sodium concentration will either not change or decrease slightly. If the patient has depletion hyponatremia from renal losses, sodium from the administered saline is retained and the excess water excreted. Urinary sodium decreases, whereas plasma sodium concentration increases.

Box 35-1 Select Causes of Syndrome of Inappropriate Antidiuretic Hormone Secretion (SIADH)

Nonosmotic stimuli

Nausea, pain, stress
Human immunodeficiency virus (HIV)
Acute psychosis
Surgery
Pregnancy (physiologic)
Hypokalemia
Congestive heart failure exacerbation

Central nervous system lesions

Tumors (neuroblastoma)
Cerebrovascular accident (stroke)
Meningitis, encephalitis
Abscess
Guillain-Barré syndrome
Hydrocephalus
Pituitary stalk lesion
Delirium tremens
Demyelinating disease
Acute porphyria

Malignancies

Lymphoma, leukemia, Hodgkin's disease
Carcinoma of uterus
Ureteral, prostate, and bladder carcinoma
Carcinoma of duodenum and pancreas
Ectopic production of vasopressin by tumors (small cell lung carcinoma, carcinoids)
Cancers of head and neck and nasopharynx
Renal cell carcinoma
Osteosarcoma

Increased intrathoracic pressure

Mediastinal tumors (thymoma, sarcoma)
Positive-pressure ventilation
Infections (pneumonia, TB, aspergillosis, lung abscess)
Bronchogenic carcinoma, mesothelioma
Bronchiectasis, empyema
Chronic obstructive pulmonary disease
Pneumothorax

Drug induced

Antipsychotics

Phenothiazines
Haloperidol

Antidepressants

SSRIs, TCAs, MAOIs
Bupropion

Anticonvulsants

Carbamazepine, oxcarbazepine
Sodium valproate

Analgesics and recreational drugs

Morphine (high doses)
Tramadol
MDMA ("ecstasy")

Nonsteroidal anti-inflammatory drugs

Colchicine, venlafaxine
Duloxetine (Cymbalta)

TB, Tuberculosis; SSRIs, selective serotonin reuptake inhibitors; TCAs, tricyclic antidepressants; MAOIs, monoamine oxidase inhibitors; ACE, angiotensin-converting enzyme; MDMA, 3,4-methylenedioxymethamphetamine.

A *reset osmostat* may be suspected when mild hyponatremia persists despite changes in fluid and salt intake. A reset osmostat may be confirmed by giving the patient a fluid bolus of 10 to 15 ml/kg. Normal patients, or those with a reset osmostat, should excrete 80% of this bolus in 4 hours, which does not occur with SIADH. Cerebral salt wasting induces SIADH-like symptoms. Salt wasting, followed by volume depletion, occurs in some patients with cerebral disease. This leads to a secondary rise in ADH levels. The mechanism underlying cerebral salt wasting is unclear.

Treatment

Management of SIADH should begin with water restriction and treatment or elimination of the underlying etiology. In all patients with hyponatremia, free-water intake from all sources should be restricted to less than 1 to 1.5 L daily. In patients with mild symptoms, the rate of urinary solute excretion, the main determinant of urine output, can be increased by a high-salt, high-protein diet or supplementation with urea (30-60 g/day) or salt tablets (200 mEq/day) (Reddy and Mooradian, 2009). However, salt therapy is generally contraindicated in patients with hypertension and edema because it leads to exacerbation of both conditions. In addition, water restriction is contraindicated in subarachnoid hemorrhage with hypovolemia, in which water restriction may result in hypotension, creating a risk for cerebral infarction. This risk is more pronounced if the patient has cerebral salt wasting, which must be treated first, with isotonic or hypertonic saline solution, until adequate volume status is demonstrated.

In general, plasma sodium concentration should be corrected at a rate of 1 mEq/L/hr until the reversal of neurologic symptoms. The correction rate is then reduced to 0.5 mEq/L/hr until the plasma sodium has reached a level of 120 to 125 mEq/L. This approach effectively prevents the devastating neurologic consequences of acute hyponatremia and is associated with reduced risk of osmotic demyelination of pontine and extrapontine neurons.

The most specific treatment for SIADH is to block the V2 receptors in the kidney that mediate the diuretic effect of ADH.

Vasopressin antagonists are currently indicated for the treatment of euvolemic and hypervolemic hyponatremia (Loh and Verbalis, 2008). For hospitalized patients, conivaptan is given as an intravenous (IV) loading dose of 20 mg delivered over 30 minutes, then as 20 mg continuously over 24 hours. Subsequent infusions may be administered every 1 to 3 days at 20 to 40 mg daily by continuous infusion (Reddy and Mooradian, 2009). More recently, an orally active vasopressin receptor antagonist, tolvaptan, became available. Rapid correction of hyponatremia has been reported in patients receiving these agents; therefore, frequent checks of plasma sodium are needed. Chronic SIADH can occur in patients with ectopic ADH-producing tumors and in whom antipsychotic drugs cannot be discontinued. If water restriction and salt tablet therapy is ineffective, attempt (1) administration of loop diuretic along with salt tablets; (2) demeclocycline; (3) lithium carbonate; and (4) orally active vasopressin antagonists such as tolvaptan (cost limits its utility). Demeclocycline is nephrotoxic in patients with cirrhosis and is contraindicated in children because of interference with bone development and teeth discoloration. Lithium carbonate may induce interstitial nephritis and renal failure. Therefore, lithium should be considered for use only in patients in whom demeclocycline is contraindicated.

KEY TREATMENT

Hydrocortisone is given to ACTH-deficient adults at 20 to 30 mg daily, increased twofold to threefold during illness and other stresses (Coursin and Wood, 2002; Toogood and Stewart, 2008) (SOR: A). The goal of thyroid replacement should be to achieve a normal serum free-thyroxine concentration and clinical euthyroidism (Oiknine and Moordian, 2006) (SOR: A). A dopamine agonist is first-line treatment of prolactinomas (Mancini et al., 2008) (SOR: A). Transsphenoidal surgery to remove the pituitary adenoma is usually the treatment of choice in individuals with acromegaly (Melmed et al., 2009) (SOR: A). Octreotide (Sandostatin) is often effective in normalizing GH and IGF-1 levels. Pegvisomant is a GH receptor antagonist also approved for treatment of acromegaly (Melmed et al., 2009) (SOR: A).

Treatment of Cushing's syndrome should be directed at the cause of hypercortisolism. The treatment of choice for Cushing's disease is selective transphenoidal resection (Biller, 2008) (SOR: A).
 Desmopressin is the primary treatment for central diabetes insipidus (Loh and Verbalis, 2008; Reddy and Mooradian, 2009) (SOR: A).
 Water restriction and salt replacement are the most important treatment modalities in hyponatremia. The underlying cause should be identified and treated, when possible (Reddy and Mooradian, 2009) (SOR: A).
 Vasopressin antagonists are currently indicated for the treatment of euvolemic and hypervolemic hyponatremia (Loh and Verbalis, 2008; Reddy and Mooradian, 2009) (SOR: A).

Thyroid Disorders

Key Points

- Primary thyroid disorder is caused by abnormal function of the thyroid gland.
- Secondary thyroid disorder is the result of abnormalities at the level of the pituitary.
- Tertiary thyroid disorder results from malfunction at the level of the hypothalamus.

Thyroid disorders include processes that affect function (physiology) as well as structure (anatomy). Extraglandular causes include metastatic neoplasia, pituitary disorders, dietary issues, autoimmune diseases, infections, and genetic or familial diseases, such as multiple endocrine neoplasia IIA and familial medullary thyroid carcinoma. Other causes are intrinsic to the thyroid and include cysts, nodules, and goiter. In either case, all thyroid diseases exist in one of three functional states: euthyroid, hyperthyroid, or hypothyroid; each is defined by the level of total bound and free, circulating thyroid hormone. The presence of any one of these states in an individual can be transient, static, or progressing. Laboratory abnormalities of circulating thyroid hormone, at any point in time, do not prove disease and do not depend on the etiology of thyroid dysfunction. All three states may exist at different times during the course of an illness, and each state can exist with or without disease or clinical findings. In addition, the various thyroid structures can reflect disease independent of endocrinologic function.

Accurate assessment of thyroid function, with determination of presence or absence of disease, requires data in addition to levels of circulating thyroid hormones. These data include serum free and total thyroid hormone levels, thyrotropin (TSH) levels, and in some cases, antithyroid antibody (ATA) titers. This battery of tests will provide diagnosis in the majority of common thyroid disorders. When imaging studies and fine-needle aspiration are added, 90% to 95% of patients with thyroid disease who present in the primary care setting can be diagnosed and appropriately managed.

Thyroid disorders affect 60 to 80 per 1000 adults worldwide and up to 8.9% of the adult U.S. population (Bagchi et al., 1990; Vanderpump et al., 1995). Since most have an insidious onset or closely mimic other, more common disorders, thyroid disorders are easily missed and, although rarely fatal, can cause significant morbidity. Early recognition is critical to minimizing morbidity. With the exception of conditions such as simple goiter or visible nodule, patients who ultimately are

diagnosed with thyroid disease rarely present to the family physician with complaints suggesting thyroid disorder.

Anatomy and Physiology

Key Points

- Thyroxine (T_4) is the major product of the thyroid gland.
- Triiodothyronine (T_3) is the active hormone at the cellular level.
- The majority of circulating T_3 is formed in the peripheral circulation by deiodination of T_4 .
- Thyroxine serves as a reservoir (prohormone) for T_3 .
- Serum thyrotropin (sTSH) is required in all evaluations of dementia or depression.

Histologically, the thyroid gland consists of five primary elements: follicular cells, colloid, interstitial tissue, "C" cells, and lymphoid cells. The most prominent element is the follicular cell, which produces colloid. The thyroid follicle is the functional unit of the gland and the site where colloid is stored. It is within the follicle where thyroid hormone (thyroxine, or T_4) synthesis occurs. The remaining cellular elements are C cells and lymphoid cells. The few C cells are located in the intrafollicular space and produce calcitonin. Lymphoid cells are found scattered throughout the gland stroma in small, isolated clusters.

Circulating Thyroid Hormones

Biosynthesis of thyroid hormone is unique among endocrine glands because final assembly occurs extracellularly in the follicular lumen. The source of thyroid hormones (T_4 and triiodothyronine, or T_3) is *thyroglobulin* (Tg), an iodoprotein produced by thyroid follicular cells. Thyroglobulin is the major portion of intraluminal colloid and is the most important protein of the thyroid gland (Kopp, 2005). Thyroglobulin provides a matrix for the synthesis of thyroid hormones and a vehicle for subsequent storage. Stored thyroglobulin is oxidized by thyroid peroxidase (TPO), adding an iodine molecule to tyrosine to form moniodotyrosine (MIT) and diiodotyrosine (DIT). MIT and DIT are then assembled into the final products, tetraiodothyronine (T_4) and triiodothyronine (T_3), which are stored in the follicular colloid for future use. When stimulated by serum thyrotropin (sTSH), thyroglobulin within the colloidal space is internalized by thyroid cells and enzymatically degraded to release T_4 and T_3 into the peripheral circulation. Approximately one third to one half of T_4 released into the peripheral circulation is deiodinated to form T_3 .

In the peripheral circulation, T_4 and T_3 are bound to thyroid-binding globulin (TBG). Thyroxine is bound to TBG in concentrations 10 to 20 times greater than T_3 , and neither bound T_4 nor bound T_3 is directly available to tissues. Only unbound or "free" portions of T_4 and T_3 are metabolically available at the cellular level. The free portion of T_4 represents 0.02% to 0.05% of total serum T_4 and the free portion of T_3 represents 0.1% to 0.3% of total serum T_3 (Benvenega, 2005; Meier and Burger, 2005; Toft and Beckett, 2005). Most T_3 (>99.5%) is bound to TBG, but T_3 is not as tightly bound as T_4 , allowing easier release into the free state.

Thyroid hormones exert their effect by binding to thyroid receptors (TRs) within cells. At the cellular level, T_3 is about

twice as biologically active as T₄, partly because T₃ binds to TRs 10 to 15 times more than T₄ (Yen, 2005). T₃ is the biologically active form of thyroid hormone. Thyroxine's role in this process appears to be that of a prohormone, providing a readily accessible reservoir for conversion to T₃; otherwise, its exact purpose is unknown (Bianco and Larsen, 2005).

Thyroid hormones (T₄ and T₃) regulate growth, development, and metabolism by affecting oxygen consumption and protein, carbohydrate, and vitamin metabolism. Around puberty, the effect on growth and development begin to wane, and in adults, thyroid hormones essentially affect only metabolism (Yen, 2005).

Normal thyroid function, in terms of circulating levels of T₄, T₃, free T₄ (FT₄), free T₃ (FT₃), and the thyrotropin feedback system, appears to remain stable throughout life. Without intrinsic disease of the hypothalamic-pituitary-thyroid axis, age does not appear to have an adverse effect on the function of the thyroid gland or its component parts, in terms of serum concentration of T₄ and T₃ (Oiknine and Mooradian, 2006). Although changes in measurable levels of total serum T₄ and T₃ do result from changes in transport protein concentrations, FT₄ and FT₃ levels remain mostly constant (Hassani and Hershman, 2006).

Laboratory Testing

Tests for thyroid disorders include laboratory, imaging, and biopsy. Before imaging or biopsy is undertaken, it is important to determine the functional state of the thyroid gland, even when the initial presentation is a thyroid mass or thyromegaly. This is accomplished via laboratory testing of a peripheral blood sample. These simple, and readily available, tests will provide direction for further workup.

The initial laboratory tests, regardless of the presenting complaint or finding, include sTSH and FT₄. The results of these initial studies help determine the functional state of the gland (hyperthyroid, euthyroid, or hypothyroid) and thus suggest which additional tests are required (Table 35-1).

Second-tier laboratory tests include thyroid antibodies and FT₃ if T₃ toxicosis is suspected. As noted previously, aging and comorbidities that affect circulating levels of thyroid transport protein can result in T₄ levels that appear abnormally low, suggesting a hypothyroid state. However, FT₄ and FT₃ will be normal, as will sTSH. Thyroid antibodies are useful in evaluating several disease states, primarily Graves' disease and chronic autoimmune thyroiditis (CAT, Hashimoto's thyroiditis). In Graves' disease the primary antibody class is TSH receptor-stimulator antibodies (TSH-RS Abs). In CAT the primary antibodies are thyroid antiperoxidase antibodies (TPO Abs) and thyroglobulin antibodies (Tg Abs). Patients with hypothyroidism occasionally exhibit TSH receptor-blocker antibodies (TSH-RB Abs), although the role this plays in the disease course is unclear. Thyroid microsomal antibodies (TPO Abs, Tg Abs) are occasionally seen in the self-limited processes of postpartum thyroiditis and silent thyroiditis.

Figure 35-1 provides an algorithm for diagnosing thyroid dysfunction.

Imaging

In the primary care office, ultrasonography is the first-line study for a palpable thyroid mass. The goal is to determine whether the mass is cystic, solid, or mixed. It is also used to provide a presumptive diagnosis of malignancy in the hands of an experienced radiologist, since malignant thyroid nodules have some very specific ultrasonographic characteristics. If the patient is hyperthyroid, with suppressed sTSH, ultrasound is done in conjunction with radioisotope scan.

Nuclear imaging utilizes iodine 123 (¹²³I) to evaluate gland activity. Patients with normal gland function will show homogeneity throughout the gland, with the exception of areas where cysts or nonfunctioning nodules are located. Patients with autonomously functioning nodules or multinodular goiter will show ¹²³I uptake in nodular areas,

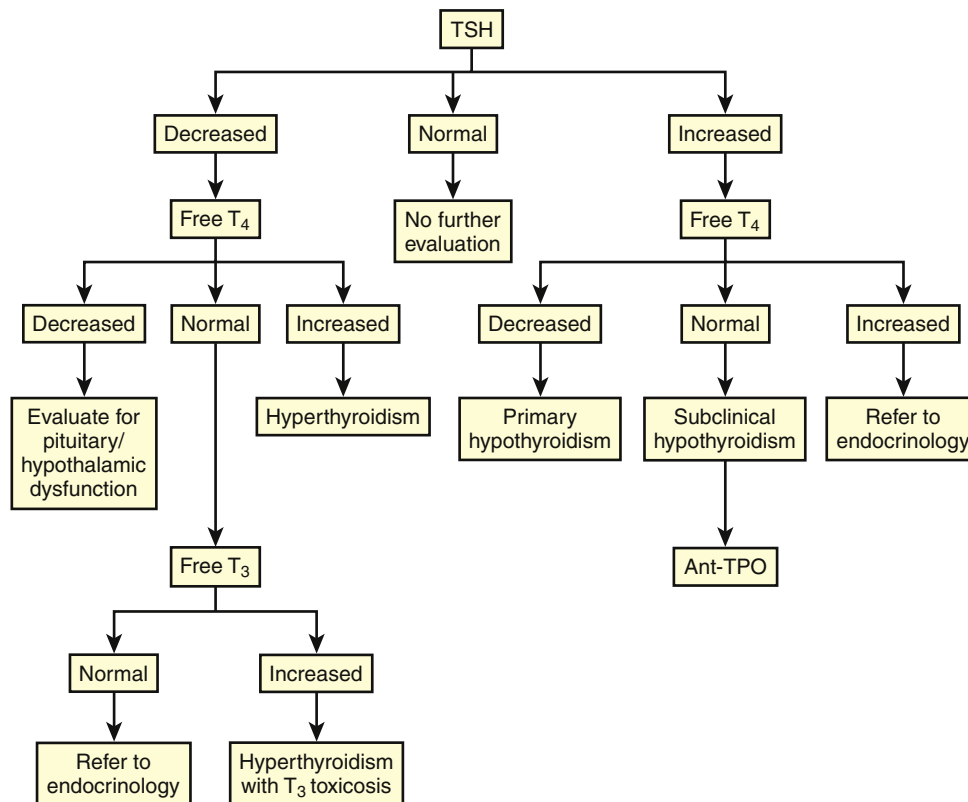

Figure 35-1 Algorithm for diagnosis of thyroid dysfunction, beginning with abnormal serum thyrotropin (sTSH) level.

with the remainder of the gland, under the control of sTSH, being hypoactive or inactive.

Computed tomography and MRI are not useful in diagnosis and treatment of nonmalignant diseases of the thyroid and thus are not recommended as initial studies. For biopsy-proven malignancy, CT and MRI can be useful preoperatively to define the area of involvement and for postoperative follow-up. CT and MRI should be reserved for the surgeon and oncologist.

Biopsy

Fine-needle aspiration (FNA) biopsy is a well-defined procedure for evaluating thyroid masses. It is safe and virtually painless in the hands of an experienced interventional radiologist, endocrinologist, or pathologist. When a definitive diagnosis cannot be made, and there is concern for possible malignancy, surgical referral is required. This usually results in a lobectomy or subtotal thyroidectomy.

Hyperthyroidism

Key Points

- Hyperthyroidism is diagnosed with a suppressed TSH and increased FT₄.
- Graves' disease is caused by abnormal response to circulating antithyroid antibodies.
- Serum TSH in Graves' disease is usually less than 0.1 mIU/L and may be unmeasurable.
- Diagnosis of Graves' disease in a patient without goiter and ophthalmic abnormality should be suspect.

Hyperthyroidism is a biochemical process represented by an increase in thyroid hormone biosynthesis and secretion (Toft, 2001). Diagnosis of hyperthyroidism is based on (1) sTSH level less than 0.1 mIU/L and (2) elevated FT₄ and/or T₃, and is often associated with symptoms consistent with a hypermetabolic state (Box 35-2). Determining the exact etiology requires further testing that includes laboratory studies and imaging (Box 35-3).

Graves' Disease

Graves' disease is the most common cause of hyperthyroidism and results from the development of TSH-RS Abs. These antibodies attach to TSH receptors in the thyroid gland and "mimic" action of TSH, stimulating production and release of T₄. Because of excess circulating T₄, the pituitary feedback loop for TSH production is suppressed, resulting in sTSH levels significantly less than 0.01 mIU/L. Serum TSH levels greater than 0.05 mIU/L, although not impossible with Graves' disease, should make the diagnosis suspect.

Graves' disease can present at the family physician's office as thyrotoxicosis or thyroid storm, but more often it presents with hypermetabolic symptoms or goiter. How it is treated initially will be determined by age, comorbidities, and acuity of symptoms. The primary symptomatic treatment is directed toward the cardiovascular responses of tachycardia, systolic hypertension, and volume depletion. Concurrent with this is the administration of antithyroid medication (propylthiouracil or methimazole). Once the patient's symptoms have been controlled, and there is evidence the hyperthyroid state is resolving, planning for long-term treatment can ensue.

Box 35-2 Symptoms Consistent with Hypermetabolic state

Tachycardia, wide pulse pressure
 Systolic hypertension
 Fever, tremor
 Warm moist skin
 Anxiety, hyperactivity
 Diarrhea, weight loss

Modified from Braverman LE, Utiger RD. Introduction to thyrotoxicosis. In Braverman LE, Utiger RD [eds]. *The Thyroid: a Fundamental and Clinical Text*. 9th ed. Philadelphia, Lippincott, Williams & Wilkins, 2005.

Box 35-3 Common Causes of Hyperthyroidism

Autonomous functioning (toxic) nodule
 Toxic multinodular goiter (TMNG, Plummer's disease)
 Factitious disorder (Munchausen's disease)
 Iatrogenic disease
 TSH receptor-stimulator antibody production (Graves' disease)
 Acute thyroiditis
 TSH-producing pituitary tumor (adenoma)

TSH, Thyroid-stimulating hormone (thyrotropin).

Two courses of action can be followed for long-term treatment of Graves' disease. The goal is to maintain a euthyroid state. This can be accomplished with continued use of anti-thyroid medication, adjusting dose to maintain sTSH in a normal range. The alternative treatment is ablation of the thyroid gland using ^{131}I , usually requiring post-radiation thyroid hormone replacement. Either is appropriate, and usually the patient must take some medication on a permanent basis. Occasionally, a patient will undergo spontaneous remission, so a trial of antithyroid medication for 6 months to 1 year may be worthwhile. This requires close follow-up, however, once the antithyroid medication is discontinued, in case the patient rebounds. The majority of patients elect radioactive ablation and long-term treatment with thyroxine replacement.

Intervention in hyperthyroidism begins with a β -adrenergic receptor blocker as a temporizing agent to control sympathetically mediated symptoms. Specific therapy is deferred pending confirmation of etiology. For Graves' disease, autonomously functioning nodule, or toxic multinodular goiter (TMNG), specific intervention includes propylthiouracil (PTU) or methimazole (MMI) to control thyroxine synthesis and, with PTU, to reduce conversion of T_4 to T_3 in the peripheral circulation. Once the patient is converted to a euthyroid state, specific treatment based on cause can be instituted.

With treatment of Graves' disease, the goiter found in more than 90% of these patients may shrink. However, large goiters often require surgery for satisfactory cosmetic appearance.

Thyroxine-Producing Nodules

Autonomously functioning thyroid nodules are found occasionally during workup for a hypermetabolic state or palpation of a thyroid mass. Autonomous nodules have a much

higher incidence of occurring in iodine-deficient areas, accounting for approximately 60% of cases of thyrotoxicosis.

Autonomous functioning nodules and TMNG (Plummer's disease) result in sTSH and FT_4 values similar to those in Graves' disease, although sTSH is generally not less than 0.05 mIU/L. In both cases, one would expect the TSH-RS Abs to be negative or, at most, an extremely low titer. Evaluation includes radioisotope scan with ^{123}I , which will demonstrate the nodule(s). These tumors are rarely malignant, and treatment is surgical after appropriate thyroid suppression. Long-term results are excellent, with no expectation of recurrence.

For patients with TMNG and those with autonomous nodules who cannot tolerate surgery, ^{131}I ablation can be used. The ^{131}I is picked up by the most active portion(s) of the gland, so residual normally functioning thyroid gland often remains. However, iatrogenic hypothyroidism is always possible. After ^{131}I treatment of an autonomous nodule or TMNG, sTSH levels are required to determine if the gland can provide sufficient T_4 to meet physiologic requirements.

Other

See online text for other forms of hyperthyroidism (fictitious/iatrogenic thyrotoxicosis).

Thyrotoxicosis

Thyrotoxicosis is a physiologic process manifesting as hypermetabolism and hyperactivity that is caused by high serum concentrations of T_4 , T_3 , or both (Braverman and Utiger, 2005). It is not necessarily caused by excess hormone production and therefore may not represent a true hyperthyroid state. The cause of thyrotoxicosis in 2% to 4% of patients is elevated T_3 levels, with concomitant upper-limit normal T_4 levels (Meier and Burger, 2005).

Thyrotoxicosis has a predilection for female patients, tends to be more common in persons of northern European extraction, and is rare in blacks. Spontaneous thyrotoxicosis is most often caused by Graves' disease, accounting for 60% to 90% of all cases, followed by *silent*, or postpartum, thyroiditis caused by the sudden spike of circulating T_4 , although it is transient and usually not clinically significant. Other less common, but not rare, causes of thyrotoxicosis include TMNG, autonomous functioning adenoma, and ingestion of exogenous thyroid hormone. Acute onset of thyrotoxicosis is almost always caused by thyroiditis. Thyrotoxicosis associated with Graves' disease has a more insidious course, evolving over a more protracted period. If a patient is thyrotoxic and the thyroid gland is not palpable, consider painless thyroiditis, unsuspected Graves' disease, or exogenous thyroxine. A thyrotoxic patient with a goiter or ophthalmopathy has Graves' disease until proven otherwise. Treatment of hypermetabolic symptoms should not be delayed pending further testing or referral.

Symptoms of hyperthyroidism in younger individuals are usually the result of sympathoadrenal activity, whereas elderly patients have an age-related desensitization of β -adrenergic receptors, which probably accounts for a blunting of some symptoms usually associated with hyperthyroidism (Oiknine and Mooradian, 2006; Trivalle et al.,

1996). In older individuals with altered sympathetic and parasympathetic function, symptoms of thyrotoxicosis tend to include cardiovascular dysfunction, dyspnea, weight loss, and proximal muscle weakness. Cardiovascular symptoms in elderly patients usually consist of resting tachycardia, wide pulse pressure, exercise intolerance, and dyspnea on exertion. Atrial fibrillation is uncommon but occurs more often in older individuals (5%-15%) (Franklyn and Gammage, 2005). Other cardiovascular effects that affect both young and old patients are decreased peripheral resistance, decreased cardiac filling times, increased blood volume, and fluid retention. Individuals with preexisting coronary artery disease (CAD) may have ischemic congestive heart failure (CHF) as a result of their hypermetabolic state, but this generally improves with appropriate antithyroid therapy. Atrial flutter, paroxysmal supraventricular tachycardia, premature ventricular beats, and ventricular fibrillation are rare as complications of thyrotoxicosis and may be a sign of unsuspected CAD.

Signs and symptoms of CHF are common in both young and old patients with thyrotoxicosis (Trivalle et al., 1996). Because of decreased effective circulating arterial volume, aldosterone secretion increases, with a concomitant increase in sodium retention that results in dependent edema. After thyrotoxicosis is effectively treated, all CHF symptoms quickly resolve. When present, periorbital edema is caused by Graves' disease. TSH-RS Abs needs to be checked.

Apathetic thyrotoxicosis is an uncommon presentation but represents the most common mental disorder associated with excess thyroid hormone production and release. Symptoms include apathy, lethargy, pseudodementia, weight loss, and depressed mood. It usually occurs in older patients without symptoms of tachycardia, hyperphagia, sweating, warm skin, or goiter (Wagle et al., 1998). This syndrome is easily confused with depression or dementia and, unless specifically sought, is easy to miss. A screening sTSH should be included in every depression or dementia workup.

Treatment of thyrotoxicosis is straightforward with three objectives: ameliorate acute symptoms, suppress synthesis and secretion of thyroid hormones, and treat the primary cause to prevent recurrence. Acute symptoms respond readily to beta-receptor blockers, which should be continued until FT₄ levels have returned to the normal range. Calcium channel blockers (CCBs) can be used in patients who cannot tolerate beta blockers. Inhibition of synthesis of thyroid hormones is achieved with PTU or methimazole. Adjunct therapies include fluid resuscitation with 5% dextrose or 10% dextrose in normal saline and administration of steroids. Fever generally responds satisfactorily to acetaminophen. The high fevers associated with thyroid storm may require cooling blankets. Nonsteroidal anti-inflammatory drugs (NSAIDs) and salicylates should be avoided in the acute phase due to competition for thyroid hormone-binding sites on transport proteins. This can cause release of bound thyroid hormone into the peripheral circulation. With aggressive therapy, acute symptoms of thyrotoxicosis should improve within 12 to 24 hours.

Once acute symptoms are controlled, treatment of the primary cause can be considered. This could include watchful waiting in the case of thyroiditis, surgery for an autonomously functioning adenoma, or ¹³¹I in Graves' disease.

Thyroid Storm

Key Points

- Unrecognized thyroid storm has mortality as high as 75%.
- Thyroid storm is usually the result of another disorder that unmasks a preexisting but unidentified hyperthyroid state.
- Thyroid storm is a clinical diagnosis not defined by levels of TSH, T₄, or T₃.
- Suspicion of thyroid storm is a medical emergency with close monitoring (ICU) and appropriate consultation (endocrinologist).

Thyroid storm is a severe variant of thyrotoxicosis in which the metabolic state is sufficiently increased such that organ system failure can occur. It represents a rare complication of thyrotoxicosis and has a mortality rate as high as 75%, depending on how quickly it is recognized and treated (Tiegens and Leinung, 1995; Trzepacz et al., 1989; Wartofsky, 2005). Diagnosis of thyroid storm is based on clinical findings, not measured levels of circulating T₄ or sTSH. Thyroid storm is often precipitated by infection, which can cause symptoms that mask a thyrotoxic state. Clinical findings in thyroid storm include hyperpyrexia (>38.8° C [102° F]), tachycardia out of proportion to temperature, gastrointestinal (GI) dysfunction (nausea, vomiting, diarrhea, jaundice), and CNS dysfunction (marked hyperirritability, anxiety, confusion, apathy, coma) (Wartofsky, 2005). There is usually pronounced decompensation of one or more organ systems. Any patient presenting with goiter, fever, and marked tachycardia should be considered to be in thyroid storm and treated accordingly. Admission to the MICU and consultation with an endocrinologist is appropriate.

Treatment of thyroid storm includes beta blockers, antithyroid drugs, antipyretics, aggressive fluid replacement, and identification and treatment of any precipitating process. For patients with severe symptoms, Lugol's solution or potassium iodide (SSKI) will help inhibit release of T₄ into the peripheral circulation. If either is used, it should only be given after loading doses of antithyroid drugs, to block iodine-induced synthesis of T₄. Lithium also has an antithyroid effect and can be used in severe cases of thyroid storm. Severe thyrotoxic symptoms, unresponsive to all these regimens, may respond to sodium ipodate at 500 mg/day.

Hypothyroidism

Hypothyroidism is a hypometabolic state resulting from levels of circulating thyroid hormone insufficient to meet body requirements. Primary causes are listed in Box 35-4.

Chronic Autoimmune Thyroiditis (Hashimoto's Thyroiditis)

Key Points

- Hashimoto's thyroiditis is an autoimmune disorder that results in fibrosis of the thyroid gland.
- Hashimoto's thyroiditis is the most common cause of hypothyroidism in the United States.
- Diagnosis of Hashimoto's thyroiditis is based on an elevated TSH, low FT₄, and antithyroid peroxidase antibodies (TPO Abs).

Box 35-4 Causes of Hypothyroidism

Insufficient intake of dietary iodine (uncommon in U.S.)
 Autoimmune disease (primarily Hashimoto's thyroiditis)
 Surgery (thyroid surgery)
 Radiation exposure (head and neck)
 Viral infection
 Central disease (primary pituitary failure)

The most common cause of hypothyroidism worldwide is inadequate dietary intake of iodine. Because of the addition of iodine to table salt, however, this is a rare cause in the United States. In the U.S. and the rest of the developed world, the most common cause of hypothyroidism is chronic autoimmune thyroiditis (Hashimoto's disease). CAT is caused by the development of antithyroid antibodies that attack the thyroidal struma, causing progressive fibrosis; TPO Abs and Tg Abs appear to be responsible, with TPO Abs considered the primary cause (Dayan and Daniels, 1996). Diagnosis is based on elevated sTSH (>10.0 mIU/L), low-normal or low FT₄, and presence of TPO Abs.

Hashimoto's thyroiditis occurs most often in women, with a female/male ratio of 10:1 to 14:1. CAT is usually diagnosed in the fifth decade and is progressive (Vanderpump, 2005). As it progresses, more functioning thyroid gland will become fibrotic, and less endogenous T₄ will be produced. After diagnosis, replacement doses of T₄ should be used. In adults, average replacement dose of L-thyroxine is 1.6 µg/kg daily. Serum TSH is followed annually to ensure adequate control.

Other Forms of Hypothyroidism

Central hypothyroidism is caused by pituitary failure and is rare. The diagnosis is suggested with low to nonexistent sTSH levels in a patient without symptoms of hypermetabolism (thyrotoxicosis) and with low circulating FT₄. Generally, when presented with these data, further evaluation to determine the etiology of the hypothyroidism is not necessary. However, the patient should be evaluated for pituitary failure if not already done (see Pituitary Disorders).

Depending on the degree of injury to the thyroid gland, thyroiditis (postpartum, sporadic, and subacute) can result in a transient hypothyroid state, with eventual recovery. Subacute thyroiditis is more likely to undergo this process, with insufficient T₄ production for 3 to 6 months. Treatment is usually unnecessary, but low-dose thyroxine replacement can be used on a temporary basis for patients who become symptomatic.

Other causes of hypothyroidism include dietary iodine deficiency, surgery, ¹³¹I radiation therapy, and nonthyroid head and neck cancer treatment.

Hypothyroidism is typically treated with L-thyroxine replacement alone. However, some believe that patients occasionally have T₄-resistant disease and recommend mixed T₄/T₃ replacement. Although true T₄ resistance is controversial, if a patient receiving replacement T₄ has sTSH in the therapeutic range but continues to complain of hypothyroid symptoms, combination T₄/T₃ can be tried to alleviate these symptoms.

Initial doses of L-thyroxine depend on the patient's age, duration of hypothyroid state, and comorbidities. The starting dose is generally 0.05 mg (50 µg) in a healthy young

adult, with increases of 0.025 to 0.05 mg weekly, depending on clinical response. If the patient becomes tachycardic, is tremulous, or sweats, the increases are reduced to every 2 to 3 weeks. Once the patient is stabilized on 0.1 to 0.125 mg of L-thyroxine daily, further increases are made based on sTSH response. Serum TSH needs to be checked only every 4 to 6 weeks. More frequent testing does not allow sufficient interval for developing homeostasis and can result in overdosing. Once the patient is receiving a steady dose, further treatment is adjusted so that sTSH remains at 0.5 to 4.5 mIU/L (mean, 2.5). Doses of L-thyroxine resulting in sTSH less than 0.1 mIU/L indicate iatrogenic hyperthyroidism and should be avoided.

Thyroiditis

Forms of thyroiditis include postpartum (silent); sporadic, which is a variant of postpartum but outside the postpartum period; subacute (granulomatous); chronic autoimmune (Hashimoto's); and "other," which includes bacterial or pyogenic (Farwell, 2005; Lazarus, 2005). The forms usually encountered in primary care are postpartum, sporadic, and chronic autoimmune, which are all autoimmune diseases, and subacute, which is thought to be viral in etiology.

The mechanism of injury to the thyroid gland is disruption of thyroid architecture caused by lymphocytic infiltration, resulting in leakage of colloid-stored thyroxine into the peripheral circulation. This nonphysiologically triggered leakage of stored T₄ causes a spike in peripheral circulating T₄ and transient hypermetabolic symptoms. Early testing in the disease can demonstrate an elevated FT₄ level, although not necessarily outside the normal range. Depending on duration of the destructive process and degree of injury, sTSH may be normal, low normal, or low. If the cause of this variability is not appreciated, it could lead to the erroneous initial diagnosis of Graves' disease (increased FT₄ and low sTSH). With protracted acute thyroiditis, however, sTSH is not as low as in Graves' disease and TSH-RS Abs titers are low to absent. In addition, patients with acute thyroiditis will lack the optic findings and goiter of Graves' disease.

As a general rule, acute thyroiditis is a short-lived process, with T₄ stores being rapidly depleted. This represents a case of thyrotoxicosis (increased circulating T₄) but not hyperthyroidism (increased production of T₄). Follow-up testing over the next few weeks demonstrates progressively lower T₄ levels, which eventually return to normal. As T₄ levels return to normal (and below), the acute hypermetabolic symptoms will begin to decline. Duration of T₄ elevation determines how low the sTSH value will go and how quickly it will return to normal.

Subclinical Thyroid Disease**Key Points**

- Subclinical thyroid disease is based on TSH levels only marginally outside the normal reference ranges in an asymptomatic patient with normal FT₄.
- Screening for subclinical thyroid disease is *not* recommended by the American Association of Clinical Endocrinologists (AACE), U.S. Preventive Services Task Force (USPSTF), or American Academy of Family Physicians (AAFP).

- The American Thyroid Association (ATA) recommends screening all adults for thyroid disorder beginning at age 35 and then every 5 years.
- Treatment of subclinical hyperthyroid disease is not recommended, although follow-up should occur every 6 months.
- Treatment of subclinical hypothyroid disease is recommended by the American College of Physicians (ACP) for women over 50 with symptoms consistent with hypothyroidism.

Discussion about subclinical thyroid disease has focused on whether it is a real clinical entity. Subclinical thyroid diseases are defined as (1) subclinical hyperthyroidism (or subclinical thyrotoxicosis) with sTSH less than 0.1 mIU/L and normal circulating FT₄ and FT₃ or (2) subclinical hypothyroidism with sTSH greater than 4.5 mIU/L but less than 10.0 mIU/L with normal circulating FT₄. Both entities assume a patient who is asymptomatic or has minimal signs and symptoms (Ross, 2005a, 2005b).

The primary question concerning subclinical thyroid disease is whether early intervention is beneficial and patients should be screened. The only disease state that has been directly related to subclinical thyroid disease is overt hypothyroidism. Individuals with subclinical hypothyroidism have a higher incidence of progression to overt hypothyroidism than the general population. Annually, 3% to 5% of patients identified with subclinical hypothyroidism will progress to overt hypothyroidism with sTSH levels over 10.0 mIU/L (Toft and Beckett, 2005). The majority of these represent early CAT (Hashimoto's thyroiditis). Currently, no consensus exists among national organizations as to whether these patients should start therapy during this phase of their disease. Treating those with symptoms seems appropriate, but there is no evidence to support the premise that early treatment alters the disease course or associated comorbidities (hyperlipidemia, hypertension, CAD) (Helfand, 2004).

Studies demonstrate a two to three times higher incidence of atrial fibrillation in patients with subclinical hyperthyroidism compared to individuals with normal sTSH levels (Ross, 2005b). The Framingham data suggest some individuals with subclinical hyperthyroidism are at increased risk of paroxysmal atrial fibrillation (Oiknine and Mooradian, 2006). However, no data support early intervention. Osteoporosis is associated with overt hyperthyroidism, and some speculate that treating subclinical hyperthyroidism may prevent or delay this process. The American Association of Clinical Endocrinologists (AACE, 2002) recommends treatment of subclinical hyperthyroidism caused by nodular thyroid disease.

Anatomic Diseases

Anatomic diseases of the thyroid gland include a number of primary and secondary disorders (Box 35-5). The list includes goiter, nodules, primary neoplasia, metastatic neoplasia (rare), and familial disorders.

Goiter

Goiter is the most common anatomic disease, and the major cause of goiter worldwide is iodine deficiency. When simple goiter occurs in areas of adequate iodine intake, there appears to be a strong genetic component to the disease. In the United States, goiter is usually associated with CAT

Box 35-5 Anatomic Diseases of Thyroid

Goiter: Simple, toxic, iodine deficiency

Nodule: Adenoma, incidental, toxic

Cyst: Simple, complex

Malignancy

Primary: Papillary/follicular, medullary, lymphoma

Metastatic: Lymphoma, breast, pulmonary, other

Familial: Multiple endocrine neoplasia type IIA (MEN-IIA)

Familial medullary carcinoma of thyroid (FMCT)

(Hashimoto's thyroiditis) as the disease progresses to a hypothyroid state. Goiter is the result of both hypertrophy and hyperplasia of the thyroid gland. In the case of iodine deficiency, this is caused by excess thyrotropin production, leading to glandular growth and colloid production.

In Graves' disease, stimulation of the thyroid by TSH-RS Abs causes excess production of T₄ and T₃, in turn resulting in uncontrolled production of colloid to store the excess production of thyroid hormone. In fact, goiter is the most common clinical finding in Graves' disease after thyrotoxicosis, occurring in almost 100% of patients (Chiovato et al., 2001). Goiter is one of the five hallmarks of Graves' disease. Goiter, associated with hypothyroidism, will often improve once euthyroid doses of thyroxine have been achieved, although it may take 6 months to 1 year. If the goiter does not involute with thyroxine replacement, excision may be required. Besides goiter, the other four hallmarks of Graves' disease are thyrotoxicosis, ophthalmopathy, local myxedema, and acropachy (clubbing of fingers and toes).

Nodules and Cysts

Thyroid nodules come in a variety of sizes and types. The incidence of malignancy in nodules less than 1.0 cm, which are found incidentally during nonthyroid-related diagnostic procedures (e.g., head and neck ultrasonography), is less than 0.5%. Current recommendations for evaluation of incidentalomas include a sTSH and FT₄ and careful palpation of the thyroid gland (Cooper et al., 2009). If tests and palpation are normal, only annual follow-up with palpation by the physician is recommended. As long as growth remains minimal, and there are no ultrasonographic hallmarks of malignancy on the initial scan, these nodules can be monitored clinically. Exceptions might include patients with a family history of thyroid cancer, personal history of head and neck radiation, primary malignancy in another part of the body, or rapid growth.

A palpable thyroid mass requires evaluation. If the sTSH is within normal range, and a local endocrinologist experienced in FNA is available, referral without imaging is appropriate. If the patient has a suppressed sTSH, however, the nodule may be functioning autonomously. Before any intervention (surgical or FNA), a radioisotope ¹²³I scan is indicated. If the lesion is "hot," suppression is the course of action. If "cold," this could represent a cystic, mixed, or solid mass requiring further evaluation by FNA (first choice) or surgical exploration (Fig. 35-2).

Benign nodules do not require therapeutic intervention. If the nodule is large, a trial of thyroxine to decrease its size is

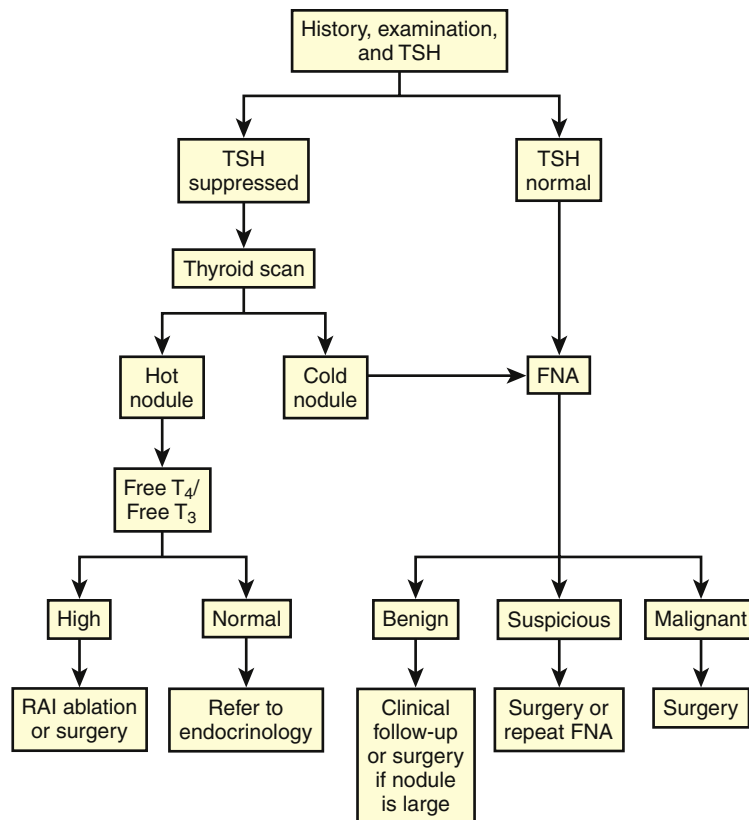

Figure 35-2 Algorithm for clinical evaluation of thyroid nodule.

appropriate but generally ineffective. If the nodule's size is causing symptoms (tracheal compression or pain), excision is the treatment of choice.

Malignancy

Malignancy of the thyroid, both primary and secondary, is rare, accounting for less than 2% of all cancers, and generally, tumors are not aggressive. *Papillary carcinoma* is the most common, accounting for approximately 80% of primary thyroid malignancies. Follicular carcinoma, which arises from the same cell type as papillary carcinoma, accounts for about 5% of thyroid neoplasia. Undifferentiated and anaplastic carcinoma makes up less than 10% of all thyroid malignancies and medullary carcinoma of the thyroid about 5% (Baloch and Livolsi, 2005). The most common cancers that metastasize to the thyroid are breast, lung, and kidney. Primary lymphoid cancer occurs in the thyroid, but its incidence is unknown since it cannot be distinguished from lymphoma that originates elsewhere in the body. Treatment of thyroid cancers is generally surgical with ^{131}I therapy after near-total thyroidectomy. As with cancer elsewhere in the body, primary treatment will depend on tissue diagnosis and clinical evaluation.

Two familial thyroid malignancies are multiple endocrine neoplasia type IIA (MEN-IIA) and familial medullary thyroid carcinoma (FMTC). MEN-IIA is an autosomal dominant disorder that can cause "C" cell hyperplasia and hyperparathyroidism. Diagnosis is often serendipitously found during evaluation for hypercalcemia or renal calculi.

Nodules less than 1.0 cm usually do not require FNA, but any solitary nodule occurring before 14 years of age is an exception, with greater than 50% incidence of malignancy.

Long-Term Follow-up of Thyroid Disorders

For patients receiving long-term thyroid therapy for hypothyroidism, monitoring is through sTSH unless there is hypothalamic-pituitary disease. It takes 2 to 4 weeks after initiating treatment (or changing dose) before clinically significant change occurs in sTSH level. In most patients, checking sTSH once monthly is sufficient until steady state is reached. After the patient is stabilized, sTSH can be checked annually unless the patient develops new symptoms or dosing changes.

Patients with benign nodules should be followed annually with careful palpation of the thyroid gland. Unless there is a change in size, no additional testing is required. Ultrasound of the thyroid is not recommended for follow-up of nodules less than 1.0 cm. Repeat ultrasound is required in patients with an enlarging nodule, evidence of a new thyroid mass, or who complain of pain or pressure. Unless the patient is experiencing symptoms of hyperthyroid or hypothyroid, repeat testing of sTSH or FT₄ is not indicated.

Sick Euthyroid Syndrome (Thyroid Hormone Adaptation Syndrome)

Thyroid function can be suppressed during severe illness and may not represent abnormal thyroid function. Serious illness has been shown to affect laboratory tests of thyroid function

(sTSH, T_4 , thyroglobulin), but there is no clear evidence this reflects a disease state (Chopra, 1997). Because these changes appear to have no direct adverse effect on the patient's overall clinical state, this condition is labeled "sick euthyroid syndrome." In broad terms, sick euthyroid syndrome is more of academic interest than clinical. Administration of T_4 to a seriously ill individual does not improve outcome for most patients, although evidence suggests that high doses of T_3 immediately after cardiac surgery may be beneficial (Wiersinga, 2005). The physician should remember the rare patient whose thyroid disease is uncovered by serious illness. If a seriously ill patient is not responding as expected (e.g., difficulty in weaning from ventilator support), checking thyroid function may be appropriate, although any interpretation of results should be reviewed by a clinician experienced in interpreting thyroid tests in seriously ill patients before intervention. Patients with preexisting thyroid dysfunction will continue to require thyroid therapy during a severe illness. However, individuals who were euthyroid at presentation generally do not require or improve with thyroid replacement therapy.

Drugs Affecting Thyroid Function and Testing

Key Points

- Therapeutic drugs have a variety of effects on thyroid function, including delayed or suppressed synthesis.
- Therapeutic drugs may block the effect of thyroid hormone at the cellular level.
- Phenothiazines, dopamine, phenytoin, and glucocorticoids block release of TSH from the pituitary.
- Amiodarone can cause both hyperthyroidism and hypothyroidism. In the United States, because of generally adequate dietary iodine, amiodarone causes a hypothyroid state.

Many common drugs can affect thyroid function, bioavailability of thyroid hormone, and laboratory testing. Drugs that affect thyroid function fall into several categories; some inhibit synthesis of T_4 , some block secretion of T_4 , some block TSH release, some affect extrathyroidal conversion of T_4 to T_3 , and some influence thyroxine at the tissue/cellular level. PTU and methimazole (MMI) inhibit thyroid hormone synthesis by interfering with thyroid peroxidase. PTU has the added advantage of inhibiting extrathyroidal conversion of T_4 to T_3 . Neither PTU nor MMI inhibits T_4 release (secretion) from the thyroid gland.

Amiodarone, lithium, and cytokines can affect synthesis and secretion. In the absence of iodine, amiodarone can precipitate both hyperthyroid and hypothyroid events. In the United States, where dietary iodine is plentiful, patients taking amiodarone tend to develop hypothyroidism from fibrosis of the thyroid gland. The incidence is approximately 20% (Harjai and Licata 1997; Roti and Vagenakis, 2005). Patients taking these drugs, especially amiodarone, should be screened regularly with sTSH for developing thyroid dysfunction. Dopamine, glucocorticoids, and phenytoin inhibit release of TSH from the anterior pituitary. Salicylates and other NSAIDs, furosemide, heparin, and enoxaparin compete for binding sites on thyroid hormone transport proteins. Use of these drugs in acute thyroid disease can potentially

Table 35-2 Drugs that Affect Thyroid Function at Glandular Level

| Drug | Inhibits T_4 Synthesis | Blocks T_4 Secretion | Blocks TSH Release |

T₄, Thyroxine; *TSH*, thyroid-stimulating hormone (thyrotropin).

exacerbate thyrotoxic symptoms by releasing thyroid hormone into the peripheral circulation. TSH and FT_4 should be monitored in regular users of these medications (Table 35-2).

Phenytoin, phenobarbital, carbamazepine, and rifampin stimulate hepatic enzymatic activity, thus shortening thyroid hormone clearance times and increasing conversion of T_4 to T_3 . Serum TSH levels should be monitored routinely, until stable, when these medications are added or deleted from a patient's regimen. Sucralfate, cholestyramine, calcium carbonate, aluminum hydroxide, soy products, and ferrous sulfate inhibit absorption of exogenous L-thyroxine from the gut. Again, oral L-thyroxine should be taken on an empty stomach.

Beta blockers exert their effect on thyroid hormones at the cellular level, and benzodiazepines block T_3 uptake at the cellular level (Wartofsky, 2005; Tiegens and Leinung, 1995; Hedley et al., 1989). Calcium channel-blocking agents inhibit uptake of thyroid hormone by hepatic and muscle cells (Table 35-3).

Thyroid Disease in Pregnancy

Pregnancy can exacerbate an already-existing thyroid disorder, thus requiring extra vigilance by the family physician. Careful monitoring and proactive clinical intervention are key. The majority of women with hypothyroidism, who are euthyroid on stable doses of thyroid replacement, will require increased doses of thyroxine replacement during their pregnancy. Being aware of this need and prepared to make dosage adjustments in a timely manner is important. Consulting an endocrinologist to help with the care of these patients is advised (Shankar et al., 2001).

Silent (postpartum) thyroiditis during pregnancy is essentially a benign, short-term disease and requires only symptomatic treatment. Occasional checks of sTSH and FT_4 levels are justified to monitor recovery.

Table 35-3 Drugs that Affect Thyroid Function at the Peripheral Level

| Drugs | Compete for Protein Binding | Inhibit Deiodination of T ₄ to T ₃ | Inhibit Action at Tissue Level | Inhibit Uptake of T ₃ at Tissue Level | Affect Thyroid Hormone Clearance Time | Inhibit GI Absorption | Adverse Effect on Lab Tests |

GI, Gastrointestinal; NSAID, nonsteroidal anti-inflammatory drug; Al, aluminum; Ca, calcium; PTU, propylthiouracil; CCB, calcium channel blocker.

For the rare pregnant patient who requires suppression of T₄ synthesis, judicious use of antithyroid drugs (PTU and MMI) is generally considered safe. There is some concern that MMI may cross the placental barrier more readily than PTU, but this has not proved to be a concern in the clinical setting. It is important, however, to remember that prolonged suppression of the thyroid, or suppression late in pregnancy, can result in a transient depression of neonatal thyroid function and may induce goiters in the neonate. PTU and MMI can be found in breast milk. This has not been of concern as long as the dose is kept low. PTU (maximum, 150 mg/day) and MMI (maximum, 20 mg/day) caused no problems with a nursing child (Glinoe, 2005). Both PTU and MMI are category D pregnancy risk; the American Academy of Pediatrics reports no sign or symptom in infants of adverse effects on lactation and supports use of drugs during breastfeeding. In the United States, PTU has generally been the antithyroid drug

of choice in pregnant and nursing women, although in June 2009 the FDA issued a MedWatch warning for PTU concerning reports of hepatotoxicity, which may change this pattern.

Screening for Thyroid Disease

Screening for asymptomatic thyroid disease is controversial, although screening in specific populations may be beneficial. Women over age 50 have the highest incidence of spontaneous hypothyroidism compared with all males and mixed younger populations, approaching 5% per year. Thus, screening has a good chance of finding disease early. However, the evidence supporting benefit from early intervention is weak and probably does not justify cost. Patients who present with paroxysmal atrial fibrillation should be routinely screened for hyperthyroidism, although the incidence of positive findings is low (AACE, 2002).

One area where screening is advantageous is patients with newly diagnosed dementia. This is especially true if the clinical course is atypical or accelerated. Both hypothyroidism (myxedema) and hyperthyroidism (apathetic thyrotoxicosis) can present with dementia-like symptoms, and in these patients, timely intervention can completely reverse the signs and symptoms of dementia or depression caused by thyroid dysfunction. If screening is undertaken, the test of choice is sTSH. When coupled with FT₄, the vast majority of clinically significant hyperthyroidism and hypothyroidism can be diagnosed. If symptoms are present, or there are overt signs of disease, the initial testing should include sTSH, FT₄, and FT₃. Thyroid panels providing T₄, T₃, T₇, FT₄ index, and T₃ uptake are no longer advocated (AAFP, 2009; Helfand, 2004; Ladenson et al., 2000).

KEY TREATMENT

Thyrotoxicosis is treated initially with beta blockers and antithyroid medication to control symptoms and stop synthesis/release of thyroid hormone into the peripheral circulation (Oiknine et al., 2006; Trivalle et al., 1996) (SOR: A).

Hypothyroid (TSH >10 mIU/L) replacement T₄ dose is approximately 1.6 µg/kg/day (Oiknine et al., 2006) (SOR: A).

With the exception of thyroid antibody-positive subclinical hypothyroidism, prophylactic treatment has not shown positive effect on lipids or CAD risk (Helfand, 2004) (SOR: A).

Subclinical hyperthyroidism should be treated when caused by nodular thyroid disease (ACCE, 2002) (SOR: B).

Adrenal Glands

The adrenal glands are located at the superomedial aspects of the kidneys. The glands consist of two endocrine tissues of different embryologic origin: the primarily steroid-producing adrenocortical tissue in the cortex and the catecholamine-producing chromaffin cells in the medulla. The adrenal cortex consists of three zones that vary in both morphologic features and hormones produced. The outer *zona glomerulosa* is the unique source of the mineralocorticoid aldosterone. The intermediate *zona fasciculata* and the inner *zona reticularis* produce the glucocorticoids cortisol and corticosterone and the androgens dehydroepiandrosterone (DHEA) and DHEA sulfate. The chromaffin cells in the adrenal medulla mainly secrete the catecholamines epinephrine and norepinephrine (Williams and Dluhy, 2008) (Box 35-6).

Mineralocorticoids are major regulators of extracellular fluid volume and potassium metabolism. Volume is regulated through a direct effect on the collecting duct of the kidney, where aldosterone causes an increase in sodium retention and in potassium excretion. The release of aldosterone is regulated by the renin-angiotensin system, plasma potassium levels, and adrenocorticotropic hormone (ACTH). The renin-angiotensin system maintains the circulating blood volume constant by regulating aldosterone secretion. Aldosterone-induced sodium retention occurs in volume deficiency states, but the aldosterone-dependent sodium retention is reduced when volume is ample. An increase in plasma potassium or a decrease in plasma sodium stimulates aldosterone release. ACTH stimulates mineralocorticoid output, but this effect on aldosterone secretion is transient.

Medulla

Epinephrine

Norepinephrine

Dopamine

The release of *cortisol*, the main glucocorticoid in humans, is pulsatile and is directly stimulated by ACTH or its precursors, such as pro-opiomelanocortin. The release of ACTH from the anterior pituitary is regulated by corticotropin-releasing hormone (CRH) produced by the hypothalamus. High cortisol levels inhibit the biosynthesis and secretion of CRH and ACTH through a negative-feedback mechanism. Cortisol release follows a circadian rhythm, with its highest level in the morning, and is sensitive to light, sleep, stress and disease. The glucocorticoid effects are multisystemic. They stimulate proteolysis and gluconeogenesis, inhibit muscle protein synthesis, and increase fatty acid mobilization. Gluconeogenesis results in the increase of blood glucose concentrations. At high levels, glucocorticoids are catabolic and result in loss of lean body mass. Glucocorticoids modulate the immune response through their anti-inflammatory effects, and modulate perception and emotion in the CNS.

The production of the adrenal androgens is controlled by ACTH, not by gonadotropins. Among the adrenal androgens, DHEA is the most abundant circulating hormone in the body and is readily conjugated to its sulfate ester DHEA-S. The adrenal androgens are converted into androstenedione and subsequently into potent androgens (testosterone) or estrogens (estradiol) in the peripheral tissues. The adrenal secretion of DHEA and DHEA-S increases in children at age 6 to 8 years and peaks at 20 to 30 years. However, the production of DHEA-S by the adrenal glands is reduced by 70% to 95% during the aging process; at age 70, serum DHEA-S levels are at approximately 20% of their peak values and continue to decrease with age. Adrenal androgens have minimal effects in males whose sexual characteristics are predominantly determined by gonadal steroids (testosterone). In females, adrenal-derived testosterone is important in maintaining pubic and axillary hair. Adrenal androgen hypersecretion in adult males causes no clinical signs but in females manifests with signs of hirsutism and masculinization.

The adrenal medulla secretes epinephrine, norepinephrine, and dopamine. Most catecholamine output in the adrenal vein is epinephrine; norepinephrine also enters the circulation from noradrenergic nerve endings. In emergency

situations, secretion of adrenal catecholamines is increased to prepare the individual for stress (“fight or flight” response). Hypoglycemia and certain drugs are also potent stimuli to catecholamine secretion.

Disorders of Cortical Hypofunction

Primary Adrenal Insufficiency

Key Points

- Primary adrenal insufficiency is defined as the failure of the adrenal cortex to produce glucocorticoids and mineralocorticoids.
- The most frequent cause of primary adrenal insufficiency is autoimmune. In the developing world, however, tuberculosis remains the most common cause.
- Symptoms are usually insidious, including fatigue, orthostatic hypotension, weight loss, and hyperpigmentation.
- Acute adrenal insufficiency should be considered in critically ill patients with unexplained hypotension.
- A baseline cortisol and ACTH level followed by an ACTH stimulation test can establish diagnosis.
- Detection of adrenal cortex antibodies or 21-hydroxylase autoantibodies supports the diagnosis of autoimmune adrenalitis. Abdominal CT may be helpful if other causes are suspected.

Primary adrenal insufficiency (AI) is defined as the failure of the adrenal cortex to produce adequate amounts of glucocorticoids and mineralocorticoids. Primary AI can result from processes that damage the adrenal glands or from drugs (ketoconazole, etomidate) that block the synthesis of cortisol. All causes of primary AI involve the adrenal cortex as a whole and result in a deficiency of cortisol and aldosterone (plus adrenal androgen), although the severity of the deficiencies may vary. An exception is the *syndrome of isolated glucocorticoid deficiency*. The reported prevalence of primary AI (Addison’s disease) in developed countries is 39 to 60 per 1 million population. In adult patients, mean age at diagnosis is 40 years (range, 17-72).

The most frequent cause of primary AI in developed countries is *autoimmune adrenalitis*. However, in the developing world, tuberculosis remains the most common cause of adrenal failure. Autoimmune adrenalitis is sometimes accompanied by other autoimmune endocrine deficiencies (autoimmune polyglandular syndromes, APS). The adult form (type II, Schmidt’s syndrome) of polyglandular syndrome consists mainly of AI, autoimmune thyroid disease, and insulin-dependent (type 1) diabetes mellitus. Several infectious processes associated with acquired immunodeficiency syndrome (AIDS) such as cytomegalovirus (CMV), *Mycobacterium tuberculosis*, *Cryptococcus neoformans*, *Mycobacterium avium intracellulare*, *Histoplasma capsulatum*, and Kaposi’s sarcoma, may damage the adrenal gland and lead to insufficiency. In young males, adrenoleukodystrophy (or the less severe adrenomyeloneuropathy), an X-linked recessive disorder of metabolism of long-chain fatty acids, can cause spastic paralysis and adrenal insufficiency. AI can precede neurologic symptoms and should prompt the clinician to perform careful neurologic examination in young males with primary AI. Other causes are listed in Box 35-7.

Box 35-7 Causes of Primary Adrenal Insufficiency

Autoimmune

Isolated adrenal insufficiency (Addison’s disease)
Polyglandular autoimmune syndrome types I and II

Infectious

Tuberculosis
Fungal
 Histoplasmosis
 Paracoccidioidomycosis
HIV/AIDS
Cytomegalovirus
Syphilis
African trypanosomiasis

Vascular

Bilateral adrenal hemorrhage
Sepsis (Waterhouse-Friderichsen syndrome)
Coagulopathy
Thrombosis, embolism
Infarction

Infiltrative

Metastatic carcinoma (most often lung, breast, stomach, colon)
Lymphoma
Sarcoidosis
Amyloidosis
Hemochromatosis

Congenital

Congenital adrenal hyperplasia
 21 α -Hydroxylase deficiency
 11 β -Hydroxylase deficiency
 3 β -ol-Dehydrogenase deficiency
 20,22-Desmolase deficiency
Familial adrenocorticotrophic hormone resistance syndromes
Familial glucocorticoid deficiency
Adrenoleukodystrophy
Adrenomyeloneuropathy
Adrenal hypoplasia

Iatrogenic

Bilateral adrenalectomy
Anticoagulation therapy
Drugs
 Adrenolytic: mitotane, aminoglutethimide, metyrapone, trilostane
 Other: ketoconazole, rifampin, etomidate, phenytoin, barbiturates, megestrol acetate

Chronic (Primary) Adrenal Insufficiency

Most of the symptoms are nonspecific and occur insidiously. Chronic AI manifestations include weakness, chronic fatigue, anorexia, unintentional weight loss, listlessness, joint pain, and orthostatic hypotension. Some patients may initially present with GI symptoms (abdominal pain, nausea, vomiting, diarrhea), whereas others may present with symptoms that can be attributed to depression or anorexia nervosa. In contrast to secondary AI, primary AI is often

associated with lack of aldosterone as well as cortisol. Thus, signs of mineralocorticoid deficiency (salt craving, postural hypotension, electrolyte abnormalities) are usually indicative of primary AI. The most specific sign of primary AI is *hyperpigmentation* of the skin and mucosal surfaces, which results from the melanocyte-stimulating activity of β -lipotropin derived from the same precursor as ACTH. Patients with autoimmune adrenalitis present with vitiligo, Hashimoto's thyroiditis (70% in APS-II), type 1 diabetes, and pernicious anemia. Thinning or loss of pubic and axillary hair may occur in women as a result of lack of androgen production by the adrenal cortex. Both systolic and diastolic blood pressure (BP) are usually reduced (systolic BP <110 mm Hg).

Acute (Primary) Adrenal Insufficiency

In critically ill patients, it is crucial to consider the possibility of adrenal insufficiency. AI should be suspected in the presence of unexplained catecholamine-resistant hypotension, especially if the patient has pallor, hyperpigmentation, vitiligo, scanty axillary and pubic hair, hyponatremia, or hyperkalemia. Furthermore, AI due to adrenal hemorrhage and adrenal vein thrombosis should be considered in a severely ill patient with abdominal pain or rigidity, vomiting, confusion, and arterial hypotension. In acutely ill patients, plasma cortisol level greater than 25 g/dL rules out adrenal insufficiency, but a level in the normal range does not; further testing may be required.

Laboratory Evaluation

Patients with adrenal insufficiency present with hyponatremia (frequent), hyperkalemia, acidosis, mild elevation of plasma creatinine concentrations, hypoglycemia, hypercalcemia (rare), mild normocytic anemia, lymphocytosis, and mild eosinophilia. In addition, hormone levels are useful in diagnosis. A random measurement of serum cortisol level is usually inadequate to assess adrenal function because of the pulsatile and diurnal variation of cortisol secretion. However, a morning cortisol level (8-9 AM) of 3 μ g/dL or less indicates primary AI and obviates the need for further tests; a level of 19 μ g/dL or greater rules AI out; patients with levels of 3 to 19 μ g/dL need further testing. If primary AI is suspected, basal ACTH and cortisol levels should be measured, followed by a short ACTH stimulation test. For testing, synthetic ACTH (cosyntropin) is given IV or IM at 250 μ g and serum cortisol is measured 60 minutes after injection. A normal response to this test (cortisol 20 μ g/dL or higher) excludes primary AI. In patients with severe secondary AI, plasma cortisol increases little or not at all after the administration of cosyntropin because of adrenocortical atrophy.

Detection of adrenocortical antibodies or 21-hydroxylase autoantibodies supports the diagnosis of autoimmune adrenalitis. Antibodies against other endocrine glands are common in patients with autoimmune AI, and evaluation might be warranted. However, the incidence of antiadrenal antibodies in serum from patients with normal adrenal function who have other autoimmune endocrine diseases is low (2%), with the exception of those with hypoparathyroidism (16%). Abdominal CT scan may be helpful if infection, hemorrhage, infiltration, or neoplastic disease is suspected.

Treatment

In chronic AI, any underlying cause, such as infection or malignancy, should be treated. Glucocorticoid replacement is usually required for symptomatic patients and is given in two or three daily doses with half to two thirds of the daily dose given in the morning to mimic the physiologic daily pattern of cortisol secretion. Hydrocortisone (15-25 mg/day) or cortisone acetate (25-37.5 mg/day) is preferred because of its mineralocorticoid action and shorter biologic half-life, which prevents unfavorably high nighttime glucocorticoid activity. The goal is to use the smallest dose that relieves the patient's symptoms to prevent side effects from steroid use, such as weight gain and osteoporosis. Because a reliable marker of glucocorticoid action is lacking, clinical judgment and careful assessment of clinical signs and symptoms guide treatment.

In patients with primary AI, mineralocorticoid replacement is necessary and is attained by fludrocortisone, in a single daily dose of 0.05 to 0.2 mg, as a substitute for aldosterone. The dose can be adjusted based on measurements of BP, serum sodium and potassium, and renin activity (aiming at concentrations within the middle or upper-normal range). All patients should carry a card or wear a medical alert bracelet or necklace with information on current treatment and recommendations in emergency situations. Patients should be advised to double or triple the dose of hydrocortisone temporarily when they have a febrile illness or injury. In addition, they should be given ampules of glucocorticoid for self-injection or glucocorticoid suppositories to be used in case of vomiting.

Secondary and Tertiary Adrenal Insufficiency

Key Points

- Secondary adrenal insufficiency results from ACTH deficiency and is often seen in panhypopituitarism or after chronic glucocorticoid excess.
- Lack of production of CRH from the hypothalamus results in tertiary adrenal insufficiency.
- In secondary adrenal insufficiency, mineralocorticoid production is maintained by the renin-angiotensin system. Thus, hyperkalemia is absent while hyponatremia may result from loss of glucocorticoid effect on free-water clearance.
- Low ACTH and cortisol levels suggest secondary or tertiary adrenal insufficiency.

Secondary adrenal insufficiency is defined as a deficiency of ACTH. Isolated ACTH deficiency is rare and may be congenital or caused by lymphocytic hypophysitis. Secondary AI more often occurs in the setting of panhypopituitarism from underlying causes such as pituitary or metastatic tumors, craniopharyngioma, infections (TB, histoplasmosis), infiltrative disease (sarcoidosis), head trauma, or postpartum pituitary necrosis (Sheehan's syndrome). Chronic glucocorticoid excess, either exogenous (glucocorticoid treatment for more than 4 weeks) or endogenous (Cushing's syndrome), causes secondary AI by prolonged suppression of CRH production. Tertiary adrenal insufficiency results from the lack of CRH production from the hypothalamus.

Clinical Presentation

Signs and symptoms are similar to those of primary AI, but electrolyte and fluid abnormalities and hypotensive symptoms are absent because the mineralocorticoid production is still maintained by the renin-angiotensin system. Hyperpigmentation is not seen. Menstrual dysfunction, headache and visual symptoms, hypothyroidism, and diabetes insipidus may be present as a result of panhypopituitarism (see Pituitary Disorders).

Laboratory Evaluation

Plasma cortisol and ACTH levels should be checked initially. Low ACTH (<5 pg/mL) and cortisol levels suggest secondary or tertiary adrenal insufficiency, and pituitary CT or MRI is indicated. The cosyntropin stimulation test may be helpful in identifying adrenal insufficiency. With an abnormal result, ACTH level may determine primary (high ACTH) versus secondary (normal or low ACTH) disease. However, in secondary AI the ACTH-stimulation test might not be abnormal because sufficient ACTH might be present to prevent adrenal gland atrophy. In these patients, CRH stimulation test can assess ACTH response. Secondary AI shows little or no increase in the ACTH or cortisol level throughout the test, but in tertiary AI the ACTH increases in an exaggerated fashion and remains elevated longer. The insulin tolerance test and the metyrapone test are also available (but less often used) to assess the integrity of the hypothalamic-pituitary-adrenal (HPA) axis by its response to hypoglycemia or the inhibited cortisol synthesis, respectively.

Treatment

As described in primary AI, treatment of underlying disorders and glucocorticoid replacement are necessary in secondary and tertiary AI, but not mineralocorticoid replacement.

Isolated Aldosterone Deficiency

See the discussion online at www.expertconsult.com.

Disorders of Cortical Hyperfunction: Hypercortisolism

Cushing's Syndrome

Key Points

- Cushing's syndrome results from chronic exposure to excessive levels of glucocorticoids.
- Cushing's syndrome may be ACTH dependent (pituitary or ectopic tumors) or ACTH independent (exogenous glucocorticoids).
- Reddish purple striae, plethora, proximal muscle weakness, easy bruising, and unexplained osteoporosis are discriminatory symptoms.
- CT or MRI of the adrenals may differentiate between the various types of ACTH-independent Cushing's syndrome.

Cushing's syndrome is a group of signs and symptoms that result from prolonged and inappropriately high exposure of tissue to glucocorticoids. Excess cortisol production is the hallmark of endogenous Cushing's syndrome and may result from excess ACTH secretion from the pituitary

(Cushing's disease) or from ectopic tumors secreting ACTH or CRH. ACTH-independent adrenal production of cortisol is caused by adrenocortical tumors or hyperplasias. However, the most common cause of Cushing's syndrome is *iatrogenic* from exogenous glucocorticoid administration. Certain psychiatric disorders (anxiety, depression), poorly controlled diabetes, and alcoholism can be associated with mild hypercortisolism and may produce results suggestive of Cushing's syndrome (Nieman et al., 2009).

Clinical Presentation

Although Cushing's syndrome might be easy to diagnose when full blown, the diagnosis can be challenging in mild cases. The spectrum of clinical presentation is broad. Some discriminatory symptoms include reddish purple striae, plethora, proximal muscle weakness, bruising without any obvious trauma, and unexplained osteoporosis. More often, patients present with features caused by cortisol excess, such as obesity, depression, diabetes, hypertension, or menstrual irregularity. Dorsocervical fat pad (buffalo hump), facial and supraclavicular fullness, thin skin, peripheral edema, hirsutism or female balding, and poor skin healing are typically seen in Cushing's syndrome. Children usually have slow growth, abnormal genital virilization, short stature, and pseudoprecocious or delayed puberty.

Laboratory Evaluation

Before the diagnosis of Cushing's syndrome is considered, exogenous intake of glucocorticoids should be excluded. According to the 2008 Endocrine Society Clinical Practice Guidelines, tests to consider for diagnosis include urine free cortisol (UFC), late-night salivary cortisol, 1-mg overnight dexamethasone suppression test (DST), or the longer, low-dose DST (2 mg/day for 48 hours). UFC and salivary cortisol should be obtained at least twice. The diagnosis of Cushing's syndrome is made if two tests are unequivocally abnormal. The diagnostic accuracy of other tests previously used, such as random cortisol levels, is too low to recommend them for testing (Fig. 35-3).

The UFC provides an integrated assessment of cortisol secretion over 24 hours and measures the cortisol not bound to cortisol-binding globulin (CBG). Unlike serum cortisol, which measures both free and CBG-bound cortisol, UFC is not affected by conditions and medications that alter CBG. A 24-hour urine cortisol secretion or an overnight urine sample (10 PM to 8 AM) can be ordered in conjunction with urine creatinine to ensure accuracy of the results. UFC reflects renal filtration, and values are significantly lower in moderate to severe renal impairment. A patient can be assumed to have Cushing's syndrome if basal urinary cortisol secretion is more than three times the upper limit of normal and one other test is abnormal. However, UFC may be normal in patients with mild Cushing's syndrome, in whom salivary cortisol may be more useful.

Late-night salivary cortisol is usually measured at bedtime or between 11 PM and 12 AM as the loss of circadian rhythm, with absence of a late-night cortisol nadir, is a consistent biochemical abnormality with Cushing's syndrome. The active free cortisol in the blood is in equilibrium with cortisol in the saliva, and the concentration of salivary cortisol does not appear to be affected by the rate of saliva production. Overall in adults, the accuracy of the test is similar to that of UFC.

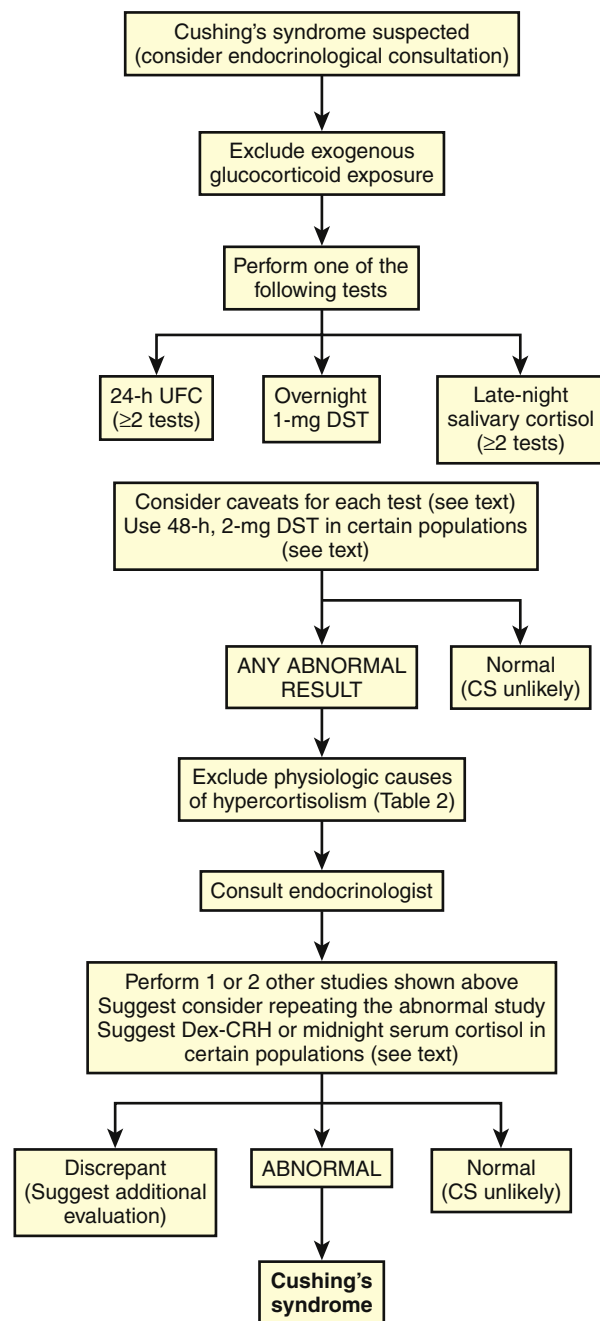

Figure 35-3 Clinical approach to a patient with suspected Cushing's syndrome. (Courtesy The Endocrine Society.)

Various protocols have been used for the DST but most often, 1 mg of dexamethasone is given between 11 PM and 12 AM and cortisol measured between 8 and 9 AM the following morning. In patients with endogenous Cushing's syndrome, a low dose of dexamethasone fails to suppress ACTH and cortisol secretion. A normal response is a serum cortisol of 5 µg/dL or less. To enhance DST sensitivity, experts advocate requiring a lower cutoff for suppression of the serum cortisol to 1.8 µg/dL or less to achieve sensitivity rates greater than 95%.

Some endocrinologists prefer to use the 48-hour, 2-mg/day, low-dose DST (LDDST) as an initial test because of its improved specificity compared with the 1-mg test. LDDST

may be helpful in conditions with overactivation of the HPA axis but without true Cushing's syndrome, such as in certain psychiatric disorders, obesity, and alcoholism. Dexamethasone is given in doses of 0.5 mg every 6 hours for 48 hours, beginning at 9 AM on day 1, at 6-hour intervals (at 9 AM, 3 PM, 9 PM, and 3 AM). Serum cortisol is measured at 9 AM, 6 hours after the last dose of dexamethasone (Funder et al., 2008).

Additional testing is recommended for patients with initial abnormal or discordant results, such as the dexamethasone-CRH stimulation test or the midnight serum cortisol test. The dexamethasone-CRH stimulation test has been developed to improve the sensitivity of the LDDST. Dexamethasone at 2 mg/day over 48 hours is followed by administration of CRH (1 µg/kg IV) 2 hours after the last dose of dexamethasone. Cortisol is measured 15 minutes later. ACTH and cortisol should increase after administration of CRH in patients with Cushing's disease.

After hypersecretion of cortisol is confirmed, the next step is to determine if the Cushing's syndrome is ACTH dependent or independent. This is accomplished through measurement of the late-afternoon ACTH level, which is normally low. Cushing's syndrome is ACTH *dependent* if plasma ACTH is greater than 10 pg/mL and ACTH *independent* if ACTH is less than 5 pg/mL. For an intermediate ACTH level, further testing with the CRH stimulation test is performed. A rise in cortisol by 20% or in ACTH of at least 50% over baseline after administration of CRH is considered evidence for an ACTH-dependent lesion. In these patients, high-dose dexamethasone suppression test (HDDST), combined with cranial MRI studies, may help in localizing the site of ACTH overproduction. HDDST (2 mg dexamethasone every 6 hours for 2 days) provides close to 100% specificity if the criterion used is suppression of urinary free cortisol by more than 90% and can differentiate Cushing's disease from ectopic ACTH production. If workup results are still equivocal, or suggestive of ectopic ACTH production, inferior petrosal sampling is performed, obtaining ACTH samples from the periphery and petrosal sinuses simultaneously. A petrosal sinus/peripheral ACTH ratio of 2:1 is diagnostic of a pituitary source and can be further used to localize the side of ACTH production from the pituitary gland.

For patients with ACTH-independent lesions, abdominal CT or MRI may localize the site of the lesion.

Treatment

The treatment of Cushing's syndrome depends on the cause. For endogenous disease, surgical resection of the causative tumor is indicated. The treatment of choice for Cushing's disease is transsphenoidal hypophysectomy. Other treatments include various forms of radiation therapy and pharmacologic inhibition of ACTH secretion.

Patients with adrenal adenomas are treated with unilateral adrenalectomy and have excellent prognosis. These patients require glucocorticoid therapy both during and after surgery until the residual adrenal gland recovers. For patients with biopsy-proven adrenal carcinoma that is not amenable to surgery, mitotane is the treatment of choice. For ectopic ACTH syndrome, ideal treatment is the excision of identified benign tumors. However, for ectopic tumors that are unidentified or unresectable, medications that block steroidogenesis, such as ketoconazole, metyrapone, and aminoglutethimide, may be useful.

Aldosteronism

Key Points

- In primary aldosteronism, secretion of aldosterone is inappropriately high and, when the result of an adrenal adenoma, it is relatively autonomous from renin-angiotensin secretion.
- Secondary aldosteronism is generally related to hypertension, and the aldosterone secretion is driven by high plasma renin.
- Patients present with hypokalemia and hypertension that may be resistant to treatment.
- The plasma aldosterone/renin ratio is the most reliable test for screening for primary aldosteronism.
- A plasma aldosterone/renin ratio of 20 or greater and plasma aldosterone higher than 15 ng/dL support the diagnosis of primary hyperaldosteronism.

Primary aldosteronism (PA) was first described by Jerome Conn in 1955 as a syndrome (Conn's syndrome) characterized by hypertension and hypokalemia caused by an adrenal aldosterone-producing adenoma. The secretion of aldosterone from the adrenal zona glomerulosa is regulated mainly by the renin-angiotensin system (RAS) and by potassium anions. PA is now recognized to be the most common form of secondary hypertension. In PA the secretion of aldosterone is inappropriately high, relatively autonomous from the RAS, and nonsuppressible by volume expansion or sodium loading. In secondary aldosteronism associated with hypertension, the aldosterone secretion is driven by high plasma renin and is suppressed by volume expansion (Funder et al., 2008; Young, 2007).

Primary aldosteronism is typically caused by an aldosterone-producing adenoma (APA, 35% of cases), by unilateral or bilateral idiopathic adrenal hyperplasia (IHA) (2% and 60%, respectively), by an adrenal carcinoma (rare), or in rare cases, familial hyperaldosteronism (FH), either type I (glucocorticoid-remediable aldosteronism [GRA]) or type II (familial occurrence of APA or IHA, or both). There are two types of aldosteronomas: a corticotrophin-responsive (and renin-unresponsive) type and a renin-responsive type. PA had been previously described in less than 1% of patients with hypertension. However, recent studies estimate the prevalence of PA is 5% to 13% among hypertensive patients.

Clinical Presentation

Few symptoms are specific to the syndrome. Patients present with moderate to severe hypertension that may be resistant to usual pharmacologic treatments. Hypokalemia is usually present, and serum sodium concentration tends to be high-normal or slightly above the upper limit of normal. Patients with marked hypokalemia may have muscle weakness and cramping, headaches, palpitations, polydipsia, polyuria, or nocturia. However, hypokalemia might be absent; thus any patient with hypertension could be a candidate for this disorder. Patients with PA may be at higher risk than other patients with hypertension for target-organ damage of the heart and kidney. A significantly higher rate of cardiovascular events (stroke, atrial fibrillation, myocardial infarction) has been noted in patients with APA or IHA when compared with patients matched for age, gender, and hypertension. Patients with APA have more severe hypertension, more frequent hypokalemia, higher plasma and

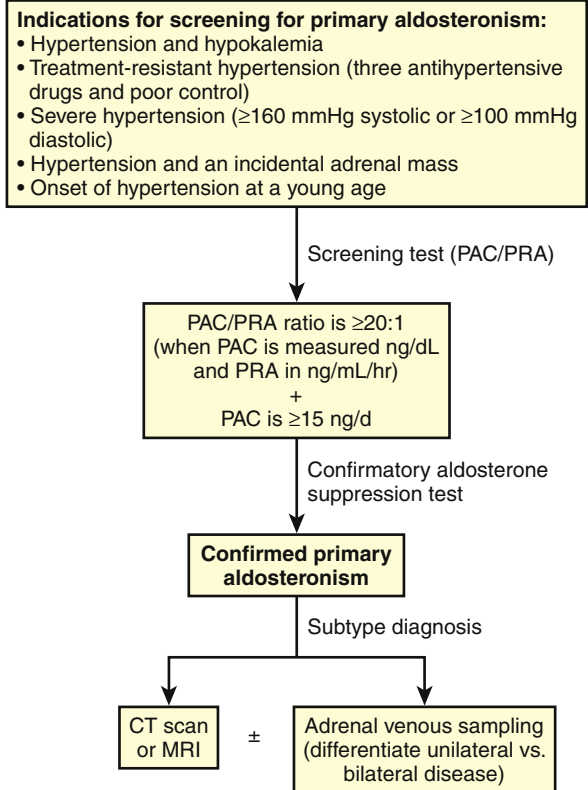

Figure 35-4 Indications for screening for primary aldosteronism and flow chart for clinical assessment.

urinary levels of aldosterone, and are younger (<50 years) than those with IHA.

Hypokalemia, when present, strongly suggests associated mineralocorticoid excess. However, most patients with primary PA have baseline blood levels of potassium in the normal range. Therefore, hypokalemia should not be the criterion used to make the diagnosis of PA. Screening for PA should be considered in patients with: hypertension and hypokalemia, treatment-resistant hypertension (three antihypertensive drugs and poor control), severe hypertension (≥ 160 mm Hg systolic or ≥ 100 diastolic), hypertension and an incidental adrenal mass, and onset of hypertension at a young age (Fig. 35-4). When an evaluation for secondary hypertension is performed, the diagnosis of PA should also be considered. In patients with suspected PA, the screening can be accomplished by measuring a morning ambulatory paired random plasma aldosterone concentration (PAC) and plasma renin activity or concentration (PRA or PRC). This test can be performed while the patient is taking antihypertensive medications (except for spironolactone, eplerenone, and high-dose amiloride) and without posture stimulation. The aldosterone/renin ratio (ARR) is currently the most reliable means of PA screening. A test is considered positive when the PAC/PRA ratio is 20:1 or greater (when PAC is measured in ng/dL and PRA in ng/mL/hr) and the PAC is higher than 15 ng/dL. All positive results should be followed by a confirmatory aldosterone suppression test to verify autonomous aldosterone production before treatment is initiated.

Aldosterone suppression testing can be performed with oral sodium chloride and measurement of urinary aldosterone or with IV sodium chloride loading and measurement

of PAC. On the third day of the high-sodium diet, a 24-hour urine specimen is collected for measurement of aldosterone, sodium, and creatinine. Hypertension and hypokalemia should be controlled before the administration of the sodium load. Urinary aldosterone excretion greater than 12 $\mu\text{g}/24$ hr, when there is adequate sodium repletion (24-hour urinary sodium excretion ≥ 200 mmol), is consistent with autonomous aldosterone secretion. The IV saline infusion will suppress PAC to less than 5 ng/dL in normal subjects, but not to less than 10 ng/dL in patients with PA.

If the diagnosis of PA is confirmed, lateralization of the source of the excessive aldosterone secretion is critical to guide further management. All patients with PA should undergo an adrenal CT scan as the initial study in subtype testing and to exclude large masses that may represent adrenocortical carcinoma. MRI has no advantage over CT in subtype evaluation of PA. In patients with PA, adrenal venous sampling is the reference standard test to differentiate unilateral from bilateral disease. This is important because unilateral adrenalectomy in patients with APA or primary adrenal hyperplasia results in normalization of hypokalemia and improvement of hypertension in all patients and cure of hypertension in 30% to 60%. Glucocorticoid-remediable aldosteronism is an autosomal dominant disease and may be diagnosed by genetic testing.

Treatment

The treatment approach depends on the cause of PA. Unilateral laparoscopic adrenalectomy is an excellent treatment option for patients with APA or unilateral hyperplasia. BP control improves in almost 100% of these patients postoperatively, and the average long-term cure rates of hypertension after unilateral adrenalectomy for APA range from 30% to 72%. A potassium supplement and/or a mineralocorticoid receptor antagonist should be given preoperatively to correct the hypokalemia but should be discontinued postoperatively.

Medical management is recommended for patients with APA who do not undergo surgery and for these with IHA or GRA. Spironolactone has been the drug of choice for PA and is titrated to achieve BP control and normokalemia without the aid of oral potassium supplement. Eplerenone is a competitive and selective aldosterone receptor antagonist and may be used as an alternative agent. Compared with spironolactone, eplerenone has less antiandrogenic and progestational actions but is more expensive. In patients intolerant to aldosterone receptor antagonists, amiloride may be an alternative treatment that can reduce BP and normalize potassium levels, but it does not protect against the negative effects of aldosterone excess. Patients with IHA may be resistant to drug therapy because of hypervolemia and may require a second antihypertensive agent such as a thiazide diuretic in combination with the aldosterone receptor antagonist.

Disorders of Hyperfunction: Adrenal Medulla

Pheochromocytoma

Key Points

- Pheochromocytomas are catecholamine-secreting neuroendocrine tumors that originate in the adrenal medulla (85% of cases) or in any sympathetic ganglion (paragangliomas).
- Hypertension, tachycardia, pallor, palpitations, diaphoresis, and anxiety are common.
- Paroxysmal hypertension often occurs, even in normotensive persons, and may result in hypertensive emergencies.
- Plasma and urine catecholamines and metanephrines are measured to diagnose pheochromocytoma.
- CT, MRI, and ^{123}I -MIBG may be helpful for tumor localization.

Pheochromocytomas are catecholamine-secreting neuroendocrine tumors arising from chromaffin cells of neural crest origin. About 80% to 85% of pheochromocytomas originate in the adrenal medulla, and 15% to 20% are extra-adrenal (paragangliomas). Pheochromocytomas are rare tumors, with an incidence of 1 to 2 per 100,000 adults per year. Sporadic forms of pheochromocytoma are usually diagnosed in individuals age 40 to 50 years, whereas hereditary forms are diagnosed earlier, most often before age 40. The traditional "rule of 10" for pheochromocytomas (10% bilateral, 10% extra-adrenal, 10% familial, 10% malignant) is now challenged by advances in diagnosis and genetics. Hereditary pheochromocytomas occur in MEN-II, von Hippel-Lindau syndrome, neurofibromatosis type 1, and familial paragangliomas. Pheochromocytoma is rare in children but, when found, are often extra-adrenal, multifocal, and associated with hereditary syndromes (Lenders et al., 2005).

Clinical Presentation

Paroxysmal signs and symptoms caused by the episodic secretion of catecholamines provide clues to the diagnosis of pheochromocytoma. The presentation can vary greatly, and therefore the pheochromocytoma is often referred to as the "great mimic." Anesthesia and tumor manipulation are the most well-known stimuli to elicit a catecholaminergic crisis. Hypertension, tachycardia, pallor, palpitations, diaphoresis, headache, and feelings of panic or anxiety are common. The hypertension is often paroxysmal and may occur in patients with hypertension or in normotensive persons. The hypertensive episodes can be severe, resulting in hypertensive emergencies. Persons with paragangliomas may have normal BP or hypotension. Orthostatic hypotension (a result of hypovolemia), fever, nausea, flushing, leukocytosis, and polycythemia are less common findings. Metabolic abnormalities may be present and include hyperglycemia, lactic acidosis, and weight loss.

Laboratory Evaluation

All patients with suspected pheochromocytoma should undergo biochemical testing. Traditional tests include measurements of urinary and plasma catecholamines, urinary metanephrines (normetanephrine and metanephrine), and urinary vanillylmandelic acid (VMA). Measurement of plasma-fractionated metanephrines (normetanephrine and metanephrine) is a newer test. Plasma and urine metanephrine measurements are the most sensitive tests for diagnosis but do not always indicate a pheochromocytoma. Many physiologic stimuli (e.g., stress), drugs (e.g., phenoxybenzamine, tricyclic antidepressants), and clinical conditions (e.g., hyperthyroidism, heart failure, stroke) may cause an increase in circulating catecholamines and metabolites and lead to false-positive results. The use of clonidine or glucagon to suppress catecholamine release from the sympathoadrenal system provides a dynamic pharmacologic test to distinguish increased catecholamine release due to sympathetic activation from increased release due to a pheochromocytoma.

If there is biochemical evidence for pheochromocytoma, tumor localization by CT scan of the entire abdomen (and pelvis), with and without contrast, should be performed. MRI with gadolinium has similar diagnostic sensitivity (90%-100%) and specificity (70%-80%) and is usually the preferred modality, especially for extra-adrenal lesions. Iodine-123 metaiodobenzylguanidine (¹²³I-MIBG) isotope scanning has increased specificity (95%-100%) over CT and MRI and is more appropriate for patients with extra-adrenal, metastatic, multifocal, or recurrent disease.

Treatment

Preoperatively, phenoxybenzamine, prazosin, doxazosin, or urapidil can be used for the blockade of alpha adrenoceptors. Phenoxybenzamine is often preferred because it blocks alpha adrenoceptors noncompetitively. Alternative drugs for preoperative management are labetalol or calcium channel blockers, either alone or in combination with α -adrenergic receptor blockers. Treatment must be initiated 10 to 14 days preoperatively and is titrated until mild orthostasis (systolic BP should not fall below 90 mm Hg in standing position) is present. Blockade of beta adrenoceptors should never be initiated before blockade of alpha adrenoceptors. Laparoscopic removal of intra- and extra-adrenal pheochromocytomas is the preferred surgical approach. All patients should be followed up every year for at least 10 years after surgery. BP and catecholamines should be monitored indefinitely in patients with extra-adrenal or familial pheochromocytoma to detect possible recurrence. For malignant disease, radical surgical removal is recommended, but survival remains poor (~50%). Treatment with ¹³¹I-MIBG or combination chemotherapy has shown disappointing results.

Mixed Disorder: Congenital Adrenal Hyperplasia

See the discussion online at www.expertconsult.com.

KEY TREATMENT

In primary adrenal insufficiency, long-term glucocorticoid and mineralocorticoid replacement is necessary. Baseline steroid dose should be increased twofold to threefold during febrile illness or injury (Arlt and Allolio, 2003; Oelkers, 1996; Salvatori, 2005) (SOR: A). Therapeutic intervention for secondary and tertiary adrenal insufficiency requires treatment of underlying disorders. Glucocorticoid replacement is necessary (Arlt and Allolio, 2003; Oelkers, 1996; Salvatori, 2005) (SOR: A). Oral fludrocortisone (0.05-0.20 mg daily) is the treatment of choice for aldosterone deficiency. In hyporeninemic hypoaldosteronism, furosemide with reduced salt intake can ameliorate acidosis and hyperkalemia (Arlt Allolio, 2003; Oelkers, 1996) (SOR: A). Surgical resection is usually the treatment of choice for Cushing's disease and ACTH-independent Cushing's syndrome (Nieman et al., 2009) (SOR: A). Treatment of aldosteronism is directed at the underlying cause. Aldosterone antagonists such as spironolactone are effective therapy (Funder et al., 2008) (SOR: A). Laparoscopic removal of intra- and extra-adrenal pheochromocytomas after alpha-adrenoceptor blockade is the preferred treatment (Lenders et al., 2005) (SOR: A). Treatment of congenital adrenal hyperplasia with glucocorticoids may result in amelioration of symptoms (New, 2004) (SOR: A).

Ovarian and Testicular Disorders

Sexual development in both males and females is driven by the hypothalamic-pituitary axis. The normal process is the result of pulsatile release of GnRH from the hypothalamus, which stimulates the pituitary to release FSH and LH (GHRH and GH also play a role). Release of FSH and LH activates the ovary and testis to produce estrogen and testosterone and is responsible for stimulation of gametogenesis. This process is assisted by conversion of adrenal androgens from the adrenal cortex into androstenedione and subsequently into potent androgens (testosterone) or estrogens (estradiol) in the peripheral tissues (see Adrenal Glands). Errors can occur along this complex pathway, resulting in early sexual development (precocity), delayed sexual development (delayed menarche), errors of translation (male feminization syndrome), early loss of reproductive function (premature menopause), and inappropriate response to stimuli (polycystic ovary syndrome).

Normal Sexual Development

Sexual differentiation in humans is controlled by genetics (presence of Y chromosome determines development of testis and absence determines development of ovary with additional X chromosome), environment (e.g., nutrition), and hormones (MacLaughlin and Donahoe, 2004). Congenital conditions associated with aberrations of chromosomal, gonadal, or anatomic sexual development are called "disorders of sex development (DSD)" (Houk et al., 2006). In the postgonadal phase, hormones control external genitalia differentiation and secondary sexual development. Puberty refers to a physiologic transition phase (>4 years) between childhood and adulthood during which there is pubertal growth spurt and development of secondary sexual characteristics. Puberty is preceded by adrenarche (6-7 years in females and 7-8 years in males), marked by increasing amounts of adrenal androgens (DHEA, DHEA-S, and androstenedione). The growth spurt (striking increase in growth velocity during puberty) is a complex hormonal phenomenon in which GH, thyroid hormones, and sex steroids play a major role. Gonadarche (secretion of gonadal sex steroids) follows adrenarche and is initiated by activation of the GnRH pulse generator in the hypothalamus. These GnRH pulses result in increased gonadotropin secretion and subsequent production of sex hormones by the gonads.

Sexual maturation in females starts with breast development (thelarche) at a mean age of 11 years, followed by pubic hair development and menses (menarche). In males it starts with scrotal corrugation and testicular enlargement at a mean age of 11.5 years, followed by growth of the penis and pubic hair.

In males, release of LH stimulates testicular Leydig cells to produce testosterone. FSH, in conjunction with testosterone, stimulates spermatogenesis. In females, FSH stimulates development of primary ovarian follicles and increases production of estrogen from ovarian granulosa cells. LH in females stimulates ovarian theca cells to produce androgens and the corpus luteum to synthesize progesterone. LH induces ovulation through the midcycle surge.

Estradiol production in males increases the bone age, bone mineral density, and rate of epiphyseal fusion. In females it stimulates the development of breasts, labia, vagina, and

uterus and proliferation of endometrium. In addition, estradiol enhances development of, and increase in, the ducts of the breast and body fat. Estrogen in low levels enhances linear growth, and high levels increase the rate of fusion of epiphyses. Testosterone is responsible for the increase in muscle mass, sebaceous glands, and voice changes seen in pubertal males and is a linear growth accelerator. In females, testosterone accelerates linear growth and stimulates pubic and axillary hair development. Progesterone in females is responsible for development of a secretory endometrium and plays a role in breast development. Linear growth and pubic hair development in both males and females are caused by androgens from the adrenal gland. **Figures 35-5 and 35-6** show normal pubertal developmental stages of Marshall and Tanner.

- Diagnoses of true puberty and pseudopuberty should be differentiated.
- Evaluation includes a comprehensive history and physical examination, growth chart, and wrist radiograph.
- If true puberty is suspected, consider cranial CT or MRI to rule out CNS lesions.

Evaluation of suspected abnormal puberty begins with obtaining a detailed history, including growth and development (timing of physical and developmental milestones), medical conditions, dietary history, social history, ethnicity, and family history. Physical examination should be thorough, including current weight and a focus on development of secondary sexual characteristics and genitalia. A detailed growth chart from birth to present day should be obtained. A radiograph of the left wrist is needed to estimate bone age (Blondell et al., 1999).

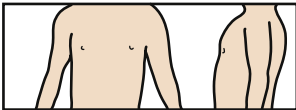

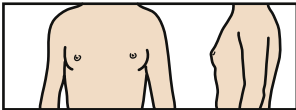

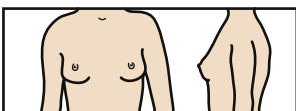

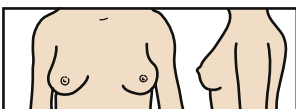

Abnormal Puberty

Key Points

- Evaluation should begin if signs of puberty develop in girls younger than 8 years or boys younger than 9 years.

Precocious Puberty

Precocious puberty (early puberty) may be defined as the appearance of secondary sexual maturation at an early age. The age of onset of puberty before age 8 years in girls and

| Tanner stage | Breasts* | Standard | Pubic hair* | Standard | Growth | Other |
|--------------|---|---|--|--|--|--|
| 1 | Prepubertal, elevation of papilla only |  | Prepubertal, villus hair only | — | Basal; about 5.0 to 6.0 cm (2.0 to 2.4 in) per year | Adrenarche Ovarian growth |
| 2 | Breast bud appears under enlarged areola (11.2 years) |  | Sparse growth of slightly pigmented hair along the labia (11.9 years) |  | Accelerated: about 7.0 to 8.0 cm (2.8 to 3.2 in) per year | Clitoral enlargement Labia pigmentation Uterus enlargement |
| 3 | Breast tissue beyond areola without contour separation (12.4 years) |  | Hair is coarser, curled and pigmented; spreads across the pubes (12.7 years) |  | Peak velocity: about 8.0 cm (3.2 in) per year (12.5 years) | Axillary hair (13.1 years) Acne (13.2 years) |
| 4 | Projection of areola and papilla forms a secondary mound (13.1 years) |  | Adult-type hair but no spread to medial thigh (13.4 years) |  | Deceleration: <7.0 cm (2.8 in) per year | Menarch (13.3 years) Regular menses (13.9 years) |
| 5 | Adult breast contour with projection of papilla only (14.5 years) |  | Adult-type hair with spread to medial thigh but not up linea alba (14.6 years) |  | Cessation at about 16 years | Adult genitalia |

*The Tanner stages of puberty in girls are based on breast size and shape and pubic hair distribution. Mean age of milestone attainment is shown in parentheses for the reference population of Marshall and Tanner. Actual age at milestone attainment may vary among individuals and among different study populations.

Figure 35-5 Pubertal milestones for girls. (From Blondell Rd, Foster MB, Dave KC. Disorders of puberty. *Am Fam Physician* 1999;60:209, 223.)

9 years in boys is considered precocious puberty. The Lawson Wilkins Pediatric Endocrine Society guidelines recommend that breast development or pubic hair in white girls before age 7 and black girls before age 6 should be evaluated for precocious puberty. Boys of all races should be evaluated for precocious puberty with signs of secondary sexual development at age 9 or younger (Kaplowitz and Oberfield, 1999). These guidelines are under some debate as setting perhaps too early an age for defining precocity. Some child endocrinologists believe that defining precocity as only those children with sexual development younger than 7 years will lead to missing some conditions that may respond to early intervention; they prefer the formerly used age of less than 8 years in girls to trigger investigation (Carel and Léger, 2008; Midyett et al., 2003; Traggiai and Stanhope, 2003). Children with developmental disabilities have a higher incidence of precocity (Siddiqui et al., 1999). However, most patients (>75%) investigated for precocious puberty will have benign diagnoses that are considered normal variations and do not require treatment (Kaplowitz, 2004).

Precocious puberty is classified as *central* (GnRH dependent) or *peripheral* (non-GnRH dependent). The peripheral group includes autonomous gonadal activation, gonadal tumors with production of sex steroids, adrenal disorders, and exposure to exogenous agents with properties of sex

steroids. Precocious puberty may be differentiated into *progressive* (one stage to next in 3-6 months) or *nonprogressive* (no progression of pubertal signs over time). Other terminology is based on the pubertal signs in relation to the individual's gender. *Isosexual* refers to precocity in the same gender (e.g., feminization of a female). *Heterosexual* (or *contrasexual*) would be precocious puberty resulting in virilization of a female.

Benign variants of precocious pubertal development (incomplete precocious puberty or variations in pubertal development) include nonprogressive precocious puberty, isolated precocious thelarche, isolated precocious pubarche, isolated menarche, and adolescent (male) gynecomastia. *Isolated thelarche* (unilateral or bilateral breast development) without progression of other signs of puberty generally resolves spontaneously, especially in girls younger than 2 years, and requires no treatment. *Isolated precocious pubarche* (pubic hair development) as a result of early adrenarche is usually self-limited. Evaluation beyond a complete history, physical examination, and bone-age determination would include ACTH stimulation test to rule out late-onset congenital adrenal hyperplasia. *Gynecomastia* in adolescent males is common and presents more of a social than a physical problem. Careful explanation with reassurance for the child and parent that this is a self-limited condition is the best approach.

| Tanner stage | Standard | Genitalia* | Pubic hair* | Growth | Other |
|--------------|---|---|---|---|---|
| 1 |  | Prepubertal testes: <2.5 cm (1.0 in) | Prepubertal, villus hair only | Basal: about 5.0 to 6.0 cm (2.0 to 2.4 in) per year | Adrenarche |
| 2 |  | Thinning and reddening of scrotum (11.9 years) Testes: 2.5 to 3.2 cm (1.0 to 1.28 in) | Sparse growth of slightly pigmented hair at base of penis (12.3 years) | Basal: about 5.0 to 6.0 cm (2.0 to 2.4 in) per year | Decrease in total body fat |
| 3 |  | Growth of penis, especially length (13.2 years) Testes: 3.3 to 4.0 cm (1.32 to 1.6 in) | Thicker, curlier hair spreads to the mons pubis (13.9 years) | Accelerated: about 7.0 to 8.0 cm (2.8 to 3.2 in) per year | Gynecomastia (13.2 years) Voice break (13.5 years) Muscle mass increase |
| 4 |  | Growth of penis and glands, darkening of scrotum (14.3 years) Testes: 4.1 to 4.5 cm (1.64 to 1.8 in) | Adult-type hair but no spread to medial thigh (14.7 years) | Peak velocity: about 10.0 cm (4.0 in) per year (13.8 years) | Axillary hair (14.0 years) Voice change (14.1 years) Acne (14.3 years) |
| 5 |  | Adult genitalia (15.1 years) Testes: >4.5 cm (1.8 in) | Adult-type hair with spread to medial thighs but not up linea alba (15.3 years) | Deceleration and cessation (about 17 years) | Facial hair (14.9 years) Muscle mass continues to increase after Stage 5 |

*The Tanner stages of puberty in boys are based on the development of the genitalia and pubic hair distribution. Mean age of milestone attainment is shown in parentheses for the reference population of Marshall and Tanner. Actual age at milestone attainment may vary among individuals and among different study populations.

Figure 35-6 Pubertal milestones for boys. (From Blondell Rd, Foster MB, Dave KC. *Disorders of puberty*. *Am Fam Physician* 1999;60:209, 223.)

Accidental precocity occasionally results from unusual dietary habits or inappropriate use of medications (estrogen creams). A careful review for these habits early in the evaluation is helpful.

Central (GnRH-Dependent) Precocious Puberty

Central (or true) precocious puberty is caused by early activation of hypothalamic GnRH secretion. Most patients have no identifiable cause, and the precocity is labeled "idiopathic." Initial evaluation begins with history, examination, growth chart, and wrist radiographs. Morning testosterone levels are useful in boys, and GnRH-agonist stimulation tests are helpful in females to identify a central etiology. Various CNS lesions are known to cause central isosexual precocity, so cranial CT or MRI is indicated to rule out these pathologies. An underlying CNS disorder is not unusual in boys presenting with precocious puberty. Treatment is focused on managing the underlying cause. GnRH analogues that reversibly inhibit gonadotropin secretion can be used to prevent secondary sexual development and early epiphyseal fusion that occurs in children who are very young at the onset of puberty, especially when it progresses rapidly (Carel et al., 2004). Optimal age to discontinue therapy is 11 years. When therapy is discontinued, puberty commences normally. There is a slowly progressive form of central isosexual precocity in which no height is lost. These patients may be considered for a nontherapeutic approach with careful observation (Palmert et al., 1999) (Table 35-4).

In many studies the most common causes of precocity are benign and need no treatment. Detailed evaluation with hormonal studies and imaging may be reserved for patients with severe symptoms and signs (de Vries and Phillip, 2005; Kaplowitz, 2004, 2005).

Delayed Puberty

Key Points

- Lack of thelarche (breast development) by age 12 years in girls or lack of testicular enlargement by age 14 years in boys indicates delayed puberty.
- Constitutional delay is characterized by delayed but spontaneous onset of puberty, whereas organic delay is caused by gonadal, pituitary, or central dysfunction.

Delayed puberty in girls is defined as lack of thelarche by age 12 years or duration between thelarche and menarche longer than 5 years. In boys, delayed puberty is defined as no testicular enlargement by age 14 years with more than 5 years between initial and complete development of the genitalia. Delayed puberty in both males and females is classified as *constitutional* (idiopathic) or *organic* (gonadal, pituitary, or central cause). A retrospective study of 232 male and female patients with delayed puberty revealed that the majority (53%) had constitutional delay of growth and maturation, with much higher incidence in males (63%) than females (30%). The remaining 47% of the total 232 patients had mixed etiologies; 19% had functional hypogonadotropic hypogonadism, 12% permanent hypogonadotropic hypogonadism, 13% permanent hypergonadotropic hypogonadism, and no clear etiology for the remaining 3% (Sedlmeyer and Palmert, 2002).

Constitutional delay is characterized by physiologic delay but subsequent spontaneous onset of puberty and is a diagnosis of exclusion. The cause is a delay in GnRH pulse generation, with low levels of gonadotropins. Height and weight in these children tend to be below the fifth percentile, but most catch up during adolescence, reaching normal adult height and weight. Family history may reveal similar delays of puberty in one or both parents, which can be reassuring for the child and parent. Values for FSH, LH, DHEA-S, prolactin, testosterone, and estradiol levels will be consistent with prepubertal values until onset of puberty and normal sexual maturation.

The two common causes of delayed puberty from organic etiologies are pituitary dysfunction or hypogonadotropic hypogonadism. Panhypopituitarism in children may present as delayed puberty, but in conjunction with growth failure, secondary hypothyroidism, and adrenal insufficiency. Differentiation of organic forms of delay from constitutional delay may be difficult to establish in certain patients, requiring a series of observations and testing (no single study or imaging technique will differentiate these). *Hypogonadotropic* hypogonadism presents with low levels of FSH and LH as a result of defective GnRH pulsation. Causes include anorexia nervosa, excessive weight loss, extreme exercise (cross country runners), tumors, head trauma, infiltrative processes, infection, and radiation. *Hypergonadotropic* hypogonadism is usually caused by gonadal failure and presents with high levels of gonadotropins and low levels of sex steroids.

Evaluation of delayed puberty, as with all evaluations for abnormal sexual development, begins with a detailed history focusing on growth patterns, presence of any secondary sexual development, diet, exercise habits, congenital abnormalities, neurologic symptoms, and family history. Physical examination includes a thorough search for early signs of sexual maturation using Tanner staging. Measurement of arm span in relation to height is helpful in growth assessment. Arm span that exceeds height more than 5 cm is consistent with adult configuration. When present in children, this may mean delayed epiphyseal closure due to hypogonadism. Wrist radiography is useful to determine bone age. Initial laboratory screening should include complete blood cell count (CBC), erythrocyte sedimentation rate (ESR), and liver function tests (LFTs). Serum FSH, LH, estradiol, and testosterone levels can distinguish between primary and secondary hypogonadism. In primary hypogonadism (ovarian and testicular failure), serum gonadotropin levels will be elevated. In patients with constitutional delay of puberty and congenital GnRH deficiency, serum gonadotropin levels will be low. Prolactin, TSH, adrenal androgens, and karyotype (to rule out Turner's, Klinefelter's, and Noonan's syndromes) should be evaluated if the clinical presentation warrants.

Therapy for delayed puberty is targeted at the underlying disorder, if identified. If the cause is unknown, observation with reassurance and psychosocial support and reevaluation after 4 to 6 months is an option. Hormonal therapy with estrogen (girls older than 12 years) or testosterone (boys older than 14 years) is another option. Short-term use of exogenous hormones does not appear to have long-term sequelae, except for the potential effect on skeletal maturation, which might result in failure to achieve potential adult

Table 35-4 Precocious Puberty: Types, Causes, and Treatment

| Etiology | Symptoms | Tests/Treatment |
|--|---|--|
| Central Precocity* | | |
| Idiopathic | Secondary sexual characters development | GnRH analogues Discontinue at 11 years. |
| CNS lesions (including congenital defects): hamartomas, tumors, infection, trauma, radiation, after androgen exposure, craniopharyngioma, others | History of trauma Medical history Headache, visual changes possible | FSH, LH, prolactin, sex steroids, TSH MRI of brain Treatment per pathology |
| Primary hypothyroidism | Signs of hypothyroidism without increase in growth velocity | Thyroid profile Treatment with thyroxine |
| Incomplete Isosexual Precocity | | |
| <i>Females:</i> Isolated precocious thelarche | Breast enlargement without other secondary sexual changes | Most cases are benign. |
| <i>Females:</i> Isolated precocious adrenarche | Pubic hair development, adult odor, acne | DHEA may be increased. Adrenal steroid hormones and sex hormones: normal ACTH stimulation test to exclude CAH Usually benign; no treatment needed |
| <i>Females:</i> Isolated precocious menarche | Menarche precedes breast development or appearance of pubic hair. | Normal bone age Ultrasound: normal pelvis with prepubertal uterus Usually benign; check for abuse and ovarian and genital pathology. |
| <i>Females:</i> Estrogen-secreting tumors of ovary or adrenals Ovarian cysts | Abdominal symptoms Signs of precocious puberty | CT or MRI in addition to hormonal tests Treat as per pathology |
| <i>Females/males:</i> McCune-Albright syndrome | Autonomous hyperfunction of gonads; rapid development of precocity Café au lait spots, fibrous dysplasia | Ultrasound/CT of abdomen: large ovarian masses LFTs, DHEA sulfate, TSH, phosphate, cortisol |
| <i>Males:</i> Gonadotropin-secreting tumors; excessive androgen production Testicular or adrenal tumors Virilizing CAH Premature Leydig's and germinal cell maturation | Excessive virilization Enlargement of testis (unilateral) | CT/MRI of abdomen Ultrasound Hormonal tests Treat per pathology. Surgery may be indicated. |
| <i>Males/females:</i> Iatrogenic | History of using sex steroids and related products | Stop causative agent. |
| Contrasexual Precocity (Isolated Virilization) | | |
| Isolated precocious adrenarche. | | |
| <i>Females:</i> Virilizing CAH; androgen-secreting ovarian or adrenal neoplasm; Cushing's syndrome; glucocorticoid resistance; arrhenoblastoma | Prepubertal masculinization | Tests for CAH Cortisol Testosterone MRI of abdomen and pelvis Treat per pathology. |
| <i>Males:</i> Estrogen-secreting tumor, chorionepithelioma; increased extraglandular aromatization of adrenal steroids causing increased extraglandular estrogen production and unusual CAH variations | Prepubertal feminization in boys is rare. | Tests for CAH Cortisol and estrogen levels Testosterone MRI of abdomen and pelvis Treat per pathology. |
| Iatrogenic | History of using sex steroids and related products | Stop causative agent. |
| Nonprogressive precocious puberty | Stabilization of precocity Normal bone age | Normal bone age Ultrasound: normal pelvis with prepubertal uterus |

height. In females taking estrogen replacement therapy, progestins should be added to the regimen after breakthrough bleeding occurs or after 1 year of therapy.

Problems of the Testicle and Other Male Endocrine Issues

Male Hypogonadism

Male hypogonadism is defined as “inadequate gonadal function” manifested by deficiency in gametogenesis or secretion of gonadal hormones. Primary hypogonadism is caused by dysfunction in the testes from either chromosomal or acquired disorders (Box 35-8). Secondary hypogonadism is caused by an abnormality of the hypothalamic-pituitary axis. Males may present with infertility, decreased testicular size, changes in libido, impotency, gynecomastia, delayed puberty, or a combination of these (Swerdloff and Wang, 2004).

Diagnosis

Clinical diagnosis again begins with history, including information about sexual developmental milestones, current symptoms, ambiguous genitalia at birth, cryptorchidism, behavioral abnormalities, anosmia, surgeries, sexually transmitted diseases (STDs), and medications. History should include the presence of acute and chronic medical conditions and neurologic symptoms. Physical examination is directed toward sexual characteristics, body habitus, gynecomastia, and signs of hypogonadism. Testis should be measured for length and width with an orchidometer. Consistency of the testes should be noted and a scrotal examination done for the presence of varicocele. A nonpalpable prostate may imply testosterone deficiency. A low morning (8-10 AM) serum testosterone level confirms hypogonadism. Serum LH and FSH levels are elevated in primary hypogonadism and are normal to low in secondary hypogonadism. Semen analysis will assess the capability of spermatogenesis. An increase in sex hormone-binding globulin (SHBG) may imply hyperthyroidism, severe androgen deficiency, liver disease, or estrogen excess. A low level of SHBG may indicate hypothyroidism, polycystic ovary syndrome (PCOS), obesity, or acromegaly. Prolactin level should be measured to identify a prolactinoma, followed by CT or MRI, if elevated. Other studies, such as bone mineral density (BMD), pituitary imaging, genetic studies, and in some cases testicular biopsy, may be indicated.

Klinefelter's syndrome is the most common genetic cause of male infertility. It is caused by a chromosomal aberration, most often 47,XXY. Phenotypic males can present with small firm testicles, infertility, tall height, long legs, gynecomastia, and varying symptoms of androgen deficiency and undervirilization. Treatment is replacement of testosterone to prevent the sequelae of androgen deficiency.

Kallmann syndrome is an inherited disorder (see Pituitary Disorders). The most common form is isolated gonadotropin deficiency caused by defective GnRH secretion from the hypothalamus. Patients with Kallmann syndrome usually come to medical attention because of delayed puberty or incomplete sexual development. Anosmia or hyposmia is present in 80% of patients (remember the coffee grounds everyone carried around in medical school?) and establishes

Box 35-8 Causes of Hypogonadotropic Hypogonadism (HH)

Congenital

Male Infertility

Infertility is defined as failure to achieve pregnancy after 1 year of unprotected intercourse. A specific cause can be identified in approximately 80% of couples, one third of which are female factors alone, one third male factors alone, and one third a combination of both. Unexplained infertility, in which no specific cause can be identified, occurs in approximately 20% of infertile couples. The initial step in evaluation of the male is a thorough medical history, focusing on general health, erectile function, STD history, medications, surgical history, previous successful pregnancy, contraception use, drug or alcohol use, and family history of genetic disease. The first and often only test needed in evaluating male factors is semen analysis. If two consecutive analyses indicate oligospermia or azoospermia, ordering blood tests for testosterone, LH, FSH, and prolactin levels is warranted. *Varicocele* is the most common cause of male infertility (Griffin and Wilson, 2003)(Table 35-5).

Management consists of treating underlying infection with appropriate antibiotics, varicocelectomy, appropriate counseling about environmental factors, and referral to an infertility specialist for more extensive therapy (Frey and Patel, 2004).

Gynecomastia

Key Point

- Although breast cancer is an uncommon cause of breast enlargement in men, this diagnosis must be ruled out because the prognosis is worse for men diagnosed with breast cancer than for women.

Gynecomastia refers to a benign enlargement of the male breast resulting from proliferation of breast glandular tissue. When the male breast is enlarged from adipose tissue, it is

called *lipomastia* or *pseudogynecomastia* and is not caused by proliferation of breast tissue. Gynecomastia can be unilateral or bilateral, or it can be asymmetric. Any palpable breast tissue in men is abnormal except for three physiologic situations: transient gynecomastia of the newborn (caused by maternal or placental estrogens), pubertal gynecomastia (observed in 40%-70% of adolescent boys, resolving by age 18), and gynecomastia that occasionally occurs in older adult men (resulting from changes in estrogen and androgen metabolism). Gynecomastia can also be iatrogenic as a result of some medications.

Gynecomastia occurs as concentric, palpable glandular tissue beneath the areola that is not fixed to underlying structures. Prevalence is highest in men 50 to 80 years old and generally presents as bilateral. The cause of pathologic gynecomastia is a relative or absolute increase in circulating estrogen compared with androgen. Careful history (including drugs, legal and illegal) and physical examination can usually rule out Klinefelter's syndrome, androgen insensitivity syndrome, and testicular tumors (Griffin and Wilson, 1995) (Table 35-6).

Breast cancer is very uncommon in men but does occur, and generally the prognosis is much worse for men than for women diagnosed with breast cancer. Typically, breast cancer will present as a painless, central breast lump that may advance to pain, bloody discharge, and skin ulceration. Diagnosis is confirmed by biopsy (Wise et al., 2005).

Treatment of nonphysiologic gynecomastia involves removal of the offending drug or correction of the underlying condition, either of which usually results in regression of the glandular breast tissue. If the gynecomastia persists, a trial of antiestrogen therapy may be considered. Gynecomastia present for more than 1 year will undergo fibrosis and usually will not respond to medications. Surgical correction is required for alleviation of symptoms.

Problems of the Ovary and Other Female Endocrine Issues

Menopause and Hormone Replacement Therapy

See the discussion online at www.expertconsult.com. (Table 35-7).

Amenorrhea

Key Points

- Amenorrhea is categorized as primary or secondary, although this distinction may be misleading in certain patients.
- Primary amenorrhea can be caused by obstruction of the outflow tract, androgen insensitivity, gonadal dysgenesis, hyperprolactinemia, and dysfunction of the hypothalamus, pituitary, or thyroid.
- Pregnancy is the most common cause of secondary amenorrhea.

Primary Amenorrhea

Menses is a normal, physiologic function in a sexually mature female. Amenorrhea is the absence of menses in a sexually mature female. Amenorrhea is divided into two large categories, primary and secondary, depending on whether the female has ever had menarche, with attendant menstrual flow. *Primary* amenorrhea is defined as failure of menarche

by age 16 in a female with apparently normal sexual development or in a female age 14 who does not demonstrate evidence of developing secondary sexual characteristics. *Secondary* amenorrhea is failure of menstruation after normal menses are established, with the caveat that at least 3 months have passed with apparently normal menses or 9 months have passed in a woman with oligomenorrhea.

Menstruation is a complex process with many interacting and co-dependent processes that must occur in specific chronologic order. Dysfunction of any organ or system involved with these processes has the potential to disrupt the menstrual cycle and cause amenorrhea. The organs and systems involved in the menstrual cycle are CNS (influenced by environment, stress), hypothalamus (through GnRH), anterior pituitary (FSH, LH), thyroid gland, adrenals, ovary (estrogen, progesterone), and uterus. Secondary amenorrhea is more common than primary amenorrhea, with the most common cause being pregnancy. The distinction between etiologies of primary and secondary amenorrhea may be misleading, as in the woman with PCOS who presents with primary amenorrhea, or the woman with partial gonadal dysgenesis who has rudimentary ovarian development and may initially ovulate, thus presenting with secondary amenorrhea (Box 35-9).

The more common causes of primary amenorrhea fall into congenital or anatomic abnormalities. Congenital absence of the uterus and vagina, known as müllerian agenesis or Mayer-Rokitansky-Küster-Hauser (MRKH) syndrome, is a

significant cause of amenorrhea. Other congenital causes of primary amenorrhea include chromosomal abnormalities, prenatal adrenal hyperplasia, and female virilization syndrome. An anatomic cause of primary amenorrhea, usually discovered at menarche, is imperforate hymen.

To evaluate a patient with primary amenorrhea, after a thorough clinical history, the physical examination must focus on development of secondary sexual characteristics (breast development, pubic/axillary hair). Pregnancy as a cause of primary amenorrhea is less common than in secondary amenorrhea, although it should be excluded before any testing or imaging is initiated. Laboratory testing includes FSH, LH, TSH, and prolactin. If FSH is normal or reduced, this may mean the patient has chronic anovulation, functional hypothalamic amenorrhea, or PCOS. Increased FSH with breast development is likely secondary to ovarian failure. Increased FSH without secondary sexual characteristics may be caused by congenital agenesis of the ovaries. In the patient without a uterus, serum testosterone level and karyotype should be determined. In the presence of a uterus and normal secondary sexual characteristics, serum TSH levels should be evaluated (Sybert and McCauley, 2004) (Box 35-10).

Secondary Amenorrhea

Pregnancy is the most common cause of secondary amenorrhea and must always be ruled out at the initial clinical visit. Structural changes may cause amenorrhea, such as adhesions

Box 35-9 Causes of Amenorrhea*

- Hyperprolactinemia
 - Prolactin-secreting tumor
 - Centrally acting medications, including dopamine antagonists
- Pituitary disease
 - Non-prolactin-secreting pituitary tumor
 - Generalized pituitary insufficiency, including previous pituitary surgery
- Hypothalamic amenorrhea
 - Nutrition/exercise disorders
 - Idiopathic hypogonadotropic hypogonadism

after instrumentation (Asherman's syndrome) or infection in the form of TB or endometritis. Patients with PCOS present with irregular or absent menses, hirsutism, acne, subfertility secondary to a hyperandrogenic state, or a combination. Adrenal or ovarian tumors, hyperthecosis, and late-onset or mild congenital adrenal hyperplasia may also result in secondary amenorrhea and hyperandrogenism. Hypergonadotropic hypogonadism (premature ovarian failure), hypogonadotropic hypogonadism, thyroid disease, menopause, extreme exercise, anorexia nervosa, bulimia, and hyperprolactinemia are all potential causes of secondary amenorrhea.

A thorough history and physical examination will provide the diagnosis, with laboratory studies and imaging serving as collaborative evidence. Particular attention should be paid to menstrual history, diet, exercise, medications, pubertal development, hirsutism, acne, galactorrhea, and other medical conditions. Initial laboratory evaluation includes pregnancy test and TSH and prolactin levels. If these are normal, and there are no signs of hyperandrogenism (e.g., hirsutism, acne, voice change), proceed with progesterone challenge by using medroxyprogesterone (Provera), 10 to 20 mg daily for 5 to 10 days. In the presence of a uterus, the progesterone withdrawal test will induce withdrawal bleeding within 10 days in a woman with adequate estrogen production. If there is no withdrawal bleed, consider repeating the test with progesterone in oil (100-200 mg IM) or with norethindrone or micronized progesterone. If this test is also negative, a 21-day course of conjugated estrogen (1.25 mg/day) or a cycle of combined oral contraceptives (OCs) should provide adequate stimulation of the endometrium to support a withdrawal bleed. If all these measures fail to result in menstrual flow, additional tests may be ordered, beginning with FSH and, if there are clinical signs of hyperandrogenism, DHEA-S and testosterone levels. Elevated FSH indicates ovarian failure (including gonadal dysgenesis and secondary ovarian failure or menopause); normal or low values indicate hypogonadotropic hypogonadism or uterine abnormality (Asherman's syndrome). Proceed with a workup for PCOS (discussed later), late-onset congenital adrenal hyperplasia, or Cushing's syndrome if there are features consistent with these illnesses. Features of hyperandrogenemia or substantially increased serum testosterone levels should prompt appropriate studies to rule out a neoplastic source of

androgen. **Figure 35-7** is a diagnostic algorithm for evaluating a patient with primary and secondary amenorrhea. Hirsutism can be subjective.

Management of amenorrhea depends on establishing a diagnosis, specific treatment directed to the underlying cause, restoration of ovulatory cycles, and treating infertility, if desired. Also, appropriate treatment is provided for hypoestrogenemia and hyperandrogenemia (medical and surgical).

Turner's Syndrome

See the discussion online at www.expertconsult.com.

Female Infertility

Infertility is defined as failure of conception after 1 year of unprotected intercourse. From 15% to 20% of all couples are infertile. In women, fertility peaks between ages 20 and 24. After this, there is progressive decline in fertility until about age 32, followed by a steep decline after 40. Causes of infertility in couples tend to be one-third male factors, one-third female factors, and one-third combination. Female causes of infertility include ovarian dysfunction (40%), tubal factors (20%), cervical factors (infection, stenosis), uterine factors (infection, fibroids), and other (endometriosis, adhesions). The course of investigation for infertility should be based on a couple's wishes for fertility, their age, duration of infertility, and unique features in the history and physical examination.

Evaluation of the male partner is an integral part of the infertility workup and should coincide with the female partner's evaluation. Comprehensive history and physical examination of the female partner should include menstrual

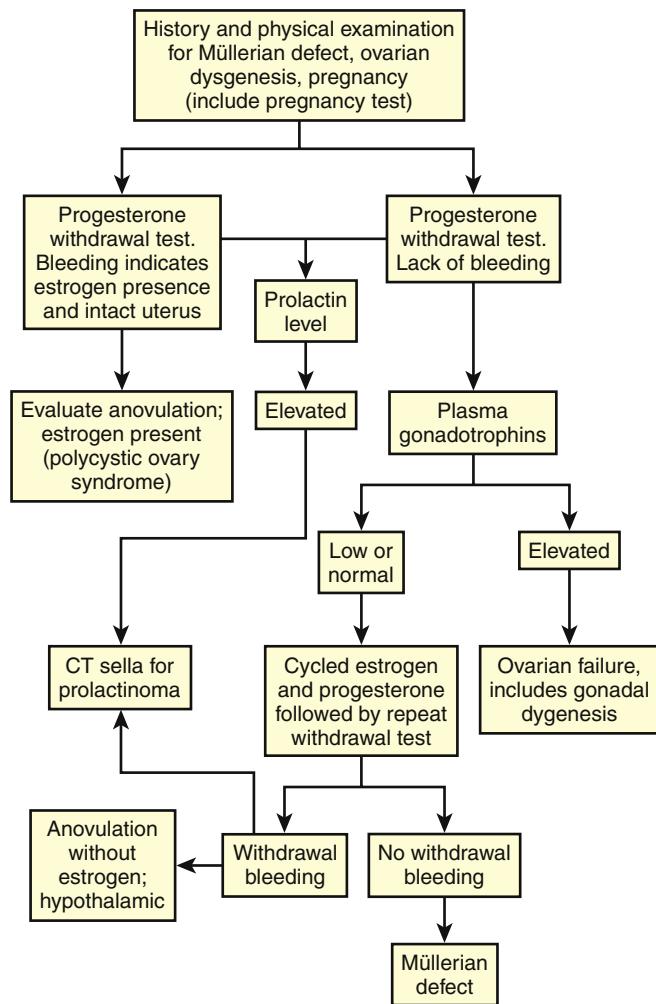

Figure 35-7 Diagnostic algorithm for evaluating a patient with primary and secondary amenorrhea. (Modified from Carr BR. Disorders of the ovaries and female reproductive tract. In Wilson JD, Foster DW [eds]. *Williams' Textbook of Endocrinology*, 8th ed. Philadelphia, Saunders, 1992.)

history, prior obstetric history, secondary sexual characteristics, recent and remote history of STDs, pelvic inflammatory disease (PID), pelvic surgeries or instrumentation, hirsutism, weight changes (up and down), medications, and comorbidities. Personal and family history should include use of drugs (including alcohol, tobacco, caffeine), physical activity, douching, frequency and timing of sexual intercourse, and family history of infertility or genetic disorders. Initial laboratory testing for the female partner includes a CBC, urinalysis, STD screen, confirmation of rubella and varicella immunity, and Papanicolaou smear. Ovulation should be verified by urinary ovulation prediction kits that detect the LH surge, determination of the mid-luteal phase serum progesterone level (7 days before anticipated menses), or both. Assessment of fallopian tube patency is by hysterosalpingography (first choice) or laparoscopy (if history strongly suggests prior tubal damage). Women over age 35 should have serum FSH checked on day 3 of their menstrual cycle. A value higher than 12 IU/L is associated with poor ovarian response, and referral to a reproductive endocrinologist should be considered. Postcoital tests, endometrial biopsies, and basal body temperature records

Table 35-8 Tests for evaluating Female Infertility

| Female Infertility | Common Tests |
|--------------------|---|
| Ovulatory factors | Basal body temperature or urinary LH test (ovulatory predictor test); serum progesterone (during luteal phase); transvaginal ultrasound; TSH, FSH, prolactin, and androgens |
| Cervical factors | Cervical mucus evaluation; postcoital test (not sensitive) |
| Uterine factors | Ultrasound, hysterosalpingography, hysteroscopy, sonohysterography (for submucosal myomas and endometrial polyps), magnetic resonance imaging |
| Tubal factors | Hysterosalpingography; laparoscopy and chromotubation; fluoroscopic/hysteroscopic tubal cannulation |
