are no longer recommended as routine studies in the initial evaluation (Brassard et al., 2008; Practice Committee, 2004) (Table 35-8).

Treatment should be directed toward the underlying cause. For tubal disease, surgery and in vitro fertilization are options. Endometriosis can be managed with conservative surgery based on the degree of disease or can be circumvented through intrauterine insemination or in vitro fertilization. Ovulatory dysfunction is treated based on the underlying cause: bromocriptine for prolactinoma, metformin or clomiphene citrate for PCOS, human menopausal gonadotropin for hypogonadotropic hypogonadism, clomiphene citrate plus glucocorticoids for adrenal hyperplasia with elevated levels of androgens, and antibiotics for infection. The family physician should strongly consider early referral to a reproductive specialist if the patient or couple have complex medical histories or advanced reproductive age.

Galactorrhea and Hirsutism

See the discussions online at www.expertconsult.com.

Polycystic Ovary Syndrome

Polycystic ovary syndrome is the clinical condition seen most frequently with androgen excess. Women with PCOS present with complaints of abnormal menses, infertility, hirsutism, acne, and obesity, all of which are related to excess androgen. PCOS is the single most common endocrine abnormality of women of reproductive age and affects 6% to 8% of women worldwide. The definition of PCOS is constantly being revised. The Task Force on the Phenotype of the Polycystic Ovary Syndrome from the Androgen Excess and PCOS Society (AE-PCOS Society) defines PCOS by the presence of hyperandrogenism (clinical and/or biochemical), ovarian dysfunction (oligo-anovulation and/or polycystic ovaries),

Box 35-11 Causes of Androgen Excess in Women

From Ehrmann DA, Barnes RB, Rosenfield RL. Hyperandrogenism, hirsutism, and the polycystic ovary syndrome. In DeGroot LJ, Jameson, JL (eds). *Endocrinology*, 5th ed, vol 3. Philadelphia, Elsevier-Saunders, 2006.

and the exclusion of related disorders (Azziz et al., 2009) (Box 35-11).

Typical presentation of PCOS includes hirsutism, menstrual dysfunction, obesity, insulin resistance, acanthosis nigricans, decreased fertility, and polycystic appearance to the ovaries. The onset of symptoms is usually around menarche, but it may occur after puberty as a result of weight gain or other environmental factors. Differential diagnosis includes idiopathic hirsutism, ovarian hyperthecosis, ovarian tumor, adrenal tumor, nonclassic adrenal hyperplasia, Cushing's syndrome, glucocorticoid resistance, and androgen-producing neoplasms.

A patient with PCOS is at higher risk for infertility, dysfunctional bleeding, obesity, endometrial hyperplasia, endometrial carcinoma, type 2 diabetes mellitus, dyslipidemia, hypertension, obstructive sleep apnea, and possibly cardiovascular disease with familial tendency (increased risk for mother and daughter) (Azziz et al., 2009; Ehrmann, 2005) (Table 35-9).

The diagnosis of PCOS is made with evidence of hyperandrogenism (clinical or biochemical), presence of ovarian dysfunction (clinical or anatomical), and excluding other conditions producing hyperandrogenism and ovarian dysfunction. Initial laboratory testing should include the determination of serum free testosterone, androstenedione, DHEA-S, and 17-hydroxyprogesterone. Other studies include prolactin, TSH, fasting glucose/insulin, and serum lipid profile. Obtaining circulating levels of LH and FSH does not contribute significantly to the diagnosis of PCOS, so these laboratory tests are not indicated with initial evaluation. Pelvic or transvaginal ultrasound should be performed to identify the ovaries and determine their size and shape and the presence of cysts;

Table 35-9 Signs and Symptoms in Relation to Presence of Polycystic Ovary Syndrome (PCOS)

| Symptoms/Signs | Patients with PCOS (% and % range) |
|------------------------------------|------------------------------------|
| Hirsutism and unwanted hair growth | 78.4 |

| Hyperprolactinemia | <1 |

Modified from Azziz R, Carmina E, Dewailly D, et al. Task Force on the Phenotype of the Polycystic Ovary Syndrome of the Androgen Excess and PCOS Society. The Androgen Excess and PCOS Society criteria for the polycystic ovary syndrome: the complete task force report. *Fertil Steril* 2009;91:456-488.

typical PCOS ovaries have increased volume and contain 10 to 12 subcapsular follicular cysts 2 to 9 mm in diameter.

Treatment of hirsutism and acne in PCOS focuses on decreasing androgen levels, production, and effects. Metformin is used extensively to reduce insulin resistance and hyperinsulinemia related to hormonal changes and ovulation (Nestler, 2008). To decrease risk of endometrial hyperplasia and carcinoma, cyclic progestin or a combination OC should be considered to inhibit endometrial proliferation.

In the long-term management of PCOS, steps should be taken to reduce cardiovascular complications, diabetes, obesity, and psychosocial morbidities (Fig. 35-8). Screening for glucose-intolerance with a 75-g 2-hour FTT and determination of serum lipid levels (total cholesterol, LDL, HDL, triglycerides) should be carried out. Lifestyle management changes include weight loss, exercise, and use of metformin and thiazolidinediones for patients with abnormal GTT results. In addition, clinicians should consider cardiovascular risk reduction, psychosocial issues, management of subfertility and hirsutism, and other lifetime management with insulin sensitizers and protection of the endometrium with hormonal manipulations.

KEY TREATMENT

Common causes of precocity are benign and require no treatment. Careful nontherapeutic observation may be considered (Carel et al., 2004) (SOR: A).

Treatment of precocity with GnRH analogues, which reversibly inhibit gonadotropin secretion, can be used to prevent secondary sexual development and early epiphyseal fusion (Carel et al., 2004) (SOR: A). Hormonal therapy with hCG or GnRH can be used to increase the likelihood of testicular descent (Henna, 2004) (SOR: A).

Inguinal orchiopexy is a well-established procedure for palpable undescended testicle and is generally considered the standard of care for cryptorchidism in the United States (Engeler, 2000; Kollin, 2007; Ritzèn, 2008) (SOR: A).

Present clinical practice suggests treating menopausal symptoms on an individual basis; predominantly with lifestyle therapies, risk modification, screening strategies, and nonhormonal therapies (Barton and Loprinzi, 2004; Brewer et al., 2003; Krebs et al., 2004; MacGregor et al., 2005) (SOR: C).

SSRIs, clonidine, and gabapentin are recommended for treatment of menopausal symptoms (Barton and Loprinzi, 2004; Brewer et al., 2003; Krebs et al., 2004; MacGregor et al., 2005) (SOR: C).

Tibolone is effective in controlling menopausal symptoms and reduces risk of fracture and breast cancer, but with an increased risk of stroke (Cummings et al., 2008) (SOR: A).

Patients with polycystic ovary syndrome require cardiovascular risk reduction, psychosocial counseling, management of subfertility and hirsutism, and possible insulin sensitizers and protection of endometrium with hormonal manipulations (Azziz, 2003; Azziz et al., 2009; Ehrmann, 2005; Nestler, 2008) (SOR: A).

Newer selective estrogen receptor modulators (SERMs) are being used to treat depressed libido in women, which minimizes risk to the endometrium while preserving benefits to breast and bone (MacGregor et al., 2005) (SOR: A).

Diagnosis of secondary amenorrhea can be facilitated with a progesterone challenge (Sheeler et al., 2007) (SOR: B).

Disturbances in Calcium and Phosphate

Calcium homeostasis is a delicate balance among a number of organ systems and functions. These include kidneys, thyroid, parathyroid, bone, adrenal glands, gastrointestinal tract, nutrition, infectious disease, and medication. Malfunction in any of these modalities can result in hypercalcemia or hypocalcemia with the potential for serious morbidity and mortality. Total body calcium is balanced between plasma and the bony skeleton in a state of dynamic equilibrium. Approximately 1% of total calcium is in circulation, and the remaining 99% is stored in bone. In plasma, circulating calcium is approximately 40% protein (albumin) bound; 45% exists in an ionized state (Ca^{++}); and about 15% is found as various salts (calcium citrate, calcium lactate, calcium phosphate, calcium sulfate). Bony calcium exists in an active state with constant deposition and resorption under the influence of parathyroid hormone (PTH, parathormone), calcitonin, osteoclastic and osteoblastic activity, and neoplastic disease.

The primary factor driving increases in circulating calcium is PTH, which increases bone resorption and converts vitamin D_3 (cholecalciferol) into 1,25-dihydroxycholecalciferol, the active form of vitamin D_3 . Cholecalciferol is primarily formed in the skin from solar irradiation, and some evidence suggests that ultraviolet (UV) radiation exposure of tanning beds can raise vitamin D_3 (Tangpricha et al., 2004). Dietary sources are

also important and can be obtained from fortified milk, fruit juices, fish oil, and other sources. The active form of vitamin D_3 is required to facilitate calcium absorption from the gut. Calcium homeostasis is further maintained by circulating levels of ionized calcium and calcitonin's negative effect on osteoclastic bone resorption (Hall, 2011). **Figure 35-9** shows the pathway for conversion of vitamin D_3 into its active form and vitamin D 's role in controlling plasma calcium concentration.

Normal levels of total circulating calcium, with normal albumin levels, range between 8.5 and 10.5 mg/dL (≈ 2.4 mmol/L). Ionized levels, which are not albumin dependent, will range between 1.17 and 1.33 mmol/L (≈ 4.7 mg/dL) (Bringham and Leder, 2006).

Hypercalcemia

Causes of hypercalcemia are generally divided into two types; primary and secondary. Primary causes are excessive parathormone secretion, and secondary causes include disease processes that directly affect bone metabolism and calcium excretion. The most common cause of primary hyperparathyroidism (PHPT) is a solitary parathyroid adenoma, accounting for approximately 80% of cases. Multiple adenomas are found in 2% to 4% of cases. The second most common cause of PHPT (15%) is parathyroid hyperplasia of multiple (usually ≥ 4) parathyroid glands. The etiologies for these include a mix of congenital and familial diseases (MEN-I, MEN-IIA). Less than 1% of PHPT is caused by primary parathyroid malignancy (Silverberg and Bilezikian, 2006) (**Box 35-12**).

Primary hyperparathyroidism does not present with classic symptoms. Symptoms may be as nonspecific as generalized weakness in the proximal muscles, fatigue, headache, weight loss, and constipation or as profound as renal failure, hypovolemic shock, and death (usually in patients with malignancy, although sometimes previously undiagnosed). Patients rarely present with signs and symptoms immediately suggesting hypercalcemia. PHPT is usually uncovered through routine nonspecific screening laboratory tests, during evaluation for nephrolithiasis, or occasionally in a patient with accelerated osteoporosis and pathologic fracture.

There is a classic "quadrad" of symptoms associated with hypercalcemia that, although seen in many disease processes, may be helpful in a patient with hypercalcemia, irrespective of etiology. The mnemonic taught to medical students is "bones, stones, moans, and abdominal groans," representing the four symptoms of the classic quadrad: bone pain, renal calculi, psychiatric disorder, and nausea and vomiting (Silverberg and Bilezikian, 2006).

The primary dysfunction in PHPT is an excess of circulating parathormone. However, with bony metastases, PTH levels will be appropriately suppressed in the presence of elevated serum calcium levels caused by osteolytic metastases. When the cause of hypercalcemia is malignancy, the patient usually has a history; an exception is unsuspected multiple myeloma, which may present with chronic low back pain and elevated serum calcium. Calcium levels in malignancy are typically higher (>14 mg/dL) than those found with parathyroid adenomas (<13 mg/dL), although this is not always the case (**Table 35-10**).

Thiazide diuretics, lithium, and calcium carbonate are common medications seen in primary care that, if not properly

| Urine PYD | 46.8 ±2.7 nmol/L/ mmol/L creatinine | <51.8 nmol/L/mmol/ L creatinine |

From Silverberg SJ, Bilezikian JP. Primary hyperparathyroidism. In DeGroot LJ, Jameson JL (eds). Endocrinology, 5th ed, vol 2. Philadelphia, Elsevier-Saunders, 2006.

monitored and prescribed, can result in hypercalcemia. It is also important to inquire about nonprescription (OTC) medications because excess vitamin D (intoxication) can be a cause. If a patient is taking any of these substances and is asymptomatic, with serum calcium level less than 14 mg/dL, the approach is to discontinue the medication and repeat the calcium level in a week. If the serum calcium is stable or declining, continue to monitor until it returns to normal.

Occasionally, adrenal insufficiency and hyperthyroidism are uncovered in the evaluation of a patient with an elevated serum calcium level.

Patients who have symptoms consistent with hypercalcemia or serum calcium levels in excess of 13.5 mg/dL may require more aggressive treatment. These patients will almost always be volume depleted as a result of hypercalciuria with resultant polyuria. Treatment is aimed initially at aggressive rehydration. Isotonic saline at 2 to 4 L/day until calcium level returns to normal is appropriate. Furosemide (loop diuretic) can be used with fluid replacement in older patients and those with renal or cardiac disorders to prevent fluid overload. Careful fluid management must be maintained to prevent inadvertent fluid overload or depletion (Table 35-11). Other treatments include IV bisphosphonate, calcitonin, and gallium nitrate or plicamycin (Table 35-12).

If the patient is determined to have a parathyroid adenoma, the only currently available option for cure is parathyroidectomy. For asymptomatic patients, patients who have failed surgery, and those who do not meet surgical criteria, medical treatment includes moderate calcium intake,

Table 35-11 Summary of Most Generally Useful Medical Therapies for Hypercalcemia

| Treatment | Onset of Action | Duration of Action | Advantages | Disadvantages |
|---|------------------------|---------------------------|---|---|
| Rehydration | Hours | During treatment | Rapid action Rehydration invariably needed | None |
| Forced saline diuresis (with or without loop diuretics) | Hours | During treatment | Rapid action | Modest calcium-lowering effect Potential for volume overload Electrolyte disturbance Transient efficacy Inconvenient for patients |
| Calcitonin | Hours | 1-2 days | Rapid onset of action | Modest calcium-lowering effect Tachyphylaxis develops in a few days |
| Bisphosphonates | | | | |
| Etidronate | 1-3 days | 5-7 days | First-generation bisphosphonate Well tolerated | 3-day infusion protocol Less effective than other bisphosphonates |
| Pamidronate | 1-2 days | Weeks to months | Second-generation bisphosphonate Normalizes calcium levels in many patients | Fever Occasional hypocalcemia, hypophosphatemia, and hypomagnesemia |
| Zoledronate | 1-2 days | Weeks to months | Third-generation bisphosphonate More potent than second-generation bisphosphonates Normalizes calcium levels in 90% of patients Can be given in 30 min | Fever Hypophosphatemia Hypocalcemia Renal toxicity occasional |

estrogen replacement (when applicable), bisphosphonates, and selective estrogen receptor modulators (SERMs).

For the patient with PHPT not caused by malignancy, determining if there is one adenoma or multiple functioning adenomas and the location(s) is important in minimizing both duration and extent of surgery. It is possible to determine preoperatively which parathyroid gland(s) may be the source of the PTH utilizing ultrasound, CT, or MRI. If none of these provides definitive results, technetium-labeled (Tc-99m) sestamibi nuclear scan may localize the adenoma (Silverberg and Bilezikian, 2006).

Hypocalcemia

Hypocalcemia has a number of primary and secondary causes. Primary causes involve some defect in PTH availability, including (1) lack of production (surgical removal of parathyroid gland or hypoparathyroidism from autoimmune disease), (2) impaired secretion (with profound hypomagnesemia), and (3) end-organ resistance. With the first two, there is a deficit in circulating PTH, but with the third, PTH is elevated, in contrast to a low serum calcium and hyperphosphatemia. An example of end-organ resistance is Albright's syndrome. Secondary causes include severe vitamin D deficiency, "hungry bone syndrome" with chondrosarcoma, and HIV/AIDS (Box 35-13).

Signs and symptoms are generally lacking in the outpatient setting. The primary clinical findings are caused by neuromuscular irritability. If hypocalcemia is suspected, although negative responses do not rule out hypocalcemia, two physical tests may assist in the diagnosis: Chvostek sign (tapping the facial nerve across the cheek with contraction of the facial muscle) and Trousseau's sign (carpal spasm via BP cuff). Deep tendon reflexes may be hyperactive, and the patient may appear anxious, confused, demented, or psychotic. The signs and symptoms of hypocalcemia are related to the level of ionized calcium rather than total calcium, as well as the rapidity of decline (Levine, 2006). Alkalosis,

either primary or compensatory, can cause a shift in ionized calcium to a bound state, thus exacerbating a borderline hypocalcemia situation.

Cardiac changes caused by hypocalcemia include prolongation of the QT interval, resulting in life-threatening dysrhythmia and cardiac dysfunction. Generalized seizures are also possible. The cardiac dysfunction is generally reversible with normalization of the ionized calcium levels. In acute and severe cases, IV calcium is the treatment of choice. Concurrent management of hyperphosphatemia, alkalosis, and hypomagnesemia is required. Long-term management is with oral calcium and vitamin D. Although use of thiazide diuretics is contraindicated in patients with hypercalcemia, they can be used with hypocalcemia and may have a beneficial effect. On the other hand, loop diuretics must be used cautiously because they increase renal excretion of calcium and may exacerbate the problem.

Pseudohypoparathyroidism is a rare phenomenon representative of several congenital endocrinologic disorders in which tissue resistance to PTH is present. The classic form of this disorder is *Albright's hereditary osteodystrophy* (AHO). The AHO patient has short stature, mental retardation, brachydactyly, and PTH resistance (elevated PTH levels). Another form of AHO does not involve PTH dysfunction, called pseudo-pseudohypoparathyroidism. Although the clinical course of these diseases may vary and in some cases is protracted, AHO usually is associated with a shortened life expectancy. Treatment is primarily supportive (Levine, 2006).

Hyperphosphatemia

The most common cause of hyperphosphatemia, and most familiar to primary care physicians, is impaired renal function. It is also a characteristic of all forms of hypoparathyroidism, from the loss of inhibitory effect of PTH on phosphate reabsorption at the proximal renal tubule (Levine, 2006). High-phosphate formula provided to infants can result in hypocalcemia and tetany (Box 35-14).

From Levine MA. Hypoparathyroidism and pseudohypoparathyroidism. In DeGroot LJ, Jameson JL (eds). Endocrinology, 5th ed, vol 2. Philadelphia, Elsevier-Saunders, 2006. PTH, Parathyroid hormone (parathormone).

Hypophosphatemia

Dietary causes of hypophosphatemia are virtually nonexistent, although excessive use of oral phosphate binders (aluminum and magnesium hydroxide antacids) can result in binding of phosphate in the intestine, thus preventing absorption. Generally, when use of oral antacids is excluded, the most common cause of hypophosphatemia is elevated levels of serum calcium caused by increased PTH or malignancy (Silverberg and Bilezikian, 2006). Hypophosphatemia in association with hypocalcemia is usually caused by renal wasting or is seen in severe illness. One form of infant hypophosphatemic rickets is transmitted as an autosomal dominant trait (Box 35-15).

Overview

Key Points

- Body mass index (BMI) determines the classification of obesity for clinical use.
- Waist circumference reflects the distribution of adipose tissue and helps determine obesity risk.
- Central obesity, reflected by a high waist measurement, is associated with more complications.

Obesity has been a rapidly developing health concern in the United States. The ongoing Behavioral Risk Factor Surveillance System (BRFSS) and National Health and Nutrition Examination Survey (NHANES) provide a longitudinal view of changes in the obesity problem. BRFSS data are from a state-based telephone survey, and NHANES data are based on measurements of a representative sample of the U.S. population. The self-reporting design of BRFSS tends to underestimate weight, but ongoing studies can be examined for trends. NHANES reported that the prevalence of U.S. adults in the overweight category (BMI ≥ 25 kg/m²) increased from 46% to 61% between the late 1970s and 1990s

(Zimmerman, 2002). As of 1999–2000, 64.5% of adults were overweight and 30.5% were obese (BMI ≥ 30 kg/m²) (Flegal et al., 2002). Prevalence estimates from the Centers for Disease Control and Prevention (CDC) for 2007–2008 found that 32.2% of men and 35.5% of women were obese. In addition, surveys from 1976–1980 and 2003–2006 found that obesity increased from 5.0% to 12.4% among children age 2 to 5 years; from 6.5% to 17.0% for ages 6 to 11 years; and 5.0% to 17.6% for ages 12 to 19 years. Changes in obesity prevalence have affected all U.S. regions (Fig. 36-1).

The problem of obesity is not limited to the United States. Globally, *overnutrition* has now surpassed undernutrition as a public health concern. An estimated 8.5% of the world population is overweight versus 5.8% underweight (Zimmerman, 2002). Although obesity prevalence estimates vary among countries, the World Health Organization (WHO) has projected that 2.3 billion adults will be overweight and 700,000 million obese by 2015.

Improved treatment of comorbidities has made assessing obesity's impact on mortality more difficult, but estimates of the excess mortality associated with obesity in the United States range from 100,000 to 300,000 deaths each year. Persons in the overweight category have 20% to 40% increased mortality, and obese persons have a twofold to threefold increase in mortality (Adams et al., 2006).

| 6'1" | 140 | 188 | 189 | 204 | 226 | 227 | 265 | 303 | 340 |
| 6'2" | 144 | 193 | 194 | 210 | 232 | 233 | 272 | 311 | 350 |
| 6'3" | 148 | 199 | 200 | 216 | 239 | 240 | 280 | 319 | 359 |
| 6'4" | 152 | 204 | 205 | 221 | 245 | 246 | 287 | 328 | 369 |

The increased prevalence of obesity has many other health ramifications. An increase in body mass index (BMI) is a risk factor for short-term disability in the workplace. Overweight and obese individuals have odds ratios of 1.26 and 1.76, respectively, compared to normal-weight workers (Arena et al., 2006). Obesity increases "presenteeism," or the reduced productivity in workers still on the job. Workers with BMI over 35 kg/m² experienced a 4.2% health-related drop in productivity (Gates et al., 2008). Evidence indicates that the 37% increase in obesity rates (BRFSS) between 1998 and 2006 is a significant factor driving health care costs. The medical consequences of obesity have been estimated to account for 9.1% of annual medical spending (Finkelstein et al., 2009).

Assessment

The primary parameter used to categorize weight is BMI: 18.5 and 24.9 is normal in adults; 25 to 29.9 is overweight; and 30 or greater is obese. Class III, "severe," or "extreme" obesity is 40 and higher. Calculated from height and weight

and expressed in kg/m², BMI is a readily available tool in the assessment of obesity (Table 36-1). Because it correlates with total body fat and with the complications of obesity better than body weight, BMI is a recommended parameter to assess obesity, but an imperfect tool to measure adiposity. A high value may reflect greater lean body mass rather than adiposity in muscular individuals. In addition, BMI does not reflect distribution of body fat, a factor that influences risk.

Body fat percentage is a more precise assessment of adiposity but is difficult to measure accurately in the office setting. The techniques of skin fold measurements and bioelectric impedance assays can be used, but skin fold measurements may not be accurate, and both measures generally do not change assessment or treatment goals for most patients. Cut-off levels for body fat percentage selected by WHO are used to stratify health risks associated with overweight and obesity but may not be practical in clinical practice.

From birth to age 2 years, overweight is assessed by the weight-for-length percentile; at or above the 95th percentile is considered overweight or obese. For the pediatric population age 2 to 19 years, percentile ranks based on

Table 36-2 Classification of Obesity Based on BMI and Waist Circumference

| | BMI* (kg/m ²) | Obesity Class | Disease Risk | |
|--------------------|------------------------------|------------------|---------------------|-----------------------------------|
| | | | Low Waist Cir | High Waist Cir [†] |
| Underweight | <18.5 | — | — | — |
| Normal | 18.5-24.9 | — | — | — |
| Overweight | 25.0-29.9 | — | Increased | High |
| Obesity | 30.0-34.9 | I | High | Very high |
| | 35.0-39.9 | II | Very high | Very high |
| Extreme obesity | ≥40 | III | Extremely high | Extremely high |

From National Heart, Lung, and Blood Institute, National Institutes of Health. The Practical Guide to the Identification, Evaluation, and Treatment of Overweight and Obesity in Adults (NIH). Pub No 00-4084. NIH, Bethesda, Md, 2000.

*Body mass index can be calculated as wt (kg)/ht² (m), or wt (lb) × 703/ht² (in).

[†]High waist circumference is defined as >40 inches in men and >35 inches in women.

the 2000 CDC growth charts for the United States are used to define overweight and obesity. The CDC defines overweight between ages 2 and 19 years as a BMI between the 85th and 95th percentiles for age and sex. A child or adolescent with BMI at or above the 95th percentile is considered obese.

The *distribution* of body fat also affects health risks. *Central obesity*, also referred to as visceral, abdominal, or android obesity, is associated with a greater risk of complications, including the metabolic syndrome, as discussed later. Waist-to-hip ratio has been used to assess central obesity, but gender-specific waist circumference, taken at the level of the iliac crest, has proved to be a better assessment of the distribution of body fat. Health risks increase above a waist circumference of 35 inches in women and 40 inches in men, and as a continuous variable with increasing waist circumference, but these cutoffs facilitate a simple classification of risk in a continuous variable. Magnetic resonance imaging (MRI) and computed tomography (CT) of the abdomen have also been used to assess visceral deposition of fat in research settings, but cost and lack of easy accessibility make them impractical for clinical use. **Table 36-2** lists the classification of obesity based on BMI and waist circumference.

Demographics

Key Points

- Men are more likely than women to have central obesity.
- African Americans, Hispanics, and Native Americans are at greater risk of obesity than whites.
- Obesity is inversely related to education and socioeconomic status.
- Obesity is more prevalent in rural than urban areas.

Table 36-3 Obesity Prevalence (BRFSS Surveys, 2006–2008)

| | White, non-Hispanic | Black, non-Hispanic | Hispanic |
|-------|---------------------|---------------------|----------|
| Men | 25.4% | 31.69% | 27.8% |
| Women | 21.8% | 39.2% | 29.4% |
| Both | 23.7% | 35.7% | 28.7% |

Data from Behavior Risk Factor Surveillance System. Differences in prevalence of obesity among black, white, and Hispanic adults—United States, 2006–2008. <http://www.cdc.gov/mmwr/preview/mmwrhtml/mm5827a2.htm>.

Obesity is a concern within virtually all demographic groups (**Table 36-3**). The high prevalence of obesity is seen in both genders, most ethnic groups, and at all ages. Within those groups, the impact is not uniform.

Gender Differences

Men are more likely than women to be overweight, whereas women are more likely to be obese. Men, however, are more likely to have central obesity, associated with greater health risks.

Race and Ethnic Origin

African Americans, Hispanics, and Native Americans are at greater risk for obesity. Blacks have a 51% higher prevalence of obesity and Hispanics a 21% higher prevalence than whites (Pan et al., 2009). Asians are at lower risk as an ethnic group. However, health risks of overweight and obesity may appear at a lower weight in Asians, and thus a lower cutoff for overweight has been proposed for Asians (BMI >23 kg/m²). Gender differences are seen within ethnic groups. The prevalence of obesity is greater among African American women than among African American men, whereas these differences are not as evident among non-Hispanic whites. Immigrants have an increased incidence of obesity, starting about 10 years after arrival in the United States (Goel et al., 2004).

Socioeconomic Status

The increase in the prevalence of obesity worldwide reflects, in part, economic development. The prevalence ranges from approximately 2% in the least developed countries to over 30% in the most developed countries. In developed countries, however, lower socioeconomic status is associated with an increased risk. Proposed reasons for this observed difference include reduced access to medical care, healthy foods, and exercise facilities among lower socioeconomic groups. Furthermore, foods that are more energy dense (through the addition of added sugar) are less costly than nutrient-dense foods (Thompson et al., 2009).

Education Level

Education level is inversely related to the risk of obesity, which may partly explain the decreased risk with increased socioeconomic status in developed countries. Access to

health care, greater awareness of healthy lifestyle habits, and more access to recreational facilities are potential factors in this association.

Rural and Urban Differences

Analysis of BRFSS data shows that the prevalence of obesity is greater in rural than urban areas. Factors that reduce physical activity may play a role, ranging from less access to exercise facilities to lack of sidewalks. Reduced availability of healthy food choices is also thought to contribute. As in other settings, African Americans and Native Americans in rural areas have the highest prevalence of obesity. Although Asians in urban environments have a low prevalence of obesity, the prevalence among Asians in rural settings approaches that of other ethnic groups (Jackson et al., 2005).

Age

The incidence of overweight increases steadily after age 20 until the seventh decade of life. At that point, it levels off and begins a gradual decline. Even within the low-risk age ranges of 18 to 29 and older than 70 years, the prevalence of overweight has increased according to BRFSS. The increased prevalence of overweight is especially alarming in the pediatric population, in whom the most dramatic increase has been in the severely obese, similar to the adult population. More than 30% of children and adolescents are overweight or obese. Older children are more likely to be in a higher weight category.

Determinants of Obesity

Key Points

- Obesity results from the interaction of genetic makeup, environment, and lifestyle.
- Genetic factors are estimated to account for 30% to 40% of the variability in adult weight.
- Genetic influence is polygenic.
- Specific metabolic or endocrine disorders account for less than 1% of the obese population.

When reduced to basics, obesity results from calorie consumption in excess of expenditure. What complicates this simple principle is the role of genetics, lifestyle, and environmental factors. Throughout human evolution there has been a survival advantage to storing energy as fat. The conveniences of modern life have led to a decrease in energy expenditure. At the same time, greater access to energy-dense food, along with other factors, has increased energy consumption. These changes, in the relatively recent past, negate the survival advantage of fat storage for most segments of the population.

Genetics vs. Lifestyle

The relative contribution of genes versus lifestyle and environment in the development of obesity has not been precisely delineated. A child's risk of adulthood obesity is three times greater if one parent is obese and 10 times greater if

both are obese. Indeed, for children younger than 3 years, parental weight is a greater determinant of risk of obesity than the child's own weight (Whitaker et al., 1997). However, the influence of parental weight does not reflect only genetic predisposition, because family members also share the same environment. A correlation in adult weight between identical twins is seen, even when they have been raised apart. Among adoptees, weight correlates with the weight of their biologic parents, but the correlation is not as strong as in twin studies. In summary, genetic makeup plays a permissive role, with adult weight being determined by interaction with the environment. Overall, genetic factors are estimated to be responsible for 30% to 40% of the variability in adult weight.

Genetic Factors

Most of the genetic influence on obesity is polygenic. More than 250 genes and chromosomal regions are associated with phenotypic obesity (Larsen et al., 2003). In some cases, the genes code specifically for visceral as opposed to subcutaneous obesity. Although specific genetic factors to explain common obesity have not been identified, several single-gene defects cause obesity in animals, with some correlates in humans.

Single-gene mutations related to obesity often involve leptin and melanocortin. *Leptin* is a protein produced in adipose tissue that provides negative feedback to appetite control centers. Obesity may reflect lack of hormone production or a lack of leptin receptors. There are leptin-deficient animal models, and rarely, this deficiency has been identified in humans. In leptin-deficient people, weight loss results when leptin is replaced. Leptin supplementation in non-leptin-deficient obese subjects does not result in weight loss (Bray, 2002).

Rare defects in *melanocortin* receptors in the adrenals have also been associated with obesity. Most often, a person must be homozygous for the abnormal gene for the trait to be expressed. A defect in the melanocortin-4 receptor is the most common single-gene mutation associated with severe obesity but still accounts for only about 5% of this population. Other single-gene mutations have been found in animal models as well as humans, but all are extremely rare. Recently identified genes include the FTO (fat mass and obesity-associated) gene. Each of these genes seems to be associated with a modest increase in weight.

There are a number of congenital syndromes in which obesity is part of the phenotype. The best known, *Prader-Willi syndrome*, results from a defect in the long arm of chromosome 15 and causes poor muscle tone in the newborn period, with hyperphagia, hypogonadism, behavioral problems, and developmental delay noted later. As with other medical causes of childhood obesity, linear growth is poor while growth in weight is excessive. Although the exact mechanisms by which the genetic abnormalities lead to obesity are unclear, patients with Prader-Willi syndrome have elevated levels of *ghrelin*, a peptide produced in the stomach and duodenum that stimulates eating.

Modulation of Appetite

Many hormonal factors are involved in appetite, as well as in the absorption, storage, and use of calories. Factors providing input to the brain include leptin levels, vagal afferent activity,

and fluctuation in plasma glucose levels. Neuropeptides and monoamine neurotransmitters are also involved in appetite control. Some weight loss medications exert their influence through modulation of neurotransmitter levels, which may affect appetite or satiety.

Influences on Central Obesity

Central obesity suggests increased visceral fat deposits, likely caused by increased production of peptides and other metabolic messengers. Hormonal influences most likely play a role in the distribution of fat. Central obesity is believed to result partly from increased androgenic effects, which is why men have a greater tendency for central obesity. Central obesity is also associated with hyperandrogenic states in women, such as polycystic ovary syndrome (PCOS). The increase in visceral deposition of fat that can occur after menopause in women may be related to a decrease in growth hormone and estrogen production (see Chapter 35).

Lifestyle Influences

Key Points

- Increased caloric intake is related in part to “portion distortion,” linked to eating away from home.
- Smoking cessation is associated with weight gain of 4 to 5 kg (on average).
- Many antidepressants, neuroleptics, and anticonvulsants are associated with weight gain.
- Decreased overall physical activity (not just “exercise”) is a major factor associated with the increasing prevalence of overweight and obesity.

As mentioned, obesity develops when caloric intake exceeds caloric expenditure against a background of genetic influences. The chief determinants of energy imbalance are lifestyle factors. Individual total energy requirements depend on the *basal metabolic rate* (BMR), thermic effect of food, and energy needed for the day’s physical activities. The chief determinant of BMR is the amount of lean body mass, which can be difficult to increase. Some data indicate that the *thermic effect* of food (amount of energy needed to absorb, digest, and assimilate nutrients) is lower in obese persons than in lean subjects, but this difference is quite small. Physical activity (exercise and activity throughout the day) is the most variable component of energy expenditure. The major reasons for weight gain are therefore excessive calorie intake and decreased overall physical activity.

Caloric Intake

Over the past 40 years, the tendency in the U.S. population has been to consume more calories needed; per-capita consumption of calories increased from 2220 kcal in 1970 to 2680 kcal in 1997 (Putnam, 2000). Some of this increase is related to increased portion size; a normal portion in 1970 is much less than a normal portion in 2010. This “portion distortion” has been linked to people eating more away from home. The typically larger restaurant portion size has been adopted as the in-home standard as well (Foreyt and Poston, 2002).

Energy density also plays a role. Satiety helps determine food intake and is largely determined by the volume and weight of food consumed. Foods that are high in caloric content for a given volume lead to excessive calorie intake. This includes fat and highly processed foods such as sugar and other refined carbohydrates that are high in energy density. Per-capita consumption of sugar has greatly increased at the same time as the increasing prevalence of obesity.

The frequency of meals may play a small role. Eating smaller meals more frequently is associated with less overweight. Large meals are associated with more insulin release. This might be a mechanism whereby meal size influences weight gain.

Activity Changes

Decreased energy expenditure may play a greater role in the development of obesity than increased caloric intake. In the United States a progressive decrease in energy expenditure has coincided with the increase in calorie consumption (Foreyt and Poston, 2002). The amount of exercise has not changed much over the past few decades, so most of the decrease in physical activity energy expenditure has occurred in daily physical activities, not exercise.

Smoking Cessation

Often cited by smokers as a reason to continue smoking, stopping cigarette smoking does lead to weight gain. The average weight gain is 4 to 5 kg (~9-11 lb) over months (Flegal et al., 1995). Typically, the person gains 1 to 2 kg (~2-4 lb) in the first few weeks after cessation (Bray, 2002). Approximately 10% of people gain 10 kg (22 lb) or more.

Medications

A number of medications are associated with weight gain, including antidepressants, antipsychotics, anticonvulsants, and hypoglycemic agents. Tricyclic antidepressants, monoamine oxidase inhibitors, and mirtazapine are the antidepressants most likely to cause weight gain. Of the more common selective serotonin reuptake inhibitors (SSRIs), paroxetine is most likely to be associated with weight gain, although individual effects vary. Many neuroleptics can lead to weight gain. Phenothiazines and haloperidol, as well as some newer agents such as clozapine and olanzapine, tend to increase weight. Among anticonvulsants, valproic acid and gabapentin have been most closely tied to weight gain. Lamotrigine is thought to be weight neutral, whereas topiramate may actually promote weight loss. Insulin, as well as oral hypoglycemics that increase production or release of insulin, promote weight gain. It should be noted that metformin, which increases insulin sensitivity, is associated with modest weight loss and may ameliorate the weight gain from other hypoglycemics. Chronic systemic steroid use can cause a cushingoid type of obesity.

Endocrine and Metabolic Factors

Specific identifiable endocrine or metabolic disorders known to cause obesity account for less than 1% of the obese population, contrary to what is commonly believed (see also Chapter 34).

Hypothyroidism

Although rarely found in children, hypothyroidism is associated with slow statural growth and developmental delay. More common among adults and more often seen in women, hypothyroidism is a relatively rare cause of obesity. If undiagnosed, it is typically accompanied by other symptoms of thyroid deficiency, such as cold intolerance, decreased energy, constipation, and increased thinning of the scalp.

Neuroendocrine Factors

The rarely seen neuroendocrine causes for obesity result from injury to the ventromedial hypothalamus, the result of tumor, trauma, or surgery to the posterior fossa. Other symptoms indicative of endocrine and neurologic abnormalities are seen along with hyperphagia and subsequent obesity (Bray, 2002).

Cushing's Syndrome

This endocrine disorder is associated with central obesity and "buffalo hump" along with axillary striae, glucose intolerance and hypertension. In children with Cushing's syndrome, linear growth is restricted.

Polycystic Ovary Syndrome

More than 50% of women affected by this relatively common disorder are obese. Some controversy surrounds whether PCOS is a cause or consequence of obesity, although most evidence points to the latter. Other common features include menstrual irregularities, hirsutism, and elevated testosterone and luteinizing hormone blood levels. Insulin resistance is a consistent finding, even in the absence of obesity. This resistance is thought to be associated with other findings in PCOS, although exact mechanisms are unclear.

Growth Hormone Deficiency

Although growth in height is impaired in growth hormone deficiency, there is also an increase in truncal obesity. This corrects with replacement of growth hormone.

Medical Complications

Key Points

- Obesity is more closely related to elevated triglycerides and low HDL cholesterol than elevated total and LDL cholesterol.
- Weight loss is the most effective lifestyle change to lower blood pressure.
- Up to 80% of cases of type 2 diabetes mellitus are attributable to overweight and obesity.
- Obesity plays a role in 14% of cancer deaths in men and 20% in women.

Based on observational studies, obesity is a risk factor for a number of chronic medical conditions. In conjunction with

other risk factors, obesity can greatly impact the chances of developing many diseases. In general, the increased risk for morbidity and mortality begins in the overweight range and correlates more strongly with BMI over 30 kg/m² (Flegal et al., 2004). The risk of specific conditions associated with obesity, such as diabetes and hypertension, varies with gender and ethnic origin.

Hypertension

Obesity has long been recognized as a risk factor for hypertension and appears to be associated with the increasing incidence of hypertension seen with aging. The obesity-related increase in blood pressure (BP) is associated with an increase in vascular resistance as well as sodium resorption. The increased vascular tone may reflect increased sympathetic tone because of insulin resistance and the resultant increase in insulin levels. In the Nurses' Health Study (NHS), for BMI at age 18 and again at midlife, the relative risk of hypertension in women gaining 5 to 9.9 kg (11-22 lb) in that time was 1.7, and in those with weight gain over 25 kg (55 lb) was 5.2 (Huang et al., 1998). Controlling overweight would reduce the incidence of hypertension in whites by an estimated 48% and in African Americans by 28% (Bray, 2003). Weight loss is the most effective lifestyle change to decrease blood pressure. For every 1-kg loss in weight, there is an average decrease of 0.6 mm Hg in systolic and 0.34 mm Hg in diastolic BP (Stevens et al., 1993). In the National Heart, Lung, and Blood Institute (NHLBI) obesity guidelines, weight loss is recommended to lower elevated BP in overweight and obese persons.

KEY TREATMENT

Modest weight loss can reduce morbidity of obesity-related disease (Shepherd, 2003) (SOR: A).

Dyslipidemia

Obesity is associated with elevated triglyceride (TG) levels, reduced high-density lipoprotein cholesterol (HDL-C), and an increase in the more atherogenic, small, dense LDL particles. Despite common belief, obesity causes only a small mean elevation in total and low-density lipoprotein cholesterol (LDL-C) values. There is strong evidence that weight loss through lifestyle measures will reduce TG and increase HDL-C levels. This weight loss is generally accompanied by a decrease in total cholesterol and LDL-C, in part because the same lifestyle changes in diet that decrease weight also decrease LDL-C. The favorable effect on lipids from aerobic exercise is most noticeable when accompanied by weight loss. NHLBI recommends weight loss to reduce elevated total cholesterol, LDL-C, and TG levels and to raise HDL-C in overweight/obese persons.

Type 2 Diabetes Mellitus

According to BRFSS, the prevalence of type 2 diabetes mellitus (T2DM) increased from 4.9% in 1990 to 7.9% in 2000 (Mokdad et al., 2003). This change has been clearly linked to the increase in obesity. The risk of T2DM is lowest below a BMI of 22 to 23 kg/m². At a BMI of 31, the risk for women

in the NHS was 40-fold greater than in women with a BMI less than 22 (Colditz et al., 1995). For men in the Health Professionals Follow-up Study, the risk of T2DM above a BMI of 35 kg/m² was increased 60-fold. Up to 80% of cases of T2DM can be attributed to overweight and obesity. There appears to be a time delay of about 10 years between the development of overweight and onset of the diabetes (Bray, 2003). As weight increases, insulin resistance and compensatory insulin secretion also increase. At some point, the body's ability to secrete insulin does not meet requirements, and blood glucose rises. Weight loss is recommended to lower elevated glucose levels in overweight and obese persons with T2DM.

Metabolic Syndrome

The metabolic syndrome brings together a number of the comorbidities associated with obesity. The definition used by the National Cholesterol Education Program (NCEP) Adult Treatment Panel III requires the presence of three of the following five disorders: (1) BP elevation of at least 130/85 mm Hg, (2) serum TG level higher than 150 mg/dL, (3) HDL-C level less than 50 mg/dL in women and 40 mg/dL in men, (4) fasting blood glucose level at least 110 mg%, and (5) waist circumference more than 35 inches in women and 40 inches in men. WHO and American Association of Clinical Endocrinologists (AACE) criteria are similar but add increased urinary albumin excretion and require the presence of impaired glucose tolerance or T2DM. The waist circumference indicates abdominal or visceral obesity. It is not clear whether visceral obesity is a factor in the development of the metabolic syndrome or if it is simply a marker for the disorder. An estimated 40% of the U.S. population over age 65 meet the criteria for the metabolic syndrome. Although other factors may be involved in the pathogenesis, a common thread linking these disorders is insulin resistance. The presence of the metabolic syndrome increases the risk of T2DM, hypertension, coronary artery disease (CAD), and cerebrovascular disease.

Heart Disease

The presence of obesity in the absence of other risk factors may lead to cardiomyopathy and congestive heart failure (CHF) as the workload of the heart increases. Beyond the direct impact on cardiac function, obesity may be an independent risk factor for CAD. Obesity is associated with a number of well-established risk factors for CAD, and most of the increased risk associated with obesity is caused by these factors. The NHS indicated that for women with BMI more than 29 kg/m², CAD risk increases 3.3-fold compared with women with BMI less than 21 kg/m² (Manson et al., 1995). The Finnish Heart Study found that for each increase in weight of approximately 1 kg, the risk of mortality from CAD was increased by 1% to 1.5% (Jousilahti et al., 1996). The NHS and the Health Professionals Follow-up Study showed a significant increased risk of CAD among participants who gained more than 10 kg after age 20. A 4% increased risk of atrial fibrillation has been found for each 1-unit increase in BMI. Left atrial enlargement is a predictor of atrial fibrillation and has been associated with increased BMI (Zalesin et al., 2008).

Cancer

Although not all studies have found a positive correlation between specific cancers and obesity, it is thought to be associated with many and perhaps most cancers. Obesity may be the largest avoidable cause of cancer for nonsmokers. A 16-year prospective study of over 900,000 people found a 52% increase in cancer mortality in men and a 62% increase in women who were severely obese (Calle et al., 2003). Cancers of many different primary sites were associated with obesity, with increased mortality risk from cancer of the esophagus, colon, kidney, gallbladder, and pancreas, as well as multiple myeloma and non-Hodgkin's lymphoma. There was a significant trend toward increased risk of prostate, gastric, ovarian, and endometrial cancers. The relative risk for obese subjects who had never smoked was even greater than for smokers. It was estimated that overweight and obesity played a role in 14% of cancer deaths in men and 20% in women.

The mechanisms accounting for the increased risk of cancers vary with the primary site. One proposed mechanism for endometrial and breast cancer is an increase in circulating estrogen levels. Central obesity in particular has been associated with breast cancer. Increasing evidence shows an association between obesity and prostate cancer, with the increased risk likely related to changes in testosterone as well as leptin, insulin-like growth factor 1, and interleukin-6 levels.

The World Cancer Research Fund and American Institute for Cancer Research (2007) state that maintenance of a healthy weight throughout life may be one of the most important ways to protect against cancer. Adults should maintain BMI between 21 and 23.

Obstructive Sleep Apnea

Although obstructive sleep apnea (OSA) is not always associated with obesity, excessive weight is a major risk factor. About 70% of OSA patients are obese. Among obese persons, the incidence of OSA is approximately 40% (Poulain et al., 2006). The increased risk may be related to increased neck circumference and pharyngeal fat deposits. Often unrecognized, OSA has significance beyond daytime somnolence and the spousal impact of disruptive snoring and has been associated with systemic effects as well, such as pulmonary hypertension, right-sided CHF, and erectile dysfunction. Weight loss may benefit the OSA patient. Conversely, a patient with mild OSA who has a 10% increase in body weight then has a sixfold increased risk of progressing to moderate or severe sleep apnea (Caples et al., 2005).

Pulmonary Disease

Obesity can have an impact on overall lung function. It increases the work of breathing through a decrease in chest wall compliance as well as a reduction in respiratory muscle strength. Obesity increases pressure on the diaphragm, reducing residual lung volume (reduced FEV₁, FVC, TLC, and FRC). The result can be a mild restrictive pattern, although typically only in the severely obese population (Poulain et al., 2006). Asthma is exacerbated with increased weight, and obesity-hypoventilation syndrome (hypercapnic respiratory failure and cor pulmonale) is associated with marked degrees of obesity.

Fatty Liver Disease

Fatty liver disease is the most common reason for elevated serum liver enzymes and affects an estimated 20% of the U.S. population (Angelico et al., 2005). First described in obese diabetic females, fatty liver disease is widely recognized as a complication of obesity and is associated with the features of the metabolic syndrome. The spectrum of fatty liver disease ranges from nonalcoholic fatty liver disease (NAFLD) to nonalcoholic steatohepatitis (NASH). Fibrosis and cirrhosis can develop in NASH, which has been linked to insulin resistance, as with metabolic syndrome (Choudhury and Sanyal, 2004). The increased insulin level likely causes fatty acid flux from adipose tissue to be deposited in the liver. Inflammatory cytokine release triggered by hyperinsulinemia contributes to the steatohepatitis and fibrosis.

Orthopedic Disorders

Overweight children have an increased risk of slipped femoral capital epiphysis, genu valgus, pes planus, and scoliosis (Speiser et al., 2005). In adults, an association between obesity and degenerative joint disease (DJD), particularly of the knee, is related in part to mechanical factors resulting in increased compressive forces on the knee. Obesity-related cytokine production has been associated with a chronic inflammatory state promoting osteoarthritis. Obesity is associated with knee weakness and balance problems, increasing the risk of falls. Functional impairment from obesity in elderly persons has been linked to these factors (Messier, 2008).

Gallbladder Disease

Obesity, along with hyperinsulinemia and the metabolic syndrome, are risk factors for gallbladder disease, apparently related to changes in cholesterol metabolism. Cholesterol production increases with weight gain, and cholesterol is excreted into bile. The increased cholesterol relative to bile acids can lead to the formation of stones. Cholesterol flux during weight loss increases risk of symptomatic gallbladder disease, which increases with the rapidity of weight loss (Bray, 2003).

Psychological Impact

Self-awareness of overweight and the associated psychological impact can be seen in children as young as 5 years old. The social repercussions of overweight can result in poor self-esteem. This may result in poor body image, especially in young women. Eating disorders, particularly binge eating, can complicate the management of obesity. In adults, obesity is associated with depression in women, although not in men (Carpenter et al., 2000).

Complications in Childhood and Adolescence

In addition to childhood overweight being a risk factor for adult obesity, medical complications of excessive weight occur in the pediatric population. These range from a slipped femoral capital epiphysis to self-esteem issues. Adult diseases (T2DM, NAFLD, OSA) are being increasingly identified in the pediatric population.

Management and Interventions

Key Points

- An initial goal of a 5% to 10% reduction in weight is reasonable.
- A process-oriented target (lifestyle) may be more beneficial for some than a target weight.
- A weight reduction rate of 1 to 2 pounds weekly is achievable if intake is reduced by 500 to 1000 kcal daily.
- Caloric restriction alone is not as effective as combining it with an exercise program.
- A low-energy-dense diet composed of generous quantities of vegetables and fruits promotes health and facilitates weight management.

Although long-term treatment of obesity has generally had disappointing results, some individuals have lost and maintained significant amounts of weight. Weight loss programs have typically shown modest benefit, with variable results depending on the method, but most weight is eventually regained in 4 to 5 years. An exception is bariatric surgery, although its use is restricted to a small subset of the extremely obese population. Primary prevention strategies using many interventions at the individual and population levels are needed to limit the growing epidemic of obesity. Early intervention should start in childhood, and because excessive weight gain can occur at any age, strategies should be continued through adulthood. Family physicians should calculate BMI for all patients at least yearly to monitor for a developing weight disorder, with further screening for comorbidities if overweight is found.

Childhood Overweight and Obesity

Key Points

- Childhood obesity rarely is associated with a primary medical disorder.
- When present in childhood obesity, underlying disorders are almost always associated with statural growth reduction.
- The risk of adult obesity increases with the age of the obese child.
- Intervention can be more effective in children than in adults and should involve the entire family.

Only a small proportion of obese children participate in a medically supervised program. Although many studies of obesity management in the pediatric population have had methodologic limitations, efforts to make lifestyle behavioral changes in physical activity and diet have been found to be of benefit (Oude et al., 2009). Family therapy, school-based programs, and in particular involvement of parents are also beneficial (Hill et al., 2002). Interventions for children may be more effective than those for adults.

The approach of treatment in childhood is primarily related to the lifestyle issues of proper diet and exercise. The goals of treatment should be a reduction in BMI to less than the 95th percentile for age and prevention or reversal of comorbidities. Parental involvement is a key component

in childhood weight management. However, parents may not recognize the problem of overweight and obesity in their children, particularly in their sons (Jeffery et al., 2005). Poor parental recognition of their own obesity is also noted. In addition, health care providers may overlook obesity at well-child visits (Cook et al., 2005). Therefore, health care providers may need to educate themselves and their patients about the appropriate recognition and treatment of obesity. Individual and family counseling may be indicated in patients with more severe obesity.

During well-child visits, BMI should be calculated and risk factors for obesity noted. These include parental obesity, maternal smoking during pregnancy, a predilection for sedentary activities, and poor dietary habits. When followed through early childhood, BMI typically will decrease until a period known as *adiposity rebound* occurs between ages 5 and 7 years. An early adiposity rebound noted on BMI for age charts increases the risk of adult obesity. The physician should discuss with all parents the importance of developing healthy eating habits early in life, as well as limiting sedentary activities such as television and computer games. Encouraging parents to model this lifestyle is beneficial.

In children, underlying hormonal factors leading to obesity also tend to lead to short stature. The association of short stature with excess weight gain should therefore prompt an investigation into a possible underlying endocrine disorder (Brown et al., 2002). In contrast, childhood obesity related to exogenous factors is associated with an increased rate of statural growth. This increased growth in height is associated with increased bone age and early puberty.

An adolescent who has been identified as overweight should be screened for comorbidities. The Expert Committee on Clinical Guidelines for Overweight in Adolescent Preventive Services recommends a lipid panel and fasting blood glucose for adolescents with a BMI over the 85th percentile if there is a family history of lipid disorders or early-onset cardiovascular disease (Brown et al., 2002).

A staged treatment approach is recommended depending on the child's age and degree of obesity (Barlow, 2007). For the child between the 85th and 95th percentile for BMI, diet and exercise continue to be key components of treatment. The approach should involve modest calorie restriction while increasing energy expenditure. Overly restrictive diets have the potential of interfering with growth rate, bone mineralization, and menstruation. At a BMI over the 95th percentile, a more structured and aggressive approach may be appropriate, perhaps with referral to a subspecialist.

In an infant, breastfeeding should be encouraged up to the age of 1 year. Restriction or elimination of sweetened beverages such as soft drinks and sports drinks can greatly reduce calorie consumption in children who consume large amounts. The American Academy of Pediatrics (AAP) recommends that sweetened beverages and fruit juice be limited to 4 to 6 ounces daily for children age 1 to 6 years and 8 to 12 ounces for children and adolescents age 7 to 18 years. Replacing sugar-sweetened beverages with milk not only reduces calorie intake but also provides calcium needed for adequate mineralization of bone. All children older than 2 years should be receiving low-fat dairy products such as skim or 1% milk rather than whole milk, which has higher saturated-fat content. Increasing consumption of foods low in energy density but high in nutritional density, such as

vegetables and fruits, can reduce calorie intake and improve nutritional status. In general, food should not be used as a reward, and children should not be required to clean their plate at every meal; rather, they should be taught to choose an appropriate portion size when selecting food. Health-supporting foods should be available through school cafeterias and vending machines.

A sedentary lifestyle is a risk factor for obesity among children and, therefore, there is good reason to promote a physically active lifestyle as a key component in the prevention and treatment of obesity. AAP recommends that sedentary activities (e.g., TV, computer) be limited to no more than 2 hours daily. Rather than requiring specific physical activities, limiting time spent in sedentary activities allows children or teenagers to explore options and find activities they enjoy and are more likely to maintain. School districts should be encouraged to include and fund physical education programs, and community exercise facilities should be readily available to children.

Because of the potential problems of restrictive dieting in children, parents should work with their children through lifestyle changes to maintain a stable weight while height increases, which will result in a decreasing BMI. However, particularly if complications of obesity have developed, a more aggressive approach might be indicated. Nutritional adequacy, growth, and maturation should be closely monitored during more restrictive diets, and referral to a registered dietitian can be beneficial.

Medication use is rarely indicated in children. Sibutramine is approved for use in those older than 16 years and orlistat in those over 12. Both medications are associated with potential side effects. In obese adolescents, sibutramine with behavioral approaches resulted in greater improvement in BMI than with placebo, but almost half the active-treatment group experienced elevated BP or heart rate, necessitating a reduction or discontinuation of the medication (Berkowitz et al., 2003). Bariatric surgery in children and adolescents is also controversial. Although good data are lacking, guidelines are available for both pharmacotherapy and bariatric surgery in children and adolescents (Apovian et al., 2005; August et al., 2008).

Management in Adults

The benefits of screening for obesity have been examined by a number of organizations. The U.S. Preventive Services Task Force (USPSTF, 2003) recommends screening adults for obesity. The amount of information needed to make the diagnosis and establish the most effective approach is modest and can be handled in the context of a typical office visit. The initial approach can be framed through three questions (Hensrud, 2004): (1) what is the patient's BMI? (2) what is the waist circumference? and (3) what comorbidities are present? Determining comorbidities may involve obtaining fasting blood glucose, thyroid-stimulating hormone (TSH), aspartate transaminase (AST) or alanine transaminase (ALT), and lipid profile, as well as BP and history information suggesting associated disorders (e.g., OSA, DJD). Having identified overweight or obesity as a medical concern, it is important to help patients become aware of the medical implications and to engage them in management. **Box 36-1** lists areas to discuss with the patient that will affect management (Hensrud, 2002).

Box 36-1 Assessment Areas of Medical History in Obese Patient Evaluation

Readiness/motivation to undertake weight loss
 Reasons/expectations for weight loss
 Available support
 Previous methods of weight loss and results (including why results were not successful)
 Potential barriers to weight loss and maintenance (time, finances, established habits)
 High school graduation weight, minimum and maximum adult weight
 Periods of increased weight gain (e.g., pregnancy, smoking cessation, stressful life periods)
 Current (and past) diet
 Triggers to eating
 Current (and past) exercise/activity
 Factors the patient believes are responsible for weight
 Binge eating, purging, laxative or diuretic use
 Family history of obesity
 Medications

(From Hensrud DD. Obesity. In Rakel RE, Bope (eds). *Conn's Current Therapy*. Philadelphia, Saunders, 2002.)

Many patients are unaware that their weight is excessive or, if aware, do not fully understand the health consequences. Given the negative societal connotations of obesity, patients may not be receptive to addressing weight issues. When obesity is approached nonjudgmentally from the perspective of health risk, patients may be more accepting of the need to change and more willing to partner with the physician in addressing the problem. Readiness to change should be assessed, and addressing barriers to success is key in weight loss and maintenance. Barriers may include emotional factors (stress, depression) or time constraints that limit exercise. A support system can be helpful for someone attempting weight loss, including a spouse or a program incorporating group support (e.g., Weight Watchers).

Preventing or reversing obesity involves finding ways to balance energy intake and energy expenditure better. To obtain the best results, people should change both sides of the energy equation—that is, raise their energy expenditure by increasing physical activity and lower their energy intake by decreasing calories consumed. Physical activity and exercise appear to be more important than diet in preventing both initial weight gain and regaining weight after weight loss. Dietary restriction appears to be more important than physical activity in promoting weight loss.

Physical activity should be increased in daily activities as well as exercise. Aerobic exercise is the most efficient way to burn calories by directly increasing energy expenditure. However, increasing physical activity during the daily routine can result in large energy expenditure. Exercise programs that incorporate resistance training may slightly increase lean body mass, possibly increasing resting energy expenditure. Dietary treatment in the absence of an exercise program produces weight loss but not as much as combining both. In addition, weight loss solely through caloric restriction without an exercise program may result in greater loss of lean body mass.

Although all weight loss programs should involve a combination of caloric restriction and increased physical activity, certain patients may be candidates for adjunctive weight loss medications or, in some situations, bariatric surgery. If the patient has BMI of 27 kg/m² or greater and an obesity-related comorbidity (e.g., T2DM, OSA), sibutramine or orlistat may be indicated as an adjunctive measure. If BMI is 30 or greater, medications may be used even without a comorbid condition, although at Mayo Clinic, we usually prescribe these medications only if the patient also has a comorbid condition. Bariatric surgery can be considered for a patient with BMI of 40 or greater with associated complications or with BMI of 35 or greater if medical complications are present. [Table 36-4](#) outlines the treatment options available based on BMI and comorbid conditions.

Setting Goals

Discussing expectations for weight loss is important as the process begins. If a target goal is too difficult, the patient may quit in frustration. Studies show that a 5% to 10% body weight reduction is achievable through lifestyle approaches, and that this amount of weight loss will benefit health. If this goal is achieved and weight is still above the desired weight, a lower target can be set. Randomized trials demonstrate that weekly weight loss of 1 to 2 lb can be achieved with a daily caloric deficit of 500 to 1000 kcal (because 1 lb of fat contains 3500 kcal). Setting a target weight may not always be the most effective approach. For some patients, a *process-oriented* target (lifestyle) rather than an *outcome-oriented* target (weight) is more effective in the long run in terms of improving health. People who have made lifestyle changes by reducing caloric and saturated-fat intake and improving cardiovascular fitness have improved their health by reducing the risk of obesity-related complications, even if they have not reached a specific weight goal. Using the process-oriented target approach may be less frustrating to some patients, allowing them to sustain their lifestyle changes more effectively, which will have greater impact on their health.

Process and other goals should be specific, measurable, achievable, realistic, and trackable (SMART). For example, instead of setting a goal of just exercising more, a starting SMART goal is exercising by walking 20 minutes 3 days per week. Progress is logged and the goal gradually and regularly increased as fitness improves. A SMART dietary goal would be to eat 1 more piece of fruit and 1 more serving of vegetables daily, monitoring progress through diet records.

Patients should be counseled about the need to maintain indefinitely the lifestyle changes found to be effective. Because the specific type of lifestyle change may vary among patients, individual management is necessary. The NHLBI (2000) recommends that the initial goal of weight loss therapy should be 10% of baseline weight.

Diet

Many different and sometimes physiologically impossible weight reduction diets exist. Patients can access information on weight loss diet plans through books, Internet sites, magazines, and organizations such as Weight Watchers, although few data exist on their effectiveness. One study comparing the

Table 36-4 NHLB/NHI Guidelines for Treatment of Obesity

| Treatment | BMI Category* | | | | |
|--|---------------|---------|---------|---------|------|
| | 25-26.9 | 27-29.9 | 30-34.9 | 35-39.9 | ≥40 |
| Diet, physical activity, and behavior therapy [†] | w/co | w/co | + | + | + |
| Pharmacotherapy [‡] | — | w/co | + | + | + |
| Surgery | — | — | w/co | w/co | w/co |

w/co, With comorbidities; +, use of treatment regardless of comorbidities.
*Prevention of weight gain with lifestyle therapy is indicated in any patient with BMI ≥25, even without comorbidities, whereas weight loss is not necessarily recommended for those with BMI of 25-29.9 or a high waist circumference, unless they have two or more comorbidities.
[†]Combined therapy with a low-calorie diet (LCD), increased physical activity, and behavior therapy provides the most successful intervention for weight loss and weight maintenance.
[‡]Consider pharmacotherapy only if a patient has not lost 1 pound per week after 6 months of combined lifestyle therapy.

effectiveness of four popular diets (Ornish, Weight Watchers, Atkins, Zone) showed little difference in results (Dansinger et al., 2005). Although differing in nutritional composition, the diets were equally effective. Results were modest, with average weight loss ranging from 2.1 to 3.3 kg at 1 year. There was a significant attrition rate noted in each program. Adherence to the respective diet was associated with greater weight loss. Thus, one dietary program appears to be no better than another, and adherence is important regardless of the dietary approach. Individualization of dietary therapy may enhance adherence.

Low-carbohydrate diets have been popular in recent years. The rationale involves lowering the insulin levels through reducing carbohydrate intake and blood glucose levels. Reducing the anabolic effect of insulin is the proposed mechanism by which people lose weight. Decreased appetite from ketosis, resulting from carbohydrate restriction, and satiety from fat are other possible mechanisms. A recent study evaluated four diets with varying compositions of carbohydrate (35%-65%), fat (20% or 40%), and protein (15% or 25%) (Sacks et al., 2009). After 2 years, weight loss was not statistically significantly different among diets. Regardless of the calorie source, total calorie intake must be reduced below energy expenditure for weight loss to occur. Difficulty adhering to any diet over time, including low-carbohydrate diets, limits effectiveness; in clinical trials of at least 1 year, almost 40% of subjects randomized to a low-carbohydrate diet dropped out, only slightly lower than those randomized to a calorie-controlled diet. Elimination or restriction of fruits and vegetables on some low-carbohydrate diets may have health consequences as well.

Very-low-calorie diets (VLCDs) restrict calories to 400 to 800 kcal/day. Usually, this consists of a high-protein drink. VLCDs may produce a more rapid initial weight loss than other diets, but results are similar over time. Close medical monitoring during a VLCD program is needed (Kazaks and Stern, 2003).

Most often, a low-calorie diet (LCD) is recommended. Reducing daily caloric intake by 500 to 1000 kcal/day can result in weight loss of 1 to 2 lb per week. Women should consider initially consuming 1000 to 1200 kcal/day, with men consuming 1200 to 1600 kcal/day (NHLBI, 2000). This

type of diet plan modestly restricts saturated fats and refined carbohydrates (e.g., sugar) as part of overall caloric restriction. Dietary recommendations should be individualized within certain parameters. For example, a dietary program may be relatively low or high in the proportion of carbohydrates and fats while lowering overall calorie intake. Regardless of diet composition, the types of carbohydrates and fats should be health supporting. Whole-grain carbohydrates such as whole-wheat bread or pasta, brown rice, and oatmeal are preferred over refined carbohydrates such as sugar and white flour. Unsaturated fats such as olive oil, canola oil, and other vegetable oils are preferred over saturated and *trans* fats, which include many cuts of meat, full-fat dairy products, margarine, and other foods that contain partially hydrogenated vegetable fats.

There are many strategies to lower overall caloric intake, such as counting calories and monitoring number of servings of certain food groups. *Portion control* is generally an important part of dietary recommendations to reduce calorie intake; dining at restaurants can be especially challenging. Eating breakfast is associated with better weight management, along with keeping diet records. Substituting low-calorie foods for higher calorie versions can be useful. Meal replacements are another strategy to consider and have been shown to be as effective as conventional dietary recommendations on weight loss (Heymsfeld et al., 2003).

The *energy density* of foods is a potentially important part of reducing calorie intake. Grapes, for example, are less energy-dense than raisins. Because people tend to eat until they feel full, consuming less energy-dense foods will in itself reduce caloric consumption. A reasonable approach is to recommend a diet high in fruits and vegetables, along with moderate amounts of whole grains, unsaturated fats, and lean sources of protein, including low-fat dairy products. This reduction in calories can be achieved by choosing foods that are less energy-dense and by reducing portion size of high energy-dense foods. Because fats and sugar are more energy-dense, the overall volume of food consumed may be closer to the individual's former eating habits. A dietician can help the patient make the proper choices; further resources are available from the American Dietetic Association and other groups to help with education and practical

implementation. A major determinant of long-term success is the ability of the person to adhere to the diet. If the program departs too much from former eating patterns, the diet may not be sustainable over time, and any weight loss may be temporary.

KEY TREATMENT

Average weight loss on low-calorie diets is 8% at 3 to 12 months. Very-low-calorie diets may increase weight loss, but results at 1 year are similar to low-calorie diets (Shepherd, 2003) (SOR: A).

Physical Activity and Exercise

Physical activity is a key component of a healthy lifestyle for reasons ranging from stress reduction to decreased risk of cardiovascular disease. It is also an important component of preventing and treating obesity. Everyone should include physical activity in their daily routine whenever possible (e.g., walk over lunch hour, using stairs) as well as a more formal exercise program. An advantage of exercise is that more calories can be expended in a given period. The choice of exercise depends on individual interests and should be scheduled into the day as a priority. For those who have been sedentary, gradually starting an exercise is advisable. In general, the goal should be 30 minutes of moderately vigorous physical activity most days of the week. To promote weight loss, a goal of 60 minutes may be more appropriate and, to maintain weight loss, even up to 90 minutes a day may be necessary. A popular program promoting physical activity encourages people to walk 10,000 steps each day or at least an initial increase of 2000 steps over baseline. A simple pedometer allows people to follow their progress. As noted earlier, children's sedentary activities (e.g., TV/computer time) can be limited to 2 hours daily or less. A similar attempt to limit sedentary activities during adult off-work hours may also be helpful (Table 36-5) (Hu et al., 2003).

Behavioral Approaches

Behaviorally based approaches have been found to improve the results of weight loss programs. In general, the longer the program, the longer the weight loss is maintained. A variety of approaches have been used, without a clear advantage to a specific modality, including self-monitoring with diet and activity records or rewarding specific behaviors such as exercise or diet changes. Identifying and avoiding environmental or social triggers for excessive eating can also help. Group support may be helpful for some people. Because emotions often play a role in eating, stress and depression should be addressed before undertaking weight loss or as part of a behavioral weight loss program.

Medications

Various medications have been used in the treatment of obesity. At one time, these included amphetamines, exogenous thyroid hormone to induce a hyperthyroid state, fenfluramine, dexfenfluramine, and phenylpropanolamine, none of which should be used currently. Appetite suppressants work through their effects on neurotransmitters. Increased levels

Table 36-5 Examples of Moderate Amounts of Physical Activity*

Energy expended in common physical activities: number of minutes to burn 150 kcal

| Common Chores (min) | Sporting Activities (min) | |
|-------------------------------------|--------------------------------------|---------------------------------------|
| Washing and waxing car (45-60) | Playing volleyball (45-60) | Less vigorous, more time [†] |
| Washing windows or floors (45-60) | Playing touch football (45) | |
| Gardening (30-45) | Walking 1.25 miles (35; 20 min/mile) | |
| Wheeling self in wheelchair (30-40) | Basketball (shooting baskets) (30) | ↑ |
| Pushing stroller 1.5 miles (30) | Bicycling 5 miles (30) | ↓ |
| Raking leaves (30) | Dancing fast (social) (30) | |
| Walking 2 miles (30; 15 min/mile) | Water aerobics (30) | |
| Shoveling snow (15) | Swimming laps (20) | |
| Stairwalking (15) | Basketball (playing a game) (15-20) | |
| | Jumping rope (15) | More vigorous, less time |
| | Running 1.5 miles (15; 15 min/mile) | |

*A moderate amount of physical activity is roughly equivalent to physical activity that uses approximately 150 calories per day or 1000 calories per week.

[†]Some activities can be performed at various intensities; the suggested durations correspond to expected intensity of effort.

From National Heart, Lung, and Blood Institute, National Institutes of Health. The Practical Guide to the Identification, Evaluation, and Treatment of Overweight and Obesity in Adults (NIH). Pub No 00-4084. NIH, Bethesda, Md, 2000.

of norepinephrine and serotonin in neurologic synapses through increased release or inhibition of neurotransmitter reuptake produce this effect. Fenfluramine and dexfenfluramine, both of which promote serotonin release, were taken off the market in 1997 after they were found to be associated with damage to heart valves. These two drugs have also been associated with pulmonary hypertension. Prolonged elevation of serotonin levels is thought to increase pulmonary vasoconstriction.

Sibutramine, a nonselective inhibitor of serotonin, norepinephrine, and dopamine reuptake, produces a feeling of satiety rather than a decrease in appetite. Until recently, sibutramine was one of the most commonly used medications for weight loss. In October 2010 sibutramine was withdrawn from the market when postmarketing data showed an increased risk of heart attack and stroke in patients with heart disease.

Orlistat inhibits gastric and pancreatic lipase, thereby reducing digestion and absorption of fats. After 1 year, subjects taking orlistat lost 2.9 kg more than those taking placebo (Rucker et al., 2007). Side effects, primarily gastrointestinal and related to fat malabsorption, occur in about 20%

of subjects but only last up to 1 week in half the patients affected. During the second year of treatment, prevalence of side effects is no greater than with placebo. Because absorption of fat-soluble vitamins may be decreased, patients taking orlistat should also take a daily multivitamin. Orlistat is not absorbed, making systemic side effects unlikely. The recommended dose is 120 mg three times daily with meals that contain fat. If patients choose high-calorie but low-fat foods, little benefit will be seen. Orlistat is available over the counter in a reduced dose of 60 mg. Whether this is effective for long-term weight loss has not been established.

Fluoxetine has shown mixed but generally unimpressive results because any initial weight loss is often regained, and side effects include nervousness, tremor, fatigue, hypersomnia, insomnia, and diarrhea. Snow and colleagues (2005) reported a 3.6-kg weight loss at 6 months with *phentermine* and a 3.0-kg loss with *diethylpropion* over placebo. *Metformin* increases peripheral insulin sensitivity and therefore insulin levels can drop. When used in glucose-intolerant patients, metformin has been associated with a decreased risk of diabetes and modest weight loss of a few pounds.

Follow-up visits after starting pharmacotherapy assess response and monitor for adverse effects. A suggested schedule includes visits at 2 to 4 weeks, then monthly for 3 months, and then every 3 months for the first year (ICSI, 2005). The weight loss seen with medication use in conjunction with diet and exercise occurs primarily in the first 6 months. If a patient has not lost 2 kg in the first 4 weeks, the drug may be ineffective for that patient and might be stopped. When the medication is effective, its continuation can help maintain weight loss, although some people do regain weight despite maintenance therapy.

Complementary and Alternative Medicine

Complementary and alternative medicine (CAM) treatments are attractive to patients with various medical concerns. The perceived safety of natural products and their availability without the expense of seeing a physician have contributed to this interest.

Ephedrine, often in combination with caffeine, has been marketed in purified form or in herbal products as *ma huang*. *Guarana* and *gotu kola* are herbal sources of caffeine. A small study showed a significantly greater loss of weight with the combination of ma huang and guarana (4.0 ± 3.4 kg, vs. 0.8 ± 2.4 kg in placebo group) (Boozer et al., 2001). Ephedrine, the most potent isomer in *ephedra*, increases thermogenesis in adipose tissue through the stimulation of beta receptors. Side effects reflect the increased sympathetic activity and typically include insomnia, tachyarrhythmias, headache, and elevated BP. Because of its association with more serious side effects (stroke, tachyarrhythmias, seizures, death), ephedra was removed from the market in 2004. *Bitter orange* has also been used for weight loss and contains the sympathomimetic alkaloids of synephrine and octopamine. An action similar to that of ephedrine has been suggested, and because little evidence supports use of bitter orange, this supplement is not recommended (Heber, 2003).

Caffeine can increase sympathetic nervous system activity and is thought to increase weight reduction through an increase in metabolic rate and fat oxidation. *Green tea* contains, along with caffeine, catechins. These antioxidants have

been thought to have sympathetic activity, increasing thermogenesis and aiding in weight loss. Any effect attributable to catechins is difficult to assess because of the presence of caffeine.

Conjugated linoleic acid (CLA) was not found to be effective for weight loss, although it may have a slight effect on body composition. Animal studies show an increase in insulin resistance that suggests safety concerns, although limited human studies have not shown adverse effects. *Hydroxycitric acid*, found in *Garcinia cambogia* (Brindall berry), was also found to be ineffective for weight loss. Increased *dietary fiber*, particularly water-soluble fiber, has been associated with modest weight reduction benefits. *Chitosan*, a nonabsorbable carbohydrate derived from the exoskeletons of crustaceans, has been purported to have fat-blocking effects through binding with dietary fats, but human studies have found no benefit (Heber, 2003).

Surgery

Weight loss surgery has been found to be effective in carefully selected patients (Maggard et al., 2005). In the United States, approximately 220,000 bariatric surgeries were performed in 2008. As noted earlier, candidates for bariatric surgery should have a BMI of more than 35 kg/m² and obesity-related complications. Before considering surgery, patients should have a strong attempt to achieve weight loss through conservative means, including diet, exercise, and behavioral modification. For the patient considering surgery, it is important to work with a team experienced in the different aspects of bariatric surgery and weight loss, including a psychologist or psychiatrist, registered dietitian, physician nutrition specialist (if available), and experienced surgeon. Patients should be well informed of the life-changing nature of the surgery, as well as potential complications.

Bariatric Procedures

The complications and degree of weight loss differ depending on the surgical approach. Current procedures are classified as being malabsorptive or restrictive, or a combination, in their mechanism of reducing calorie absorption (Box 36-2). The first surgical procedure to be widely used was the *jejunoileal bypass*, a malabsorptive approach in which most of the small bowel is bypassed by connecting the proximal with the distal small bowel. Side effects, including steatorrhea, electrolyte imbalance, and hepatic and renal injury, led to this approach being abandoned.

Current *malabsorptive* procedures include biliopancreatic diversion with or without duodenal switch. The *duodenal switch* refers to the portion of the small intestine that is transected. The *biliopancreatic diversion* is similar to the jejunoileal bypass in that much of the small intestine is bypassed. However, the bypassed small intestine continues to supply bile and pancreatic enzymes, preventing some of the most severe complications of the jejunoileal bypass. Nutrient deficiencies are still much more common than with restrictive procedures. Both types of biliopancreatic diversion include a limited partial gastrectomy, with the pylorus being maintained in the duodenal switch.

In general, *restrictive* procedures tend to result in less dramatic weight loss than malabsorptive procedures. The

Box 36-2 Types of Bariatric Surgical Procedures**Malabsorptive**

Jejunioileal bypass
Biliopancreatic diversion

Restrictive

Vertical-banded gastroplasty
Gastric banding

Malabsorptive and Restrictive

Roux-en-Y gastric bypass

Roux-en-Y gastric bypass, by far the most widely used procedure, works predominantly by restricting caloric intake, but it may also have a component of malabsorption, depending on the length of the bypassed intestine (Fig. 36-2). Most of the stomach is transected with this procedure. The small intestine is also transected, and the distal limb is attached to the stomach remnant. The bypassed stomach is attached to the remaining intact intestine through the proximal limb of the transected small intestine. The *vertical-banded gastroplasty* is also a restrictive procedure, but weight loss is less than with the Roux-en-Y gastric bypass. Restrictive procedures cause more vomiting but overall have fewer side effects related to persistent diarrhea and malabsorption of nutrients than malabsorptive procedures. Malabsorptive procedures may be more appropriate when a greater degree of weight loss is desired, but the patient should be aware of the increased side effects.

The adjustable *gastric band* is a purely restrictive procedure, usually placed laparoscopically, and its use is increasing. A band is placed around the upper portion of the stomach (Fig. 36-3). Part of the stomach is sutured over the band to help keep it in place. This band contains fluid that can be infused through a port just under the skin. By infusing fluid in the port, the band can be tightened or loosened. Adjustments in the fluid are often necessary as people lose weight because the band may loosen.

One of the side effects with the Roux-en-Y gastric bypass is *dumping syndrome*, which occurs when high-osmolality foods such as ice cream or soda are consumed and presented immediately to the small bowel through the remnant stomach. Symptoms include cramping, diarrhea, malaise, and sweating, and therefore this can be a deterrent to consuming these generally high-calorie foods. However, because the anatomy is intact with the gastric band, dumping syndrome does not occur. In fact, liquid foods such as ice cream and soda may slide more easily through the band, and therefore greater behavioral changes are required to decrease consumption of these foods with a gastric band compared to the Roux-en-Y gastric bypass. This is one reason why weight loss is not as great with the band compared to the bypass.

Perioperative risks increase with bariatric procedures because of the patient population and type of surgery, but overall mortality is under 1%. All currently used procedures can be performed laparoscopically, which is more technically difficult but associated with faster recovery.

During the immediate postoperative period, it can be anticipated that pharmacotherapy for weight-related conditions will quickly be reduced. Insulin dosing will usually need to

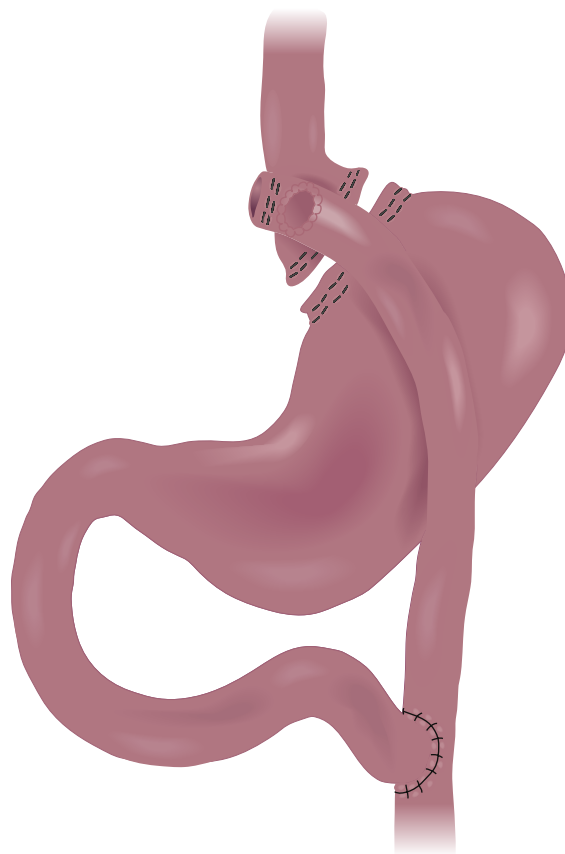

Figure 36-2 Roux-en-Y gastric bypass for obesity. (Redrawn from and courtesy Mayo Clinic © 2000.)

Figure 36-3 Gastric band for obesity. (Courtesy Mayo Clinic © 2006.)

be decreased immediately. Patients taking oral hypoglycemics preoperatively may be better controlled on a sliding scale of short-acting insulin in planning for a decreased postoperative need for medications. Similarly, antihypertensive and other medications may need to be reevaluated. Immediate-release agents may be better suited to the patient after a malabsorptive procedure than sustained-release types, because altered gastrointestinal absorption can be anticipated.

Long-term management of surgical patients requires supplementation with vitamins and minerals. Vitamin B₁₂ deficiency is common. Clinical practice at Mayo Clinic is to treat all bariatric surgery patients with 2 multivitamins (starting with chewable form), daily calcium supplementation (carbonate or citrate), vitamin D (1000-2000 U daily), and 1 mL (1000 µg/mL) of subcutaneous cyanocobalamin (vitamin B₁₂) monthly. Ferritin levels should be monitored and iron deficiency treated, as necessary. The altered ability to absorb medications will persist, and serum drug concentrations may need to be performed more frequently.

The Swedish Obese Subjects (SOS) study reported on extremely obese patients treated by bariatric surgery or conventional nonsurgical approaches over 10 years (Sjostrom et al., 2004). Peak weight loss occurred at 6 months in the control group (1% of baseline weight) and at 1 year in the surgical groups. At 1 year, weight loss was 38% for gastric bypass, 27% for vertical-banded gastroplasty, and 21% for those undergoing gastric banding. By 10 years, percentage weight loss from baseline fell to 25%, 16%, and 13%, respectively, for the three procedures, compared with 1.6% weight gain in the control group. Improvement in hypertension, T2DM, and dyslipidemia was greater in the surgical group than the control group at 2 and 10 years. Improvement in hypercholesterolemia did not differ between the groups. Reduction in the incidence of T2DM and hypertriglyceridemia was greater in the surgical patients than the control group at 2 and 10 years. The incidence of hypertension and hypercholesterolemia did not differ between the groups.

KEY TREATMENT

Diet and exercise together with behavioral modification can improve short-term outcomes, though long-term effectiveness is lacking (Shepherd, 2003) (SOR: A).

Both sibutramine and orlistat may achieve modest additional weight loss when added to diet and physical activity in patients who are appropriate candidates for pharmacotherapy (Rucker et al., 2007) (SOR: A).

Gastric bypass is more effective than vertical-banded gastroplasty for weight loss and is associated with fewer revisions but more side effects (Everson et al., 2004) (SOR: A).

Summary

The epidemic of obesity has major implications for health care now and in the future. Family physicians are in a unique position to affect this epidemic through primary as well as secondary prevention. This strategy should start in childhood but must also continue as a lifelong process. Over a lifetime, gradual restriction in caloric intake and continued participation in physical activity are necessary to maintain weight and health. Weight management should be addressed with patients and therapy tailored to the individual. Community endeavors to reduce calorie intake and increase physical activity should be supported. These efforts should be viewed as public health priorities.

Overview

The goal of improving the health of the U.S. population through approaches such as physical activity and nutrition has come to the forefront of medical concerns. The efforts of public service and health care professionals in promoting nutrition's potential to improve health is beginning to result in constructive action. The public health approach to improving diet through education is part of the focus on preventing chronic diseases in an aging population. The clinical medicine approach to nutrition is using nutritional therapies as part of disease management. This chapter discusses both approaches.

Current Dietary Guidance

The latest version of the public health dietary guidance program was introduced in 2010. This is in connection with the MyPyramid food guidance system (www.MyPyramid.gov). The MyPyramid recommendations are based on the following:

- **Variety:** Eat foods from all food groups and subgroups.
- **Proportionality:** Eat more of some foods (e.g., fruits, vegetables, whole grains, fat-free or low-fat milk products) and less of others (e.g., foods high in saturated or *trans* fats, added sugars, cholesterol, salt, alcohol).
- **Moderation:** Choose forms of foods that limit the intake of saturated or *trans* fats, added sugars, cholesterol, salt, and alcohol.
- **Activity:** Be physically active every day.

The new food pyramid has an interactive interface, allowing for customization of the food plan as well as key concepts into a visual image (see Web Resources). Although there is general agreement, many argue that the recommendations are vague and that food amounts and groupings are inappropriate. The major addition in this version of the food guidance system has been *physical activity*, which seems to be critical in the considerations of diet and the balancing of energy needs with intake. The overarching concepts of the 2010 Dietary Guidelines (www.dietaryguidelines.gov) explain the educational framework for the MyPyramid, as follows:

- Maintain calorie balance over time to achieve and sustain a healthy weight.
- Focus on consuming nutrient-dense foods and beverages.

There are more than 23 key recommendations in the latest Dietary Guidelines for the general population and six additional key recommendations for specific populations. The Key Recommendations of the latest version of the Dietary Guidelines are as follows:

- Balance calories to manage weight
 - Prevent and/or reduce overweight and obesity through eating and physical activity
 - Control total calorie intake to manage body weight
 - Increase physical activity and reduce time spent in sedentary behaviors
 - Maintain appropriate calorie balance during each stage of life

- Foods and food components to reduce
 - Reduce daily sodium to less than 2300 milligrams per day
 - Consume less than 10% of calories from saturated fats per day
 - Consume less than 300 milligrams from dietary cholesterol per day
 - Keep trans fatty acid consumption low as possible
 - Reduce calories from solid fats and added sugars
 - Limit consumption of foods that contain refined grains
 - If alcohol is consumed, it should be consumed in moderation
- Foods and nutrients to increase
 - Increase vegetable and fruit intake
 - Eat a variety of vegetables
 - Consume at least half of all grains as whole grains
 - Increase intake of fat-free or low-fat milk and milk products
 - Choose a variety of protein foods
 - Increase the amount and variety of seafood consumed by choosing seafood in place of some meat and poultry
 - Replace protein foods that are higher in solid fats with choices that are lower in solid fats and calories
 - Use oils to replace solid fats when possible
 - Choose foods that provide more potassium, dietary fiber, calcium, and vitamin D, which are nutrients of concern in American diets.

There are additional recommendations for women capable of becoming pregnant, women who are pregnant or breastfeeding, and individuals ages 50 years and older.

The specifics are many, and the latest dietary guidelines might be as confusing as previous guidelines. They are a combination of food- and nutrient-based recommendations, the latter of which is often difficult to explain. Both the professional community and general public recognize the important role of proper nutrition in maintaining health, but neither always heeds current evidence. This chapter highlights the current evidence for supporting nutritional approaches to common medical and health concerns. The recent changes in recommendations recognize that the whole diet seems to be more of a concern than specific nutrients.

Nutrition Assessment

A nutrition assessment is the process of determining an individual's nutritional status or whether adequate amounts of required nutrients are available to and absorbed by the body. Every patient in a family medicine practice deserves some level of nutrition assessment. This assessment can be a brief screen, when the patient is relatively healthy, or more in-depth, if the patient appears to have nutritional inadequacy or risk factors for malnutrition. The depth of the assessment is based on the patient and the presenting situation. Those who may require a more in-depth evaluation include patients who are grossly overweight or underweight, patients with a chronic or severe acute illness, growing infants and children, patients in poverty or otherwise unable to obtain a variety of foods, most frail older adults, and patients who maintain nontraditional diets, such as recent immigrants or fad dieters.

History

As with any other health assessment, the patient history is the first step in determining nutritional status. In a reasonably healthy adult or child, this history may be a brief screen, including determining changes in weight and appetite, eating habits such as the number of meals daily and the variety of foods consumed, and symptoms of underlying chronic or debilitating illness. Information about the ability to perform activities of daily living (ADLs), including shopping and cooking, is important when interviewing older adults or the infirm population.

Patients with chronic illness deserve a more thorough history assessment, as do patients with symptoms or signs potentially related to poor nutrition (Table 37-1). Physicians should review gastrointestinal (GI) symptoms and elicit information about supplemental vitamins or other nutritional products, alcohol and illicit drugs, appetite suppressants or stimulants, glucocorticoids, and laxatives. In at-risk patients or those with clinical evidence of poor nutrition, clinicians should consider the presence of conditions that may increase nutritional requirements. Physicians should also investigate the patient's ability to obtain, ingest, digest, metabolize, and absorb nutrients; consider whether a treatment or medication will require modification of the diet; and use information obtained in the history to plan for that change.

Conditions that May Increase Nutritional Requirements

Any condition that increases the metabolic rate of the patient is likely to increase nutritional requirements (Box 37-1).

Ability to Obtain Food

Patients in poverty and who cannot or do not receive financial assistance are at risk for poor nutrition because of an inability to obtain enough food or a variety of foods. Those who lack transportation or have other shopping access issues, such as language barriers or distance from a store, may also not be able to acquire sufficient food. Patients who rely on others to provide or prepare foods, or both, may have inadequate dietary intake. Many patients, because of poor mobility and declining health, gradually lose the ability to perform ADLs, such as shopping, cooking, and cleaning, so the history should contain specific questions directed at these activities. Individuals with substance abuse problems or poor mental health may lack the initiative or ability to acquire healthy foods.

Ability to Ingest Nutrients

Various conditions may contribute to a patient's inability or lack of desire to eat (see Box 37-1).

Digestion

A number of processes can affect the normal digestive process. Any factor that interferes with the secretion of acid or enzymes into the stomach or small intestine may impair digestion. For example, patients with partial gastrectomy or even vagotomy for peptic ulcer disease may have maldigestion and nutritional deficiencies. Similarly, patients with chronic pancreatitis may lack certain digestive enzymes and thus cannot absorb all nutrients.

Table 37-1 Summary of Major Nutrients

| Nutrient | Major Dietary Sources | Major Functions | Signs of Deficiency | Usual Causes of Deficiency | Effects of Excess | Normal Laboratory Value |
|--|---|---|--|---|--|--|
| Protein (Pro) (supplies 4 kcal/g) | Fish, chicken, beef, other animals; lentils, seeds, legumes, dried beans; dairy products; eggs, nuts | Building materials (AAs) for growth, maintenance, repair of all cells; regulates fluid balance between blood and cells; provides energy; essential AAs are threonine, tryptophan, histidine, lysine, leucine, isoleucine, methionine, valine, phenylalanine | Kwashiorkor (protein malnutrition); decreased immune response; edema; stunted growth and development; poor musculature; marasmus (protein-energy malnutrition) | Poor intake of protein, especially high-quality protein; too few calories so that protein is used for energy; malabsorption; genetic diseases of protein, AAs (e.g., PKU) | Reduced calcium retention; weight gain, obesity | Albumin, 3.5-5.0 g/dL; BUN 9-20 mg/dL; creatinine, 0.31-3 mg/dL; prealbumin 10-40 mg/dL; total protein, 6.0-8.0 g/dL |
| Carbohydrates (CHO) (supplies 4 kcal/g) | Cereal grains, dried peas and beans, bread, pasta, vegetables, fruits, dairy products, sugar, jellies, other sweets | Provides energy for body processes and physical activity; aids in use of fat and spares protein; provides energy; many vitamins and most fibers are CHO | Growth retardation; weight loss | Poor intake; malabsorption; genetic diseases of CHO (e.g., glycogen storage disease) | Weight gain, obesity; increased blood triglyceride levels | None |
| Fat (supplies 9 kcal/g) | Saturated fats: meats, dairy fats (e.g., ice cream, sour cream, butter), bacon, sausages Unsaturated fats: avocado, oils (e.g., corn, safflower, vegetable) Monounsaturated fats: olive oil, canola oil | Supplies concentrated source of energy; carries fat-soluble vitamins; supplies essential fatty acids (e.g., linoleic, linolenic, arachidonic acids); membrane structures; transport processes of cells | Flaky, scaly skin; poor growth; hair loss; impaired wound healing and immune functioning | Poor intake; malabsorption, extreme diets or supplementary feedings for long periods (e.g., IV lines, TPN without fats) | Increased blood cholesterol and/or triglyceride levels; weight gain, obesity | Total cholesterol, <200 to >140 mg/dL; HDL >45 mg/dL; LDL <100-130 mg/dL |
| Water | Water, beverages, fruits; almost all foods contain some water | Provides substrate for most of body's reactions; helps move materials to and waste from cells; helps control body temperature; lubricates joints in body | Dehydration, death | Poor intake; medications; diarrhea; vomiting; high temperatures | Excess retention of fluid related to imbalance of minerals; overconsumption rare but can result in death | Dehydration: increased albumin, BUN Fluid overload: decreased albumin, BUN |
| Vitamins | | | | | | |
| Water-Soluble Vitamins | | | | | | |
| Vitamin B ₁ (thiamin) | Lean pork, wheat germ, whole/fortified cereals, legumes, bread products | Assists in use of CHO and fat for energy; promotes growth, appetite, and muscle tone; promotes normal functioning of nervous system; coenzyme in metabolism of CHO branched-chain AAs | Beriberi; changes in nerves; excessive water retention; loss of appetite; depression; muscle tenderness; high-output cardiac failure; polyneuritis | Poor intake; malabsorption; hemodialysis | None reported | Thiamine pyrophosphate (TPP); stimulation >20% (index >2% indicates deficiency) |
| Vitamin B ₂ (riboflavin) | Dairy products, liver and other organ meats, meat, fish, dark green vegetables, fortified grain products | Functions as part of energy release; essential for growth; part of flavin coenzymes required in cellular oxidation | Cheilosis; photophobia, angular stomatitis, magenta tongue, glossitis, seborrhea, corneal vascularization | Poor intake; malabsorption | None reported | Flavin adenine dinucleotide (FAD); stimulation >40% (index >1.4% indicates deficiency) |

| Nutrient | Major Dietary Sources | Major Functions | Signs of Deficiency | Usual Causes of Deficiency | Effects of Excess | Normal Laboratory Value |
|--|--|--|--|--|---|--|
| Vitamin B ₆ comprises six compounds: pyridoxal, pyridoxine, pyridoxamine, and three 5'-phosphates: pyridoxal (PLP), pyridoxine (PNP), and pyridoxamine (PMP) | Liver, pork, poultry, whole/fortified grain products, bananas, legumes, lentils, fortified soy-based meat substitutes, nuts | Cofactor for many enzymes in metabolism of protein and AAs; functions in hemoglobin synthesis | Anemia; irritability; convulsions (in infants); skin lesions; smooth red tongue (glossitis); peripheral neuropathies; impaired all-mediated immunity | Poor intake; malabsorption; aging (increased need), medications | Sensory neuropathy marked by changes in gait and peripheral sensation | — |
| Vitamin B ₁₂ * (cobalamin) | Liver, beef, poultry, fish, eggs, brewer's yeast, (not present in plant foods) Oral initial dose: 1000-2000 µg per 1-2 weeks Maintenance: 1000 µg daily for life IM initial dose: 100-1000 µg daily or every other day for 1-2 weeks Maintenance: 100-1000 µg every 1-3 months | Maintenance of nervous tissue and blood formation; nucleic acid synthesis; recycling of tetrahydrofolate | Megaloblastic anemia (pernicious anemia); permanent damage to nervous system; peripheral neuropathy; weight loss; glossitis | Deficiency of hydrochloric acid in stomach (as occurs with aging); strict vegetarians; high intakes of folate can mask deficiency of vitamin B ₁₂ | None reported | Schilling test: 8% of radioactivity per 24-hour urine [†] |
| Vitamin C (ascorbic acid) | Citrus fruits and juices, tomatoes, potatoes, cabbage, broccoli, strawberries, spinach | Cofactor for reactions requiring reduced copper or iron metalloenzymes; protective antioxidant | Scurvy; easy bruising; slow wound healing; degeneration of skin, teeth, gums, blood vessels | Smokers have increased need, poor intake | GI disturbances; kidney stones; excess iron absorption | Plasma or leukocyte vitamin C measured by chromatography; plasma vitamin C, 0.50-1.40 mg/dL (30-80 µmol/L) |
| Folate (folic acid, folacin, pteroylpolymethylglutamates) | Dark-green leafy vegetables, whole grains, legumes, nuts, organ meats, orange juice, fortified cereal products | Assists in red blood cell maturation; cofactor for synthesis of purine and pyrimidine; coenzyme in metabolism of nucleic acids and AAs | Megaloblastic anemia; general weakness; depression; polyneuropathy; GI upsets; poor growth; maternal deficiency linked to neural tube defects in fetus (400 µg/day recommended prepregnancy) | Poor intake; malabsorption | Masks deficiency of vitamin B ₁₂ | Red blood cell folate, 4-20 ng/mL |
| Niacin (includes nicotinic acid amide, nicotinic acid, nicotinamide) | Liver, meat, bran/fortified cereal products, fish, poultry, whole/fortified grains, peanuts, tuna | Part of coenzymes for oxidation-reduction reactions; active in release of energy and biosynthesis of fatty acids | Pellagra; pigmented dermatitis; dementia; diarrhea; inflammation of mucous membranes; weakness; tremors | Poor intake; malabsorption; consumption of processed grains that have niacin removed; hemodialysis | Flushing, burning, tingling around face, neck, hands; liver damage; gastrointestinal distress | — |

Continued

Table 37-1 Summary of Major Nutrients—cont'd

| Nutrient | Major Dietary Sources | Major Functions | Signs of Deficiency | Usual Causes of Deficiency | Effects of Excess | Normal Laboratory Value |
|---|--|---|--|---|--|---|
| Pantothenic acid | Liver, egg yolks, meat, mushrooms, whole grains, brewer's yeast, broccoli, skim milk, sweet potatoes, avocados | Component of coenzyme A; functions in release of energy from CHO, Pro, and fat; coenzyme in fatty acid metabolism | Fatigue; malaise; insomnia; burning paresthesias; depression, weakness (rare) | Poor intake; malabsorption; incomplete PEN or TPN formulas | Unknown | — |
| Biotin | Nuts, soy, eggs, nonfat milk, sweet potatoes | Coenzyme for carboxylation reactions; plays a role in CHO and fat metabolism; coenzyme in synthesis of fat, glycogen, and AAs | Dermatitis; neuritis; appetite loss; nausea; glossitis; insomnia; thin hair; depression hypercholesterolemia (few known cases) | Incomplete PEN or TPN formulas | Unknown | — |
| Fat-Soluble Vitamins | | | | | | |
| Vitamin A (includes provitamin A such as retinols, carotenoids) | Liver, dairy products, fish; turkey (carotene); carrots, dark-green leafy vegetables, sweet potatoes, cantaloupe, apricots, broccoli, tomatoes | Maintenance of skin and mucous membranes; component in visual process; particular adaptation to darkness; immune function | Night blindness; xerophthalmia, keratomalacia; Bitot's spots; follicular hyperkeratosis; reduced immunity; poor growth | Poor intake; malabsorption with steatorrhea; liver disease | Loss of appetite; headache; vomiting; blurred vision with eventual eye damage; liver toxicity; teratogen in fetal growth | Serum retinol and retinol ester vitamin A, 30-80 µg/dL (1.0-2.8 µmol/L) |
| Vitamin D (also called calciferol) uptake; glucocorticoid | Fortified dairy products, fish, eggs; sunlight (15min/day for 3-4 days/wk) | Mineralization of bones and teeth; intestinal regulation of calcium and phosphorus | Rickets (children); osteomalacia (adults); costochondral beading; muscle weakness and twitching; low serum calcium | Poor sunlight exposure; poor intake; with aging, poor uptake glucocorticoid therapy may need additional vitamin D | Poor growth; weight loss; poor appetite; calcium deposits in soft tissues | 25-hydroxy-vitamin D test, costochondral |
| Vitamin E (also called α-tocopherol) | Nuts, fats, polyunsaturated vegetable oils, margarine, seeds, whole grains | Antioxidant; prevents peroxidation of polyunsaturated lipids; free radical scavenger | Hemolytic anemia of newborn; increased fragility of red blood cells; nerve and muscle disturbances in severe malabsorption | Lipid malabsorption | Interferes with vitamin K (risk of bleeding, especially in trauma); hemorrhagic toxicity; monitor patients taking anticoagulants and vitamin E supplements | Serum tocopherol measured by chromatography, 0.5-1.8 mg/dL (12-42 µmol/L) |
| Vitamin K | Dark-green leafy vegetables, liver, vegetable oils, margarines, cabbage family | Synthesis of prothrombin and clotting factors II, VII, IX, and X | Bleeding (especially in newborns); ecchymosis; epistaxis; prolonged clotting time | Bacteria destroyed in gut that produce vitamin K; liver disease; lipid malabsorption | Unknown; monitor patients taking anticoagulants with vitamin K intake | Prothrombin time (PT) to assess vitamin K indirectly |
| Minerals | | | | | | |
| Calcium | Dairy products, fish with small bones, dark-green leafy vegetables (mustard greens, kale); corn tortillas, calcium-set tofu | Structure of bones and teeth; nerve transmission; muscle contraction; essential role in blood clotting | Stunted growth; bone loss; rickets; osteomalacia; osteoporosis; tetany; possibly hypertension | Poor intake; poor consumption of vitamin D, poor sunlight exposure; lack of physical activity; high phosphorus intake | Decreased absorption of other minerals; kidney stones; hypercalcemia; milk-alkali syndrome; renal insufficiency | 8.5-10.5 g/dL |

| Nutrient | Major Dietary Sources | Major Functions | Signs of Deficiency | Usual Causes of Deficiency | Effects of Excess | Normal Laboratory Value |
|------------|--|--|---|--|--|--------------------------|
| Chloride | Table salt, seafood, meat | Acid-base balance; constituent of gastric juice; major anion of extracellular fluid | Rare; mental apathy, muscle cramps, usually seen with sodium depletion | Rare in United States (has occurred in babies whose formula did not have chloride) | None reported | 96-106 mEq/L |
| Chromium | Fish, cheese, meat, poultry, whole-grain cereals, beer | Insulin cofactor; glucose and energy metabolism | Insulin resistance; glucose intolerance | Unknown | None reported | — |
| Cobalt | Organ and muscle meats, dairy products | Constituent of vitamin B ₁₂ | Only as vitamin B ₁₂ deficiency; pernicious anemia | Those associated with vitamin B ₁₂ | None reported | — |
| Copper | Liver, shellfish, nuts, whole grains, cereals, legumes, cocoa products | Absorption and use of iron; enzyme cofactor; in myelin nerve sheath | Anemia; kinky hair; neutropenia; disturbance of bone formation | Usually genetic | Wilson's disease (genetic); iron deficiency anemia; chronic renal failure | — |
| Fluoride | Fluoridated drinking water, fluoridated dental products, seafood | Structure of bone and teeth enamel; reduces dental caries | Dental caries | Nonfluoridated water or dental products | Mottled teeth; enamel and skeletal fluorosis | — |
| Iodine | Iodized salt; seafood, saltwater fish | Constituent of thyroid hormone | Goiter; cretinism | Lack of iodine in food or in soil where food grown | Rare; goiter may be caused by excess iodine; elevated TSH | — |
| Iron | Liver, lean meats, legumes, egg yolk, fortified cereals and breads | Constituent of hemoglobin; involved in oxygen and electron transport | Microcytic hypochromic anemia; fatigue; decreased immune response | Poor intake; blood loss | Liver and pancreas damage; large dose at one time: shock, death; GI distress | Serum iron, 50-150 µg/dL |
| Magnesium | Bran cereals, nuts, legumes, green leafy vegetables, meat | Part of protein synthesis; helps muscles contract and helps nerve impulse transmission | Rare; behavioral disturbances, tremor, spasms, neuromuscular irritability | Rare | Rare; diarrhea; fatigue; nervous system disturbances (usually from pharmacologic agents, not food sources) | 1.5-2.5 mEq/dL |
| Manganese | Nuts, legumes, whole-grain cereals | Involved in formation of bone and enzymes in AAs, cholesterol, and CHO metabolism | Rare; dermatitis; weight loss | Rare | Rare; inhaled manganese linked to CNS disorders, neurotoxicity | — |
| Molybdenum | Whole-grain cereals, legumes, nuts | Oxidation-reduction reactions; enzyme helps in catabolism of sulfur AAs; metabolism of purine, pyrimidines | None | None | Unknown | — |
| Phosphorus | Dairy products, eggs, meat, whole-grain cereals, soda | Structure of bone and teeth; component of phospholipids; helps regulate acid-base balance; energy metabolism | Rare; demineralization of bone; weakness; poor growth; paresthesias of hands and feet | Rare in United States | May cause deficiency of calcium, skeletal porosity; interference with calcium absorption | 2.5-4.5 mg/dL |

Table 37-1 Summary of Major Nutrients—cont'd

| Nutrient | Major Dietary Sources | Major Functions | Signs of Deficiency | Usual Causes of Deficiency | Effects of Excess | Normal Laboratory Value |
|-----------|--|---|--|--|---|-------------------------|
| Potassium | Fruits (particularly bananas, citrus juices), dairy products, potatoes, vegetables | Major component of intracellular fluid; regulates acid-base and water balance; maintains heart/nerve function | Muscle weakness; rapid, irregular heart rate; paralysis, death | Medications (e.g., diuretics), especially with poor intake | Electrolyte imbalance; muscle weakness; disturbed heart function; death | 3.5-5.0 mEq/dL |
| Selenium | Organ meat, seafood, plants from selenium-containing soil | Antioxidant; constituent of glutathione oxidase | Rare; cardiac myopathy; muscle tenderness | Rare | Rare; hair and nail brittleness and loss | — |
| Sodium | Table salt, processed foods, in most foods except fruits | Maintains water balance; influences muscle contraction and nerve irritability | Rare; muscle cramps and reduced appetite | Rare; restricted diet with excessive medication | In some people, retention of fluids and hypertension | 135-145 mEq/dL |
| Sulfur | Protein foods (e.g., meat, dairy, legumes) | Constituent of coenzyme A, AAs, hair, cartilage | No dietary deficiency with adequate protein | Rare | Rare | — |
| Zinc | Meat, seafood, dark meat of poultry, whole grains, legumes | Component of enzymes and proteins; involved in regulation of gene expression | Growth failure; impaired wound healing, taste changes, decreased immune response | Poor consumption of protein foods; phytate consumption inhibits absorption | Fever, nausea, vomiting, diarrhea; reduction in copper | 115 ± 12 ng/dL |

‡Not all dairy products are fortified.

AAs, Amino acids; BUN, blood urea nitrogen; CNS, central nervous system; GI, gastrointestinal; HDL, high-density lipoprotein; LDL, low-density lipoprotein; PEN, peripheral enteral nutrition; PKU, phenylketonuria; TPN, total parenteral nutrition; TSH, thyroid-stimulating hormone.

Box 37-1 Select Conditions that Increase Nutrient Requirements

- Pregnancy
- Lactation
- Healing wounds, including skin ulcers
- Surgery
- Trauma
- Burns
- Chronic lung disease
- Cancer
- Acquired immunodeficiency syndrome
- Infection
- Inflammatory diseases
- Hyperthyroidism

Absorption

Patients may demonstrate poor absorption of nutrients for a variety of reasons, including loss of absorptive surface area in the intestinal tract from surgery, Crohn's disease, infectious processes, or other inflammatory conditions, such as celiac

disease (National Digestive Diseases Information Clearinghouse [NDDIC], 2005) (Table 37-2). Incomplete digestion and processing of fats, carbohydrates, proteins, and vitamins can also lead to decreased absorption of those nutrients. Table 37-3 lists various nutrients and their sites of metabolism and absorption.

Metabolism and Excretion

Many chronic diseases result in poor metabolism of foods, which leads to poor availability of calories and other nutrients. Additionally, any condition that results in excessive losses of nutrients through the intestinal tract or kidneys may also result in malnutrition. Certain foods, such as non-absorbable fat substitutes, cause excessive loss of fat-soluble vitamins, with steatorrhea caused by the fat not being absorbed (Table 37-4).

Dietary History

It is important to obtain information about the patient's usual and recent diet as part of the history. The dietary history refers to a patient's usual pattern of food intake and any factors that may influence food choices and availability.

Table 37-2 Celiac Disease: Grains with and without Gluten

| Grains or Flours Allowed | | Grains or Flours with Gluten: Not Allowed |
|--------------------------|----------------------------|---|
| Rice | Millet | Wheat (e.g., durum, semolina, kamut, spelt) |
| Soy | Buckwheat | Rye |
| Potato | Arrowroot | Barley |
| Tapioca | Amaranth | Triticale |
| Beans | Tef | Oats (most likely because of contamination) |
| Garfava | Wild grass seeds (Montina) | |
| Sorghum | Nut flours | |
| Quinoa | | |

Table 37-3 Nutrients and Sites of Metabolism/Absorption

| Nutrient | Site of Absorption |
|--------------------------|--|
| Macronutrients | |
| Amino acids | Throughout small intestine (more rapid proximally) |
| Sugars | Throughout small intestine |
| Fats | |
| Fatty acids | Throughout small intestine (mostly proximal) |
| Bile acids | Ileum |
| Short-chain fatty acids | Colon |
| Minerals | |
| Calcium | Duodenum, jejunum |
| Iron | Duodenum |
| Magnesium | Small intestine |
| Vitamins | |
| Folic acid | Proximal small intestine |
| Vitamin B ₁₂ | Ileum |
| Fat-soluble (A, D, E, K) | Small intestine |

Screening questions include number of daily meals and examples of food consumed. A more thorough evaluation delves into cultural or religious food practices, personal preferences, and use of the food pyramid as a tool to help patients identify food groups from which they may be consuming too few or too many servings.

A specific part of the dietary history is a *nutrient intake* analysis. This history relies on a food diary kept by the patient for a specific period, usually 3 to 7 days, including times, food and beverages consumed, and activity. Clinicians also use *dietary recall* as a method to assess nutrient intake. With this tool, patients report foods and beverages consumed over the past 24 to 48 hours. This retrospective analysis has less validity than the prospective food diary because people typically are unable to remember the details of their past eating habits accurately (Hammond, 2004).

Table 37-4 Conditions Affecting Metabolism and Excretion

| Type of Impairment | Possible Contributing Condition |
|----------------------------------|---|
| Impaired dietary intake | AIDS Anorexia nervosa Cancer Depression Dental problems Hyperemesis gravidarum Poverty Stroke Substance abuse |
| Maldigestion | Cholestasis Enzyme deficiencies Intestinal bacterial stasis Pancreatitis or insufficiency Radiation enteritis Short bowel syndrome |
| Malabsorption | AIDS Celiac disease Intestinal lymphoma Radiation enteritis |
| Impaired metabolism | AIDS Cancer Chronic disease (liver, kidney) Corticosteroid use |
| Increased excretion of nutrients | Diarrhea (zinc, magnesium) Glucosuria Inflammatory bowel disease Protein-losing enteropathy Gastrointestinal bleeding (iron) |
| Increased requirements | Burns Trauma Surgery Chronic infection Inflammation Chronic lung disease Hyperthyroidism Sepsis |

Modified from Newton JM, Halsted CH. Clinical and functional assessment of adults. In Shils ME, Olson JA, Shike M, Ross AC (eds). *Modern Nutrition in Health and Disease*, 9th ed. Lippincott-Williams & Wilkins, 1999, Chapter 55. AIDS, Acquired immunodeficiency syndrome.

Physical Examination

Key Points

- Significant weight loss— 5% in 1 month, 7.5% in 3 months, or 10% in 6 months, from usual weight— indicates the need for further evaluation to determine the cause.
- Albumin and transferrin can be artificially low when C-reactive protein level (inflammation) is high. Prealbumin is a more accurate marker of nutritional status with systemic inflammation.

A systematic physical examination is important in evaluating nutritional status. General inspection may immediately

reveal obvious overweight or underweight. Anthropometry, or physical measurements of an individual that are compared with reference standards, plays a role as well. These parameters include height, weight, skin fold thickness, head circumference (especially in infants and children), and waist and hip circumferences. These measurements are most helpful when taken at several intervals over time.

Height and Weight

It is useful to measure height and weight to assess nutrition. Patients tend to overestimate their height and underestimate their weight. In considering weight alone in adults, the *usual body weight* is a more useful parameter than ideal body weight obtained from published tables. In children, body weight is more useful than height in estimating body fat and also provides information about recent nutrient intake (Hammond, 2004). Changes in weight over time from the usual body weight may reflect a change in nutritional status. However, it is important to remember that acutely, weight loss or gain may signify a change in fluid status rather than in nutritional well-being. In an obese individual or older adult, loss of lean body mass indicating malnutrition may be masked by the presence of excess body fat.

Significant weight loss is defined as a 5% loss in 1 month, a 7.5% loss in 3 months, or a 10% loss in 6 months. A severe weight loss is defined as any loss higher than those percentages in the same interval. The following method is also used to assess nutritional status as a function of weight loss (Hammond, 2004):

- Weight within 85% to 90% of usual body weight—*mild* malnutrition.
- Weight within 75% to 84% of usual body weight—*moderate* malnutrition.
- Weight less than 74% of usual body weight—*severe* malnutrition.

Both height and weight are needed to calculate the body mass index (BMI), which is highly correlated with independent measures of body fat in adults (Balcombe et al., 2001; Keys et al., 1972). The formula for calculating BMI is weight (kg)/[height (m)]². Table 37-5 lists parameters for overweight, obesity, and underweight according to the BMI (see Web Resources for BMI calculator).

It is important to note the limitations of the BMI as a nutritional assessment tool. It may overestimate body fat in trained athletes, and it may underestimate body fat in older patients and in those who have lost lean body mass because

of nutritional deficiency. There are no clear guidelines on the use of the BMI in pregnancy (National Heart, Lung, and Blood Institute [NHLBI], 2000).

Body Composition

Assessment of body composition reveals the relative amount of body fat and lean body mass. One common method for assessing subcutaneous fat is the measurement of *skin fold thickness*. Several areas of the body have demonstrated good correlation with body fat, including the triceps, biceps, subscapular tissue, and tissue above the iliac crest. Measurements are taken with calipers and compared with standardized tables to determine the percentage of body fat. This type of assessment can be limited by the accuracy of the measuring technique. Changes in skin fold thickness take place over 3 to 4 weeks, so this measurement is not a useful gauge for determining acute changes in nutritional status.

Circumference measurements are useful in assessing nutritional status. The waist circumference correlates with abdominal fat content. Increased waist circumference has been associated with cardiovascular disease risk factors (Dalton et al., 2003). The correct method for waist circumference is to measure the distance around the smallest area below the rib cage and above the umbilicus. Waist measurements of more than 40 inches in men and 35 inches in women are independent risk factors for disease (NHLBI, 2005). The waist circumference has less predictive value in patients shorter than 5 feet tall and in those with BMI greater than 35.

General Physical Examination

Certain findings on physical examination may alert the physician to the potential for malnutrition. These include temporal wasting, decreased muscle mass in general, proximal muscle weakness, and certain skin changes, such as scaling, poor wound healing, and bruising. Tissues in the body that undergo rapid cell turnover, such as mucous membranes, skin, and hair, may be the first to show signs of nutritional insufficiency (see Table 37-1).

Laboratory Evaluation

Physiologic changes related to adequacy of nutrition occur slowly; the first signs of a change in nutritional status usually appear at the cellular level. These changes may be detected by a variety of laboratory tests. Single laboratory tests may have value in screening for nutritional problems, whereas a series of values is important for assessing ongoing nutritional problems and treatment.

Assessment of Protein Status

One traditional method of determining nutritional status is to measure the *nitrogen balance*, calculated by comparing protein gain with protein loss. In healthy adults the nitrogen balance is zero; that is, the amount of nitrogen consumed should equal the amount of nitrogen excreted. Calculation of the nitrogen balance gives an indication of short-term changes in protein status. Approximately 16% of protein mass in the body is made up of nitrogen. In calculating nitrogen balance, the clinician can determine protein intake in the diet and then

Table 37-5 Weight Categories according to Body Mass Index (BMI)

| Category | BMI (kg/m ²) |
|-------------|--------------------------|
| Underweight | <18.5 |
| Normal | 18.5-24.9 |
| Overweight | 25-29.9 |
| Obese | ≥30 |

From National Heart, Lung, and Blood Institute (NHLBI). Clinical guidelines on the identification, evaluation, and treatment of overweight and obesity in adults, BMI calculator. <http://www.nhlbisupport.com/bmi/bmicalc.htm>.

measure nitrogen output in urine and feces. The nitrogen balance is negative when protein-calorie intake is insufficient; it is positive in growing children and pregnant women. The following formula is used for calculating nitrogen balance:

$$\text{Nitrogen balance} = \text{Nitrogen intake (g/24 hr)} \\ - (\text{Urinary nitrogen [g/24 hr]} + 2 \text{ g/24 hr})$$

where the 2 g/24 hr accounts for nitrogen losses from GI epithelium, skin, hair loss, and sweat. The total urine nitrogen can be determined by dividing the 24-hour urinary urea nitrogen by 0.85. In patients with extensive diarrhea or other losses of nitrogen (e.g., through pancreatic fistula), other methods must be used to calculate nitrogen losses, such as by the use of pyrochemiluminescence.

There are limitations in calculating nitrogen balance. It is difficult to assess the amount of protein intake in a person eating by mouth because of the need to measure portions and amounts consumed accurately. Determination of the nitrogen balance is more accurate for patients receiving defined formulas of enteral or parenteral nutrition.

Measuring Visceral Protein: Albumin

The protein contained in visceral organs constitutes about 10% of total body protein, whereas the protein in plasma and extravascular body fluids makes up about 3% of total protein. *Albumin* is a plasma protein produced by the liver that can be used as an indicator of visceral protein balance. The measurement of serum albumin reflects changes in the protein status over a longer time than the nitrogen balance, in part because albumin has a serum half-life of 2 to 3 weeks.

Using serum albumin as a marker for protein nutrition status also has limitations. Albumin is a negative acute-phase reactant and tends to decrease in concentration under conditions of inflammation. Because of its long half-life, this change may be misleading. In protein-calorie starvation, albumin levels tend to decrease, but in total-calorie deprivation, albumin levels may remain more stable (Hammond, 2004). Finally, there is a large extravascular albumin pool, which tends to equilibrate by entering the vascular system when plasma concentration of albumin decreases.

Transferrin

Transferrin is another plasma protein that reflects overall protein balance. Like albumin, transferrin is a negative acute-phase reactant, but because of its shorter half-life (8 days), it may be somewhat more accurate than albumin as a tool for assessing nutritional status. Transferrin has limitations, however, in that its concentration is related to the patient's overall iron status. Also, as with albumin, serum concentration of transferrin does not change rapidly with changes in protein-calorie intake.

Other Plasma Proteins

Several other plasma proteins have been proposed as good markers for protein energy status. The level of transthyretin (TTT), also known as *prealbumin*, has been shown to correlate with visceral protein status, but it is an acute-phase reactant and is also affected by zinc concentrations. Retinol-binding protein (RBP) has a short serum half-life (12 hours) and correlates with protein energy status in some patients with malnutrition, but it also is a negative acute-phase reactant and has limitations for the assessment of nutritional status.

It is possible to circumvent the problems raised by inflammation in interpreting the plasma levels of the proteins mentioned. *C-reactive protein* (CRP) level provides an indication of the amount of inflammation present at a given time. Some clinicians may ascribe more usefulness to levels of albumin, transferrin, transthyretin, and RBP when the CRP level is low.

Urinary Creatinine and Creatinine/Height Ratio

The urinary creatinine level reflects the amount of ongoing muscle metabolism. The amount of creatinine excreted in the urine is proportional to the muscle mass of an individual. Using a mathematical formula, it is possible to derive an expected amount of creatinine excretion over 24 hours based on a person's height. This formula is limited in the case of a tall, thin, or short muscular subject. The amount of urinary creatinine also varies depending on the diet; diets high in meat will result in increased urinary creatinine excretion.

Vitamin and Mineral Assays

In general, protein-calorie malnutrition is associated with low levels of vitamin A, zinc, and magnesium. Fat-soluble vitamins may be deficient in conditions of malabsorption of fat. Folic acid and iron are not well absorbed in celiac disease.

Hematologic Tests

Changes in red blood cell production may result from insufficient levels of iron, vitamin B₁₂, folic acid, and other vitamins. It is important to note that determining the complete blood count (CBC) is important in assessing nutritional status. Patients with poor nutritional status may also demonstrate weak immune status. T-cell-mediated responses are more severely affected by nutritional inadequacy than B-cell functions, such as immunoglobulin function. Evaluating the total lymphocyte count can be helpful in assessing T cells. Using skin testing for energy is one method of testing T-cell immune competence.

Nutrition in the Life Cycle

Pregnancy and Lactation

Pregnancy has long been recognized as a time of increased nutritional needs. Recommendations vary but one constant remains: with adequate caloric intake comes a greater likelihood of ingesting adequate nutrients. Weight checks are a standard part of all prenatal visits. In recent years, concern has focused on the woman's health status after the pregnancy. As Table 37-6 demonstrates, in older pregnant women or biologically immature women (those who become pregnant within 5 years of starting to menstruate), the caloric intake and weight gain are specific to the particular health needs of the woman during as well as after the pregnancy. The usual weight retained with each pregnancy by women in the United States is 10 pounds (McGanity et al., 1999). This retained weight may have a significant influence on future chronic disease development for women.

Table 37-6 Pregnancy Outcomes Linked to Weight Gain

| Increased Risk of LBW Infant | Best Outcomes | | Increased Risk of Gestational Diabetes* |
|--|--|-------------------------------|--|
| Biologically immature or too thin (BMI <18.5 kg/m ²) | BMI 18.5-24.9 kg/m ² | BMI 25-29.9 kg/m ² | BMI ≥30 kg/m ² or older than 35 years |
| Recommended Weight Gain | | | |
| Approximately 28-40 pounds (1.1 lb/wk) | 25-30lb (0.7 lb/wk) Not nursing: 0.8 lb/wk Nursing: 0.9 lb/wk Twins: 1.4 lb/wk | 15-25 lb | 11-20 lb |

Data from Institutes of Medicine (IOM). Report on weight gain during pregnancy: reexamining the guidelines, 2009.
*Increased risk of LBW infant or infant too large.
LBW, Low-birth-weight; BMI, body mass index.

It is now known that the nutritional needs for pregnancy begin before conception. The state of nutrition 60 to 90 days before conception influences pregnancy outcomes. The major nutrient changes from conception through the first trimester are increases in folic acid, iron, and calories. The overall nutritional needs throughout the pregnancy are as follows:

1. Adequate calories for development of the fetus, placenta, and lactation after delivery (with adequate calories increasing the opportunity for adequate nutrients)
2. Adequate protein
3. Adequate iron
4. Adequate folic acid, vitamin C (especially critical if the woman is a smoker, because there is a much higher need in smokers), and vitamin B₁₂
5. Adequate calcium and iodine

Community-based programs such as Women, Infants, and Children (WIC) can be a resource for helping women in need. It has been demonstrated that infants of women who participate in these programs have higher birth weights than those who were not in the programs and who are in the same social, economic, or other problematic circumstances.

Many of the nutritional issues in *lactation* are influenced by the nutritional status of the pregnant woman. The nutritional stores of the newly delivered woman are an important source of supplies for her and the infant. Certain nutrients are stable regardless of the maternal diet (Table 37-7). Studies of lactation have found that after about 6 months of breastfeeding, maternal weight decreases by about 10 pounds without any changes in the composition or production of breast milk (Barbosa et al., 1997). This may be important when considering that the average weight retained with each pregnancy is about 10 pounds.

Infancy and Childhood

An excellent summary of the nutrients and development needs for food in this age group has been recently published (Fig. 37-1). This figure provides guidance about major

Table 37-7 Intake of Nutrients in Maternal Diet and Effect on Amount of Breast Milk

| Intake Causes No Increase in Amount of Breast Milk | Intake Causes Some Increase | Intake Causes Significant Increase |
|---|---|---|
| Calories Fluid Protein Calcium Phosphorus Magnesium Sodium Potassium Folate Vitamin C Iron* | Fatty acid content Selenium Iodine Water-soluble vitamins (excluding folate and C) Fat-soluble vitamins | Vitamin D Vitamin B ₆ Iodine Selenium |

*Although supplementation is needed because of increased needs of infant (IOM. Nutrition during Lactation, 1991.)

nutrient needs and how the infant and child can meet these needs. These evidence-based guidelines were developed by a panel of pediatricians, nutritionists, and the U.S. Department of Agriculture (USDA) after comprehensive review of the literature.

It is important to help parents understand that the introduction of new foods takes time. Researchers found that it takes at least eight different attempts of introducing a new food before a child will show true acceptance or rejection (Birch et al., 1991; Satter, 2000). Parents must understand that their role is to provide a healthy range and variety of foods in a pleasant eating environment, whereas the child's role is to consume the food in the amounts that he or she needs and wants. This foundation of good food habits will carry through to the adolescent stage, in which independence and finding ways of expressing this independence are achieved not only in social functioning but also in food and health habits.

Adolescence

Adolescents gain independence by taking a greater role in food choices and amounts eaten. It is frustrating for parents who worked to establish standards to see the young person seek independence, even with foods consumed. This is a stage in life that demands high caloric intake, because growth needs are second only to those in infancy—more kilocalories per kilogram are needed than in any other life stage. This high caloric consumption is favorable to nutritional status because with high calories comes the increased likelihood of taking in more nutrients. Parents must remain hopeful that good health habits will guide the teenager. There may be concern over peer pressure leading to "strange" or different food habits, such as disordered eating, sports nutrition, and vegetarian diets, which many teens attempt. Such exploration is often a natural part of expressing independence. These food patterns can be healthy, such as improving food habits with vegetarianism or sports nutrition. The family physician needs to determine when the teen's exploration could become harmful. Nutrition assessment is appropriate in this life stage in regard to determining whether a nutritional problem is present.

| Development stage | Newborn | Head up | Supported sitter | Independent sitter | Crawler | Beginning to walk | Independent toddler |

Figure 37-1 Summary of physical and eating skills, hunger and fullness cues, and appropriate food textures for infants and children. (From Butte N, Cobb K, Dwyer J, et al. *The Start Healthy feeding guidelines for infants and toddlers.* J Am Diet Assoc 2004;104:455-467.)

Adulthood

The study of adult nutrition tends to focus on prevention and treatment of chronic diseases. There is new interest in optimizing nutrition during this stage to enhance the older adult's quality of life. The public has demonstrated a strong interest in this process with the use of nutrition and nutritional products as an alternative medicine source. Some of these developments, such as antioxidant vitamins, plant-based estrogens, and other functional foods, have not had the desired outcomes (i.e., longer life, enhanced functional status). The *Dietary Reference Intakes* (National Academy of Sciences, 2005) has addressed this concept of enhanced nutrient intakes through supplements and other products by introducing a new category called *tolerable upper intake levels* (see Terminology). Many values in this category of nutrient levels are still being researched.

The research on caloric restriction as a means for decreasing the problems of aging is still at an animal model level. Studies concerning the risks of obesity and the positive effects of physical activity have the most promise to helping to understand the effects of overnutrition and caloric restriction on human longevity.

Osteoporosis

With the possibility of a 20% bone mass loss in the 5 to 7 years following menopause, the best treatment for osteoporosis (reduction in amount of bone mass) is the prevention of bone loss. The following three steps are recognized as most helpful for women (80% of osteoporosis population):

1. Balanced diet rich in calcium and vitamin D (Table 37-8; see also Table 37-1)
2. Weight-bearing exercise, such as walking
3. Healthy lifestyle, with no smoking or excessive alcohol intake

Peak bone development occurs throughout adolescence, with smaller bone gain during the 20s and less calcium needed at this age. Bone loss starts with menopause for women, which increases the need for calcium and vitamin D to prevent bone loss. High dietary intake of calcium does not seem to present any risk; previous concern about kidney stone formation with increased calcium intake appears to be unfounded (Curhan et al., 1997). Side effects of high calcium supplement intake include constipation and dyspepsia, and calcium supplementation with more than 2000 mg/day of vitamin D may lead to soft tissue calcification.

Cancer Prevention through Nutrition

Caloric Restriction

In animal studies, caloric restriction has shown promise in increasing the life span of the animals studied, but human studies have not been as encouraging. This may be an extremely difficult area to investigate because there is no clear understanding of where in the human life span caloric restriction would be the most beneficial. In humans the balance between starvation and overnutrition seems to be more difficult to determine. People with a BMI less than 18 kg/m² seem to have a higher mortality rate, but those who are obese (BMI >30) also probably do less well. Currently, there is insufficient evidence to recommend caloric restriction as a means

Table 37-8 Supplement or Food Sources of Calcium and Vitamin D

| Supplement or Food | Elemental Calcium/ Tablet | Calcium Compound | Vitamin D (IU)* |
|--|---------------------------|------------------|-----------------|
| Supplement | | | |
| Caltrate 600 | 600 mg | Carbonate | 0 |
| Caltrate 600 + D | 600 mg | Carbonate | 200 |
| Tums | 600 mg | Carbonate | 0 |
| Citracal | 400 mg | Citrate | 0 |
| Calcium Gummy Bears (2) | 200 mg | Phosphate | 200 |
| Viactiv | 500 mg | Carbonate | 100 |
| Food (1 cup) | | | |
| Milk (skim) | 300 mg | | 100 |
| Juice fortified with calcium | 300 mg | | 0 |
| Tofu prepared by calcium precipitation | 260 mg | | 0 |
| *Adequate intake of vitamin D in cholecalciferol (1 µg cholecalciferol = 40 IU vitamin D): 31-50 years old, 5 µg/day; 51-70 years old, 10 µg/day; older than 70 years of age, 15 µg/day. | | | |

of treatment or prevention of cancer, although evidence does suggest that a high BMI (>30) may be a cancer-promoting factor. Physical activity to balance the energy intake is probably the best preventive measure against cancer at this time.

Vitamin Supplementation

Epidemiologic studies note that populations who consume diets high in vitamins and minerals have a lower incidence of cancer. Three studies, the Alpha-Tocopherol Beta-Carotene Cancer Prevention Study Group (1994), β-Carotene and Retinol Efficacy Trial (CARET; Omenn et al., 1996), and Physicians' Health Study (PHS; Hennekens et al., 1996), investigated smokers and asbestos workers to see whether provitamin A and beta carotene supplementation would decrease the incidence of cancer. Those who received supplementation developed cancers earlier than those who did not, and the studies were suspended. The question of whether supplementation with antioxidant vitamins prevents cancer has not been answered, because several other antioxidant vitamins have not been studied. Supplementation has lost its support as a positive intervention, particularly in men who smoke. Foods rich in the antioxidant vitamins (beta carotene, vitamins C and E) and minerals (potassium) are recommended rather than supplements until the problems of dietary supplement research can be solved.

Therefore, the dietary elements that seem to be the most favorable, according to epidemiologic studies, are as follows: *More* fruits, vegetables, whole-grain products, and calcium-containing foods
Less saturated fats, particularly those found in red meats

Aging

The only difference in the nutritional needs of older adults was long thought to be the decrease in caloric needs, about a 2% to 5% decrease with each decade of life. The smaller decrease in caloric need (2%) is for those who exercise and the higher decrease (5%) is for those who do not exercise. Decrease in caloric need is complicated by the well-established phenomenon that weight gain tapers as humans age. Peak weights for men are at around 55 years, with weight loss after that age (slowly, because rapid weight loss has significant risks in the older adult). Peak weights for women are at around 65 years with decreases after that age. Rapid weight loss can identify critical problems; one of the first signs of dementia is often unintended weight loss. Additional changes in nutrient needs occur mainly because of the physiologic changes of aging (Box 37-2). The Tufts University USDA Human Nutrition Center on Aging has developed a food pyramid based on the different nutrient needs that are critical to older adults (Russell et al., 1999).

Because psychosocial components are so important in determining nutritional status in older adults, reliable nutrition assessment includes consideration of these elements for evaluation (Fig. 37-2). Functional status and mental status influence nutrition and well-being.

Diet in Prevention and Management of Major Disease

Vascular and Related Conditions

Key Points

- Dietary improvements for the general population as well as for patients with cardiovascular disease, including low saturated fats, increased omega-3 fatty acids of nuts and fish, and nutrient-rich foods, seem to improve disease risk.
- Dietary supplements have not reduced the risk of cardiovascular disease in the general population or in patients with cardiovascular disease.
- Foods seem to be better than supplements in disease prevention.

Hypertension

The report of the Seventh Joint National Committee on Prevention, Detection, Evaluation and Treatment of Hypertension (JNC-7) has identified patients with systolic blood pressure (SBP) of 130 to 139 mm Hg and diastolic blood pressure (DBP) of 85 to 89 mm Hg as having *prehypertension* (Chobanian et al., 2003). Persons with prehypertension and stage I hypertension (SBP 140-159; DBP 90-99) are candidates for lifestyle and diet modification. Persons with stage I hypertension with complicating conditions such as diabetes or cardiovascular disease or stage II hypertension (SBP 160-179; DBP 100-109) and stage III hypertension (SBP \geq 180; DBP \geq 110) not only should receive recommendations for dietary and lifestyle modification, but also are candidates for appropriate pharmacotherapy, with diuretics as the mainstay of treatment.

Several lifestyle modifications are recommended for prehypertension and all treatment categories (stages I-III), regardless of whether medications are indicated for ideal control (Dosh, 2002). Aerobic exercise (45-60 minutes at least 3 days/wk and preferably daily); a low-salt, low-fat, high-fruit, high-vegetable diet; limited alcohol consumption (<3 drinks/day); and modest weight loss (3%-9% of total body weight) have been shown to result in modest blood pressure reductions. There is insufficient evidence that these measures alone reduce morbidity and mortality rates in persons with hypertension.

A Cochrane review of 58 clinical trials found that sodium restriction led to significant reductions in systolic and diastolic blood pressures, with a greater effect in blacks than in whites (Jurgens and Graudal, 2004). SBP decreased by an average of 4.2 mm Hg and DBP by 2.0 mm Hg in white patients. Trials in black patients indicated that SBP decreased by an average of 6.4 mm Hg and DBP by 2.0 mm Hg. Based on these trials, JNC-7 recommended that patients with hypertension limit daily sodium intake to about 2 to 4 g daily (Chobanian et al., 2003). This recommendation may be suitable for prehypertension and early stage I hypertension, but not for stages II and III hypertension alone. Isolated systolic hypertension, which is more common in older adults, is also more responsive to sodium restriction. Reducing sodium intake (<2-4 g/day) does lead to a slightly lower average BP, especially in black Americans. No evidence has shown that reducing sodium intake decreases morbidity or mortality or that modest sodium restriction is harmful (Smucny and FPIN, 2004).

A combination diet known as DASH (*dietary approach to stop hypertension*) is low in saturated fat, high in fruits and vegetables (8-10 servings, or 4-5 cups/day), and high in low-fat dairy products. DASH resulted in significant reductions in systolic (>11 mm Hg) and diastolic (>5 mm Hg) BP in persons with stage I hypertension (Appel et al., 1997; Svetkey et al., 1999). With the addition of sodium restriction (<2 g daily), further BP reductions have been observed (He and MacGregor, 2004; NIH, 1992). The DASH diet, or a similar combination, with modest sodium restriction should be considered as first-line treatment for prehypertension and early stage I hypertension.

Other dietary considerations for hypertension, but with weaker evidence than sodium restriction, include increasing fiber and maintaining potassium intake; these recommendations are based on observational studies comparing

vegetarians with nonvegetarians and differences in systolic and diastolic BP (Berkow and Barnard, 2005). Vegetarian diets are generally high in fruits, vegetables, legumes, and nuts. They have a relatively low total fat and high potassium, magnesium, and fiber content. No evidence shows that potassium or magnesium supplementation has beneficial effects in hypertension, except when there is wasting of these elements because of diuretic use (Beyer et al., 2006).

Hyperlipidemia

Diet is the mainstay of therapy for mild and moderate hyperlipidemia. Patients with high low-density lipoprotein (LDL) levels (>160 mg/dL) and those with borderline high LDL cholesterol (130-160 mg/dL), but with two risk factors for coronary heart disease, should be considered for dietary modification. The National Cholesterol Education Program (NCEP) has recommended a diet for therapeutic lifestyle changes that includes less than 200 mg of cholesterol daily and less than 7% saturated fat, 25% to 35% total fat, 50% to 60% carbohydrates, and 15% protein of total calories (Expert Panel, 2001; Henley, 2002). Although diet will reduce the cholesterol level, there is no clear evidence that diet low in saturated fat or cholesterol will reduce cardiovascular morbidity and mortality. The Irish Heart Foundation focused on limiting saturated fat intake and encourages the use of eggs in a balanced, healthy diet (Gray and Griffin, 2009). Dietary therapy should be offered in conjunction with weight reduction and exercise, all of which also reduce triglyceride levels, increase high-density lipoprotein (HDL) levels, reduce BP, and improve glucose tolerance.

Increased consumption of fruits and vegetables is associated with a lower incidence of vascular disease events in observational studies (Clinical Evidence, 2001). The Ornish program, which combines a high-vegetable and very-low-fat diet with stress reduction and prescribed exercises, has shown reversal of coronary vascular disease on pre- and postangiographic studies (Ornish et al., 1998; Pischke et al., 2008). Many patients found long-term maintenance difficult because of the strict dietary modification required.

In an attempt to increase the effectiveness of diet in reducing serum cholesterol, NCEP has recommended the use of functional foods high in components that reduce cholesterol, such as viscous fibers, soy protein, plant sterols, and nuts (Expert Panel, 2001).

Dietary fiber intake, independent of fat intake, has been shown to have an inverse association with myocardial infarction (MI) (Rimm et al., 1996). During a 6-year follow-up of 734 cases of MI, patients in the highest quartile of dietary fiber had the lowest incidence of MI. A 10-g increase in total dietary fiber corresponded to a relative risk reduction (RR) of 0.81 in MI. A multicenter, population-based cohort study of 2909 healthy black and white adults followed for 10 years showed inverse linear associations with increasing fiber diets with reductions in weight gain, insulin levels, LDL levels, and BP (Ludwig et al., 1999). Fiber consumption predicted these coronary vascular disease risk factors more strongly than total-fat or saturated-fat consumption. Similar associations, especially with higher oral fiber intake, have been reported in women (Wolk et al., 1999) and elderly patients (Mozaffarian et al., 2003).

No evidence shows that treating isolated high triglyceride (TG) levels in the absence of other risk factors prevents

coronary events. Weight reduction, restricting alcohol use, and increased exercise are the important interventions in lowering TGs. Although carbohydrate intake may influence blood TGs in some individuals, the practicality of the glycemic index of foods has not shown improvement in risk factors for heart disease (Kelly et al., 2004). Coincident lowering of TG levels while treating other dyslipidemias (e.g., high LDL, low HDL) can contribute to decreasing coronary events (Cucuzzella et al., 2004).

Secondary Prevention of Cardiovascular and Cerebrovascular Disease

A systematic review graded the evidence of dietary recommendations for the prevention of further events in patients with existing cardiovascular disease (Hooper et al., 2004a). The recommendation is ranked grade 1 (evidence from RCTs, systematic reviews of RCTs) and level A evidence of the effect of the intervention on morbidity and mortality rates (SORA, 1).

Recommend an increase in omega-3 fats to all patients with established coronary disease. Reduced saturated fat results in decreased recurrent coronary events. Recommend the Mediterranean diet to all patients after MI (Hooper et al., 2004b). The Mediterranean diet is a combination of increased omega-3 fats, fruits, vegetables, and fresh foods, together with a reduction in saturated fats and processed foods. In a prospective cohort of 1302 Greek men and women with CAD followed for 3.78 years, a 27% reduction in all-cause mortality and 31% reduction in cardiovascular disease-specific mortality were seen in those with the highest adherence to the Mediterranean diet (Trichopoulou et al., 2005) (see Web Resources, American Heart Association). There is no clear systematic evidence for dietary protection in patients with cerebrovascular disease. Multicomponent programs focusing on diet, exercise, and stress management can have additive benefit to patients with CHD (Daubenmier et al., 2007).

Dietary Supplements and Vascular Diseases

Is folate supplementation indicated with coronary artery disease (CAD)? Evidence is insufficient to recommend the routine use of folate supplementation to treat CAD (Albert et al., 2008). High levels of serum homocysteine are associated with increased risk for CAD in case-control studies. Folate supplementation decreases the level of serum homocysteine (Gill, 2004). The American Heart Association and American College of Cardiology do not recommend the routine use of high-dose folic acid or vitamin B supplements for primary or secondary prevention of cardiovascular events. The Canadian Task Force on Preventive Health Care has not recommended screening for homocystinemia but has recommended meeting the daily allowances for folate (400 µg), vitamin B₁ (2.4 µg), and vitamin B₆ (1.7 µg) (Booth and Wang, 2000).

Do vitamin C supplements reduce cardiovascular disease mortality (Aukerman, 2004; Bloom et al., 2002; Riccioni et al., 2007; Sesso et al., 2008)? There is insufficient evidence to recommend vitamin supplements for prevention of cardiovascular disease (USPSTF, 2003).

Does vitamin E supplementation have a benefit in reducing cardiovascular disease? The Heart Outcomes Prevention Evaluation (HOPE) followed 3994 patients with vascular disease or diabetes over age 55 for 5 to 7 years (Lonn et al., 2005). Patients received 400 IU of vitamin E or matching

placebo. Vitamin E supplementation had no long-term benefit to prevent major cardiovascular events and may increase the risk of heart failure. Vitamin E supplementation, in a variety of doses, does not decrease the incidence of cardiovascular or all-cause mortality. There is no evidence that vitamin C decreases mortality in patients at CAD risk (Aukerman, 2004; Bloom et al., 2002).

Vitamin D deficiency and low blood levels of D have been associated with heart disease and hypertension, especially in regions with low sunlight and in individuals with dark skin pigmentation. Whether supplementation of vitamin D would reduce high BP or heart disease is unclear; research is ongoing.

The dietary supplement of omega-3 fatty acids for the prevention and treatment of cardiovascular disease has received widespread interest. It is unclear whether omega-3 fatty acid intake alters mortality, cardiovascular events, or cancers in those at risk or in the general public (Cochrane review; Hooper et al., 2004b). Further studies are being conducted.

KEY TREATMENT

Sodium restriction significantly reduces systolic and diastolic blood pressure, with a greater effect in blacks than whites (Jurgens and Graudal, 2004) (SOR: A).

The DASH diet significantly reduces systolic (>11 mm Hg) and diastolic (>5 mm Hg) BP in persons with stage I hypertension (Appel et al., 1997; Svetkey et al., 1999) (SOR: A).

Diabetes Mellitus

Diet is one of the cornerstones of management of types 1 and 2 diabetes mellitus. The American Diabetes Association (ADA, 2006) has published a comprehensive guide to the management of diabetes, including recommendations for *medical nutrition therapy* (MNT). Some goals for all diabetic patients include controlling weight, blood lipids, and BP and keeping blood sugar levels in the normal range or at a level that avoids acute complications of diabetes. Diabetic patients should consume a diet that is appropriate for their particular needs, with consideration of coexisting medical conditions, cultural patterns, tastes, and levels of physical activity.

Type 1

Some specific goals of MNT in type 1 diabetes are to provide adequate nutrition to allow normal growth in children and to provide food intake that, when combined with insulin therapy, results in stable and safe blood glucose levels.

The ADA recommends the terms *sugar*, *starch*, and *fiber* to refer to the different types of carbohydrate. Traditionally, dietitians have paid great attention to carbohydrates in the diet in patients with diabetes. Many diabetic diets affirm the role of the *glycemic index*, which is the amount that the blood glucose level increases in 2 to 3 hours after consuming different foods. Some believed that the different glycemic responses from different types of carbohydrate influenced diabetic outcomes, but studies have shown that the glycemic response in type 1 and type 2 diabetes is related to the total amount of carbohydrate consumed and does not depend on the type of carbohydrate (Franz et al., 2002). Most patients have a limited ability to maintain a diet containing only foods with a low glycemic index. No definitive evidence exists on the value

of low-glycemic index diets. Thus, it is probably not practical or realistic to educate type 1 diabetic patients about the roles of various carbohydrates in maintaining the glycemic index.

Fiber

Patients with type 1 diabetes should be educated about the healthy benefits of fiber in the diet. Although early studies showed some benefit for blood glucose levels with a high-fiber diet, these results have not been supported by larger trials (Franz et al., 2002).

Sweeteners

Many diabetics and health care providers operate under the misconception that plain sucrose as a sweetener results in hyperglycemia and should be avoided. However, studies have not shown this to be true, and patients do not need to restrict sucrose intake, but rather should monitor the total carbohydrate load in the diet. Some recommend replacing sucrose with fructose in the diet because fructose has a lower glycemic index. There is some concern that fructose adversely affects lipids, however, so this substitution is probably not beneficial. All appear to be safe.

Diabetic patients should consume carbohydrates through fruits, whole grains, vegetables, and low-fat milk. The total amount of carbohydrate in a meal is important; it is not necessary to consume particular foods based on the glycemic index. Sucrose and sucrose-containing foods do not need to be avoided by diabetic patients, but should be counted as part of the total carbohydrate load in the diet. The four FDA-approved nonnutritive sweeteners—*aspartame*, *saccharin*, *acesulfame*, and *sucralose*—are generally safe when consumed in recommended amounts established by the U.S. Food and Drug Administration (ADA, 2002).

Because the postprandial glycemic response is strongly related to the premeal insulin dose, patients should learn how to adjust insulin doses based on the total carbohydrate content of the meal. The usual calculation of carbohydrate (CHO) to insulin starts at 15 g CHO for each unit of regular insulin (see Web Resources for additional information on foods and portion sizes). Adjustments are then made for the individual patient based on how closely this works to help maintain blood glucose levels.

Protein

Some patients with hyperglycemia need extra protein in the diet—0.8 g protein/kg body weight in adults (National Academy of Sciences, 2004). Most adults consume at least 50% more protein than required, so modifying the amount of protein in the diet is usually not necessary for diabetic patients. Dietary intake of the usual amount of protein does not appear to affect the development of nephropathy. However, there are no long-term studies to evaluate the nephropathic effect of consuming more than 20% of calories from protein.

Dietary Fat

Patients with diabetes should attempt to limit the amount of saturated fat and cholesterol in the diet. No studies have demonstrated that modifying fat in the diet of diabetic

patients modifies serum lipid levels any differently than such changes in the nondiabetic population. Interestingly, some metabolic studies show that low-saturated fat (10% of energy level), high-carbohydrate diets actually increase postprandial glucose, insulin, and TG levels compared with diets consisting of high proportions of monounsaturated fats. However, high-monounsaturated fat diets have not been shown to improve hemoglobin A_{1c} (HbA_{1c}) levels, and instructing patients to increase consumption of a particular type of fat may result in undesirable weight gain.

Diabetic patients should lower the amount of fat in their diet by replacing high-fat foods with those containing lower amounts of fat, and they should avoid saturated fats. Although FDA-approved fat substitutes are safe, when included as fat replacers in the diet, these substances have not resulted in significant weight loss over time and can cause diarrhea when overconsumed.

Diabetic patients should obtain less than 10% of their daily calories from saturated fats. Some patients (e.g., those with elevated LDL levels) may benefit by lowering their total daily saturated fat intake to less than 7% of total calories. Dietary cholesterol intake should be less than 300 mg/day in diabetic patients, and patients with elevated LDL levels may benefit by lowering daily cholesterol consumption to less than 200 mg (ADA, 2002).

Micronutrients

Although diabetes puts body tissues under increased oxidative stress, there is no evidence that increasing dietary consumption of antioxidants improves health outcomes in diabetic patients. Deficiencies of the minerals potassium, chromium, magnesium, and zinc may exacerbate glucose intolerance. Supplementation with these minerals has not been of benefit, except in the case of potassium and magnesium, for which serum levels can easily demonstrate correctable deficiencies.

KEY TREATMENT

Diet as a whole should be considered in the balanced food intake (with energy expenditure and basal metabolic rate) for determining medication needs of diabetic patient. Diet should be individualized to the patient's unique needs (ADA, 2008) (SOR: A).

Monitoring carbohydrate intake, despite the form of carbohydrate, is a crucial component in dietary management of type 1 diabetes (ADA, 2008) (SOR: A).

Nonnutritive sweeteners are safe when used at established intake levels (FDA, 2008) (SOR: A).

Diabetic patients should limit saturated fat intake to less than 7% of daily energy intake (ADA, 2008) (SOR: A).

Type 2 Diabetes Mellitus

Prevention

Obesity and overweight are important risk factors for developing type 2 diabetes mellitus. Lifestyle modifications, including diet, have been shown to reduce the risk of developing type 2. Diets that result in long-term weight loss of 5% to 7%, along with exercise of moderate intensity for at least 150 minutes per week (30 minutes for 5 days per week), reduce the incidence of type 2 diabetes (Knowles et al., 2002).

Treatment

Obesity tends to increase insulin resistance, so weight loss is an important tool in the prevention and management of type 2 diabetes (see Chapter 36). Dietary recommendations for type 2 patients are similar to those for type 1 patients. It is important to emphasize the importance of other lifestyle changes, such as increasing activity by these patients.

In patients with insulin resistance, reduced calorie intake and modest weight loss can improve insulin resistance and blood glucose levels in the short term. Structured programs for making lifestyle modifications (e.g., increased physical activity, <30% of calories from fat, regular participant contact) can result in weight loss of 5% to 7% (ADA, 2002).

Metabolic Syndrome

The metabolic syndrome consists of components that are all susceptible to dietary management (NCEP Expert Panel, 2001). Because many patients with the metabolic syndrome are overweight or obese, a focus on modest weight loss with dietary modification and increased activity is important.

The dietary recommendations for patients with the metabolic syndrome should be similar to those for patients with diabetes. Additionally, these patients should lower sodium intake, as with hypertension. The Diabetes Prevention Program was a study that evaluated the effect of intensive lifestyle changes; it focused on diet and exercise versus the use of standard lifestyle changes with or without metformin (placebo group) in the prevention of metabolic syndrome in over 3000 patients with impaired fasting glucose levels (Orchard et al., 2005). Patients were evaluated over a 3-year period. At the end of 3 years, significantly more patients in the group receiving standard lifestyle change recommendations and medication had developed the metabolic syndrome than patients with intensive lifestyle modification alone. In the study, intensive lifestyle changes were also associated with a decrease in the prevalence of the metabolic syndrome in patients who met criteria for the syndrome at baseline.

KEY TREATMENT

Lifestyle changes (increased activity, weight loss, smoking cessation, decreased saturated fat and increased fiber intake, moderation in alcohol intake) are the only treatment shown to affect all components of the metabolic syndrome and should be implemented in all patients (Finnish Medical Society, 2007) (SOR: A).

Nutrition Decisions in the Hospitalized Patient

Patients who are hospitalized require appropriate nutritional support to heal wounds and recover from illness. Up to 40% of hospitalized patients have some degree of malnutrition (Coates et al., 1993). Clinical studies have shown that length of stay and hospital costs are higher in patients at risk for poor nutrition than patients who are not at risk (Chima et al., 1997). The Joint Commission (formerly Joint Commission on Accreditation of Healthcare Organizations, JCAHO) requires a nutritional screen to be completed on

each patient within 24 hours of admission. Often, patients with chronic illness are nutritionally depleted before hospitalization, and trauma and surgery increase nutritional demands significantly. Patients may rapidly fall behind in caloric and nutrient intake, particularly older adults.

Subjective Global Assessment

A useful instrument for assessing nutritional status in the hospitalized patient is the subjective global assessment (SGA) (Brugler et al., 2005). The SGA incorporates five features of the history and four components of the physical examination findings, enabling the physician to make a rapid determination of a patient's nutritional status (Fig. 37-3). The history components are weight loss, food intake, presence of significant GI symptoms, functional

status or energy level, and metabolic demand of the underlying disease state. The physical components are depletion of subcutaneous fat, muscle wasting in the quadriceps and deltoid muscles, edema, and ascites. Each component is evaluated as category A (patient well nourished), B (mildly malnourished), or C (severely malnourished).

Weight loss is one of the most important components of the assessment. Generally, if the patient loses at least 5% of body weight over 2 weeks, the ranking in that category is B; a 10% loss puts the patient in category C.

After completing the assessment, the clinician makes a global judgment about the overall status. This is not a numeric assessment, but rather is based on the clinician's sense of the overall nutritional picture, mainly through evidence of weight loss, poor intake, muscle wasting, and loss of subcutaneous fat. This instrument has been validated with

SUBJECTIVE GLOBAL ASSESSMENT SCORING SHEET

Patient name: _____ Patient ID: _____ Date: _____

Part 1: Medical history

1. Weight change

A. Overall change in past 6 months: _____ kgs.

B. Percent change: _____ Gain < 5% loss
 _____ 5–10% loss
 _____ > 10% loss

C. Change in past 2 weeks: _____ Increase
 _____ No change
 _____ Decrease

2. Dietary intake

A. Overall change: _____ No change
 _____ Change

B. Duration: _____ Weeks

C. Type of change:
 _____ Suboptimal solid diet _____ Full liquid diet
 _____ Hypocaloric liquid _____ Starvation

3. Gastrointestinal symptoms (persisting for >2 weeks)

____ None ____ Nausea ____ Vomiting ____ Diarrhea ____ Anorexia

4. Functional impairment (nutritionally related)

A. Overall impairment: _____ None
 _____ Moderate
 _____ Severe

B. Change in past 2 weeks: _____ Improved
 _____ No change
 _____ Regressed

Figure 37-3 Subjective global assessment (SGA). (From Kalantar-Zadeh K, Kleiner M, Dunne E, et al. Total iron-binding capacity-estimated transferrin correlates with nutritional subjective global assessment in hemodialysis patients. *Am J Kidney Dis* 1998;31:263-272; and Brugler L, Stankovic AK, Schlefer M, Bernstein L. A simplified nutrition screen for hospitalized patients using readily available laboratory and patient information. *Nutrition* 2005;21:650-658.)

trained clinicians (Baker et al., 1982a, 1982b; Detsky et al., 1984) but not with untrained physicians.

Other assessment tools have been proposed and may eventually be validated (Brugler et al., 2005). Most of these take into account the same key factors: risk for malnutrition based on preexisting conditions, oral intake, need to heal wounds, and biochemical or hematologic parameters, such as serum albumin level and total lymphocyte count. The family physician can find most of these data readily and obtain a reasonable assessment of nutritional status.

Deterioration of Nutritional Status and Need for Support

Caloric Requirements

Even previously healthy patients may lose nutritional ground rapidly once they are hospitalized. Surgery and the stress of disease increase caloric requirements. The amount of these increases can be calculated using one of a number of predictive equations for determining *resting metabolic rate* (RMR) in kilocalories per day (kcal/day), which is the largest component of overall calorie expenditure. One frequently used model is the *Harris-Benedict equation* (1919), as follows: For men:

$$\text{RMR} = 66.47 + (13.75 \times \text{Weight [kg]}) + (5.0 \times \text{Height [cm]}) - (6.75 \times \text{Age [yr]})$$

For women:

$$\text{RMR} = 665.09 + (9.56 \times \text{Weight [kg]}) + (1.84 \times \text{Height [cm]}) - (4.67 \times \text{Age [yr]})$$

Frankenfield and colleagues (2005) compared validation studies on several equations and found that the *Mifflin–St. Jeor equation* performed best in terms of predicting RMR compared with calorimetry. Although all the equations are less accurate for obese subjects, the following Mifflin–St. Jeor equation is least affected by obesity.

For men:

$$\text{RMR} = (9.99 \times \text{Weight [kg]}) + (6.25 \times \text{Height [cm]}) - (4.92 \times \text{Age [yr]}) + 5$$

For women:

$$\text{RMR} = (9.99 \times \text{Weight [kg]}) + (6.25 \times \text{Height [cm]}) - (4.92 \times \text{Age [yr]}) - 161$$

(See Web Resources for resting metabolic rate/basal metabolic rate and resting energy expenditure/basal energy expenditure calculators.)

These predictive equations do have weaknesses. They have not been validated in all subsets of the population, such as the elderly and nonwhite ethnic groups. Chronic illness can affect the relationship between RMR and body size, with loss of lean body mass in chronic illness.

These equations predict the *resting metabolic rate*, and caloric requirements increase beyond this figure, based on the patient's illness and other metabolic demands. The *resting energy expenditure* (REE) is 1.2 to 1.3 multiplied by the RMR. This figure is further altered by the level of stress. An example is to multiply REE by 1.1

by the number of degrees (Celsius) above normal in a patient with fever. Other multiples are 1.2 for mild stress, 1.4 for moderate stress, and 1.6 for severe stress. It is important to remember that all these calculations only *estimate* caloric requirements and should be considered as a starting point in nutrition repletion rather than the goal (Table 37-9).

Macronutrient Requirements

Hospitalized patients, and especially surgery and trauma patients, often suffer from *protein-calorie malnutrition* (PCM). It is important that patients in the hospital receive adequate calories to meet energy needs and adequate protein to maintain cellular integrity. Caloric requirement can be estimated by a formula, as noted earlier. Protein should make up 1.5 to 2 g/kg/day of that caloric requirement. Specific amino acids (e.g., glutamine, arginine) may be especially important in catabolic states (e.g., cancer, burns). These amino acids are therefore called *conditionally essential* amino acids. Carbohydrates make up about 70% of the total caloric requirement and lipids about 30%.

When to Start Nutritional Supplementation

There is a general trend to delay nutritional supplementation in hospitalized patients in the belief that oral intake will improve imminently, but this may exacerbate the existing malnutrition. The decision to initiate supplemental feeding (over what the patient willingly consumes at meals) must be individualized according to the patient's overall health and likely clinical outcome.

Calorie counts can be obtained for patients receiving oral nutrition. If the patient is falling short on caloric or protein intake, oral supplements are appropriate, given one to three times daily. The commercially available, canned oral supplements provide about 250 kcal and 9 g of protein per can.

For a variety of reasons, hospitalized patients are often unable to consume the calories and protein required to maintain nutrition. At some point, a patient may require enteral or parenteral nutrition. The American Society for Enteral and Parenteral Nutrition has published evidence-based guidelines for assessment and management of supplemental

Table 37-9 Estimated Caloric Need (kcal/kg)

| Weight Goal | Level of Activity or Severity of Illness | | |
|-----------------|--|------------------|--------------|
| | Low kcal/kg | Moderate kcal/kg | High kcal/kg |
| Lose weight | 15 | 20 | 25 |
| Maintain weight | 20 | 25 | 30 |
| Gain weight | 25 | 30 | 35 |

Examples: A 165-pound woman (height 5'2"; BMI 30.2) needs to lose weight but does not want to do any physical activity (low activity, lose weight); 165 lb = 75 kg, 75 × 15 = 1125 kcal estimated. A 200-pound man (height 6'4"; BMI 24.3) is hospitalized with sepsis and needs to maintain his weight (moderate activity, maintain weight); 200 lb = 91 kg, 91 × 25 = 2275 kcal estimated.

nutrition in patients with various disease states and surgical procedures (Albina et al., 2002; also available through the National Guideline Clearinghouse, www.guideline.gov). Depending on the disease state, these guidelines recommend that hospitalized patients begin *specialized nutrition support* (SNS) (enteral or parenteral feeding) when it is anticipated that patients will not otherwise be able to meet their nutritional needs for 7 to 10 days.

Enteral Nutrition

Most experts agree that when SNS is required, enteral feeding is the most appropriate method as long as the GI tract is competent (ADA, 2006; SORT A). This is partly because enteral feeding can supply complex nutrients such as fiber and intact proteins that parenteral nutrition cannot supply. Also, evidence indicates that enteral feeding has beneficial effects on the GI mucosa. Some cells lining the GI tract rely on luminal nutrients to flourish, and enteral feeding maintains the absorptive capacity of the epithelial cells. Enteral feeding also stimulates the immune function of the gut. Enteral feeding is usually safer and less expensive than parenteral feeding.

Delivery Methods

Nasogastric feeding is the least invasive form of enteral feeding and is appropriate when there is no gastric outlet obstruction, delayed gastric emptying, or elevated risk for aspiration. If a patient does not tolerate gastric feeding, has one of the previous contraindications, or requires prolonged nutritional supplementation, as is often the case with head and neck cancers, a *postpyloric feeding method* such as duodenal or jejunal tube placement is appropriate. Jejunal tubes are preferred to duodenal tubes because the latter still pose a reasonably high risk for aspiration.

Formulas

One type of tube-feeding formula is blenderized food, which can be any type of food that can be successfully liquefied. There are also nutritionally complete commercial formulas that are sterile, easy to use, and appropriate for patients with normal digestive and absorptive function. Elemental formulas contain predigested, chemically formulated nutrients in low-molecular-weight form and may be useful in patients with a stressed GI tract that cannot digest and absorb nutrients in a more complex form. Specialized modular formulas are available for specific disease states, such as a formula appropriate for a patient with chronic kidney or lung disease.

Complications

Clinicians should be aware of the potential complications of enteral feeding, such as aspiration (especially with gastric feeding), gut perforation, and functional problems, such as gastric distention, nausea, vomiting, and diarrhea. Serum electrolyte and glucose level abnormalities are common in patients receiving enteral nutrition, and monitoring of these parameters is important.

Parenteral Nutrition

Most hospitals now use multidisciplinary teams to help plan and implement parenteral nutrition when it is deemed appropriate. *Peripheral* parenteral nutrition

(PPN), using a peripheral vein, is appropriate for short-term administration of nutrients (7-10 days) when the GI tract is not functional. *Total* parenteral nutrition (TPN) is administered through a more central vein and is used longer term (>10 days). TPN may be used to administer higher concentrations of glucose and protein than PPN, as well as for infusion of lipids.

Complications

The complications of PPN and TPN include phlebitis and other local reactions to infusion, maintenance of venous access, infection, air embolism, and refeeding syndrome. The *refeeding syndrome* is more common with TPN and may result in sudden death, more often affecting severely malnourished patients as they transition suddenly from deriving energy from stored fat to obtaining energy from infused glucose. This can cause a sudden depletion of phosphate stores, resulting in cardiac dysfunction. Patients who have lost more than 30% of their body weight should undergo gradual repletion of nutrients, with a slow increase in the rate of TPN over several days.

EVIDENCE-BASED SUMMARY

- To determine total daily calorie needs, multiply the basal metabolic rate (BMR) by the appropriate activity factor:
Sedentary (little or no exercise; mild stress): $BMR \times 1.2$
Light activity (light exercise, sports 1-3 days/wk; moderate stress): $BMR \times 1.4$
Moderately active (moderate exercise, sports 3-5 days/wk; severe stress): $BMR \times 1.6$
Very active (hard exercise, sports 6-7 days/wk): $BMR \times 1.725$
Extra active (very hard exercise, sports + physical job or cross-training): $BMR \times 1.9$
- To determine the BMR or basal energy expenditure (BEE), use the on-line calculator (<http://www.calculator.org/bmr.html>).
- Whenever possible, nutritional supplementation should be through the enteral route rather than parenteral.

Behavioral Modifications to Improve Diet and Lifestyle

Diet and lifestyle can be improved to promote good health through changes in behavior.

Patient Counseling on Dietary Changes

The family physician advising the patient about improving diet and lifestyle must specify the behaviors needed (rather than outcomes), help build the patient's behavioral change skills, address factors impeding change, and have an interactive discussion.

Specify Behaviors, Not Just Outcomes

Many chronic conditions have dietary implications, and dietary change is required for the condition to improve. For example, obesity involves calorie reduction; diabetes involves changes in food types eaten, portions, and spacing of eating episodes; and hypertension often involves sodium restriction. Thus, it is important to focus on the behavior necessary (e.g.,

reducing intake of simple carbohydrates) to reach the outcome (improved HbA_{1c} levels). Often, dietary advice involves the patient being told to do the outcome, such as “lose some weight” or “improve A1c.” Although important goals, these should not be confused with what *action* a patient can take. A patient cannot stand still and lose weight but can only change eating patterns and increase physical activity (behaviors). In communicating with patients, it is important to state not only the desired outcome and why (e.g., “It is important to get your hemoglobin A1c below 7% so that you can reduce the chance that you will have complications from your diabetes, such as loss of vision or amputation”), but also to discuss how the patient might accomplish that outcome (e.g., “Eating a healthy diet and increasing physical activity can improve A1c. Which of these would you like to talk about today?”).

Build Skills for Behavior Change

A second common problem with diet counseling is that the focus is often on the patient acquiring knowledge rather than learning the skills for change. Patients who are critically ill need specific instructions on dietary restrictions for their condition. However, most patients who need diet counseling (e.g., those with hypertension, obesity, type 2 diabetes) need to know how to change their habits more than specific details of “dieting dos and don’ts.” Too much information also overwhelms most patients, who begin to feel helpless to make all these changes correctly. Instead, encourage patients to consider how they will make the diet changes needed. Use a step-wise approach; start with small goals in short time increments and build to long-term goals so that patients may gain confidence in their ability to be successful with a new diet plan. Research shows that patients are best able to change behavior when the following elements are incorporated into the plan:

- *Readiness to change.* Patients are in different places with regard to their readiness to change (see Chapter 7). Some are ready to make a change immediately, some are reluctant and cannot decide, and others have tried repeatedly and failed. The family physician’s goal is to move the patient to the next logical step (Prochaska et al., 1992).
- *Goal setting and tracking.* Proper goal setting and knowing the patient’s current state can facilitate successful change by encouraging confidence in the ability to change. Start off with a small, attainable goal and build over time (Locke et al., 1981; Strecher et al., 1995).
- *Relapse prevention.* Patients who have an active plan for avoiding temptation and returning to past behaviors are much more successful than patients who have not planned coping strategies to use during tempting situations (Larimer et al., 1999; Marlatt and George, 1990).
- *Support.* Consider how people and environments can support the patient making changes.

These strategies collectively affect self-efficacy and perception of the patient’s ability to make successful change in a specific area (Bandura, 1977, 2004).

Consider Factors Impeding Change

Many behavioral theories describe why patients act appropriately or not in regard to healthy behaviors, but in the daily practice of medicine, it is useful to break this into

a simple and workable system. *Motivational interviewing* shows great promise as a technique for encouraging behavior change discussions with patients regarding diet improvement (Burke et al., 2003; Thorpe, 2003; vanWormer and Boucher, 2004). Physicians should consider two main factors affecting patient motivation for changing a behavior: importance and confidence. *Importance* is the priority the patient places on the behavior change in question. “How important is it that I make this change?” *Confidence* is the patient’s perception that he or she can actually execute the change. Both are needed. When discussing dietary change with patients, it is important both to engage the patient in considering his or her level of importance and confidence relating to the behavior or task in question and to encourage the patient to consider how the importance and confidence are preventing progress toward a goal, as well as what specific barrier to change (Miller and Rollnick, 2002; Rollnick, 1996).

Factors that influence importance include the following:

- The expected benefit of the change and the value of that benefit
- Competing priorities
- How others view the behavior, and how much the patient values their views
- Cues in the environment
- Perception of connection to a healthy outcome (how severe, how likely)
- Quality of available information

Factors that influence confidence are as follows:

- Success of options for change (does anything work?)
- Past experiences with change
- Barriers
- Support from others
- Resources and skills needed
- Supportive environment (e.g., foods available, social situation)

Have an Interactive Discussion

It is important to communicate dietary information in a way tailored to each patient by considering each patient’s specific circumstances, readiness to change, and motivation. Patients often tire of a canned lecture. Consider the patient an expert on him/herself, and ask open-ended inquiring questions, then incorporate the patient’s response into a plan. In general, try to focus on encouraging your patient in the process of change rather than the emphasis on specific foods or details of diet instructions that they can read or learn about on their own.

Office Changes

To assist patients with dietary change, it is helpful to have a system in place to accomplish the following (at the least): identify dietary risks, assess readiness to change, and assist with change and referral to programs. Although not thoroughly tested for dietary interventions, many family physicians find that the “five As” construct—assess, advise, agree, assist, and arrange—adapted from tobacco cessation interventions in clinical care, is a workable framework to use for health behavior clinical interventions (Whitlock et al., 2002). Practices that incorporate a systematic process, with

specified roles for clinical staff members to be involved in the five As, have the greatest success with helping patients meet their health behavior change goals. For example, receptionists can provide patients as they are waiting with a short dietary assessment; medical assistants can ask dietary assessment questions and cue the physician with a brochure or notation on the record; clinicians can advise patients to choose healthy foods and explain the importance to their health; and other practice team members can create referral mechanisms to community programs. Practice support tools may include flow sheets, chart cues, readily available patient education information, program referral forms and information, and mechanisms for tracking and obtaining feedback about the system.

Current research is investigating the patient-centered medical home (Backer, 2007; Berenson et al., 2008; Lewis, 2008; Nutting et al., 2009; Reid et al., 2009; Rosenthal, 2008; <http://www.pcpcc.net/node/14>). One component of the medical home is a physician-directed team approach to care that may include practice support in the form of nurses, health educators, dietitians, and other health professionals who directly or indirectly work with primary care practices (see Chapter 2). As such approaches emerge, there is greater opportunity to assist the patient with dietary needs in this team care model.

Community Resources

Physicians at a primary care or family medical practice may not have the time or necessary training to guide patients regarding dietary change. Most communities have resources for patient referral, including diet counseling (dietitian), commercial programs (e.g., Weight Watchers), hospital programs, health plans (on-line, telephone education resources; case management for disease-specific diet concerns), and Internet sites. The most common referral is to a dietitian for dietary counseling. Many patients report frustration after a visit with the dietitian for the reasons outlined earlier: too much information that is too difficult to change too fast, as well as a lack of follow-up with the physician on the necessary changes. For this reason, it is important to consider how a program will help the patient learn the necessary information about nutrition and diet changes and how to make these behavior changes. Other considerations regarding community programs include cost, availability, and user needs.

Summary

- Dietary changes are difficult to make and thus need to be small, stepwise changes that patients can sustain.
- Dietary change instructions need to be straightforward, direct, and understandable.
- The patient needs to feel “ownership” of the dietary changes and must be able and agree to make the changes.
- The behavior changes need to be reviewed and must continue to be supported by the physician so that the patient is motivated to continue.
- Practice redesign may provide opportunities for other health professionals to work with physicians to support dietary and other behavioral needs of patients.

Future in Nutrition

Genomics and Diet: The Future

Consider the following hypothetical case:

A woman in her early 60s is seen by a nutritional genomic counselor because she has had difficulty controlling her significantly elevated low-density lipoprotein (LDL) cholesterol level with diet and exercise. Several different statins were tried without effect.

Her diet history reveals total fat intake less than 30%, polyunsaturated fatty acid (PUFA) intake near 5%, and monounsaturated fat intake as 17% of total energy intake. Her diet suggests appropriate fat intake, but her genome includes a polymorphism in the APOA1 gene. This polymorphism results in a low high-density lipoprotein (HDL) level when PUFA intake is low. She will need to increase her PUFA intake to improve her HDL as a protective effect against heart disease. She has a hepatic lipase gene that raises HDL when her fat intake is less than 30% of total energy. Her 3-hydroxy-3-methylglutaryl-CoA reductase gene has a variant that explains her poor response to statins in lower lipid levels. Lifestyle changes and keeping her PUFA intake relatively elevated with a diet low in animal fat are specific options for prevention of cardiovascular disease based on her genotype (Debusk et al., 2005).

This scenario may become a reality in the future. The emerging field of nutritional genomics may improve treatment options and preventive measures so that they are tailored to the specific genetic makeup and needs of the individual. A central theme in a comprehensive review of studies on genomics and nutrition is the importance of the family history “as a tool for chronic disease prevention and health promotion” (Khoury and Mensah, 2005). In 2004 the U.S. Surgeon General launched a campaign urging all citizens to know their family history and to discuss it with health care providers using an online family history collection tool (USDHHS, 2004). The presence of a disease in a family member, especially a first-degree relative, increases individual risk. Although “old-fashioned,” family history remains the least expensive and “best genomic tool” compared with other tests (Khoury and Mensah, 2005). Family physicians who often see a number of family members at once are in a perfect position to construct the best family histories that may predict individual risks for diseases.

Diet-related diseases that will benefit from nutritional genomics research and applications are chronic diseases such as cardiovascular diseases, cancers, diabetes, neurologic disorders, obesity, osteoporosis, and inflammatory disorders (Debusk et al., 2005). These conditions result when homeostasis is disrupted by bioactive dietary components affecting the genotype and environmental factors influencing cellular changes, leading to altered protein and metabolite expression and, eventually, altered physiologic function.

The approach that “one diet fits everyone” for prevention and for treatment may be obsolete with the onset of

nutritional genomics. Presently, standardized diet programs tested with experimentally designed population-based studies with significant long-term outcomes are the best approaches that clinicians can offer patients. Nutritional genomics has considerable potential for diet-related diseases in the future. Family physicians are well suited to assist individual patients who may have a diet-related disease or who are at risk for these diseases because of family history. Family physicians should prepare themselves to become more sophisticated with genomic medicine and nutrition as research advances.

Terminology

The following list of definitions is taken from *Dietary Reference Intakes* (National Academy of Sciences, 2004).

Recommended daily allowance (RDA): Average daily nutrient intake level sufficient to meet the nutrient requirements of nearly all those (97% to 98%) in a life stage and gender group. It is intended to be used for assessing the diets of healthy subjects, not for assessing or planning diets for groups.

Estimated energy requirement (EER): Dietary energy intake that is predicted to allow for a level of physical activity consistent with normal health and development and for the deposition of tissues at a rate consistent with growth.

Acceptable macronutrient distribution range (AMDR): Range of macronutrient intakes for a particular energy source associated with reduced risk of chronic disease while providing adequate intakes of essential nutrients.

Tolerable upper intake levels (TULs): Highest average daily nutrient intake likely to pose no risks of adverse health effects to almost all those in a life stage and gender group.

Adequate intake (AI): Recommended average daily nutrient level based on observed or experimentally determined estimates of average nutrient intakes by a group of healthy subjects. It is used when an RDA cannot be determined and may be used to plan and evaluate diets of individual subjects or groups.

Estimated average requirement (EAR): Nutrient intake value estimated to meet the requirement defined by a specific indicator of adequacy in 50% of those in a life stage and gender group, expressed as a daily value over time (for most nutrients, at least 1 week). It includes an adjustment for bioavailability, is intended to be used as one factor in assessing the adequacy of intake of groups or individual subjects, and should not be used as an intake goal for just one person.

PEARLS AND PITFALLS

PEARLS

- Changing one's diet is hard, and the outcome is often unpredictable. Small changes can often be maintained and are influential in improving health. Before any changes, assessment of the current diet and nutritional status is imperative.
- Extreme changes, whether medically prescribed or self-prescribed, often lack supporting evidence, and moderate changes might work for the biologic improvements desired.
- The interaction between diet and genetics (nutrient needs) is still being researched. Although genetic differences exist in humans' nutrient needs, their extent is not currently well understood.
- Behavioral changes for improving dietary intake involve a series of conversations over time, not just handing out a diet sheet.

PITFALLS

- A nutrient being beneficial for humans does not mean that more of that nutrient will be even better. An example of this is iron; an adequate amount is important, and too much iron is dangerous. The tolerable upper intake levels recognize this dangerous pitfall (National Academy of Sciences, 2004).
- Assumptions about nutritional status are problematic. Often, men assume that if they exercise, it does not matter what they eat. Women often assume that if their weight is within normal limits (or even lower), their diet or exercise patterns, or both, are healthy. These gender assumptions will misdirect the physician about the nutritional status of their patients.
- Health through nutrition is influenced throughout the life cycle. A single short period of eating well or eating poorly will not profoundly affect a person's health status. However, poor food and nutrient intake at certain periods in the life cycle, such as at conception and in older adults, may set a new or different course for that life stage.

Conclusion

Nutrition is a foundation for human health. In the future, as more is understood about genetics, nutritional needs will become more tailored to individual diverse needs. In the review of a person's nutritional status, the clinician should consider food and supplements, as well as how these balance with exercise, diseases, and other environmental factors (e.g., smoking). Overweight, normal-weight, and underweight people are not necessarily well nourished, and weight may not be an indicator of healthy eating. *Biologic balance* involves energy balance (between what is needed or eaten and what is used) and nutrient balance; too few nutrients can cause malnutrition and even chronic diseases, and too many nutrients may be toxic or may even cause chronic disease.

He who does not mind his belly will hardly mind anything else.

Samuel Johnson (1763)

Thought depends absolutely on the stomach, but in spite of that, those who have the best stomachs are not the best thinkers.

Voltaire (1770)

Epidemiology and Social Impact of Gastrointestinal Disease

Although diseases of other organ systems (e.g., cardiovascular disease) may appear to be more dramatic illnesses with higher rates of morbidity and mortality, the overall impact of gastrointestinal (GI) disorders is often underestimated from both a biopsychosocial and a resource standpoint. Typically, diseases of the GI tract are misdiagnosed, mistreated, misunderstood, or missed altogether, ultimately leading to substantial psychological morbidity and tremendous direct and indirect expense. Digestive diseases cost an estimated \$91 billion annually in U.S. health care costs, lost days from work, and premature deaths. More than 70 million Americans are diagnosed each year with disorders of the digestive tract, including gastroesophageal reflux disease, peptic ulcer disease, inflammatory bowel disease, GI cancers, motility

disorders, hepatitis, cirrhosis, and food-borne illness (Foundation, 2009).

This chapter serves as an overview of common GI diseases and disorders encountered in family medicine practices, encompassing both adult and pediatric populations. The most recent evidence-based diagnostic and therapeutic guidelines and reviews are highlighted, and radiographs, endoscopy photos, and video segments are integrated where applicable.

Approach to the Patient with Gastrointestinal Complaints

Psychosocial Factors of Gastrointestinal Disease

Locke's review in *Sleisenger and Fordtran's Gastrointestinal and Liver Disease* (8th edition) provides an excellent framework of the biopsychosocial approach to the patient with GI complaints. In caring for patients with both acute and chronic GI disorders, family physicians should obtain a patient-centered, nondirected history, using open-ended questions that enable patients to tell the history in their words. Medical and social histories should be integrated so that symptomatic complaints are described in the context of the psychosocial events surrounding the presenting illness, including the setting of symptom onset and exacerbation. Throughout the encounter, the provider's questions should communicate a sincere willingness to address both biologic and psychologic

aspects of the illness. Evaluation and treatment of GI symptoms depend on a strong physician-patient therapeutic relationship, allowing the family physician to elicit, evaluate, and communicate the role of potential psychosocial factors in the disease state. Patient reassurance, acknowledgment of patient adaptations to chronic illness, reinforcement of healthy behaviors, and the consideration of psychopharmacologic medication are paramount (Locke, 2006).

The failure to find a specific structural etiology for a patient's GI symptoms is usually the rule rather than the exception in the ambulatory care setting. Because functional GI disorders may represent an "illness without an evident disease," some providers do not regard these as legitimate, especially within the biopsychosocial model of disease. This phenomenon often leads physicians (and patients to coerce physicians) to pursue unnecessary, costly, and invasive diagnostic tests to find the etiology of a patient's symptoms, rather than focusing directly on symptom management and potential psychological comorbidities. Family physicians must establish clear boundaries with their patients to prevent unnecessary workups and, when indicated, should consider a referral to a mental health professional skilled in the care of patients with functional GI conditions, to assist in symptom management (Locke, 2006).

The Abdominal Examination

For descriptive purposes of location, the abdomen has been divided into four quadrants, constructed by an imaginary vertical line from the tip of the xyphoid process to the pubic symphysis and an imaginary horizontal line bridging the anterior superior iliac crests, referred to as the right upper (RUQ), right lower (RLQ), left upper (LUQ), and left lower (LLQ) quadrants (Bickley, 2008). The abdomen can be further divided into the epigastric, umbilical, hypogastric or suprapubic, and right and left flank regions. Knowledge of anatomic structures that lie in each of these quadrants and regions is imperative for the clinician to form an accurate differential diagnosis in relation to a patient's presenting symptoms (Box 38-1).

Clinicians should remember that a comprehensive physical examination, not just abdominal, should be performed in patients presenting with digestive complaints. The clinician should ensure patient comfort and modesty because the abdominal examination (and pelvic, if indicated) may cause significant pain, anxiety, and embarrassment to the patient. Infants, young children, and pregnant women may require additional care during the abdominal examination. A thorough explanation of examination techniques and findings is necessary to minimize patient anxiety.

The anorectal examination is an important component of the abdominal examination that may often be omitted. Although uncomfortable and embarrassing to the patient, it should not be neglected and should be approached with a calm, gentle attitude on the part of the clinician. The examiner should comment on both external and internal components of the anorectal examination, specifically anal sphincter tone; presence or absence of hemorrhoids, fissures, fistulas, or masses; prostatic abnormality in the male patient; and consistency of the stool. Anoscopy should be considered as an adjunct to the anorectal examination when indicated, allowing for direct visualization of the internal anorectal canal. In female patients, the pelvic examination

may provide additional information in the diagnosis of abdominal symptoms, as it is often challenging to differentiate between GI and genitourinary complaints.

Common Pediatric Gastrointestinal Disorders

Infantile Regurgitation

In the infant with recurrent vomiting, a thorough history and physical examination are often sufficient to establish a diagnosis of uncomplicated gastroesophageal reflux disease (GERD), labeling the infant as "the happy spitter." Diagnostic evaluation is indicated if there are signs of poor weight gain, GI obstruction, excessive crying and irritability, disturbed sleep, or feeding or respiratory problems suggesting suspected asthma or recurrent pneumonia. In the infant with uncomplicated GERD, parental education, reassurance, and anticipatory guidance are recommended; no specific intervention is necessary because the process is usually self-limited. Thickened formula and a trial of a hypoallergenic formula are the best treatment options. A trial of time-limited acid-suppression therapy, usually with histamine-2 receptor antagonists (H₂RAs), is useful in determining if GERD is causing vomiting and regurgitation. If symptoms worsen or do not improve by 18 to 24 months of age, reevaluation for complications of GERD is recommended, including an upper GI series (barium swallow study) and consultation with a pediatric gastroenterologist. In otherwise normal children who have recurrent vomiting or regurgitation after age 2 years, management options include an upper GI series, upper endoscopy with biopsy, and antisecretory therapy (Rudolph, 2001).

Diarrhea and Dehydration

Diarrhea is exceedingly common in pediatric and adult populations worldwide. Dehydration and electrolyte (e.g., sodium, potassium, bicarbonate) losses associated with severe diarrhea account for significant morbidity and may lead to mortality in cases of acute gastroenteritis, especially in countries with poor access to adequate healthcare. Rotavirus infection is the most common cause of diarrhea in U.S. infants and children, especially in winter months and temperate climates; Norwalk-like virus is the most common agent in adults (King et al., 2003).

A thorough history should be the first step in evaluating the patient who presents with a significant diarrheal illness, including the following (Guerrant et al., 2001):

- When and how the illness began (abrupt or gradual onset and duration of symptoms)
- Stool characteristics (watery, bloody, mucous, purulent, greasy)
- Frequency of bowel movements and relative quantity of stool produced
- Presence of dysenteric symptoms (fever, tenesmus, blood/pus in stool)
- Symptoms of volume depletion (increased thirst, tachycardia, orthostasis, decreased urine output, lethargy, decreased skin turgor, decreased tear production)
- Associated symptoms and their frequency and intensity (nausea, vomiting, abdominal pain, cramps, headache, myalgias, altered sensorium)

Box 38-1 Differential Diagnosis for Abdominal Pain Based on Location**Left upper quadrant**

Cardiac: Angina pectoris, myocardial infarction

Dermatologic: Herpes zoster

Gastric: Peptic ulcer disease, gastritis, pyloric stenosis, hiatal hernia

Intestinal: High fecal impaction, perforated colon, diverticulitis

Pancreatic: Pancreatitis, neoplasm, stone in pancreatic duct or ampulla

Pulmonary: Pneumonia, empyema, pulmonary infarction

Renal: Calculi, pyelonephritis, neoplasm

Splenic: Splenomegaly, rupture, abscess, splenic infarction

Trauma

Vascular: Dissecting or ruptured aortic aneurysm

Right upper quadrant

Biliary: Calculi, infection, inflammation, neoplasm

Cardiac: Myocardial ischemia or infarction (particularly involving the inferior wall), pericarditis

Dermatologic: Herpes zoster

Fitz-Hugh-Curtis syndrome (perihepatitis)

Gastric: peptic ulcer disease, pyloric stenosis, neoplasm, alcoholic gastritis, hiatal hernia

Hepatic: Hepatitis, abscess, hepatic congestion, neoplasm, trauma

Pancreatic: Pancreatitis, neoplasm, stone in pancreatic duct or ampulla

Pulmonary: Pneumonia, pulmonary infarction, right-sided pleurisy

Renal: calculi, infection, inflammation, neoplasm, rupture of kidney

Intestinal: retrocecal appendicitis, intestinal obstruction, high fecal impaction, diverticulitis

Trauma

Left lower quadrant

Intestinal: Diverticulitis, intestinal obstruction, perforated ulcer, inflammatory bowel disease, perforated descending colon, inguinal hernia, neoplasm, appendicitis

Psoas abscess

Renal: Renal or ureteral calculi, pyelonephritis, neoplasm

Reproductive: Ectopic pregnancy, ovarian cyst, torsion of ovarian cyst, salpingitis, tuboovarian abscess, mittelschmerz, endometriosis, seminal vesiculitis

Trauma

Vascular: Dissecting, ruptured, or leaking aortic aneurysm

Right lower quadrant

Cholecystitis

Intestinal: Acute appendicitis, regional enteritis, incarcerated hernia, cecal diverticulitis, intestinal obstruction, perforated ulcer, perforated cecum, Meckel's diverticulitis

Psoas abscess

Reproductive: Ectopic pregnancy, ovarian cyst, torsion of ovarian cyst, salpingitis, tuboovarian abscess, mittelschmerz, endometriosis, seminal vesiculitis

Renal: Renal or ureteral calculi, pyelonephritis, neoplasm

Trauma

Vascular: Dissecting, ruptured, or leaking aortic aneurysm

Other regions**Epigastric**

Biliary: Cholecystitis, cholangitis

Cardiac: Angina, myocardial infarction, pericarditis

Duodenal: Peptic ulcer disease, duodenitis

Gastric: Peptic ulcer disease, gastric outlet obstruction, gastric ulcer

Hepatic: Hepatitis, abscess

Intestinal: High small bowel obstruction, early appendicitis

Pancreatitis

Pulmonary: Pneumonia, pleurisy, pneumothorax

Subphrenic abscess

Vascular: Dissecting, ruptured, or leaking aortic aneurysm, mesenteric ischemia

Periumbilical

Intestinal: Small bowel obstruction or gangrene, early appendicitis

Vascular: Mesenteric thrombosis, dissecting, ruptured, or leaking aortic aneurysm

Suprapubic

Genitourinary: Cystitis, rupture of urinary bladder

Intestinal: Colonic obstruction or gangrene, diverticulitis, appendicitis

Reproductive: Ectopic pregnancy, mittelschmerz, torsion of ovarian cyst, pelvic inflammatory disease, salpingitis, endometriosis, rupture of endometrioma

Diffuse

Genitourinary: Urinary tract infection, pelvic inflammatory disease

Intestinal: Diverticulitis, early appendicitis, gastroenteritis, inflammatory bowel disease, intestinal obstruction, irritable bowel syndrome, mesenteric adenitis, insufficiency, or infarction

Metabolic: Toxins, lead poisoning, uremia, drug overdose, diabetic ketoacidosis, heavy metal poisoning

Pancreatitis

Peritonitis

Pneumonia (rare)

Sickle cell crisis

Trauma

Other: Acute intermittent porphyria, tabes dorsalis, periarteritis nodosa, Henoch-Schönlein purpura, adrenal insufficiency

Vascular: Aortic aneurysm

Modified from Differential diagnosis. In Ferri FF. Ferri's Clinical Advisor 2010. Philadelphia, Saunders-Elsevier, 2010.

In addition, all patients should be asked about potential epidemiologic risk factors for diarrheal diseases, including the following:

- Travel to an underdeveloped area
- Daycare center attendance or employment
- Consumption of unsafe foods (e.g., raw meats, eggs, or shellfish; unpasteurized milk or juices) or swimming in or drinking untreated fresh surface water from a lake or stream

- Visiting a farm or petting zoo or having contact with reptiles or with pets with diarrhea
- Knowledge of other ill persons (e.g., in a dormitory, office, or social function)
- Recent or regular medications (e.g., antibiotics, antacids, antimotility agents)
- Underlying medical conditions predisposing to infectious diarrhea (AIDS, immunosuppressive medications, prior gastrectomy, extremes of age)

- Receptive anal intercourse or oral-anal sexual contact
- Occupation as a food-handler or caregiver

In the majority of patients with acute gastroenteritis, the “gold standard” stool cultures and ova and parasite testing are seldom required, because the disease is most often viral in etiology and self-limited. In more severe cases with dehydration, metabolic derangement, longer duration, bloody stools (dysentery) and mucus in the stool, or known or suspected transmission of a pathogen, these tests are often required to identify the pathogen and to direct appropriate antimicrobial therapy (Table 38-1). Viral cultures are rarely performed and are unnecessary, except in rare cases and immunocompromised patients. Although fecal leukocytes and lactoferrin often suggest an inflammatory etiology of diarrhea, there is no consensus regarding the routine use of these tests in the initial testing of patients with either community-acquired or nosocomial diarrhea. Hospitalized patients with diarrhea, especially those with abdominal pain, should be tested for *Clostridium difficile* toxin (Guerrant et al., 2001). Oral metronidazole and oral vancomycin have been shown to be equally effective in the treatment of *C. difficile*-associated diarrhea (CDAD). Vancomycin is significantly more expensive and may select for colonization with vancomycin-resistant enterococci (VRE), and thus metronidazole should be recommended as first-line therapy.

Nonpathogenic causes of diarrhea should be considered when a viral etiology is unlikely and a diagnostic evaluation has not identified a pathogen. Differential diagnosis

includes irritable bowel syndrome, inflammatory or ischemic bowel disease, laxative abuse, partial bowel obstruction, rectosigmoid abscess, Whipple’s disease, pernicious anemia, diabetes mellitus, malabsorption syndromes (e.g. celiac disease), small bowel diverticulosis, and scleroderma in primarily adult patients, and an appropriate workup should be considered.

KEY TREATMENT

Oral metronidazole and vancomycin are equally effective in the treatment of *Clostridium difficile*-associated diarrhea (Guerrant et al., 2001) (SOR: A).

In cases of traveler’s diarrhea, (e.g. enterotoxigenic *Escherichia coli*, *Shigella*, *Salmonella*, or *Campylobacter*), prompt treatment with a fluoroquinolone or, in children, trimethoprim-sulfamethoxazole (TMP-SMX) has been shown to reduce the duration of the illness from 3 to 5 days to less than 1 to 2 days (Guerrant et al., 2001) (SOR: A).

Appendicitis

A diagnosis of appendicitis should be considered in any pediatric patient presenting with acute abdominal pain. Acute appendicitis often presents with a constellation of signs and symptoms, including fever, anorexia, nausea, vomiting, tenesmus, migratory RLQ abdominal pain, abdominal

Table 38-1 Common Pathogens and Recommended Therapy for Acute Diarrhea

| Pathogen | Therapy (Adult Doses) |
|---|---|
| <i>Campylobacter jejuni</i> | Azithromycin, 500 mg qd for 3 days or Ciprofloxacin,* 500 mg bid for 7 days |
| <i>Clostridium difficile</i> | Metronidazole, 500 mg tid, or 250 mg qid, for 10-14 days or Vancomycin, 125 mg qid for 10-14 days |
| <i>Entamoeba histolytica</i> | Metronidazole, 500-750 mg tid for 10 days or Tinidazole, 2 g qd for 3 days followed by Paromomycin, 500 mg orally tid for 7 days or Iodoquinol, 650 mg tid for 20 days |
| <i>Escherichia coli</i> 0157:H7 | No treatment with antimicrobials or antimotility drugs |
| <i>E. coli</i> (toxigenic) | Azithromycin, 1 g in 1 dose or Rifaximin, 200 mg tid for 3 days or Levofloxacin,* 500 mg for 1 dose |
| <i>Giardia lamblia</i> | Tinidazole, 2 g in 1 dose or Nitazoxanide, 500 mg bid for 3 days or Metronidazole, 500-750 mg tid for 5 days |
| <i>Salmonella</i> spp. (non-typhi)† | Ciprofloxacin, 500 mg bid for 5-7 days or Azithromycin, 1 g for 1 day, then 500 mg qd for 6 days |
| <i>Shigella</i> spp. | Ciprofloxacin, 500 mg bid for 5-7 days or Levofloxacin, 500 mg qd for 3 days or TMP-SMX-DS, 1 tablet bid for 3 days or Azithromycin, 500 mg for 1 dose, then 250 mg qd for 4 days |
| <i>Staphylococcus aureus</i> (food poisoning) | No treatment with antimicrobials or antimotility drugs |
| <i>Vibrio cholerae</i> | Ciprofloxacin, 1 g in 1 dose, plus aggressive fluid hydration |
| <i>Vibrio parahaemolyticus</i> | No treatment with antimicrobials or antimotility drugs |
| <i>Yersinia enterocolitica</i> | No treatment unless severe; if severe: Doxycycline, 100 mg IV bid, and Tobramycin or gentamicin, 5 mg/kg/day qd, or TMP-SMX and fluoroquinolones as alternatives |

Modified from Gilbert DN, Moellering RC, Eliopoulos GM, et al. The Sanford Guide to Antimicrobial Therapy, 39th ed. Vermont, Antimicrobial Therapy, 2009.

*Avoid fluoroquinolones in pediatric patients and pregnant women.

†Antimicrobial therapy not indicated in asymptomatic patients or those with mild illness. Treatment advised in patients less than 1 year old or greater than 50 years old, if immunocompromised, or if patient has a vascular graft or prosthetic joints.

TMP-SMX, Trimethoprim-sulfamethoxazole; DS, double strength; IV, intravenously; qd, once daily; bid, twice daily; tid, three times daily; qid, four times daily.

tenderness and guarding, and signs of peritoneal irritation. Classically, hours after onset, the pain migrates to *McBurney's point*, defined as the point two-thirds the distance from the umbilicus along a straight line toward the anterosuperior iliac spine of the pelvis. *Rovsing's sign* (referred tenderness from LLQ to RLQ during palpation), *psoas sign* (pain elicited by extending hip posteriorly with patient lying prone), and *obturator sign* (pain elicited by abducting right hip with patient lying supine) are often conducted but are of little diagnostic value. No sign or combination of signs has accurately predicted acute appendicitis in children (Cincinnati Children's Hospital [CCH], 2002).

While none has proved adequately predictive of acute appendicitis in the pediatric population, laboratory studies are typically performed in the emergency department because other diagnoses may need to be excluded. A series of studies discovered an elevated white blood cell (WBC) count in 87% to 92% of patients with acute appendicitis, although 8% to 13% of patients with appendicitis had a normal WBC count (CCH, 2002). The abdominal examination is particularly unreliable in women of reproductive age, so pelvic exam, urinalysis, and urine pregnancy test represent a reasonable clinical strategy to exclude genitourinary pathology.

Diagnostic imaging is not routinely recommended in patients with a high or a low probability of appendicitis, because it can alter management strategies and has not proved cost-effective; imaging is most helpful when the clinical assessment is equivocal. Controversy exists over the superiority of ultrasound versus computed tomography (CT) in accurately diagnosing appendicitis, and both tests have a positive predictive value approaching 100%. Although ultrasound may be advantageous in thin patients, CT is preferred in the evaluation of a more obese child (Halter et al., 2004). Typical radiographic findings in the evaluation of acute appendicitis include appendicoliths (Fig. 38-1), dilation of the appendix with adjacent hazy fat (Fig. 38-2), and periappendiceal abscesses (Fig. 38-3). If the abdominal CT does not show evidence of acute appendicitis, the patient may either be admitted for observation or discharged at the discretion of the examiner and parents, with instructions for follow-up if symptoms worsen. Expert opinion states

that if there is high suspicion of appendicitis on the basis of history, physical examination, and laboratory studies, the patient should go directly to the operating room for an exploratory laparotomy to evaluate the appendix, without an imaging study.

Common Adult Gastrointestinal Disorders

Esophagus

Barrett's Esophagus and Esophageal Adenocarcinoma

Barrett's esophagus is a premalignant condition related to chronic GERD. The hallmark is a change in the mucosal lining of the distal esophagus from the normal squamous epithelium to columnar-appearing mucosa resembling that of the stomach and small intestines, referred to as *intestinal metaplasia* (Fig. 38-4). The estimated risk of progression to adenocarcinoma of the esophagus with Barrett's esophagus is approximately 0.5% per year, whereas without Barrett's esophagus the risk is 0.07%, prompting development of clinical practice guidelines for surveillance endoscopy.

Figure 38-1 Appendicolith. (Courtesy Dr. Perry Pernicano, Clinical Assistant Professor, Department of Radiology, University of Michigan Medical School, Ann Arbor.)

Figure 38-3 Periappendiceal abscess (arrow). (Courtesy Dr. Perry Pernicano.)

Figure 38-4 Barrett's esophagus. (Courtesy Dr. Erik-Jan Wamsteker.)

Adenocarcinoma of the esophagus has had the fastest-rising incidence of any cancer in the United States and Western Europe over the last two decades. Family and other primary care physicians who see the vast majority of patients with GERD in its nonerosive and more complicated forms are charged with the task of suspecting and appropriately referring patients with Barrett's esophagus for EGD. Although risk factors for Barrett's esophagus and adenocarcinoma are not evidence-based, there is suggestive evidence that male gender, white race, older age, dysplasia, smoking, and obesity place patients at a higher risk (Sampliner, 2002).

Currently, no evidence-based guidelines exist for the assessment and surveillance of patients with Barrett's esophagus; routine screening will not be cost-effective unless criteria can be identified to select patients at high risk. Recommendations from the American Society for Gastrointestinal Endoscopy

(ASGE) state that screening esophagogastroduodenoscopy (EGD) for Barrett's esophagus should be considered in select patients with chronic, long-standing GERD. After a negative screening examination, further screening endoscopy is not indicated. For patients with established Barrett's esophagus of any length and with no dysplasia, after two consecutive examinations within 1 year, an acceptable interval for additional surveillance is every 3 years. Surveillance in patients with low-grade dysplasia is recommended, although the optimal interval and biopsy protocol have not been established. A follow-up EGD at 6 months should be performed, and if low-grade dysplasia is confirmed, surveillance at 12 months and yearly thereafter as long as dysplasia persists is advised (Hirota et al., 2006).

Stomach and Duodenum

Dyspepsia

Dyspepsia ("bad digestion") accounts for approximately 5% of all visits to family practitioners and is the most common reason for referral to a gastroenterologist in the United States, accounting for 20% to 40% of consultations (Jones and Lacy, 2004). The term *dyspepsia* refers to episodic or recurrent pain or discomfort arising from the proximal GI tract related to meals and is associated with heartburn, reflux, regurgitation, indigestion, bloating, early satiety, and weight loss. The lack of a standardized definition affects accurate prevalence data, given the challenge of clearly defining dyspepsia as either *functional* or *nonulcer dyspepsia* (~60% of cases), or that caused by structural or biochemical disease (40%) (Dickerson and King, 2004). Regardless of cause, dyspepsia has a profoundly negative impact on patients' health-related quality of life (HRQOL) and results in significant economic burden.

Nonulcer dyspepsia (NUD) is defined in patients who have undergone either formal radiographic or endoscopic evaluation and who do not have an organic lesion (e.g., ulcer, tumor) to explain their symptoms. Potential etiologies for NUD include gastric acid hypersecretion, gastroduodenal dysmotility, visceral hypersensitivity, emotional stress, and psychological factors. As with other functional GI disorders, the potential for underlying psychosocial and lifestyle factors must be addressed. There is no current recommendation on the role of prokinetics, cytoprotectives, or antidepressants in the management of functional dyspepsia; similarly, no clear evidence supports specific diet and lifestyle modifications or psychosocial interventions.

Peptic Ulcer Disease

Key Points

- A noninvasive *H. pylori* "test and treat" strategy is as effective as endoscopy in the initial management of patients under age 45 with uncomplicated dyspepsia.
- Eradication of *H. pylori* infection in patients with a duodenal or gastric ulcer reduces symptom recurrence.
- Ulcer prophylaxis with an H₂RA or PPI should be considered in patients at high risk for NSAID-associated PUD, including those with a history of PUD, elderly patients, and patients taking corticosteroids or anticoagulants.

Peptic ulcer disease (PUD) is the most common cause of *upper gastrointestinal bleeding* (UGIB) and a leading cause of dyspepsia (Box 38-2), with a cumulative lifetime prevalence of 8% to 14% (Fig. 38-5). Although up to 70% of patients with gastric and duodenal ulcers are 25 to 64 years old, the peak prevalence of complicated ulcer disease requiring hospitalization is age 65 to 74 (Saad and Scheiman, 2004).

Numerous options exist for the management of uninvestigated dyspepsia in primary care (Fig. 38-6). Given the high cost and often limited access to endoscopy testing, not all patients with uninvestigated dyspepsia should undergo an invasive investigation of their symptoms. The presence of “alarm symptoms” for PUD raises concern for a gastric malignancy. The American Gastroenterological Association (AGA, 2005) endorses prompt endoscopic evaluation in any patient over age 45 with new-onset dyspepsia.

The most common complications of PUD include UGIB, perforation, penetration, and gastric outlet obstruction. An upper GI hemorrhage can occur in up to 15% of patients with PUD and is most common in patients older than 60, with mortality as high as 10%. Perforation occurs in approximately 7% of patients with PUD, again classically in elderly patients receiving long-term nonsteroidal anti-inflammatory drugs (NSAIDs). Perforation can be confirmed on plain abdominal radiography; barium contrast studies and upper endoscopy are contraindicated with suspected perforation, and urgent surgical consultation is mandatory. Mortality may be as high as 30% to 50% in patients with perforation, particularly in elderly and debilitated patients. Penetration occurs when the ulcer crater erodes through and into adjacent organs, including the small bowel, pancreas, liver, and biliary tree. Often subtle, it typically presents as acute pancreatitis. Gastric outlet obstruction occurs in 1% to 3% of PUD patients, resulting from acute inflammation or mechanical obstruction caused by scarring at the gastroduodenal junction (Saad and Scheiman, 2004).

Approaches to confirm a diagnosis of PUD include double-contrast barium esophagography (upper GI series) and upper endoscopy. Although the upper GI series has accuracy of 80% to 90%, upper endoscopy is the preferred diagnostic modality, with multiple studies showing consistent diagnostic superiority in identifying gastric and duodenal ulcers. Despite a higher procedural cost and a slightly increased risk in procedure-related complications (bleeding, perforation, oversedation), upper endoscopy should be the initial diagnostic study performed in suspected PUD. Most importantly, upper endoscopy provides the distinct advantage of permitting biopsies and brushings to identify underlying pathology.

Fecal-oral infection with the bacterium *Helicobacter pylori* is a major risk factor for the development of PUD. Its prevalence and association with PUD is higher in populations who have a lower standard of living than in the United States, especially in Africa and Central America, although this may be declining. Approximately 90% of patients worldwide with duodenal ulcers are infected with the *H. pylori* pathogen, whereas 30% to 40% of U.S. ulcer patients are infected (Chey and Wong, 2007). The strongest evidence to support the role of *H. pylori* as an etiology of PUD is the elimination of ulcer recurrence when the infection has been successfully eradicated.

The evidence-based standard of care dictates that patients with dyspepsia and no alarm symptoms should be tested

Box 38-2 Causes of Dyspepsia

Common*

GERD (with and without esophagitis)
Functional (nonulcer dyspepsia)
Peptic ulcer disease

Less common†

Alcohol consumption
Biliary colic
Celiac sprue
Gastrointestinal malignancy
Gastroparesis

for *H. pylori* infection and then given eradication therapy if positive, (“test and treat”) (Chey and Wong, 2007). *H. pylori*-positive or *H. pylori*-negative patients who do not undergo endoscopy initially should do so if their symptoms persist. The effectiveness of this approach depends on the prevalence of *H. pylori* infection in patients with ulcers in the

GERD: gastroesophageal reflux disease
 ASA: aspirin
 NSAIDs nonsteroidal anti-inflammatory drugs
 PPI: proton pump inhibitor
H. pylori: *Helicobacter pylori*

* Age cutoff is controversial.
 Risk of pathology increases slightly with age but older age (50–55) cutoff in many guidelines

** Alarm symptoms include rectal bleeding or melena, weight loss, anorexia, early satiety, persistent vomiting, anemia. The presence of an abdominal mass, lymphadenopathy, dysphagia, odynophagia, family history of upper GI cancer, personal history of peptic ulcer, prior gastric surgery or malignancy should eliminate consideration of noninvasive approaches.

Figure 38-6 Evaluation of uninvestigated dyspepsia. (Modified from Saad R, Scheiman JM. Diagnosis and management of peptic ulcer disease. *Clin Fam Pract* 2004;6:569-587.)

community; as in some geographic areas, prevalence may be too low to make this approach effective.

Nonendoscopic testing for *H. pylori* includes a quantitative assay for serum immunoglobulin G (IgG) antibodies, the radiolabeled urea breath test, and the stool antigen test. The median sensitivity and specificity for serologic IgG tests are 92% and 83%, respectively (SIGN, 2003). Some patients may have persistently positive IgG antibodies for months to years after eradication therapy, yielding a false-positive result during that period if retested. In comparative studies, urea breath tests are more accurate than serologic tests. The stool antigen test is recommended as the preferred initial noninvasive diagnostic test. The urea breath test is the recommended standard to determine if *H. pylori* has been successfully eradicated (Chey and Wong, 2007).

Several medication regimens have been developed for the treatment of confirmed *H. pylori* infection, based on data from randomized controlled trials (RCTs), meta-analyses, and systematic reviews (Table 38-2). The best evidence-based recommendation for *H. pylori* eradication is for 14-day triple therapy with the use of a proton pump inhibitor (PPI), clarithromycin, and either amoxicillin or metronidazole,

yielding eradication rates from 70% to 85%. The most common salvage regimen in patients with persistent *H. pylori* is bismuth quadruple therapy. Recent data suggest that 10-day therapy with a PPI, levofloxacin, and amoxicillin is more effective and better tolerated than bismuth quadruple therapy for persistent *H. pylori* infection (Chey and Wong, 2007).

Another major etiology of PUD is the increasing and widespread use of both NSAIDs and aspirin. The use and overuse of these medications is the most common cause of PUD in *H. pylori*-negative patients, and up to 60% of unexplained cases of PUD are attributed to unrecognized NSAID use. In a meta-analysis of observational studies of GI bleeding risk from various NSAIDs, a fourfold increased risk associated with NSAID-use persisted throughout therapy and fell to baseline within 2 months of discontinuation of the drug (Hernandez-Diaz and Rodriguez, 2000). Although both *H. pylori* and aspirin/NSAIDs are involved in the overwhelming majority of PUD cases, other factors contribute to the remaining 1% to 5% (Box 38-3).

Independent risk factors that augment the impact of *H. pylori* and NSAID-related PUD risk and may promote ulcer complications include advancing age; history of PUD

Table 38-2 First-Line Regimens for *Helicobacter pylori* Eradication

| Regimen | Duration (days) | Eradication Rates (%) | Comments |
|---|-----------------|-----------------------|--|
| Standard-dose PPI bid (esomeprazole, qd); clarithromycin, 500 mg, or amoxicillin, 1000 mg | 10-14 | 70-85 | Consider in non-penicillin-allergic patients who have not previously received a macrolide. |

Minor causes

Duodenal obstruction from annular pancreas
 Use of topically injurious drugs (potassium chloride, nitrogen-containing bisphosphonates)
 Immunosuppressants (e.g., mycophenolate)
Helicobacter heilmannii infection
 Mucosal infection (herpes simplex 1, cytomegalovirus, tuberculosis, syphilis)
 Systemic processes (systemic mastocytosis, Crohn's disease, lymphoma, carcinomas)
 Radiation involving duodenum
 Use of cocaine or "crack" cocaine
 Zollinger-Ellison syndrome

From Heidelbaugh JJ. Peptic ulcer disease. In Rakek RE (ed). Essential Family Medicine, 3rd ed. Philadelphia, Saunders-Elsevier, 2006.

or complicated ulcer disease with perforation, penetration, or gastric outlet obstruction; use of multiple NSAIDs (including concomitant use of low-dose aspirin and an NSAID); and concurrent warfarin or corticosteroid use. Evidence suggests that smoking may increase the risk of PUD and ulcer complications by impairing gastric mucosal healing. Alcohol use may increase the risk of ulcer complications in NSAID users, but its overall effect in those patients without concomitant liver disease has not been clearly defined. Currently, no solid evidence implicates dietary factors in the development of PUD.

Use of NSAIDs and aspirin is frequently associated with symptoms of dyspepsia, even in the absence of PUD. Empiric antisecretory therapy with PPIs is an attractive strategy that involves subjecting only those patients to upper endoscopy

who fail to respond to a 4-week course of pharmacotherapy. The rationale for this approach is that most patients with dyspepsia do not have *H. pylori* infection or PUD (most typically have GERD), and their response to antisecretory therapy eliminates the need for further, expensive and invasive diagnostic testing (Saad and Scheiman, 2004).

KEY TREATMENT

The most efficacious therapy for *H. pylori* eradication consists of 14-day triple therapy with a PPI, clarithromycin, and amoxicillin or metronidazole, yielding eradication rates of 70% to 85% (Chey and Wong, 2007) (SOR: A).

Gastroesophageal Reflux Disease**Key Points**

- The PPIs provide the most rapid symptomatic relief and healing of esophagitis in the highest percentage of patients.
- Although less effective than PPIs, H₂RAs given in divided doses may be effective in some patients with less severe symptoms of GERD; continuous therapy to control symptoms and prevent complications is appropriate.
- Chronic acid suppression has been associated with malabsorption of iron, vitamin B₁₂, and calcium; small bowel bacterial overgrowth; increased risk of hip fracture; and community-acquired pneumonia.

A complex, chronic, and relapsing condition, GERD carries a risk of significant morbidity and resultant complications. Population-based studies revealed that 40% of U.S. adults experience heartburn at least once a month; age- and gender-adjusted prevalence of weekly heartburn or acid regurgitation approaches 20% (Heartburn, 1998; Locke 1997). Most patients with GERD self-treat with over-the-counter (OTC) medications and do not seek medical attention for their symptoms.

Most patients with GERD evaluated in primary care practices have *nonerosive reflux disease* (NERD), although some

will progress to *erosive esophagitis* (Fig. 38-7), and even fewer to more severe disease resulting in esophageal strictures, Barrett's esophagus, and adenocarcinoma of the esophagus (DeVault and Castell, 2005). Patients with NERD are prone to develop atypical or extraesophageal manifestations of disease (Box 38-4). Because of a small risk of disease progression, however, they generally do not require long-term surveillance despite persistent reflux symptoms. Symptom relapse rates in patients with NERD are similar to those in patients with erosive esophagitis, and although many will require continuous pharmacotherapy to control their symptoms, almost all continue to exhibit no definable erosive esophagitis on upper endoscopy (Fass, 2002).

Upper endoscopy is considered the gold standard in assessing esophageal complications of GERD (e.g., erosive esophagitis, Barrett's esophagus) but lacks an appreciable sensitivity and specificity for identifying pathologic reflux. Double-contrast barium radiography has limited usefulness in making an accurate diagnosis of GERD but may be useful in defining the presence of anatomic abnormalities, such as pyloric stenosis, malrotation, and annular pancreas in the vomiting infant, as well as hiatal hernia and esophageal strictures in children and adults.

The goals of GERD treatment are to relieve symptoms, heal erosive esophagitis if present, manage and prevent complications, and avoid recurrence and progression of disease using acid-suppressive medications. Initial empiric pharmacotherapy should consist of either an H₂RA or a PPI, without the need for immediate diagnostic testing in the vast majority of cases. Expert opinion supports either step-up or step-down therapy for the initial treatment of patients with GERD (Inadomi, 2002). In patients who incompletely respond to H₂RAs, PPIs taken once daily 30 minutes before the first meal of the day are preferred over continuing H₂RA therapy because of greater efficacy and faster symptom control with PPIs. An inadequate response to a 4- or 8-week trial of standard-dose PPI may indicate the need for longer treatment, more severe disease, or an incorrect diagnosis (Fig. 38-8). Additional benefit may be obtained by extending treatment for another 4 to 8 weeks with the same or a double dose of PPI (Medical Advisory Panel, 2003).

Diagnostic testing is recommended in patients with GERD who have an inadequate response to PPI therapy, need continuous chronic therapy to control frequent GERD symptoms, have chronic symptoms (>5 years) and are at risk for Barrett's esophagus, have atypical or extraesophageal manifestations suggesting complicated disease, or have alarm symptoms suggesting cancer (Box 38-5).

Lifestyle modifications should be recommended as adjunctive therapy in all patients with GERD (Box 38-6). Evidence is lacking to support the use of nonpharmacologic measures as the sole initial or long-term therapy for GERD, but expert opinion considers these to be of some potential benefit and no proven harm, although not sufficiently effective in treatment.

The basic tenets of antireflux surgery include reduction of the hiatal hernia, repair of the diaphragmatic hiatus, strengthening of the gastroesophageal junction–posterior diaphragm attachment, and strengthening of the antireflux barrier by adding a gastric wrap around the gastroesophageal junction (Nissen/Toupet fundoplication). In controlled studies comparing antireflux surgery to H₂RAs and PPIs, surgery has shown marginal superiority as measured by heartburn relief,

esophagitis healing, and improved quality of life in patients with erosive esophagitis. Long-term follow-up trials found that over half of patients resumed taking antireflux medications 3 to 5 years after surgery, most likely as a result of poor patient selection and surgical breakdown (Heidelbaugh and Nostrant, 2004).

KEY TREATMENT

Acid suppression with PPIs (proton pump inhibitors) is the mainstay of therapy for esophagitis (DeVault and Castell, 2005) (SOR: A). Lifestyle modifications should be recommended as an adjunctive therapy in patients with GERD (DeVault and Castell, 2005) (SOR: B).

Upper Gastrointestinal Bleeding

Key Points

- Comorbid risk factors for GI bleeding severity, including advanced age, shock, congestive heart failure, ischemic heart disease, and stigmata of recent hemorrhage, accurately predict the likelihood of death or rebleeding.

DIAGNOSIS AND TREATMENT OF GERD

- UGIB is confirmed by upper endoscopy, permitting direct visualization of the cause and location of the bleeding and allowing an attempt at immediate hemostasis.

Significant UGIB is defined as bleeding that results in hemodynamic instability and a decrease in the hemoglobin (Hb) and hematocrit (Hct). Although most patients with UGIB resolve spontaneously, those with an acute UGIB requiring hemostasis often present with a recent history of hematemesis

Box 38-6 Suggested Lifestyle Modifications in GERD Management

Avoid acidic foods (citrus and tomato-based products), alcohol, caffeine, alcohol, caffeinated beverages, chocolate, onions, garlic, salt, and peppermint.
Avoid large meals.
Avoid medications that may potentiate GERD symptoms (calcium channel blockers, β -agonists, α -agonists, theophylline, nitrates, sedatives)
Avoid recumbency 3 to 4 hours after meals.
Avoid tight clothing around the waist
Decrease dietary intake of fat.
Elevating head of bed 4 to 8 inches (10-20 cm).
Losing weight
Smoking cessation
*Dietary fibers and physical exercise may be protective

Modified from DeVault KR, Castell DO. Updated guidelines for the diagnosis and treatment of gastroesophageal reflux disease. The Practice Parameters Committee of the American College of Gastroenterology. *Am J Gastroenterol* 1999;94:1434-1442; and Nilsson M, Johnsen R, Ye W, et al. Lifestyle related risk factors in the aetiology of gastro-oesophageal reflux. *Gut* 2004;53:1730-1735.

(vomiting fresh blood) or “coffee grounds” emesis (black, partially digested blood). UGIB has an incidence of 40 to 150 episodes per 100,000 persons annually in the United States, with mortality of 6% to 10% (Oh and Pisegna, 2004). Box 38-7 lists the most common causes of UGIB.

Box 38-7 Common Causes of Upper Gastrointestinal Bleeding

- Arteriovenous malformations (AVMs)
- Bleeding from the nose or pharynx
- Dieulafoy's lesion (ruptured mucosal artery)
- Erosive esophagitis (severe)
- Esophageal rupture (Boerhaave's syndrome)
- Helicobacter pylori* infection
- Hemobilia
- Hemoptysis
- Mallory-Weiss tears (esophagogastric mucosal tears)
- Neoplasm (carcinoma, lymphoma, leiomyoma, leiomyosarcoma, polyps)
- Nonsteroidal anti-inflammatory drugs (NSAIDs)
- Ulcers (gastric, duodenal)
- Vascular-enteric fistulas, usually from aortic aneurysm or graft
- Varices (esophageal, gastric, duodenal)

Modified from Oh DS, Pisegna JR. Pharmacologic treatment of upper gastrointestinal bleeding. *Curr Treat Options Gastroenterol* 2003;6:157-162.

It is important to characterize patients with risk factors for the development of UGIB to identify potential preventive measures, including aspirin/NSAID use and anticoagulation or antiplatelet therapy. *H. pylori* infection, erosive esophagitis, history of UGIB, perioperative period, intensive care unit (ICU) admission, and Zollinger-Ellison syndrome are also significant risk factors for UGIB. Figure 38-9 outlines an algorithm for the diagnosis and management of acute UGIB. Hemodynamically unstable patients should be admitted to the ICU, have a large-bore intravenous (IV) and nasogastric tube placed, and should not be fed orally.

Confirmation of UGIB is by upper endoscopy, permitting direct visualization of the cause and location of the bleeding and an attempt at immediate hemostasis. During the diagnostic evaluation, the endoscopist can treat the source of UGIB by using electrocautery, injection of 0.9% saline or 100% ethanol, or a combination of these techniques. Alternative methods include laser photoablation, band ligation, and sclerotherapy and balloon tamponade for esophageal and gastric variceal bleeding. The risk of rebleeding after therapy can be predicted by the morphology and size of the ulcer at

ALGORITHM FOR ACUTE UPPER GI BLEEDING

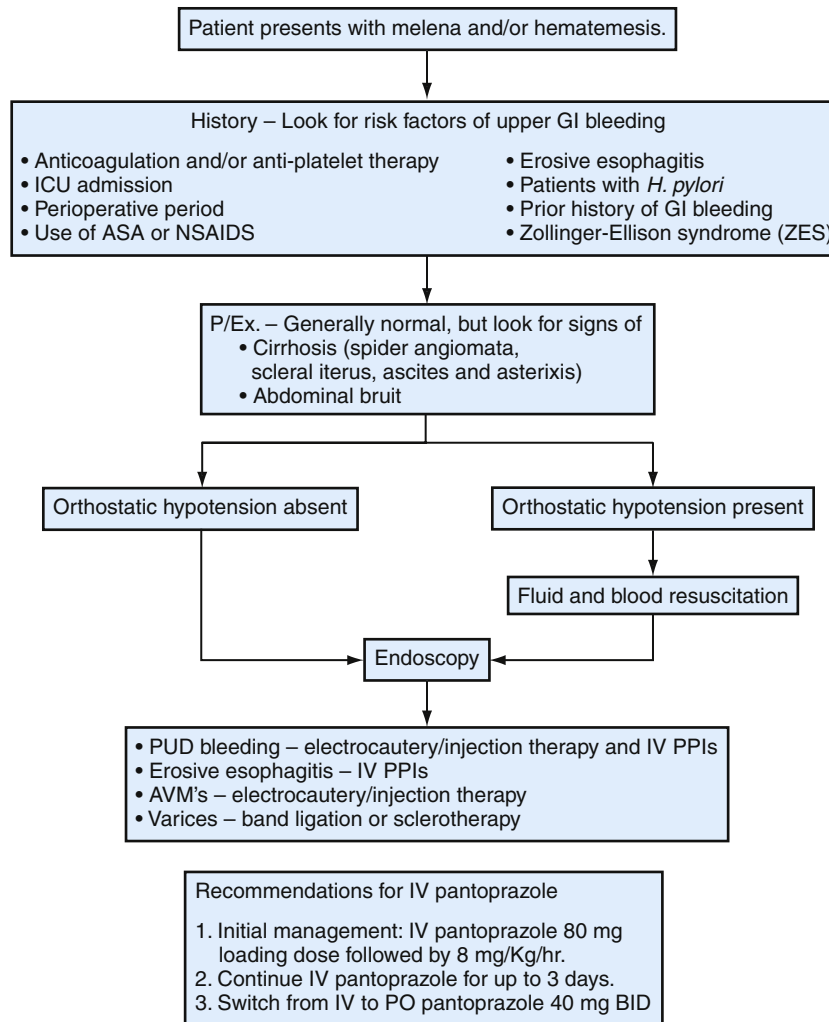

Figure 38-9 Algorithm for the evaluation of acute upper gastrointestinal (GI) bleeding. ASA, Acetylsalicylic acid; AVM, arteriovenous malformation; NSAIDs, nonsteroidal anti-inflammatory drugs; PPI, proton pump inhibitor; PUD, peptic ulcer disease. (Modified from Oh DS, Pisegna JR. Management of upper gastrointestinal bleeding. *Clin Fam Pract* 2004;6:631-645.)

upper endoscopy. Most cases of rebleeding occur within the first 72 hours after hospital admission; patients at increased risk for upper GI rebleeding should have ICU monitoring during their admission (Oh and Pisegna, 2004). The use of PPIs in reducing the risk of UGI rebleeding was demonstrated in a landmark study with IV omeprazole, showing the clinical efficacy of acid reduction therapy in preventing the complications of PUD rebleeding (Lau et al., 2000).

Gastroparesis

Clinical symptoms suggesting gastroparesis, or impaired and delayed gastric emptying, include nausea, vomiting, and postprandial abdominal fullness. Most often, gastroparesis is related to poorly controlled diabetes mellitus, autonomic neuropathies, postsurgical conditions (e.g., vagotomy, Billroth pyloroplasty), and anorexia nervosa. Vomiting needs to be differentiated from regurgitation, rumination, and even bulimia; the duration, frequency, and severity of symptoms together should be described along with any associated symptoms.

Gastric-emptying scintigraphy of a radiolabeled solid meal is the most accepted method to test for gastroparesis. Conventionally, the test is performed for 2 hours after ingestion of a radiolabeled meal; however, performing the test for up to 4 hours may increase the yield in detecting delayed gastric emptying in symptomatic patients. Breath testing can be used to measure gastric emptying using the nonradioactive isotope carbon 13 (^{13}C) (Parkman et al., 2004).

Primary treatment of gastroparesis includes dietary manipulation and administration of antiemetic and prokinetic agents. Dietary recommendations include eating more frequent and smaller meals and replacing solid food with liquids, such as soups. Foods consumed should be low in both fat and fiber content. Common antiemetic agents include prochlorperazine, trimethobenzamide, and promethazine. Currently used prokinetic agents include metoclopramide and erythromycin, administered orally or intravenously. Domperidone, a dopamine (D_2) receptor antagonist, is not approved in the United States for treatment of gastroparesis but is available in Canada, Mexico, and Europe (Parkman et al., 2004). Endoscopic injection of botulinum toxin into the pyloric sphincter can aid in relaxing pyloric sphincter resistance, allowing more food to empty from the stomach. No placebo-controlled trials have yet been reported for this therapy, and long-term control of gastroparesis should not be expected from using botulinum toxin.

Gallbladder

Cholelithiasis and Cholecystitis

Gallstones are exceedingly common among women and men of all ages, affecting approximately 20% of Americans during their lifetime. Population-based studies reveal a prevalence of gallbladder disease in women age 20 to 55 of 5% to 20%, increasing to 25% to 30% after age 50. By age 75, an estimated 35% of women and 20% of men will develop either symptomatic or asymptomatic gallstones (Attili et al., 1995). The prevalence for men is approximately one-third to one-half that for women in any given age group. The traditional clinical picture of a patient likely to have gallstones is

an obese woman over 40 years of age (The four F's: female, "fat", 40, and fertile). Prevalence is also increased in patients with cystic fibrosis with pancreatic insufficiency, diabetes mellitus, or family history of biliary colic; pregnancy; rapid weight loss; Native American Pima Indian or Scandinavian descent; patients taking estrogens, progestins, or ceftriaxone; and those requiring total parenteral nutrition (TPN).

The Rome Group for the Epidemiology and Prevention of Cholelithiasis (GREPCO, 1984) found that the overall cumulative probability of developing biliary colic over time was 11.9% at 2 years, 16.5% at 4 years, and 25.8% at 10 years, with a cumulative probability of 3% of developing complications at 10 years. The incidence of the development of biliary complications as the presenting complaint of gallstone disease is rare, ranging from zero to 5.5%. Based on these data, evidence from well-designed cohort and case-control studies summarized by GREPCO favors expectant treatment of asymptomatic gallstones.

In the approach to the patient with symptomatic gallstones, clinicians should effectively rule out other potential causes of RUQ and epigastric abdominal pain, distinguishing biliary from nonbiliary etiologies as the primary source of disease (see Table 38-1). A gallstone blocking the cystic duct or common bile duct (CBD; *choledocholithiasis*) results in acute biliary colic, which can evolve into acute suppurative cholecystitis or cholangitis. The onset of pain from biliary colic is rarely related to meals or the type of food consumed, contrary to popular opinion. Many patients with postprandial abdominal pain believe that they have gallbladder disease, but many of them suffer from dyspepsia or GERD. One meta-analysis found that heartburn, flatulence, regurgitation, and fatty food intolerance were not associated with gallstones, but that epigastric pain, nausea, and vomiting were associated with a higher odds ratio of having gallstones (Kragg et al., 1995).

In cases of acute cholecystitis, laboratory tests frequently lack adequate predictive value in making an accurate diagnosis. A complete blood count (CBC) usually reveals a moderate leukocytosis, often with a "bandemia" in cases of ascending cholangitis. Serum amylase and lipase values are usually normal but may be elevated if there is associated pancreatitis. Serum alkaline phosphatase (ALP), liver transaminases, and bilirubin levels are rarely elevated except when CBD stones are causing obstruction. Patients with choledocholithiasis often present similar to those with cholelithiasis, although they may also have obstructive jaundice, cholangitis, and pancreatitis.

The evaluation of gallstones using abdominal ultrasound is currently the best screening modality, with sensitivity and specificity above 90%. When calculi, gallbladder wall thickening, and gallbladder sludge are found, the diagnosis of acute cholecystitis is almost certain, yet the presence of stones by itself does not ensure the diagnosis of acute cholecystitis. Only 10% to 15% of gallstones are visible on plain radiographs (Fig. 38-10). A CT scan of the upper abdomen is more sensitive than conventional radiography but may miss a significant amount of cholesterol gallstones and biliary sludge readily seen on US (Fig. 38-11). Biliary scintigraphy (HIDA scan) uses technetium 99m ($^{99\text{m}}\text{Tc}$)-labeled derivatives of excreted bile acids to determine CBD obstruction. Endoscopic retrograde cholangiopancreatography (ERCP) with stent placement and/or sphincterotomy is useful

Figure 38-10 Radiographs of gallstones. (Courtesy Dr. Perry Pernicano.)

in identifying and treating CBD stones, but is invasive, expensive, and often fraught with complications, including iatrogenic pancreatitis (Fig. 38-12).

Endoscopic ultrasound is a widely used, noninvasive method with excellent sensitivity and specificity for detecting and evaluating CBD stones. Magnetic resonance cholangiopancreatography (MRCP) is another noninvasive modality for identifying gallstones and CBD stones, but it often has lower sensitivity and specificity than ultrasound and is more costly (Browning and Sreenarasimhaiah, 2006). The natural history of CBD stones suggests that 70% will pass safely into the duodenum and will not require ERCP for stone extraction.

Most surgeons advocate expectant management in patients with asymptomatic gallstones. Nonsurgical treatments include pain relief with narcotic analgesics, excluding morphine and its derivatives (which may precipitate sphincter of Oddi spasm and worsen symptoms) extracorporeal shock-wave lithotripsy, and gallstone dissolution using oral bile acid therapy and contact solvents such as MTBE). Numerous RCTs have confirmed the adoption of laparoscopic cholecystectomy as the gold standard for the treatment of gallstone disease over the open procedure (Glasgow and Mulvihill, 2006).

Liver

Hepatitis

Hepatitis is defined as acute inflammation of hepatic parenchyma. In the United States the most common types of hepatitis are secondary to viral etiologies and are labeled as hepatitis A, B, and C. Table 38-3 outlines the various

serologic markers for viral hepatitis. Viral hepatitis is less frequently attributed to Epstein-Barr virus, toxoplasmosis, and cytomegalovirus. Additional causes of hepatitis include bacterial and fungal sources, autoimmune and metabolic disorders, toxic poisoning, and various hepatotoxic medications (e.g., isoniazid, acetaminophen) and alternative supplements. Acetaminophen overdose should be considered in acute nonviral hepatitis and treated immediately with *n*-acetylcysteine to avoid permanent hepatic damage and death. Patients presenting with acute hepatitis often exhibit low-grade fever, fatigue, lethargy, anorexia, RUQ pain, nausea, vomiting, diarrhea, arthralgias and myalgias, and in severe cases, dark urine and jaundice.

Serum bilirubin, transaminases, and ALP levels can be greatly elevated in all forms of acute hepatitis, but the specific values have poor prognostic value. Alarm symptoms of severe hepatic parenchymal destruction include mental status changes (hepatic encephalopathy), asterixis, ascites, and prolongation of prothrombin time (PT). These patients may require hospitalization, with attention toward improving nutritional status and specialist referral for liver transplantation evaluation. Most cases of acute hepatitis resolve without complications, so most patients can be managed as an outpatient, although they must take proper contact isolation precautions and allow for a slow return to usual activity. A patient's symptomatic improvement usually precedes the resolution of liver function serologies.

Viral Hepatitis

Hepatitis A is endemic worldwide, with 10% of U.S. children seropositive and up to 100% of preschool children seropositive in areas where sanitation and socioeconomic status is

Figure 38-11 CT scans (**A, B**) and ultrasound (**C-E**) of gallstones (arrows). (Courtesy Dr. Perry Pernicano.)

Figure 38-12 Endoscopic retrograde cholangiopancreatography (ERCP) with stent placement to identify and treat gallstones (arrows). (Courtesy Dr. Perry Pernicano.)

poor in less developed countries (Marsano, 2003). The virus has received sporadic national attention in the United States from outbreaks in restaurants from undercooked meat and vegetable sources. Spread through the fecal-oral route, severe hepatitis can be seen after an incubation period of 2 to 6 weeks, but the vast majority of patients recover completely within this time frame and without permanent hepatic damage. Once a patient contracts hepatitis A, immunity follows with the appearance of anti-HAV IgG antibodies, and there is no chronic carrier state. If exposed to hepatitis A during a known incubation period, the patient should be passively immunized with immune globulin. Vaccination is recommended in high-risk populations and before travel to endemic areas (CDC, 1999).

Despite the availability of a highly effective vaccine against hepatitis B, approximately 2 billion people worldwide are infected, 350 million with chronic active infection accounting for 600,000 attributable deaths annually worldwide (WHO, 2009). Hepatitis B is spread via blood and body fluid contact through heterosexual and homosexual relations, by sharing of needles by infected drug abusers, and by accidental needle sticks in the medical setting. In areas of high disease prevalence (e.g., Southeast Asia, China), transmission is primarily from mother to child during childbirth or in early childhood. The vaccination for hepatitis B uses recombinant DNA, requires 3 doses on a set schedule, and confers immunity in the majority of recipients. In a child born to a mother positive for hepatitis B surface antigen

Table 38-3 Viral Hepatitis Serologic Tests and definitions

| Test | Description |
|--------------------------------------|--|
| Hepatitis A virus (HAV) | |
| Anti-HAV IgM | Immunoglobulin M (IgM) antibody to hepatitis antigen. Antibody of IgM class signifies recent acute infection. This develops at onset of symptoms and resolves in less than 1 year. |
| Anti-HAV IgG | Immunoglobulin G (IgG) antibody to hepatitis A antigen. With negative anti-HAV IgM, this indicates past HAV infection, and that patient is immune. It appears 1 to 2 weeks after IgM antibody. |
| Hepatitis B virus (HBV) | |
| HBsAg | Hepatitis B surface antigen is earliest indicator of acute infection. It can be present for several months before symptoms and may remain detectable for up to 6 months. Persistence after 6 months may indicate a chronic carrier state. |
| Anti-HBs | Antibody to hepatitis B surface antigen is indicator of clinical recovery and subsequent immunity. It appears 1 to 2 months after HBsAg disappears, and it may be present for life. |
| HBcAg | No clinical significance, not readily available. |
| Anti-HBc IgG | Antibody to hepatitis B core antigen is early indicator of acute infection. It is also a lifelong marker that represents past exposure. It may precede the detection of HBsAg. This persists for years but does not necessarily confer immunity. |
| IgM Anti-HBc | Early indicator of acute active infection; usually short-lived (3-6 wk). Persistence of e antigen suggests progression to chronic carrier state. |
| HBe g | Active infection is present, and patient is highly contagious. |
| Anti-HBe | Seroconversion from antigen to antibody is prognostic for resolution of infection and, in a carrier, means very low infectivity. |
| IgM anti-HBc | IgM fraction of antibody to hepatitis B core antigen is test of choice to rule out acute HBV infection. IgM fraction disappears in first few months. |
| Hepatitis C Anti-HCV | An antibody to HCV that appears 3 to 12 months after exposure. |
| Hepatitis D Anti-HDV | This antibody to HDV may appear late and may be short-lived. |
| Hepatitis E (non-A, non-B) | No markers detectable, epidemiology parallels that of hepatitis B. |

Modified from: Rodney WM. Gastrointestinal disorders. In Rakel RE (ed). Textbook of Family Medicine, 6th ed. Philadelphia, Saunders, 2002.

(HBsAg), in addition to the vaccine, hepatitis B hyperimmune globulin should be administered during the first 12 hours of life. Patients with chronic infection can develop cirrhosis and end-stage liver disease. Antiviral treatments for hepatitis B are indicated for patients with moderate to severe disease activity diagnosed on liver biopsy. Current

therapies include interferon and more recently, lamivudine and adefovir (Marsano, 2003).

Hepatitis C affects more than 300 million people worldwide and 4 million people in the United States. At least six genotypes and 100 subtypes have been identified (Bukh, 2000). The diagnosis is established with serum testing for HCV RNA antibodies; although an antibody is induced, it is not protective against disease contraction and progression. Transmission occurs via blood or body fluid contamination through IV and intranasal drug use, blood transfusions, and in health care workers (e.g., needle stick or skin disruption with contaminated instrument). Data on sexual transmission and though tattooing have been inconsistent. Co-infection with human immunodeficiency virus (HIV) increases the risk of transmission sexually, as well as vertically mother to child. In patients with chronic hepatitis C, alcohol use rapidly accelerates liver damage and cirrhosis. Many experts believe lifelong abstinence from alcohol and IV and intranasal drugs should be immediate on diagnosis and enforced before initiating antiviral therapies.

Therapy with pegylated interferon and ribavirin has been shown to achieve sustained viral eradication in almost 50% of patients with hepatitis C (Shehab, 2004). Patients should be monitored for side effects of antiviral treatment, which may require dose adjustments or discontinuation of therapy. Duration and success of therapy depend on viral genotype and possible downward adjustments in therapeutic doses. Sustained virologic response ranges from 42% in genotype 1 to 80% in genotypes 2 and 3 (Marsano, 2003).

Hepatitis D virus (delta hepatitis) is usually only seen in IV drug users and in former carriers of hepatitis B as a co-infection. *Hepatitis E* is an enteric virus only rarely identified in the United States, characterized by an acute self-limited illness without a chronic carrier state.

Cirrhosis

Cirrhosis and chronic liver failure rank as the 12th leading cause of death in the United States, accounting for 27,555 deaths (9.2 per 100,000 population) in 2006, with a slight male predominance (NCHS, 2009). The vast majority of cirrhosis-related morbidity and mortality is secondary to excessive alcohol consumption, hepatitis B and C, and obesity (nonalcoholic fatty liver disease [NAFLD]), and is theoretically preventable. The term *cirrhosis* refers to a progressive diffuse, fibrosing, and nodular condition that disrupts the entire normal architecture of the liver. Portal hypertension ensues with multiple long-term complications. Approximately 40% of patients are asymptomatic, with cirrhosis often discovered during a routine examination, including laboratory and radiographic studies (Figs. 38-13 and 38-14), or often at autopsy. Mortality rates in patients with alcoholic liver disease are considerably higher than in those with other forms of cirrhosis.

The major complications of cirrhosis that affect HRQOL and survival include ascites formation, spontaneous bacterial peritonitis, hepatorenal syndrome, encephalopathy, and GI bleeding secondary to portal hypertension and varices. Another serious complication of cirrhosis is the development of hepatocellular carcinoma, for which screening protocols with ultrasound and serum alpha-fetoprotein testing are cost-effective (Marrero, 2005). All patients with ascites

Figure 38-13 Cirrhosis. Ultrasound shows lobulated shrunken liver with ascites and splenomegaly. (Courtesy Dr. Perry Pernicano.)

Figure 38-14 Cirrhosis. CT scans show **A**, lobulated contour of liver; **B**, splenomegaly; and **C**, ascites. (Courtesy Dr. Perry Pernicano.)

should be evaluated for liver transplantation because of poor 5-year survival (30%-40%) (Gines et al., 2004) (Fig. 38-15).

Pancreas

Acute Pancreatitis

Acute pancreatitis continues to cause significant morbidity and mortality despite dramatic advances in the understanding of its pathophysiology and its critical care management. Some studies suggest a high rate of undiagnosed pancreatitis, with approximately 40% of acute cases recognized only at autopsy. Thus, it is imperative for primary and emergency care physicians to make the diagnosis of pancreatitis within the first 48 hours of admission (AGA, 2007). In severe acute pancreatitis, parenchymal and fat necrosis ensues, as well as profound multisystem organ failure, infection, and life-threatening hemodynamic instability.

The causes of acute pancreatitis are diverse and demonstrate changing trends over time and variation by geography. Gallstones, biliary sludge, and microlithiasis are recognized as the proximate cause in more than half of reported cases. Ethyl alcohol ingestion is the second most common reported cause of acute pancreatitis, about 30% of cases, although it is unclear whether alcohol is a toxin or an exacerbating factor in individuals who have compromised pancreatic function. The remaining causes of acute pancreatitis account for less than 15% of total cases, including hypertriglyceridemia, trauma, medications, ERCP, neoplasms, perforated PUD, viral infection, and idiopathic causes.

Serum markers of acute pancreatitis have high sensitivity and specificity but no role in predicting the severity or course of disease. The most common enzymes assayed, amylase and lipase, are released at approximately the same time after the initial insult to the pancreas but are cleared from the bloodstream at different rates. Therefore, relying on total serum amylase alone to make an accurate diagnosis of acute pancreatitis is error-prone, because it is cleared almost

totally from the blood within 48 to 72 hours. The sensitivity of pancreatic amylase for the diagnosis of acute pancreatitis decreases to less than 30% between the second and fourth day after onset of the acute episode. By contrast, an elevated serum lipase level can be detected up to 14 days after the acute event and has sensitivity greater than 90% for acute pancreatitis (Orbuch, 2004).

Early prognostic factors that can be measured and indicate severity of disease include the Acute Physiology and Chronic Health Evaluation II (APACHE-II) score. The overall success at prediction of mortality from acute pancreatitis at hospital admission remains at 40%, and even at 48 hours it is no better than 80% when all diagnostic strategies of morbidity and mortality prediction are compared (Papachristou, 2004). The most important factor in the management of patients with acute pancreatitis is maintaining appropriate intravascular volume status (AGA, 2007). Many predictors of pancreatitis severity are directly related to "third spacing" of fluids and include hemoconcentration and rising creatinine level. The hematocrit may be high as a result of hypovolemia secondary to third spacing of fluids. Volume resuscitation during the first 24 hours is important because this may minimize or even prevent pancreatic necrosis (Mayerle et al., 2004).

If the bilirubin, liver transaminases, and ALP increase, a CBD stone may exist (Fig. 38-16). Similar laboratory abnormalities with a less acute presentation may occur in patients with chronic pancreatitis when bile duct stricture occurs. This possibility should be further explored with abdominal US and possibly ERCP, which can be both diagnostic and therapeutic. ERCP is especially useful in the setting of biliary pancreatitis with associated cholangitis or severe pancreatitis within 72 hours of presentation (AGA, 2007). Leukocytosis (>20,000 WBCs/mL) suggests a more severe disease (Ranson et al., 1974). Since respiratory distress syndrome may ensue, chest radiographs and arterial blood gases should be considered. In severe cases, renal failure may appear despite adequate fluid intake, and thus urine output should be closely monitored.

Contrast-enhanced computed tomography (CECT) is the most extensively studied modality for the confirmation of

Figure 38-15 Ascites (arrows). (Courtesy Dr. Perry Pernicano.)

Figure 38-16 CT scans of dilated pancreatic duct secondary to stone pancreatitis. (Courtesy Dr. Perry Pernicano.)

acute pancreatitis and provides the highest level of sensitivity and specificity of current imaging technologies (Fig. 38-17) (Papachristou and Whitcomb, 2004). Sensitivities using ultrasound for the diagnosis of acute pancreatitis range between 62% and 95% and probably reflect the failure to visualize the organ in as many as 30% of cases. When the pancreas is visualized in the setting of acute disease, tissue abnormalities are detected in 90% of those studied. The milder the disease presentation, the less likely it is that abnormalities will manifest that are detectable on CT examination. Magnetic resonance imaging (MRI) and MRCP have specific yet limited roles in diagnosing acute pancreatitis.

Medical therapy of acute pancreatitis is primarily supportive, with the major objective being hemodynamic stabilization. Nutritional support should be provided in those patients likely to remain “nothing by mouth” (NPO) for more than 7 days. Nasojejunal tube feeding, using an elemental or semielemental formula, is preferred over TPN (AGA, 2007). Pain management in the hospital setting is best achieved using morphine derivatives. Infrequently, patient-controlled anesthesia may be used for severe abdominal pain, and alternative diagnoses and complications should be considered.

Chronic Pancreatitis

Permanent pathologic damage to the pancreas results in chronic pancreatitis. In addition to exocrine deficiency (with malabsorption, diabetes, or both), a chronic pain syndrome may evolve and become a management challenge. Many patients suffer from substance abuse and other behavioral problems that require time, patience, compassion, and skill to resolve. Patients who continue to consume alcohol are more likely to have recurrent attacks. Carefully selected patients may benefit from therapeutic ERCP or pancreatic surgery, with some pain relief. Exocrine deficiency may be treated with pancreatic enzyme supplementation with each meal (Apte et al., 1999).

Chronic pancreatitis indicates some degree of progressive and permanent damage to the pancreas, usually visualized as calcifications on radiographs and CT (Figs. 38-18 and 38-19). This damage often leads to diabetes and pancreatic

Figure 38-19 Pancreatic calcifications. (Courtesy of Dr. Perry Pernicano.)

insufficiency, resulting in malabsorption with chronic diarrhea. Patients with chronic pancreatitis present with repeated attacks of abdominal pain and are often admitted for acute or chronic exacerbations. Potential complications include pseudocyst (Fig. 38-20) and abscess formation, fistula formation between pseudocysts and the gut, persistent pancreatic ascites caused by a disrupted pancreatic duct system, communication with the peritoneal cavity, mesenteric venous thrombosis, and arterial pseudoaneurysm (Apte et al., 1999).

Pancreatic Cancer

More than 37,000 people in the United States were diagnosed with pancreatic cancer in 2008, and more than 34,000 died from their disease (Cancer Facts, 2008). The major risk factors are advancing age and a history of tobacco and alcohol use; the diagnosis is rarely made early in the disease course because of vague presenting symptoms of nonspecific abdominal pain, weight loss, cachexia, and painless obstructive jaundice. Approximately 85% of patients present with locally advanced or metastatic disease, with median survival of 3 to 12 months. For these patients, conventional treatments include palliative surgery. Radiation and chemotherapy

have not substantially impacted survival. Endoscopic ultrasound and high-resolution CT allow for better preoperative selection for patients likely to benefit from exploration for resection (Fig. 38-21).

Lower Gastrointestinal Tract

Inflammatory Bowel Disease

Key Points

- Steroids are effective for inducing but not maintaining remission in IBD.
- The 5-ASA medications are effective in ulcerative colitis for therapy induction and maintenance therapy but largely are ineffective for Crohn's disease.

Inflammatory bowel disease (IBD) is a chronic condition that often requires long-term maintenance therapy for the majority of the half-million Americans affected. The two major categories include ulcerative colitis (UC) and Crohn's disease; a more recent and less common third category of *microscopic colitis* has also been identified. The incidence of

Figure 38-20 CT scans showing severe pancreatitis evolving into pseudocysts (arrows) over 2 months. (Courtesy Dr. Perry Pernicano.)

UC and Crohn's disease is 1.5 to 8 new cases per 100,000 U.S. population per year, more often in Caucasians and with no specific gender predominance, although some suggest a male predominance in Crohn's disease and a female predominance in UC. Most patients are diagnosed with IBD between ages 15 and 25, with a second peak between 55 and 65 years. The incidence of microscopic colitis is most likely underestimated because it is not well known; estimated incidence ranges from 4.3 to 9.2 per 100,000 in Western European and Icelandic population studies (Loftus, 2003).

Genetic factors play an important role in the development of IBD. First-degree relatives of patients with either form of IBD have been shown to have an almost 10% lifetime risk of developing disease and often present with a similar disease type and course as the affected family member (Higgins and Zimmerman, 2004).

Ulcerative colitis involves the mucosal layer of the sigmoid colon and rectum in the vast majority of cases, causing proctitis and proctosigmoiditis (Fig. 38-22). When there is proximal spread, it tends to be continuous and symmetric,

causing intestinal mucosal inflammation with edema and friability that is visualized from the rectum proximally. Pancolitis is caused by inflammatory exudates producing a backwash ileitis by way of a patent ileocecal valve, and can cause small bowel involvement.

Crohn's disease differs from UC in that it may involve any part of the GI tract from the mouth to the anus, including the gallbladder and biliary tree, and involves the entire thickness of the bowel wall. It is most often found in the immunologically rich terminal ileum, and Crohn's disease involves the rectum in less than 50% of cases. In contrast to UC, the mucosal abnormalities are discontinuous ("skip lesions"), asymmetric, and patchy, which account for obstruction, abscesses, and perianal fistulas and those to other organs and skin. Recurrent disease flares and healing can result in significant muscular hypertrophy and fibrosis of the intestinal wall, leading to small bowel strictures, upstream dilation of intestine and increased fistula formation, and eventual bowel obstruction and the imminent need for surgical intervention (Higgins and Zimmerman, 2004).

Figure 38-21 Pancreatic cancer, pancreatic head mass, with biliary and pancreatic ductal dilation. (Courtesy Dr. Perry Pernicano.)

Most patients with UC present with mild to moderate diarrhea without constitutional symptoms. Typically, the more severe the illness, the greater is the number of bowel movements, and the more likely that constitutional symptoms such as fever, fatigue, dehydration, and weight loss will also occur. UC can be intermittent with flare-ups, and remission can occur without therapy. A minority of patients with UC present with severe or fulminant pancolitis, ranging from an acute abdomen to toxic megacolon. Frequent urgent and bloody diarrhea usually suggests rectal disease and is most consistent with UC.

In patients with mild Crohn's disease, abdominal pain may be vague, the diarrhea intermittent, and weight loss absent. Postprandial crampy pain can suggest transient small bowel obstruction from inflamed or fibrotic, narrowed small bowel segments. Colonic involvement with Crohn's disease may present similar to UC, with predominantly bloody diarrhea. Rectal involvement produces more urgent and frequent small, bloody stools as a result of an inflamed, nondistensible rectum. Mucus in the stool is nonspecific and is found in both IBD and irritable bowel syndrome (IBS) (Higgins and Zimmerman, 2004).

Figure 38-22 Severe colitis. (Courtesy Dr. Erik-Jan Wamsteker.)

Figure 38-23 Ulcerative colitis, pseudopolyps. (Courtesy Dr. Perry Pernicano.)

Extraintestinal manifestations may be the presenting symptoms of UC or Crohn's disease. Uveitis, iritis, or episcleritis often flare concomitantly with intestinal symptoms. Large-joint pain and sacroiliitis may be a form of enteropathic arthritis. Common skin manifestations include erythema nodosum, perianal fistulas, and pyoderma gangrenosum. IBS is much more prevalent than IBD, and thus a major pitfall in the diagnosis of IBD is the mislabeling of patients with IBS.

The finding of confluent erythematous rectal inflammation is most consistent with UC and infectious colitis. Pseudopolyp formations indicate chronic inflammatory colitis (Fig. 38-23), while solitary aphthous ulcers, "rake-like" lesions, strictures, and rectal sparing are consistent with Crohn's disease. Colonoscopic evaluation should include ileal intubation and biopsies of both normal and abnormal mucosa. Anal or perianal lesions, including sinus tracts, rectovaginal fistulas, and abscesses, is consistent with Crohn's disease but not with UC. The mucosa in a patient with Crohn's disease may appear cobblestoned or nodular. Loss of haustra, distortion of normal architecture, or both may be found (Figs. 38-24 and 38-25).

Pharmacologic treatment of IBD is aimed at inducing remission and maintaining a symptom-free life, often after consultation with a gastroenterologist. Treatment of active flares with systemic steroids has been the mainstay of remission induction therapy, producing remission rates up to 70% in Crohn's disease versus 30% with placebo; similar results have been shown in the remission of UC. Budesonide, a nonsystemic steroid used in an enema formulation, has been effective for induction of remission in Crohn's disease and distal UC flares. Mild flares of UC are usually treated with 5-aminosalicylic acid (5-ASA) derivatives such as sulfasalazine, although RCTs have shown 5-ASA only marginally superior to placebo at controlling flare-ups of Crohn's disease. 5-ASA products are thought to be inferior to budesonide and systemic steroids for remission induction in Crohn's disease and generally are not used (Higgins and Zimmerman, 2004).

Azathioprine and its metabolite, 6-mercaptopurine, are slow-acting compounds proved effective for inducing

Figure 38-24 Crohn's disease. (Courtesy Dr. Perry Pernicano.)

remission in Crohn's disease. They often are added to systemic steroids to help induce and maintain remission and to ease steroid tapering. Methotrexate is also effective for remission induction in Crohn's disease. Close monitoring of CBC and serum transaminases is recommended, with monthly testing on initiation and with dosage changes. Pregnancy and exposure to live-virus vaccines should be avoided. Infliximab, an anti-tumor necrosis factor alpha antibody, is remarkably effective in treating approximately 60% of steroid-resistant patients with Crohn's disease. Infliximab has significant side effect risks, including infusion reactions, and rarely, worsening of heart failure, activation of latent tuberculosis, serum sickness, and invasive fungal infections (Feagan, 2003).

KEY TREATMENT

Systemic steroid therapy is effective in the treatment of active flare-ups of Crohn's disease and ulcerative colitis (Hanauer and Baert, 1994) (SOR: A).

Budesonide is effective for remission induction in Crohn's disease and distal ulcerative colitis flares (Kuhbacher and Fölsch, 2007) (SOR: A).

Irritable Bowel Syndrome

Key Points

- Irritable bowel syndrome likely represents the clinical expression of multiple potential pathophysiologic factors, including a genetic predisposition to the disease, disturbed CNS pain processing, visceral hypersensitivity, mucosal inflammation, abnormal colonic motility, and emotional stress.
- Anxiety disorders, somatoform disorders, and history of physical or sexual abuse have been identified in 42% to 61% of patients with IBS referred to gastroenterologists.

Figure 38-25 Crohn's disease. (Courtesy Dr. Perry Pernicano.)

Irritable bowel syndrome (IBS) is one of the most common conditions encountered in family practices, with a prevalence ranging from 1% to 20% worldwide and approximately 7% in the United States. IBS is characterized by abdominal pain, bloating, and disturbed defecation in the absence of known structural or biochemical abnormality. It typically appears in the late 20s, although it may present in teenagers and in patients as old as age 45; patients over 45 with suspected IBS should be evaluated for organic disease. IBS is responsible for over \$20 billion in direct and indirect expenditures annually in the United States, and patients with IBS consume 50% more health care resources than matched controls without IBS (ACG, 2009).

Irritable bowel syndrome likely represents the clinical expression of multiple potential pathophysiologic factors, including a genetic predisposition to the disease, disturbed central nervous system (CNS) pain processing, visceral hypersensitivity, mucosal inflammation, abnormal colonic motility, and emotional stress. Given the degree of variation of IBS symptoms in affected patients, it is likely that the etiology of IBS is a heterogeneous combination of these factors, as well as other undetermined mechanisms. Psychosocial stressors likely exacerbate symptoms in patients with functional GI disorders. Anxiety disorders, somatoform disorders, and a history of physical and/or sexual abuse have been identified in 42 to 61% of patients with IBS who have been referred to gastroenterologists (Miller et al., 2001).

The physical examination in patients with IBS is often non-specific, and may demonstrate a normal abdomen examination, a diffusely tender abdomen, or a focally tender abdomen. Multiple diagnostic screening tests have been recommended including a CBC, erythrocyte sedimentation rate (ESR), serum chemistries, thyroid function tests, stool cultures including ova and parasites, fecal occult blood test, colonoscopy, and hydrogen breath testing, specifically to rule out other causes of disease (ACG, 2009). Despite these

Box 38-8 Diagnosis of Irritable Bowel Syndrome: Rome III Criteria

Symptoms of recurrent abdominal pain or discomfort and a marked change in bowel habit for at least 6 months, with symptoms experienced on at least 3 days of at least 3 months.

Two or more of the following must apply:

- Pain is relieved by a bowel movement.
- Onset of pain is related to a change in frequency of stool.
- Onset of pain is related to a change in the appearance of stool.

Modified from Longstreth GF, Thompson WG, Chey WD, et al. Functional bowel disorders. *Gastroenterology* 2006;130:1480-1491.

recommendations, diagnostic testing should depend on the pretest probability of organic disease.

The differential diagnosis of IBS includes IBD, lactose intolerance, acute gastroenteritis, celiac disease, small intestinal bacterial overgrowth, colorectal cancer, and motility-altering metabolic disturbances (e.g., from hypo/hyperthyroidism). Currently, the Rome III criteria are the most widely accepted symptomatic classification of IBS (Box 38-8) (Longstreth et al., 2006).

There is no single evidence-based, consistently successful therapeutic approach for patients with IBS. Because it is largely a chronic condition, the goals of therapy should focus on patient reassurance, education about the natural course of the syndrome, and global symptomatic improvement, rather than on disease cure. This is best achieved through a well-developed physician-patient relationship with a clear delineation of realistic goals and expectations.

Newer treatments of IBS include tegaserod (Zelnorm), a 5-HT₄ receptor agonist, shown to be more effective than placebo in relieving global symptoms in women with constipation-predominant IBS. Alosetron (Lotronex), a 5-HT₃

antagonist, is indicated for women with diarrhea-predominant IBS and also is more effective than placebo in RCTs. Reports of ischemic colitis have limited the use of alosetron to physicians participating in the manufacturer's risk management program. Treatment of diarrhea-predominant IBS can be achieved with loperamide, although no effect over placebo for global IBS symptoms has been reported (Brandt et al., 2002).

To date, all other classes of medications used in the management of IBS have more limited impact on the global symptoms of IBS. The tricyclic antidepressants (TCAs) and selective serotonin reuptake inhibitors (SSRIs) have been shown to reduce abdominal pain, although global symptom reduction and HRQOL did not significantly improve compared with placebo. Treatment of constipation-predominant IBS can be achieved with fiber-bulking agents, but has not improved global IBS symptoms over placebo. Cognitive-behavioral therapy (CBT), interpersonal psychotherapy, group therapy, biofeedback, and hypnosis have been shown to improve individual aspects of diarrhea-predominant IBS, but these have also not been shown to improve global IBS symptoms (see Key Treatment). Complementary and alternative medicine (CAM) techniques include acupuncture, enteric-coated peppermint oil, probiotic therapy, and Chinese herbal medicine. CAM therapies are becoming increasingly popular in the treatment of GI disorders and have shown some limited symptomatic improvement in select patients with IBS (ACG, 2009).

KEY TREATMENT

Cognitive-behavioral therapy for IBS (efficacy defined as >50% reduction of symptoms) showed significant benefit with a mean number needed to treat (NTT) versus controls of approximately two (2 patients NTT for 1 to benefit) (meta-analysis of 17 studies; Lackner et al., 2004) (SOR: A).

Gut-directed hypnotherapy (GDH) can have long-lasting effects; of 204 patients with resistant IBS symptoms, 81% of initial responders had benefit 5 years after completion of treatment (Gonsalkorale et al., 2003) (SOR: B).

Fiber bulking agents can help treat constipation-predominant IBS (Mertz, 2003) (SOR: B).

Enteric-coated peppermint oil (0.2-0.4 mL [200-400 mg] three times daily in adults) reduced pain and spasm of IBS (Ford et al., 2008; Merat et al., 2009) (SOR: B).

Tricyclic antidepressants should be considered in the treatment of pain-predominant IBS (Mertz, 2003) (SOR: B).

Tegaserod is more effective than placebo at relieving global IBS symptoms in female patients who have constipation-predominant IBS (ACG, 2009) (SOR: A).

Alosetron is more effective than placebo at relieving global IBS symptoms in female patients who have diarrhea-predominant IBS (ACG, 2009) (SOR: A).

Lower Gastrointestinal Bleeding

Lower GI bleeding (LGIB) is defined as bleeding arising from a source distal to the ligament of Treitz, with the resultant potential for rapid hemodynamic instability. Physical signs of hemodynamic compromise include orthostatic hypotension, fatigue, pallor, palpitations, chest pain, dyspnea, tachypnea, and tachycardia. Hemodynamic stabilization through large-bore IV fluid resuscitation should be initiated

immediately if acute LGIB is suspected, and blood transfusion may be necessary. Laboratory testing should include CBC, comprehensive panel, coagulation profile, iron studies including transferrin saturation, and reticulocyte count (before transfusion), and blood type and crossmatch. Clotting disorders and anticoagulant use, including daily aspirin or NSAIDs, should be identified during history taking. Figures 38-26 and 38-27 provide a detailed algorithm for the workup of LGIB.

The American Society for Gastrointestinal Endoscopy Standards of Practice Committee recommends colonoscopy as the preferred modality for the evaluation and treatment of LGIB, allowing for direct visualization of the source of bleeding in over 70% of cases, as well as therapeutic intervention and tissue biopsy. Table 38-4 lists the frequency of the most common causes of LGIB. When no obvious colonic source of bleeding is discovered on lower endoscopy, upper endoscopy is done to evaluate potential causes of rapid, significant UGIB interpreted as LGIB. If there is still no identifiable source of bleeding, examination of the small intestine using enteroclysis or capsule endoscopy should be considered. Intubation of the terminal ileum at the time of colonoscopy may be useful, particularly when there is blood throughout the colon; fresh blood emanating from the ileum indicates small intestinal bleeding (Eisen et al., 2001).

The combination of an overall higher diagnostic yield and a lower rate of complications makes colonoscopy the preferred choice over angiography as the initial test in most patients with suspected GI bleeding. Colonoscopy may be performed urgently or electively, depending on the patient's hemodynamic status and risk-stratification criteria. Comorbid risk factors for GI bleeding severity, including advanced age, presence or absence of shock, congestive heart failure (CHF), ischemic heart disease, and stigmata of recent hemorrhage, accurately predict the likelihood of death or rebleeding (Rockall et al., 1996). In patients with LGIB who are hemodynamically stable, a clean-out preparation (e.g., GoLyteLy) should be used before colonoscopy to increase visibility and diagnostic yield. In patients with hemochezia and hemodynamic compromise, consideration should be given to a rapidly bleeding upper GI source, the patient should be kept NPO, and a nasogastric tube should be placed. A bloody aspirate or one without blood or bile, a history of NSAID use or previous PUD, or a patient with massive bleeding may prompt performance of upper endoscopy before evaluation of the colon (Eisen et al., 2001).

The ^{99m}Tc pertechnetate-labeled red blood cell (RBC) scan is a safe and noninvasive alternative to angiography. Slower rates of bleeding may be detected with this technique, but it is not as accurate in identifying the exact location of a bleeding site. When arteriography is used in association with a ^{99m}Tc -tagged RBC blush, the sensitivity of the arteriogram is increased to 61 to 72% (Zuckerman et al., 2000). A retrospective study using these scans showed that an "immediate blush" (positive scan) had 60% predictive value for an associated positive angiogram, and a "delayed blush" correlated with 93% predictive value for a negative angiogram.

Preoperative localization of the origin of LGIB is the standard practice, except in life-threatening cases of massive GI hemorrhage that necessitate emergency surgical

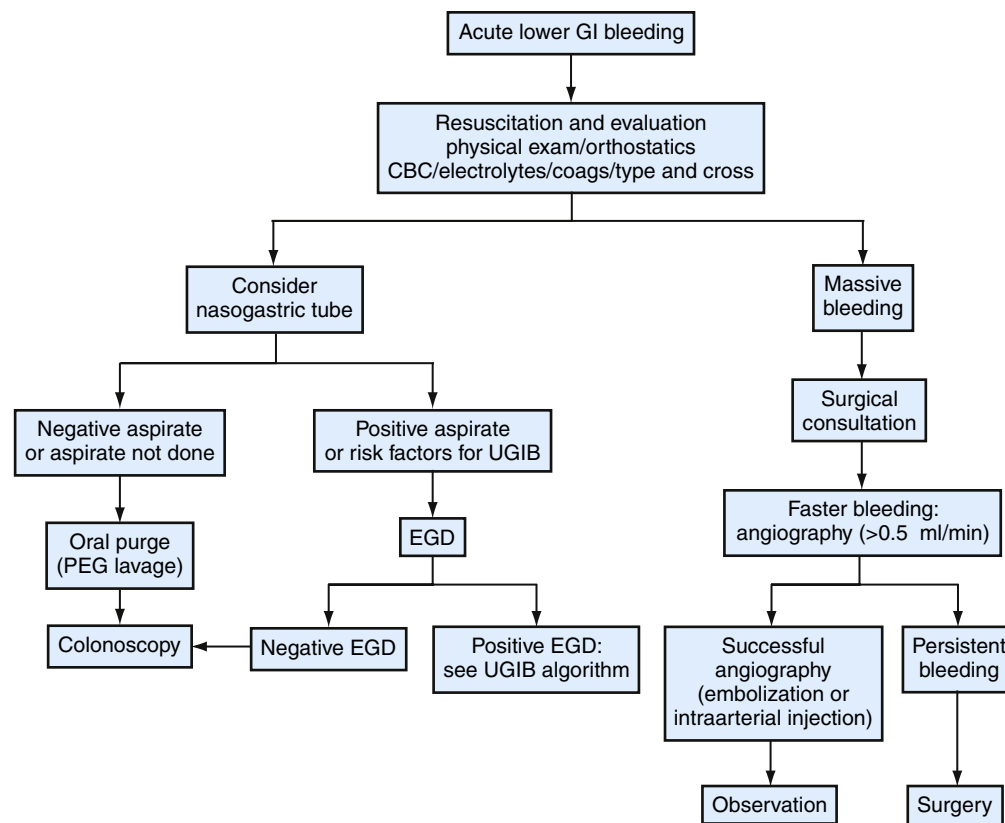

Figure 38-26 Algorithm for the management of acute lower gastrointestinal bleeding (part 1). *CBC*, Complete blood count; *UGIB*, upper gastrointestinal bleeding; *PEG*, percutaneous endoscopic gastrostomy; *EGD*, esophagogastroduodenoscopy. (Modified from Eisen GM, Dominitz JA, Faigel DO, et al; American Society for Gastrointestinal Endoscopy, Standards of Practice Committee. An annotated algorithmic approach to acute lower gastrointestinal bleeding. *Gastrointest Endosc* 2001; 53:859-863.)

exploration. Directed segmental resection is advised when the bleeding site is identified preoperatively, as seen in adenocarcinoma of the colon or diverticular disease limited to the left colon with persistent or recurrent bleeding. The removal of identified colonic lesions does not always result in effective treatment of the underlying source of bleeding. In these cases, arteriography can be used intraoperatively as an adjunct to localize a source of bleeding, facilitate segmental resection of the bowel, and prevent “blind hemicolectomy” (Manning-Dimmitt et al., 2005). A transfusion requirement of greater than 4 units of packed RBCs in 24 hours and recurrent diverticular bleeding (seen in up to 30% of patients) are common indications for surgical intervention. Other factors, such as comorbidities and individual surgical practices, play a significant role in this decision (Eisen et al., 2001).

In patients with chronic intermittent rectal bleeding, upper endoscopy is the preferred test for evaluation, with sensitivity and specificity of 92% and 100%, respectively. A barium-contrast upper GI series with small bowel follow-through (SBFT) may be considered if there is a relative contraindication to endoscopy (e.g., anticoagulation therapy, high risk for complications with conscious sedation, endoscopist unavailable). This test has sensitivity and specificity of 54% and 91% in the detection of upper GI lesions located above the ligament of Treitz (Zuckerman et al., 2000). Transcatheter embolization is an alternative when vasopressin is unsuccessful or contraindicated, but carries a risk of

acute abdominal pain and intestinal infarction (Eisen et al., 2001).

Small intestinal sources of GI bleeding account for less than 10% of all cases. When upper and lower endoscopy have failed to determine the suspected cause of bleeding, the physician should consider *push enteroscopy* (extension of upper endoscopy that allows visualization of up to 160 cm of small bowel distal to ligament of Treitz), although this procedure is limited by its inability to visualize the entire small bowel and thus carries a low diagnostic yield. The barium-contrast upper GI series with SBFT carries a very low sensitivity of zero to 5.6%. *Enteroclysis* (endoscopic placement of radiopaque contrast directly into proximal small bowel) also has low sensitivity, but has a shorter procedure time and can be used in the unconscious or uncooperative patient. Enteroclysis combined with push enteroscopy has higher diagnostic sensitivity than either method alone. Arteriography can be used in challenging cases to evaluate bleeding not identified by endoscopy. It is particularly helpful in the evaluation of older patients in whom arteriovenous malformations (AVMs) or neoplasms are suspected, because both of these lesions are associated with characteristic vascular patterns that can be identified on arteriogram. Capsule endoscopy is being studied as another modality for identifying small bowel bleeding and neoplastic pathology, but is limited in that biopsy samples cannot be obtained. Enhanced helical CT scanning is being explored as an alternative means of evaluating GI bleeding. Laparotomy with intraoperative

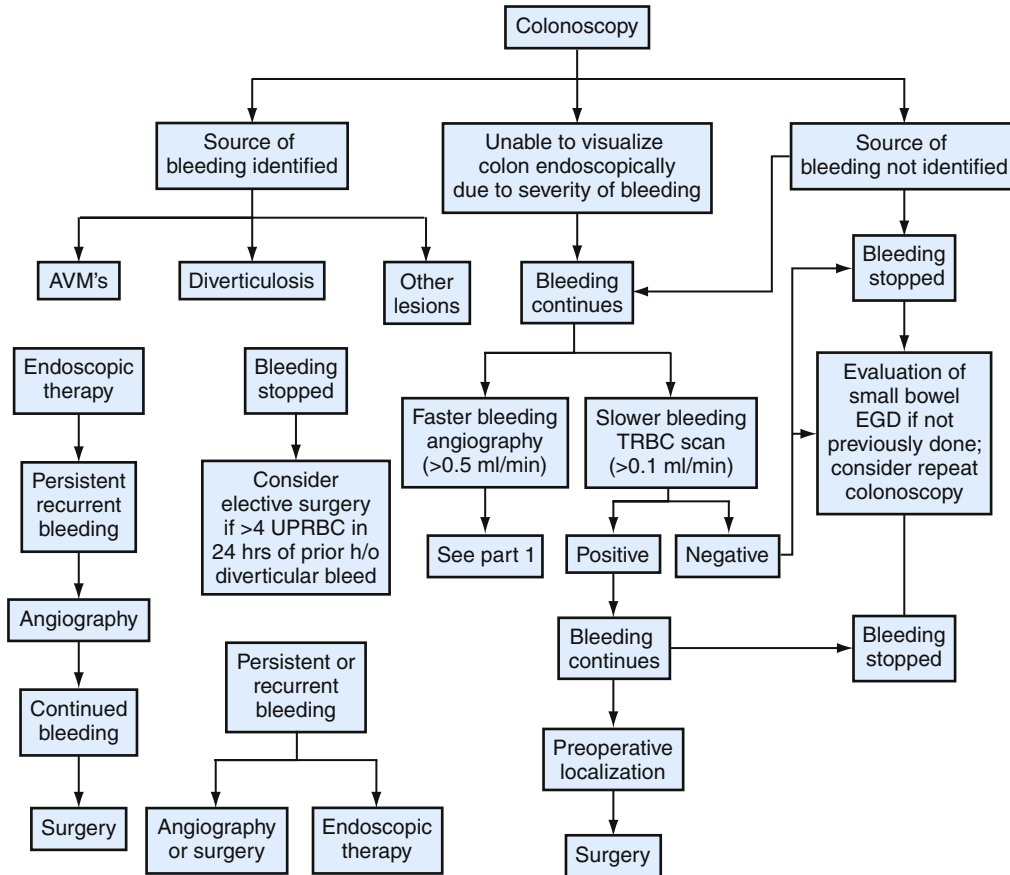

ACUTE LOWER GI BLEEDING
(PART 2)

Figure 38-27 Algorithm for the management of acute lower gastrointestinal bleeding (part 2). AVM, Arteriovenous malformation; UPRBC, units of packed red blood cells; TRBC, tagged (radiolabeled) red blood cell. (Modified from Eisen GM, Dominitz JA, Faigel DO, et al; American Society for Gastrointestinal Endoscopy, Standards of Practice Committee. An annotated algorithmic approach to acute lower gastrointestinal bleeding. *Gastrointest Endosc* 2001;53:859-863.)

enteroscopy should be considered a “last resort” in the diagnostic evaluation of nonemergent cases of GI bleeding because it is associated with higher rates of morbidity and mortality (Zuckerman et al., 2000).

KEY TREATMENT

Colonoscopy is the preferred modality used in the treatment of lower GI bleeding (Zuccaro, 1998) (SOR: A).

Diverticular Disease

Diverticulosis refers to the presence of diverticula, or herniations of the intestinal mucosa and submucosa, most often in the sigmoid colon (Figs. 38-28 and 38-29). More than one half of patients over age 50 have incidental colonic diverticula. *Diverticulitis* is the most common complication of diverticulosis, occurring in up to 20% of patients, and results from a microperforation of a diverticulum from inspissated fecal material that often becomes a phlegmon, or a pericolic or intra-abdominal abscess.

The initial assessment of the patient with suspected diverticulitis should include a thorough history and physical examination, including abdominal, rectal, and pelvic examinations.

The majority of patients will have LLQ pain (93%-100%), fever (57%-100%), and leukocytosis (69%-83%). Other associated features include nausea, vomiting, constipation, diarrhea, dysuria, and urinary frequency. The differential diagnosis includes IBS, IBD, colon cancer, ischemic colitis, bowel obstruction, and gynecologic and urologic disorders (ASCRS, 2000). Initial evaluation of the patient with abdominal pain and suspected diverticulitis includes CBC, urinalysis, and flat and upright abdominal radiographs.

The American Society of Colon and Rectal Surgeons Standards Task Force for the treatment of diverticulitis state that if the patient’s clinical picture clearly suggests acute diverticulitis, the diagnosis can be made on the basis of clinical criteria alone (ASCRS, 2000). The need for additional tests in the patient with suspected diverticulitis is determined by the severity of the presenting signs and symptoms and diagnostic confidence. When the diagnosis of diverticulitis is in question, other tests may include water-soluble contrast enema, abdominal CT, or ultrasonography.

Criteria for the diagnosis of diverticulitis on water-soluble contrast enema include the presence of diverticula (Figs. 38-30 and 38-31), mass effect, intramural mass, sinus tract, and extravasation of contrast. Ultrasound may reveal bowel wall thickening, abscess, and rigid hyperechogenicity of the colon caused by inflammation and may be helpful in female

Table 38-4 Causes of Massive Acute Rectal Bleeding

| Cause | Frequency (%) |
|--|---------------|
| Upper GI Tract | |
| Peptic ulcer disease | 40-79 |
| Gastritis, duodenitis | 5-30 |
| Esophageal varices | 6-21 |
| Mallory-Weiss tear | 3-15 |
| Esophagitis | 2-8 |
| Gastric cancer | 2-3 |
| Dieulafoy's lesion | <1 |
| Gastric arteriovenous malformations | <1 |
| Portal gastropathy | <1 |
| Lower GI tract | |
| Small Bowel | |
| Angiodysplasia | 70-80 |
| Jejunioileal diverticula | <1 |
| Meckel's diverticulum | <1 |
| Neoplasms/lymphomas (benign and malignant) | <1 |
| Enteritis, Crohn's disease | <1 |

patients to exclude pelvic or gynecologic pathology. CT with oral and IV contrast is increasingly used as the initial imaging test for patients with suspected diverticulitis, particularly if disease of moderate severity or abscess is anticipated. Endoscopy is usually avoided in the setting of acute diverticulitis because of the risk of perforating the inflamed colon, either with the instrument itself or by insufflation of air. When the diagnosis of acute colonic diverticulitis is uncertain, limited flexible sigmoidoscopy with minimum insufflation of air may be performed to exclude other diagnoses.

Conservative medical management of uncomplicated diverticulitis without associated abscess, fistula, obstruction,

**Figure 38-28** Diverticulosis. (Courtesy Dr. Erik-Jan Wamsteker.)**Figure 38-29** Diverticulitis. (Courtesy Dr. Erik-Jan Wamsteker.)

or perforation includes bowel rest and IV fluoroquinolones or extended-spectrum penicillins. If the patient does not improve after several days, an abscess should be suspected and diagnostic imaging considered. Conservative treatment results in resolution in 70% to 100% of cases (ASCRS, 2000). After recovery from an initial episode of diverticulitis, when the inflammation has subsided, the patient should be reevaluated. Appropriate examinations include a combination of flexible sigmoidoscopy and single-contrast or double-contrast barium enema or colonoscopy. Eventual resumption of a high-fiber diet is recommended after acute inflammation resolves; long-term fiber supplementation after the first

Figure 38-30 Sigmoid diverticula. (Courtesy Dr. Perry Pernicano.)

Figure 38-31 Diverticula. (Courtesy Dr. Perry Pernicano.)

episode of diverticulitis has been shown to prevent recurrence in more than 70% of patients followed up for more than 5 years.

The decision of whether to proceed with inpatient or outpatient treatment of diverticulitis depends on the clinical judgment of the physician, the severity of the disease process, and likelihood that the patient's condition will respond to outpatient therapy. Patients who are able to tolerate a diet, who do not have systemic symptoms, and who do not have significant peritoneal signs may be treated on an outpatient basis with TMP-SMX or a fluoroquinolone plus metronidazole (Gilbert et al., 2009).

Primary resection and anastomosis without a protective stoma has become the surgical treatment of choice for

uncomplicated diverticulitis and may also be performed for patients with localized pericolic or pelvic abscess. A single-stage procedure is associated with decreased hospital stay and has lower mortality and morbidity compared with two-stage and three-stage procedures. The most common two-stage operation is Hartmann's procedure, which carries a mortality range of 2.6% to 36.8% (ASCRS, 2000). Surgical treatment of diverticulitis, in both acute and chronic settings, has been successfully accomplished by laparoscopic and laparoscopic-assisted means.

Treatment of the patient with multiple attacks of diverticulitis or recurrent diverticulitis is individualized to minimize the morbidity and mortality of intervention. Factors considered when deciding whether to proceed with resection include patient's age; number, severity, and interval of attacks; rapidity and degree of response to medical therapy; and persistence of symptoms after an acute attack. The risk of recurrent symptoms after an attack of diverticulitis ranges from 7% to 45%. With each episode, the patient is less likely to respond to medical therapy (70% respond to medical therapy after first attack vs. 6% after third). Thus, after two attacks of uncomplicated diverticulitis, resection is usually recommended (ASCRS, 2000).

KEY TREATMENT

Patients who can tolerate a diet and do not have systemic symptoms or significant peritoneal signs may be treated as outpatients with TMP-SMX or a fluoroquinolone plus metronidazole (Gilbert et al., 2009) (SOR: B).

Surgery may be necessary in some patients both in uncomplicated and complicated diverticulitis and should be individualized (Stollman and Raskin, 2004) (SOR: B).

Celiac Disease

Key Points

- Tests to consider in testing for celiac disease include transglutaminase IgA, antiendomysial antibody, antigliadin antibody, and the genetic test HLA DQ2/DQ8.
- A negative HLA DQ2/DQ8 test is most helpful in ruling out celiac disease. A positive test does not rule it in but is associated with an increased risk.
- Consider an elimination/challenge diet for 2 weeks. If symptoms improve, a rechallenge with gluten-containing foods will cause a recurrence of symptoms.
- The antibody tests (TTG IgA, antiendomysial, antigliadin) can become negative after elimination of gluten protein and may be false negative.

Adult presentation of celiac disease is characterized by weight loss, diarrhea, fatigue, and anemia. Children frequently present with failure to thrive, vomiting, diarrhea, muscle wasting, signs of hypoproteinemia including possible ascites, and general irritability. Common comorbidities include type 1 diabetes mellitus, cerebral calcifications, Sjögren's syndrome, and thyroid disease. Celiac disease should be considered in cases of unexplained folic acid, iron or B₁₂ deficiency, reduced serum albumin, osteoporosis, and osteomalacia.

Other presentations may include infertility or recurrent miscarriage. Splenic atrophy commonly occurs in celiac sprue, and pneumococcal immunization should be administered in these patients.

Immunoglobulin A (IgA) antiendomysial antibodies are currently the most accurate serologic test for diagnosing celiac sprue with a sensitivity of 97% to 100% and specificity of 98% to 99%. Antigliadin antibodies are also usually quantified. Enzyme tissue transglutaminase, the antigen for antiendomysial antibodies, has a sensitivity of 95% and specificity of 94% in diagnosing celiac disease (AGA, 2006). HLA testing can now be done to evaluate persons at risk for celiac disease. About 95% of celiac patients are positive for HLA-DQ2 and 5% for HLA-DQ8. The majority of people who test positive for HLA-DQ2/DQ8 are at risk, but only 2% to 3% actually develop celiac disease. Celiac disease is rarely seen with a negative test, and thus this test is most useful when negative. A positive test does not make the diagnosis. A CBC, comprehensive biochemical profile including serum albumin concentration, transferrin saturation, serum or RBC folate, vitamin B₁₂, and liver function tests should also be obtained on diagnosis. Deficiencies of iron, folic acid, calcium, and vitamins B₁₂ and D frequently often correct after initiating a gluten-free diet, without the need for vitamin supplementation.

The diagnostic standard for celiac disease is a small intestinal biopsy using endoscopy, although this is usually not necessary to establish an accurate diagnosis. Characteristic changes include damage to the normal villous morphology with decreased villous height/crypt depth, decreased epithelial surface cell height, and increased lymphocytic infiltration of the intestinal mucosa. The accepted AGA diagnostic criteria state that small intestinal mucosa should be abnormal while patients continue on a gluten diet. A repeat biopsy should be taken 4 to 6 months after induction of treatment, and if there has been no improvement in the small intestinal mucosal morphology, the original diagnosis should be questioned. Many gastroenterologists do not obtain a subsequent biopsy specimen, and the cost-effectiveness of this approach has not been demonstrated. A gluten challenge is recommended if there is any doubt concerning the correct diagnosis (AGA, 2006).

The AGA guidelines state that the cornerstone of treatment of celiac disease and its resultant complications is gluten-free diet therapy under a nutritionist's guidance. Patients should completely omit wheat, rye, barley, beer, and breakfast cereals from their diet. It is important to explain the disease process and toxicity of gluten-containing foods to the patient, including the potential for the reversal of current celiac-related problems, including anemia, depression, and infertility. Gluten-free breads, pasta, and other products are commercially available and should be recommended as substitutes. Patients with celiac disease usually experience rapid symptomatic improvement within weeks of the exclusion of dietary gluten, providing additional diagnostic confirmation. Monitoring of antiendomysial or tissue transglutaminase antibody (TTG IgA) titers, which usually normalize with the institution of a gluten-free diet, may prove useful to check dietary compliance, but have neither become standard practice nor been cost-effective. Life-threatening hypokalemia or hypomagnesemia rarely occurs and should be appropriately corrected. Expert panels suggest that yearly weight, CBC,

ferritin, folate, calcium, and ALP levels should be obtained for disease monitoring. Oral corticosteroids may be used in unresponsive patients, but only when other causes of small intestinal villous atrophy have been excluded (AGA, 2006).

Dermatitis herpetiformis is a common extraintestinal manifestation of gluten-sensitive enteropathy, characterized by a pruritic, blistering, and vesicular rash. The diagnosis is made with immunofluorescent staining of granular IgA after skin biopsy. Treatment involves oral dapsone and a gluten-free diet, and with sufficient symptom relapse after 6 months, dapsone can be withdrawn and the gluten-free diet continued indefinitely. Osteopenia and osteoporosis, as well as bone pain, pseudofractures, and orthopedic deformities, are common features of celiac disease. Osteoporosis carries a significant fracture risk, and thus dual-energy x-ray absorptiometry (DEXA) screening of patients with celiac disease is recommended yearly. If osteoporosis is discovered, measures include strict adherence to a gluten-free diet, calcium supplementation of up to 1500 mg/day, bisphosphonate or calcitonin therapy, or consideration of hormone replacement therapy in postmenopausal women. Smoking cessation should be encouraged and an exercise regimen advised in all patients. Ulcerative jejunitis is a serious complication of celiac disease that carries a high mortality risk after intestinal hemorrhage, perforation, or obstruction in patients with a history of significant malnutrition. Diagnosis can be challenging, and small intestine radiography often is not helpful. If small intestinal ulceration or lymphoma is suspected, enteroscopy may be used to obtain biopsy specimens for histologic assessment. Surgical resection of the ulcer, especially if localized to one part of the intestine, can be curative. Again, a strict gluten-free diet should be initiated, and treatment with steroids has shown significant benefit. If a diagnosis of enteropathy-associated T-cell lymphoma is made, the patient should be referred to an oncologist for appropriate chemotherapy.

Overall mortality risks are higher in patients with celiac disease, attributed to malignant intestinal lymphoma and adenocarcinoma. One study found a fivefold increased risk of developing malignancy in patients with celiac disease, with a relative risk of 40 for developing non-Hodgkin's lymphoma. These risks decreased to the level of the normal population after patients maintained a gluten-free diet for 5 years (AGA, 2006).

Colorectal Cancer

Key Points

- Average-risk individuals should begin colorectal cancer screening at age 50, and at age 45 in African Americans.

Colorectal cancer (CRC) is the third leading cause of cancer mortality in the United States, accounting for an estimated 9% of all cancer deaths in 2009. Risk factors include increasing age, a family history of CRC, obesity, sedentary lifestyle, a diet high in red meat and low in vegetables, and excessive alcohol and/or tobacco use. Diets high in fiber, fruits, vegetables, and calcium may be protective, but data are inconclusive. African Americans have a 50% higher likelihood of dying from CRC than Caucasians, because they may

have more proximal distribution of colonic adenomas and carcinomas than the general population, and these may be missed more often on suboptimal screening (ACS, 2009).

Approximately 75% of CRCs are diagnosed in individuals who have no risk factors other than advanced age; 90% of patients are older than 50. Other risk factors include prior or family history of CRC or adenomatous polyps, chronic IBD, and genetic syndromes. Several case-control and cohort studies found an inverse association between physical activity and risk in men and women of all ages and in various racial and ethnic groups in diverse geographic areas worldwide. The long-term use of aspirin may be associated with a decreased risk of CRC, yet the risk/benefit profile for chemoprevention cannot justify broad recommendations for its use in the general population (Nease, 2004).

Up to 30% of CRCs are believed to arise secondary to a genetic predisposition. Approximately 20% of cases occur among patients who have a history of CRC in a first-degree relative. About 6% are attributable to identifiable, inherited genetic mutations known as *hereditary colorectal cancer syndromes*, including familial adenomatous polyposis (FAP) and hereditary nonpolyposis colorectal cancer (HNPCC). Although these syndromes are relatively uncommon, they confer a lifetime risk of CRC ranging from 80% to 100%.

Currently accepted methods for screening of CRC include the digital rectal examination (DRE), fecal immunochemical test (FIT), double-contrast barium enema (DCBE), flexible sigmoidoscopy, and colonoscopy. According to the AGA, "the relative virtues of each screening test can be debated, but the best test is that one that gets done" (Burt et al., 2004). Screening should begin by classifying a patient's level of risk based on personal, family, and medical history, which together determine the approach to screening in that person. **Box 38-9** details current CRC screening recommendations.

The DRE is a simple, inexpensive, and minimally invasive test that can be routinely performed in the office during yearly health maintenance examinations. It allows for palpation of the internal anal canal and examination of the prostate. Along with DRE, FIT should be performed to assess for occult blood. The DRE itself has a very low diagnostic yield, identifying less than 10% of colorectal tumors. Sensitivity of DCBE varies widely, ranging from 50% to 80% for polyps less than 1 cm, 70% to 90% for polyps greater than 1 cm, and 55% to 85% for Dukes stage A and B colon cancers (Winawer et al., 1997). In a comparison study with colonoscopy, sensitivity of barium enema for neoplasia was significantly lower (32% for polyps \leq 5 mm, 53% for polyps 0.6-10 mm, 48% for polyps $>$ 1 cm) (Winawer et al., 2000). Any suspected lesions identified by DCBE need to be confirmed, biopsied, and removed by colonoscopy. Rarely, the classic "apple core" hallmark sign of a colonic mass may be visualized on DCBE (Fig. 38-32).

Flexible sigmoidoscopy is an efficient screening tool for individuals at an average risk for CRC, allowing for direct visualization and biopsy of the colonic mucosa in the rectosigmoid, descending, and distal transverse colon. To date, no RCTs or case-control studies have shown that screening with this method decreases CRC mortality for tumors within the reach of the standard 60-cm scope. The limitation of this method is that advanced lesions may be missed in the ascending and proximal transverse colon in individuals who

Box 38-9 Current Colorectal Cancer (CRC) Screening Recommendations

Preferred Screening Tests

Cancer prevention tests should be offered first. The preferred CRC prevention test is colonoscopy every 10 years, beginning at age 50. Screening should begin at age 45 years in African Americans.

Cancer detection test should be offered to patients who decline colonoscopy or another cancer prevention test. The preferred cancer detection test is annual FIT for blood.

Alternative CRC Prevention Tests

Flexible sigmoidoscopy every 5 to 10 years.

CT colonography every 5 years.

Alternative Cancer Detection Tests

Annual Hemoccult Sensa.

Fecal DNA testing every 3 years.

Positive Family History but HNPCC Evaluation Not Indicated

Single first-degree relative with CRC or advanced adenoma diagnosed at age 60 years or older.

Recommended screening: Same as average risk.

Single first-degree with CRC or advanced adenoma diagnosed before age 60 years, or two first-degree relatives with CRC or advanced adenomas:

Recommended screening: Colonoscopy every 5 years beginning at age 40 years or 10 years younger than age at diagnosis of the youngest affected relative

Familial Adenomatous Polyposis

Patients with classic FAP ($>$ 100 adenomas) should be advised to pursue genetic counseling and genetic testing, if they have siblings or children who could potentially benefit from this testing.

Patients with known FAP or who are at risk of FAP based on family history (and genetic testing has not been performed) should undergo annual flexible sigmoidoscopy or colonoscopy, as appropriate, until colectomy is deemed by physician and patient to be the best treatment.

Patients with retained rectum after subtotal colectomy should undergo flexible sigmoidoscopy every 6 to 12 months.

Patients with classic FAP, in whom genetic testing is negative, should undergo genetic testing for bi-allelic MYH mutations. Patients with 10 to 100 adenomas can be considered for genetic testing for attenuated FAP and if negative, MYH-associated polyposis.

Hereditary Nonpolyposis CRC

Patients who meet the Bethesda criteria should undergo microsatellite instability testing of their tumor or a family member's tumor, and/or tumor immunohistochemical staining for mismatch repair proteins.

Patients with positive tests can be offered genetic testing. Those with positive genetic testing, or those at risk when genetic testing is unsuccessful in an affected proband, should undergo colonoscopy every 2 years beginning at age 20 to 25 years, until age 40 years, then annually thereafter.

Modified from Rex DK, Johnson DA, Anderson JC, et al. American College of Gastroenterology guidelines for colorectal cancer screening 2008. *Am J Gastroenterol* 2009;104:739-750.

CT, Computed tomography; FAP, familial adenomatous polyposis; FIT, fecal immunochemical test; HNPCC, hereditary nonpolyposis colorectal cancer.

do not have distal polyps. Although advocated as being more convenient than colonoscopy, because it is generally done in the office without the need for conscious sedation, only an estimated 30% of eligible patients undergo screening with flexible sigmoidoscopy (Nease et al., 2004). If polyps are identified during flexible sigmoidoscopy, a full colonoscopy is required to visualize the remaining colonic segments and to remove any remaining identified polyps.

Colonoscopy provides the most complete visualization of the entire colon and is the gold standard test for CRC screening. Since greater than half of all individuals who have advanced proximal adenomas may not have distal polyps, many investigators advocate the use of colonoscopy as the primary modality for CRC screening. The removal of precancerous adenomas decreases CRC incidence by as much as 76% to 90% compared with no screening methodology (Figs. 38-33 and 38-34). One study using colonoscopy as a screening tool in U.S. military veterans discovered advanced villous adenomas in 10.5% of subjects (Fig. 38-35). Colonoscopy carries a higher risk of adverse events attributed to therapeutic interventions such as biopsy and polyp removal, compared to FIT, DCBE, and flexible sigmoidoscopy, specifically bowel perforation and postpolypectomy hemorrhage.

Newer modalities for CRC screening are being developed. Virtual colonoscopy, or CT colonography, uses thin-section helical CT scans to generate high-resolution two-dimensional images that are reconstructed into three-dimensional images of the colon to evaluate for the presence of polyps. Direct comparison of CT colonography to colonoscopy in asymptomatic adults has shown sensitivity and specificity for polyp detection comparable to that of colonoscopy for polyps larger than 6 mm. CT colonography may be viewed as a more acceptable approach for CRC screening because it is less invasive and requires less time, without the potential adverse risks of sedation or bowel perforation. Most patients prefer conventional colonoscopy, reporting more pain, more

Figure 38-33 Precancerous adenomas. (Courtesy Dr. Erik-Jan Wamsteker.)

discomfort, and less respect from staff with CT colonography. As with conventional colonoscopy, CT colonography is limited by quality of the bowel preparation, procedural cost, lack of insurance coverage, variable physician training, and procedural time.

Capsule endoscopy is another emerging technology in the detection of CRC. The patient fasts overnight, ingests a disposable capsule, and begins water intake 2 hours after the capsule is ingested; the capsule is usually expelled within 48 hours of ingestion. The recorded information from the capsule is then downloaded and reviewed for abnormal

Figure 38-34 Precancerous adenomas. (Courtesy Dr. Erik-Jan Wamsteker.)

Figure 38-35 Advanced villous adenomas. (Courtesy Dr. Erik-Jan Wamsteker.)

pathology. Capsule endoscopy has become an accepted method for screening the small intestine for obscure GI bleeding. For colonic imaging, however, its use has been limited because of the larger colonic diameter, residual stool, and limited battery life of the capsule.

KEY TREATMENT

The removal of precancerous adenomas can significantly decrease colorectal cancer incidence by as much as 76% to 90% (Winawer et al., 1993) (SOR: A).

Overview

Key Point

- Iron deficiency anemia is more prevalent in children, women, and older adults.

Family physicians develop communication styles and relationships with patients and families that facilitate the physician's ability to define and prioritize patient problems, develop diagnostic and treatment plans for more common problems, and coordinate patients' care of less common problems with the rest of the health care system. Recognizing this primary function, the family physician needs to know how to diagnose a variety of conditions, understand their pathophysiology, know when and how to treat more common disorders, and know how to diagnose and refer more unusual disorders. This chapter organizes the subject of hematology by cellular, elemental, and functional categories; delineates the pathophysiology of hematologic disorders; and discusses the recognition, diagnostic criteria, and treatment of disorders more likely to be seen in family medicine.

Hematology is the study of the cellular elements of the blood—their origins, functions, and disorders. The frequency with which these disorders are discovered and treated in primary care varies with the population being served. The National Ambulatory Medical Care Survey of the 15 to 20 major diagnostic clusters seen in primary care practice by age group mentions only “anemia” in the cluster table of visits made by patients age 75 years and older (Woodwell and Cherry, 2004). In the National Health and

Nutrition Examination Survey (NHANES 1999–2000), the prevalence of *iron deficiency anemia* was 7% in 1- to 2-year-old and 12% in 12- to 49-year-old females, versus 3% to 5% in 12- to 60-year-old males (NCHS, 2005a). This remains largely unchanged. In a practice largely populated by younger African American patients, predominantly women of child-bearing age, the prevalence of sickle cell anemia and iron deficiency anemia would be greater than in more heterogeneous populations. Disorders of white blood cells, such as neutropenia and leukemia, are encountered infrequently in most primary care practices. Nonetheless, understanding the presentation of uncommon disorders and their pathophysiology, diagnostic criteria, and treatment principles is imperative for a competent family physician.

Hematopoiesis: Regulation of Cellular Elements of Blood

Key Points

- Stem cells have self-renewal capability and differentiate into red blood cells, granulocytes, monocytes, lymphocytes, and platelets.
- Red cell production is controlled by erythropoietin and white cell production by granulocyte colony-stimulating factor.

Blood cell production normally takes place in the bone marrow, and all the circulating cellular elements of the blood arise from the level of a pluripotent hematopoietic stem cell (Fig. 39-1). Hematopoietic stem cells have two important properties, extensive self-renewal and ability to differentiate and mature into red blood cells, granulocytes

Figure 39-1 Common cellular elements seen in bone marrow aspirate, including plasma cell, polymorphonuclear neutrophil and band, eosinophil, and nucleated red blood cell. (From the American Society of Hematology Image Bank image #505. Copyright 1996 American Society of Hematology, used with permission.)

(neutrophils, eosinophils, basophils), monocytes, platelets, and lymphocytes (T cells, B cells, and NK cells). Little is known about the molecular mechanisms that control self-renewal, but this ability of stem cells is critical to the success of treatments such as bone marrow transplantation. More is known about the factors that control hematopoietic differentiation and maturation.

Hematopoietic stem cells are rare in number, estimated at approximately 1 in 1×10^6 bone marrow cells, or 0.05% of all marrow cells. The fact that they exist at all is best defined by their ability to support bone marrow regrowth after stem cell transplantation or marrow recovery after severe marrow suppression from chemotherapy or radiation. Two major lineages arise from the pluripotent hematopoietic stem cell: the common *myeloid* progenitor cell and the common *lymphoid* progenitor cell. Lymphopoiesis then proceeds to the differentiation of T cells, B cells, natural killer (NK) cells, and some dendritic cells. The common myeloid progenitor gives rise to red cells, granulocytes of all types, monocytes and macrophages (and some dendritic cells), and platelets.

The regulation of the terminal stages of hematopoietic differentiation and maturation is under the control of a variety of hormones and cytokines. Red cell production is under the control of erythropoietin (EPO), a glycoprotein hormone secreted by the kidney in response to hypoxia or anemia. Neutrophil production is under the control of granulocyte colony-stimulating factor (G-CSF). Eosinophil production is under the control of interleukin-5 (IL-5). Monocyte and macrophage production is under the control of macrophage colony-stimulating factor (M-CSF) and, to a lesser extent, granulocyte-macrophage colony-stimulating factor (GM-CSF). Platelet production is under the control of thrombopoietin (TPO), produced in the liver. TPO also stimulates proliferation and release of hematopoietic stem cells. Of these various growth factors, EPO and G-CSF have important uses clinically; TPO is under clinical development. The number of cellular elements in the blood is tightly controlled by these regulatory hormones. **Table 39-1** shows the normal ranges for the various cellular elements of the blood in adults.

Table 39-1 Cellular Elements of the Blood (Adult)

| Red Blood Cells (RBCs) | Men | Women |
|--|--------------------------|----------------|
| Hematocrit (%) | 46.0 \pm 4.0 | 40.0 \pm 4.0 |
| Hemoglobin (g/dL) | 15.7 \pm 1.7 | 13.8 \pm 1.5 |
| RBC count ($\times 10^6/\mu\text{L}$) | 5.3 \pm 0.7 | 4.6 \pm 0.5 |

| Basophils | 0-150 | 0-1.5 |

Disorders of Red Blood Cells

Key Points

- The RBC mass reflects the oxygen-carrying capacity of the body.
- Oxygen supply depends on RBC mass, lung function, circulatory system, supply of EPO, and bone marrow.

The major role of the red blood cell (RBC, erythrocyte) is to transport oxygen from the lungs to the tissues and organs in the body. This is accomplished by the reversible binding of oxygen to the heme moiety of the hemoglobin molecule. Hemoglobin (Hb) is the most prominent RBC protein. The functional ability of the Hb molecule is determined by primary amino acid structure, pH (Bohr effect), temperature, and intracellular concentration of 2,3-bisphosphoglycerate (2,3-BPG). Abnormalities of Hb function most frequently result from mutations (amino acid substitutions) in one

or more of the globin genes. These mutations, such as the mutation that causes sickle cell disease, can alter the stability of the Hb molecule or its oxygen-binding properties. Many of these mutations result in tissue hypoxia because the instability of the molecule results in the early death of the RBC in circulation (hemolysis). Other Hb mutations can affect oxygen binding and release or can produce free-globin chains that may bind to the inner RBC membrane, resulting in membrane instability (Heinz bodies). Hemoglobin is also recognized as the major “sink” of nitric oxide (NO) in the blood. This has important implications for the control of vascular tone in the microcirculation.

Under normal conditions, regulation of erythropoiesis can be viewed as a positive control loop. Red cell production is regulated by EPO. Production of EPO occurs primarily in the kidney, although a small amount is produced by the liver; this is a holdover from fetal life, when the liver was the major source of EPO production. EPO stimulates RBC production by binding to specific receptors on the surface of erythroid progenitor cells in the marrow. This activates a number of cell division steps that results in approximately 16 to 32 mature RBCs for each progenitor cell stimulated. These new RBCs leave the bone marrow and circulate for about 120 days as mature cells. The circulating red blood cells make up the RBC mass.

The RBC mass represents the oxygen-carrying capacity of the body. As RBCs traverse the circulation, the cells provide oxygen for all metabolic functions. In the kidney, oxygen availability is sensed by specialized peritubular capillary lining cells. The sensing mechanism is mediated by hypoxia-inducible factor 1 α (HIF-1 α). The adequacy of the oxygen supply depends not only on RBC mass, but also on normal lung function, a normal circulatory system that allows RBCs to be delivered effectively to all parts of the body, an adequate supply of EPO to stimulate RBC production, and a normally functioning bone marrow. Abnormalities in any of these factors can affect RBC production and result in anemia (too few RBCs) or erythrocytosis (too many RBCs).

Anemia

Key Points

- Anemia is a reduced RBC mass, resulting in decreased oxygen-carrying capacity of the blood (>2 SD from mean for age, gender, and race).
- Patients with unrecognized anemia often present with symptoms of fatigue, loss of stamina, shortness of breath, and tachycardia (with exercise).
- Acute blood loss or anemia is almost always caused by hemorrhage or hemolysis.
- Loss of 30% of blood volume results in postural symptoms; loss of 40% blood volume produces signs of shock.
- Bone marrow responsiveness to anemia is best evaluated by reticulocyte index and marrow production index.
- Anemias can be best understood by classifying them into three types: hypoproliferative anemia, maturation disorders, and hemolytic-hemorrhagic anemia.
- Anemia of chronic disease is a hypoproliferative anemia now referred to as the anemia of inflammation (AI).

- Serum ferritin is normal or increased in AI and low in true iron deficiency
- Treatment of folate deficiency with alcoholic neuropathy without confirming vitamin B₁₂ deficiency may result in a progressively worsening neuropathy.
- Values below lower limits of normal for age/gender indicate only 25% likelihood that the person is *not* anemic.
- If creatinine is greater than 2 mg/dL and no other cause for anemia can be found, the anemia probably results from renal inefficiency.
- Bilirubin gallstones occur in 40% to 60% of sickle cell disease patients.
- The absence of free haptoglobin is diagnostic of hemolytic anemia.
- Sickle cell disease is a form of hemolytic anemia; thrombosis is more common in children, whereas hemorrhage occurs more often in adults with sickle cell disease.
- Coombs test is the diagnostic choice for autoimmune hemolytic anemia.

Definition

Anemia is best defined as a reduced RBC mass resulting in decreased oxygen-carrying capacity of the blood. [Table 39-1](#) lists normal values for hemoglobin and hematocrit (Hct); values below the lower limits of normal for age and gender indicate only 25% likelihood that the person is not anemic. Previous Hb and Hct values for a given patient are useful comparisons when interpreting currently determined levels. Both pregnant women and long-distance athletes may have increases in plasma volume so that the Hct or the Hb value, or both, fall artificially below normal ranges. They still have a normal oxygen-carrying capacity with a normal RBC mass and should not be considered anemic. Conversely, a dehydrated patient admitted to the hospital may have Hb or Hct that appears normal because of plasma volume contraction. Correction of their volume-depleted state will allow appropriate determination of their true RBC oxygen-carrying capacity. When Hct or Hb is abnormal, further investigation is indicated, whether or not the subject appears clinically well.

Prevalence

Mean hemoglobin concentration for all U.S. males older than 1 year is 14.67 g/dL, and for females older than 1 year, 13.19 g/dL (NHANES-III; NCHS, 2005b). These values vary by ethnic group; non-Hispanic white males had mean Hb of 14.05 g/dL, versus 13.87 g/dL for Mexican Americans and 13.14 g/dL for African Americans. Hb values for African American men and women are 1 g/dL lower than their white counterparts. The median Hb concentration was the same for both genders in all race and ethnic groups younger than 9 years. Mean Hb level tends to peak at 15.4 g/dL between ages 20 and 29 years and decreases to 14.36 g/dL by age 70. Anemia is defined as Hb level more than 2 standard deviations (SD) from the mean for age and race for the entire population.

The most prevalent cause of anemia in the United States is iron deficiency. [Table 39-2](#) categorizes the prevalence of iron deficiency and iron deficiency anemia (NHANES-III,

† $p \geq 0.05$ for survey comparisons.

1988–1994, 1999–2000; NCHS, 2005a, 2005b). The prevalence of iron deficiency is 9% and of iron deficiency anemia 3%, in both genders age 1 to 2 years. The prevalence for children age 3 to 5 years is 3% for iron deficiency and less than 1% for iron deficiency anemia; those 6 to 11 years old have a 2% prevalence of iron deficiency and less than 1% for iron deficiency anemia. The prevalence of iron deficiency in the nonblack population is 1% lower than the prevalence in all races combined. Women have a much higher prevalence; those age 12 to 15 have 9% prevalence of iron deficiency and 2% for iron deficiency anemia; those age 16 to 19 have 11% and 3% prevalence; women 20 to 49 years, 11% and 5%; and those 50 to 69 years, 5% and 2%, respectively. In women over age 70, prevalence of iron deficiency rises to 7% and iron deficiency anemia to 2%. Males in general have less than a 1% prevalence of iron deficiency or iron deficiency anemia until age 50, when the prevalence of iron deficiency rises to 2%. In those older than 70, prevalence of iron deficiency is 4% and iron deficiency anemia 2%.

In a comparative study (Netherlands, Japan, Poland, United States) of diagnostic encounters, blood disorders comprised 1% of all encounters, and iron deficiency was the 27th most frequent diagnosis seen in all four countries (Okkes et al., 2002). Anemia is the most frequent hematologic disorder seen in family medicine and occurs often enough that knowledge of RBC function, classification of RBC disorders, evaluation of laboratory data, and treatment of common anemias constitute an important part of the knowledge base of the competent family physician.

Clinical Features

Anemia is most often recognized by abnormal screening laboratory test results. Much less frequently, patients will present to their family physician with previously unrecognized anemia, complaining of fatigue, loss of stamina, shortness of breath, and rapid heart rate (particularly with physical exercise). In younger patients, if the anemia comes on gradually,

several compensatory mechanisms help maintain tissue oxygenation. These include peripheral vasodilation, increased cardiac output, a change in the oxygen-hemoglobin dissociation curve that facilitates oxygen unloading in the tissues, and shunting of blood away from circulation-rich organs (e.g., gut, skin, kidney) to critical organs (e.g., heart, brain).

Physicians must recognize that the signs and symptoms of anemia will be determined in part by the acuteness of onset. Acute anemia is almost always caused by blood loss or hemolysis. If blood loss is mild, enhanced oxygen delivery is achieved through changes in the oxyhemoglobin dissociation curve and in hemodynamics. With acute blood loss, however, the changes in blood volume dominate the clinical picture, and Hct and Hb levels do not reflect the volume of blood lost for at least 48 hours. Signs of vascular instability appear with acute blood losses of 10% to 15% of the total blood volume. In such patients, management issues are related not to the anemia, but to hypotension and decreased organ perfusion. When more than 30% of the blood volume is lost suddenly, patients are unable to compensate with the usual mechanisms of vascular contraction and changes in regional or organ blood flow. The patient prefers to remain lying flat and will show postural hypotension and tachycardia if placed in an upright position. If the volume of blood loss is more than 40% (>2 L in average-sized adult), signs of shock are prominent, including confusion, air hunger, sweating, hypotension, and tachycardia. These patients have significant deficits in vital organ perfusion and require immediate volume replacement.

For the family physician, certain disorders are associated more often with anemia. These include chronic inflammatory states (e.g., infection, rheumatoid arthritis, cancer) associated with mild to moderate anemia, whereas lymphoproliferative disorders (e.g., chronic lymphocytic leukemia, other B-cell neoplasms) may be associated with immune-mediated hemolysis.

Laboratory Evaluation

Key laboratory tests in the office evaluation of the anemic patient include complete blood count (CBC), reticulocyte count, and iron studies (Box 39-1). The laboratory evaluation of anemia is designed primarily to determine effective response of the bone marrow to the anemia stimulus and to detect any disturbance in iron metabolism; this information allows physiologic classification of the most common anemias. The evaluation of the marrow's response to anemia is best approximated through corrected reticulocyte count (Fig. 39-2), which provides information about the number of newly released RBCs in circulation. Normally, a newly released RBC can be seen as a reticulocyte for about 24 hours. The reticulum of a reticulocyte is made up of residual ribosomal ribonucleic acid (RNA); the cell is somewhat larger and appears bluer than mature RBCs on a Wright-Giemsa-stained peripheral blood smear.

First, however, the raw reticulocyte percentage must be corrected if it is to reflect the marrow production index. The first correction of the reticulocyte count is for dilution, as shown by the following equation for determining reticulocyte index (RI):

$$\text{RI} = \text{Reticulocyte count (\%)} \\ \times (\text{Patient's Hb or Hct}) / (\text{Normal Hb or Hct})$$

Box 39-1 Laboratory Tests in Office Evaluation of Anemia

1. Complete blood count (hemoglobin, hematocrit, red cell indices [MCV, MCH, MCHC], white cell count, and differential, platelet count)
2. Reticulocyte count (appropriately corrected)
3. Studies of iron status, including serum iron level, total iron-binding capacity (from which transferrin saturation [%] is calculated), and serum ferritin level

MCV, Mean corpuscular volume; MCH, mean cell hemoglobin; MCHC, mean cell hemoglobin concentration.

Figure 39-2 An increased number of reticulocytes are seen on a peripheral blood smear stained for reticulocytes. (From the American Society of Hematology Image Bank image #1333. Copyright 1996 American Society of Hematology, used with permission.)

The normal reticulocyte count is 1% to 2% and the normal RI is 1.0. This correction is not necessary if the laboratory reports reticulocyte count as an absolute number, normally about 40,000 to 50,000 cells/ μL .

A further correction of the reticulocyte count is necessary if there is evidence from the peripheral blood smear that reticulocytes are being released prematurely from the bone marrow (shift cells or shift reticulocytes). Under these circumstances, reticulocytes live longer than the usual 24 hours in circulation, and thus the uncorrected reticulocyte count will overestimate the rate of new cell production. The second correction is shown by the equation for determining the marrow production index: $\text{MPI} = \text{RI}/2$. The normal MPI value is 1.0. The RI is divided by a factor of 2 to account for the prolonged reticulocyte life span in the circulation.

For example, if the reticulocyte count is 15% and Hct is 15%, there is evidence of shift reticulocytes on the peripheral smear. The MPI can be calculated as follows:

$$\text{MPI} = ([15\% \times 15\%] / 45) / 2 = 2.5$$

Also critical to understanding the pathophysiology of most anemias is to characterize the availability of iron for hemoglobin synthesis. This is done by measuring the serum iron level, total iron-binding capacity (TIBC), and serum ferritin level. Transferrin saturation percent is the proportion of iron binding sites occupied by iron atoms, reflecting the amount of iron immediately available for Hb synthesis, and is very labile. Serum ferritin is an indirect reflection of the body's

total iron stores and is more stable. These values provide information about the two most common forms of anemia seen in the hospital or in the family physician's office—iron deficiency anemia and the anemia of chronic inflammation.

Physiologic Classification

The physiologic classification of anemia is based on response of the bone marrow. The three major categories are hypoproliferative anemia, maturation disorders (ineffective erythropoiesis), and hemolytic-hemorrhagic anemia (Box 39-2).

Hypoproliferative Anemia

In hypoproliferative anemias the response of the bone marrow is impaired by one of three general mechanisms. The first is *marrow damage*, which results from an injury to the bone marrow and makes it impossible for the marrow to respond to adequate EPO stimulation. Aplastic anemia is a classic example, but chemotherapy-induced marrow aplasia is more common (Box 39-3). The physiologic hallmark of marrow damage is a low RPI (<2 at Hb >10 g/dL; <2.5 at Hb of 7-10 g/dL). EPO is typically elevated, with evidence of premature release of reticulocytes from the bone marrow (shift reticulocytes, including nucleated RBCs in some cases). Despite EPO stimulation, however, the bone marrow is unable to proliferate. Bone marrow examination may reveal an empty or hypocellular marrow or one replaced by tumor cells or fibrosis. Treating these patients with recombinant human EPO is rarely useful.

A second mechanism of hypoproliferation is *inflammation*, which is the most common form of anemia seen in hospitalized patients. Often referred to as the "anemia of chronic disease" (ACD), it has more recently been termed the *anemia of inflammation* (AI) (Weiss and Goodnough, 2005). The anemia associated with inflammatory states is complex and involves altered iron homeostasis as well as decreased EPO production and an impaired response of erythroid progenitor cells in the marrow to EPO. Inflammation comes in many forms in addition to acute and chronic infection. Also

associated with changes consistent with AI is tissue damage, as caused by necrosis, surgery, myocardial infarction, and other tissue injury.

The major effect of AI is on iron metabolism. With inflammation, iron absorption from the gut is blocked, as is iron release to transferrin from reticuloendothelial stores. The net effect is a decrease in the serum iron level and in transferrin saturation. This results in an inadequate supply of iron to the erythroid marrow for hemoglobin synthesis. Over time, the clinical picture (e.g., microcytic, hypochromic RBCs) may come to resemble true iron deficiency anemia, despite the fact that iron stores in the body are normal or increased. The mediator of these alterations in iron metabolism is *hepcidin*, a small molecule made in the liver that is critical to iron homeostasis and that is upregulated in the presence of inflammation. Hepcidin interferes with the cellular iron export protein *ferroportin*. The ferroportin pathway is the mechanism by which iron absorbed from the diet is shunted through the gut and reticuloendothelial cells and released to circulating transferrin. Iron regulatory proteins (IRP-1 and IRP-2) also play a role in balancing iron storage as well as circulating iron. Although there are many similarities to iron deficiency, providing iron in this setting is generally ineffective. Recombinant human EPO (epoetin) may stimulate RBC production, but the approach to treatment is primarily to identify and reverse, if possible, the inflammatory trigger.

In addition to changes in iron homeostasis, inflammation results in the release of proinflammatory cytokines such as IL-1, tumor necrosis factor alpha (TNF- α) and interferon γ (IFN- γ). These cytokines have many effects on erythropoiesis, such as decreasing EPO production and blunting the response of erythroid progenitors in the marrow to EPO. All these changes result in marrow hypoproliferation and an inadequate marrow response to anemia.

The third major category of hypoproliferative anemia is that associated with *inadequate EPO production*, which results in understimulation of the marrow. Typically, this is seen in patients with chronic renal insufficiency whose diseased kidney cannot produce EPO despite often profound anemia. The advent of successful renal replacement therapy (peritoneal or hemodialysis) has resulted in an increasingly large population of severely and chronically anemic patients. For these patients, epoetin therapy has been lifesaving in terms of quality of life and overall health.

Box 39-2 Classification of Anemias

Hypoproliferative anemias

- Aplastic anemia
- Anemia of inflammation
- Chronic renal insufficiency
- Hypothyroidism
- Mild iron deficiency

Maturation disorders

- Megaloblastic anemias
- Myelodysplasia
- Severe iron deficiency
- Thalassemia syndromes

Hemolytic-Hemorrhagic anemia

- Autoimmune hemolysis
- Drug- or chemical-induced hemolysis
- Acute or chronic blood loss
- Sickle cell anemia

Box 39-3 Mechanisms of Marrow Damage

Aplasia

- Drug-induced (immunologic)
- Gold
- Benzene
- Autoimmune (idiopathic aplastic anemia)
- Chemotherapy
- Congenital anemia (Fanconi's, Blackfan-Diamond)

Marrow replacement

- Metastatic malignancy
- Leukemia
- Fibrosis

In the family physician's office, the question often is how much anemia can be ascribed to mild or moderate renal insufficiency. There is no easy answer, but generally, if the creatinine level is higher than 2 mg/dL with no other obvious or reversible cause for the anemia (blood loss, hemolysis after appropriate testing), it is reasonable to ascribe the anemia to renal insufficiency.

Another pathologic process resulting in inadequate EPO stimulation is *hypometabolism*, particularly hypothyroidism. The anemia may reflect a reduced need for oxygen-carrying capacity because of the reduced metabolic load resulting from the thyroid hormone deficiency.

Mild iron deficiency anemia also is associated with a hypoproliferative marrow response. Iron deficiency, with mild to moderate anemia, impairs the erythroid marrow response. If the anemia is mild, circulating RBCs are normocytic or slightly microcytic, and the red cell distribution width (RDW) index is normal (Fig. 39-3). The serum iron is usually low, transferrin saturation less than 15%, and serum ferritin less than 15 ng/mL.

Table 39-3 compares anemia of inflammation and classic iron deficiency anemia. The major difference is the serum

Figure 39-3 Hypochromic, microcytic red blood cells, with anisocytosis. (From the American Society of Hematology Image Bank image #1214. Copyright 1996 American Society of Hematology, used with permission.)

Table 39-3 Comparison of Anemia of Inflammation and Iron Deficiency Anemia

| Iron Deficiency | Anemia of Inflammation |
|--------------------------------------|---|
| Low serum iron level | Low serum iron level |
| Elevated TIBC | TIBC normal or reduced |
| Transferrin saturation low (<15%) | Transferrin saturation low (15%-20%) |
| Serum ferritin level low (<15 ng/mL) | Serum ferritin level normal or elevated |
| Microcytic, hypochromic RBCs | Normocytic to microcytic RBCs |
| RBC protoporphyrin level elevated | RBC protoporphyrin level elevated |

TIBC, Total iron-binding capacity; RBCs, red blood cells.

ferritin level, which is typically normal or increased with AI and characteristically low with true iron deficiency. Making this distinction is important because the mechanisms that lead to inflammation or iron deficiency are generally distinct, as is the approach to treatment.

Maturation Disorders

Maturation disorders are characterized by adequate EPO stimulation and erythroid marrow hyperplasia, but in the absence of a sufficiently increased reticulocyte production index. Under these conditions, premature cell death (apoptosis) takes place in the marrow, and a mismatch occurs between degree of erythroid hyperplasia on bone marrow aspiration or biopsy and the reticulocyte (effective) production index. Consequently, RBC production in such patients is considered ineffective and can involve nuclear or cytoplasmic maturation defects.

Nuclear maturation defects result in a megaloblastic bone marrow and are typical in patients with severe folate or vitamin B₁₂ deficiency. The RBCs are macrocytic, and the reticulocyte production index is normal or slightly above normal (Fig. 39-4). Examining the bone marrow of patients with vitamin B₁₂ or folate deficiency reveals increased erythroid marrow precursors and loosening of nuclear chromatin, as well as more cells with nuclear degeneration (karyorrhexis and karyolysis). These are the features of apoptosis.

Because of the degree of RBC destruction in the bone marrow, serum bilirubin may be elevated and haptoglobin decreased. It is important to distinguish between vitamin B₁₂ and folate deficiency because the pathogenesis is different and the treatment must be specific. Patients who present with folate deficiency and alcoholic neuropathy pose a particularly difficult diagnostic challenge; the neuropathy of vitamin B₁₂ deficiency should not be treated inappropriately with folic acid, because the anemia may be partly corrected with folic acid, but the neuropathy associated with vitamin B₁₂ deficiency will progress. This is rarely seen at present. The neurologic symptoms may precede the anemia, so it is important to screen older adults with unexplained memory loss for vitamin B₁₂ deficiency.

Figure 39-4 Megaloblastic changes of macrocytosis and hypersegmented neutrophils. (From the American Society of Hematology Image Bank image #2611. Copyright 1996 American Society of Hematology, used with permission.)

The diagnosis of these disorders is relatively straightforward and can be made with laboratory testing for serum vitamin B₁₂ and folate levels. RBC levels of folate may also be useful, particularly in a folate-deficient patient receiving diet therapy or an undernourished alcoholic patient being fed. Alcohol inhibits the entry of folic acid, decreasing serum folic acid levels. Thus, folic acid deficiency may result from both dietary insufficiency and inhibition of folic acid release in patients with chronic alcohol intake. Folic acid deficiency has greatly decreased since 1998, when most grains began to be fortified with folic acid in the United States.

Treatment of vitamin B₁₂ or folic acid deficiency is simply replacement with the appropriate vitamin. In patients who appear with severe megaloblastic anemia and who need treatment immediately, it is prudent to obtain blood samples, both whole blood and serum, for later diagnostic tests and then to treat the patient with both vitamins. This ensures that the anemia and central nervous system (CNS) manifestations of potential vitamin B₁₂ deficiency are adequately treated.

The *Schilling test* is useful to specify the defect leading to B₁₂ deficiency. This involves a small, oral dose of radiolabeled vitamin B₁₂ along with a large, parenteral flushing dose of B₁₂. The B₁₂ absorbed from the diet is excreted in the urine because there are no transport binding sites in the circulation. This first stage of the absorption test indicates if the patient can absorb vitamin B₁₂. The second stage is similar to the first, except the oral dose of B₁₂ is given with intrinsic factor (IF). Theoretically, the addition of IF should correct the absorption defect associated with pernicious anemia. If the absorption defect is caused by disease of the terminal ileum, both stages of the Schilling test will be positive. A host of surrogate markers for pernicious anemia include measurement of IF or anti-parietal cell antibodies. However, these markers are positive in an increasing percentage of patients as they grow older, and consequently cannot be considered definitive for the diagnosis.

Another cause of a macrocytic anemia associated with ineffective erythropoiesis is *myelodysplasia*. The myelodysplastic syndromes are primary bone marrow neoplasms, and the macrocytosis does not respond to vitamin replacement therapy. This is now an increasingly frequent diagnosis, particularly because it is a more common diagnosis in older adults and the population is aging.

Transient megaloblastic and macrocytic anemia may be seen with certain types of anticancer drugs that interfere directly with DNA synthesis and cell division. Common drugs in this category include hydroxyurea and thymidine inhibitors. Family physicians also see patients with mild anemia and macrocytosis who have a history of excessive alcoholic intake, with or without a mild to moderate degree of liver disease. The macrocytosis in these cases has two probable causes: spurious macrocytosis caused by lipid loading of the RBC membrane, and macrocytosis caused by intermittent folate deficiency associated with bouts of high alcohol consumption in the absence of other caloric intake.

Iron Deficiency

In addition to nuclear maturation defects that result in macrocytic anemia, cytoplasmic maturation defects such as severe iron deficiency occur. Extreme iron deficiency and

severe anemia may result in a pattern of ineffective RBC production. With mild anemia, iron deficiency limits erythroid proliferation, and the anemia appears to be hypoproliferative. However, as anemia becomes more profound and EPO stimulation of the marrow increases, the marrow becomes more ineffective in appearance. In either case, laboratory test results indicating low serum iron, low transferrin saturation, and extremely low ferritin are diagnostic.

Once the diagnosis of iron deficiency is definitive, the family physician needs to consider the cause. Women in their childbearing years typically have marginal iron stores, and even being an occasional blood donor may result in mild anemia, with iron deficiency. The case is different in an adult male or postmenopausal woman. Unless there is a clear explanation, gastrointestinal (GI) blood loss should be the prime suspect and must carefully be ruled out.

Treatment of iron deficiency is not always straightforward. The goal is to remedy the hemoglobin deficit and replace iron stores. Many oral iron preparations are available, but ferrous sulfate and ferrous gluconate are most often used and inexpensive. The best regimen is to give 3 iron tablets daily; this provides about 150 mg of elemental iron daily. If the patient is compliant and absorption normal, reticulocytosis will occur in a week and Hb level will increase at least 1 g/dL within 2 weeks. Microcytosis may take up to 4 months to resolve. The iron is best taken on an empty stomach because certain foods interfere with iron absorption. However, 15% to 20% of patients will have significant gastric upset with oral iron and may not be compliant. If poor absorption or noncompliance is of concern, parenteral iron may be given. Several preparations are available, including iron sucrose and iron gluconate intravenously (IV) at 125 to 250 mg/day, and have a good safety profile compared with iron dextran. In treating iron deficiency, the target for therapy is not just to correct the anemia, but also to provide some degree of iron stores, so it is recommended that iron treatment be continued for 2 to 3 months after a normal Hb level is reached.

Various preparations of ferrous salts are equally tolerated and effective for the treatment of iron deficiency anemia. Controlled-release (CR) iron formulations cause fewer GI side effects than non-CR salt preparations, but discontinuation rates are similar. Ferrous salts are the treatment of choice for iron deficiency anemia (McDiarmid and Johnson, 2002).

Hemochromatosis in hereditary form has a homozygous incidence of 0.44% and a 10% heterozygous incidence, all in populations of white European descent. Elevated transferrin saturation levels (>45%-50%) and elevated ferritin levels (>300 mg/L) are markers of increased iron stores that may indicate the need for further evaluation.

Thalassemia

Severe cytoplasmic maturation defects are usually inherited and are characteristic of the thalassemic syndromes or defects in heme synthesis. The inherited thalassemias represent a large number of mutations in the globin genes themselves or in the regulation of globin gene expression. When either the alpha or the beta globin chains are produced in unequal amounts, the excess chains aggregate and the erythroid precursor cells die, leading to ineffective erythropoiesis. β -Thalassemia produces decreased numbers of beta chains and α -thalassemia decreased alpha chains. Homozygous β -thalassemia is one of the most severe forms of

human anemia; more than 200 million people worldwide carry the β -thalassemia gene. Because of the large number of mutations that can result in thalassemia, most patients who have the clinical phenotype of homozygous thalassemia are compound heterozygotes. Homozygous α -thalassemia is not seen in adults because it results in hydrops fetalis in the newborn. β -Thalassemia trait and α -thalassemia trait, however, are common but are usually associated with only mild anemia.

With increasing numbers of immigrants from Southeast Asia, there are more people with a complex thalassemia syndrome, known as *hemoglobin Constant Spring*, who might be seen in practice. Obtaining a definitive diagnosis is important so as not to prescribe iron or other therapies inappropriately.

Hemolytic-Hemorrhagic Anemia

Hemolytic-hemorrhagic anemia (HHA) is diagnosed in patients with persistent anemia or decreasing Hb and Hct levels despite what appears to be an adequate bone marrow erythropoietic response. For patients with chronic hemolytic disease, this means a marrow production index of 3. In patients with hemorrhagic disease, this level of production may not be reached quickly because of the ongoing iron loss, and production indices about 2 to 2.5 times normal are more common. In the latter case, however, blood loss dominates the clinical picture unless the loss is internal.

In a discussion of the hemolytic anemias, which can be complex to diagnose, it is helpful to consider the pathophysiology of disease and how to categorize the hemolytic process. One should first consider whether the hemolysis appears to be intravascular or extravascular.

Intravascular Hemolysis

Intravascular hemolysis is associated with the rupture of erythrocytes and dispersion of their contents into the plasma. This results in free hemoglobin in the plasma and, if sufficient RBC destruction takes place, there is Hb spillover into the urine (hemoglobinuria). The primary Hb-binding protein in the plasma is haptoglobin, but in the presence of intravascular hemolysis, free haptoglobin becomes undetectable. This is a useful test only if the results are negative because ineffective RBC production, associated with substantial destruction of RBCs in the bone marrow (or even primarily extravascular hemolysis), will result in the release of sufficient Hb to reduce circulating haptoglobin levels.

Intravascular hemolysis can be life threatening if acute and can have several causes. For example, RBC membrane damage and intravascular hemolysis can result from burns or exposure to certain toxins that target the RBC membrane, such as *Clostridium perfringens*. Hypotonic lysis is rarely seen but could occur because of the IV infusion of free water. Immune-mediated lysis of RBCs can occur when mismatched transfusions are given. With ABO incompatibility, the operative mechanism is immunoglobulin M (IgM) antibodies that fix complement to the RBC surface and cause rapid lysis.

Mechanical fragmentation is probably the most common form of intravascular hemolysis seen in North America and is associated with microvascular diseases such as thrombotic thrombocytopenic purpura, *hemolytic uremic syndrome* (HUS; Fig. 39-5), defective mechanical heart valves, and disseminated intravascular coagulation. Acute attacks of malaria

Figure 39-5 Schistocytes and helmet cells characteristic of a hemolytic process (hemolytic uremic syndrome). (From the American Society of Hematology Image Bank image #4678. Copyright 1996 American Society of Hematology, used with permission.)

are also associated with intravascular hemolysis. *Paroxysmal nocturnal hemoglobinuria* (PNH) is an unusual form of intravascular hemolysis caused by an acquired X-linked defect in the hematopoietic stem cell. Patients with PNH have varying degrees of hemolysis throughout the day, and in crisis, this can be severe.

An inherited condition that predisposes patients to intravascular hemolysis is the Mediterranean form of *glucose-6-phosphate dehydrogenase* (G6PD) deficiency. G6PD deficiency is the most common inborn error of RBC metabolism worldwide, affecting almost 0.5 billion people. Because it is an X-linked genetic disorder, it is most severe in men. G6PD protects RBCs from oxidative stressors such as superoxide anions and hydrogen peroxide. Oxidative products in RBCs are normally neutralized by reduced glutathione, which is generated by glutathione reductase. This pathway is part of the hexose monophosphate shunt pathway and requires G6PD for proper functioning. The Mediterranean abnormality of G6PD deficiency is associated with moderate chronic hemolysis, but this may become overwhelming and even fatal when the RBCs are exposed to oxidative stress. Any oxidative stress in these patients may have severe clinical consequences that could require transfusion or exchange transfusion as part of therapy.

The more common variety of G6PD deficiency in North America is G6PD^{A-}, which affects approximately 10% of the African American population. G6PD^{A-} is an enzyme with reduced stability and catalytic activity that become more prominent as the red cell ages. In these people, hemolytic events typically involve older RBCs and are therefore benign and relatively self-limited. The accumulation of oxidized glutathione reacts with hemoglobin and causes precipitation of Hb into Heinz bodies, resulting in hemolytic disease. The hemolytic process can be enhanced by infection, surgical stress, diabetic acidosis, and certain medications, such as the antimalarials primaquine and quinacrine.

Extravascular Hemolysis

Contrasted with intravascular hemolysis is the destruction of RBCs that occurs primarily in the reticuloendothelial system (RES), so-called extravascular hemolysis. The primary site of destruction is outside the vascular compartment, in the liver,

spleen, and bone marrow. A form of extravascular hemolysis is the ineffective RBC production seen with nuclear or severe cytoplasmic maturation defects. More common sites for extravascular destruction are the liver and particularly the spleen. Again, it is useful to determine whether the hemolysis is congenital or acquired. Congenital forms include inherited hemoglobinopathies (thalassemias, sickle cell disease), inherited membrane defects (hereditary spherocytosis or elliptocytosis), and enzyme defects. Defective RBC metabolism usually causes hemolysis by creating unstable Hb or by failing to generate adequate adenosine triphosphatase (ATP) to maintain RBC membrane plasticity, as occurs in pyruvate kinase deficiency; this autosomal recessive disorder is the most common enzyme deficiency of the glycolytic pathway. Most patients with pyruvate kinase deficiency have a mild anemia and generally do not require transfusions.

Sickle Cell Anemia

Sickle cell anemia is an inherited autosomal condition in which glutamic acid in the sixth position on the β -globin chain is replaced by a valine (Glu6Val). This results in hemoglobin SS in the homozygous state. Sickle cell trait, or hemoglobin AS, is found in 8% to 10% of African Americans in the United States, and sickle cell anemia occurs in about 1 in 400, or about 70,000 individuals. The gene for HbS is prevalent in sub-Saharan Africa. Persons of Mediterranean descent from India or Saudi Arabia have varying but somewhat lower percentages of the carrier state for HbSS. Sickle cell anemia occurs worldwide but predominates in Mediterranean, Saudi Arabian, and Indian populations. This distribution appears to be associated with independent mutations in these regions. People with hemoglobin AS or SS are somewhat protected against malaria because their erythrocytes are resistant to invasion by malarial parasites. If the parasite infects the cell, the rate of sickling increases, causing the cell with the parasite to be removed from the circulation more rapidly.

The pathophysiology of the sickling process is related to the oxygenation of the molecule. When deoxygenated, HbSS tends to polymerize into long, tubelike fibrils. This results in an elongated, rigid cell subject to trapping in the microcirculation, resulting in vaso-occlusive crisis. Hypoxemia, acidosis, dehydration of the RBC, hyperosmolality of the renal medulla, and viral infections can play a role in triggering or accentuating the sickling process. Sickled RBCs are also more adhesive to endothelial cells, activate endothelial cells, and contribute to the interaction between neutrophils and activated endothelium in the microvasculature. When the conditions that cause sickling are corrected, the sickle cell may return to a more normal shape and function. However, some sickled RBCs are irreversibly changed, indicating that the membrane cytoskeleton has been damaged. Irreversibly sickled cells are generally removed in the sinusoidal RES networks, but approximately one-third may be hemolyzed intravascularly. Some degree of anemia has a protective effect in vaso-occlusive crises by helping reduce blood viscosity and deoxygenation, thereby reducing the likelihood of polymerization.

During vaso-occlusive crises, the microvascular capillaries, capillary bed, and veins become occluded. Contributing to this locally are low pH, prolonged capillary transit time, and infection. Increased numbers of sickled RBCs occlude the vessels, which leads to painful ischemia, infarction, and

reduced organ function over time. Areas particularly affected include the portal circulation, in which oxygen tension is low; the kidney, in which the renal medulla is hyperosmolar and dehydrates RBCs, increasing mean corpuscular hemoglobin concentration (MCHC); the lungs; and the brain. It is not clear why some patients have severe, frequent episodes and others do not. *Avascular necrosis* of the bone marrow is usually the cause of severe pain.

Clinical Diagnosis

A patient with sickle cell disease usually has chronic hemolysis that results in a moderate anemia, intermittent jaundice, and a marrow with a thinned, bony cortex. Vaso-occlusive episodes and the appearance of Howell-Jolly bodies occur by the time the patient becomes an adult. The presence of Howell-Jolly bodies indicates that the patient has undergone an autoinfarction of the spleen.

The diagnosis of sickle cell disease is easily made by finding sickled cells on the peripheral smear, preparing a sickle cell sample, and carrying out a screening hemoglobin electrophoresis, which will confirm the Hb type. For a sickle cell preparation, blood is mixed with 2% sodium metabisulfite, which produces sickling. The proportion of sickled cells is measured initially and then 1 hour later to make the diagnosis. The "gold standard" diagnosis is Hb electrophoresis, which shows the relative amounts of Hb forms.

Patients with long-standing sickle cell anemia may have pain syndromes related to bone marrow vaso-occlusive crises and aseptic necrosis of the femoral head. Bilirubin gallbladder stones occur in 40% to 60% of patients. Hepatic and cardiac complications may also develop. Other associated problems include vascular occlusion in the pulmonary bed, leading to acute chest syndrome. Breakdown of the skin over bony prominences in the lower extremities is common and may lead to chronic, poorly healing ulcers. Papillary necrosis of the kidney may occur and, with age, renal function may decline. In the eye, conditions such as hemorrhage and neovascularization may occur. Patients with sickle cell anemia are particularly susceptible to *Salmonella* infections because of decreased complement activation, and asplenic patients are also subject to an increased likelihood of infection from encapsulated organisms such as *Pneumococcus*. Patients with sickle cell anemia should be given Pneumovax vaccine to prevent streptococcal pneumonia and sepsis. *Haemophilus influenzae* infection is responsible for a high percentage of pneumonia cases in sickle cell anemia patients.

Neurologically, patients with sickle cell anemia are subject to cerebrovascular accident (CVA, stroke). Particularly disturbing, children with severe sickle cell anemia will have evidence of multiple small strokes on magnetic resonance imaging (MRI) or computed tomography (CT) of the head by age 10 years. This has been associated with learning impairments in affected children. Aggressive transfusion protocols have been tested to reduce the incidence of this complication, with some success. Thrombosis is more common in children, whereas hemorrhage is more common in adults, possibly because of the occlusion of small vessels in hypoxic situations. Also, sickled cells show increased attraction to the endothelium, causing proliferation of the endothelial intimal surface, which can contribute to vascular occlusion. There is a high rate of recurrent stroke within 3 years of the initial event. Parvovirus infection can also cause pure RBC

aplasia in these patients and lead to a devastating exacerbation of the anemia.

Treatment

Patients with sickle cell anemia should have Hb and Hct maintained at moderately low level to protect against vaso-occlusive complications related to viscosity. Patients with a painful crisis should be put on bed rest, hydrated vigorously, and given oral analgesics. Nonsteroidal anti-inflammatory drugs (NSAIDs), antihistamines, and benzodiazepines may also be helpful. Mild alkalinization of the blood is recommended. Oxygen should be given by nasal cannula or mask to keep the hemoglobin well oxygenated. Parenteral narcotics are rarely necessary, especially if the patient is given large volumes of fluid, oxygen, and oral morphine (or similar preparation) for pain control. Avascular necrosis of the bone marrow causes severe pain, and the patient may require intravenous (IV) narcotics and hydration for pain control.

Treatment with drugs that increase the proportion of fetal hemoglobin (HbF) show promise. Mixed polymers of HbF and HbS do not have the same propensity to sickle as SS tetramers. Azacitidine (5-AZA) increases the proportion of HbF but has significant toxicity. Hydroxyurea increases HbF level, which often results in fewer painful episodes, hospital admissions, and transfusions. The goal is to raise HbF level, if possible, to 20% to 30% of the total hemoglobin. Mortality can be reduced by as much as 40%. Unfortunately, not all patients respond to these types of interventions. Because both are antitumor drugs, azacitidine and hydroxyurea have significant toxicity, such as tumor induction. Gene therapies are being investigated but are not yet successful. In severe situations, allogenic (sibling) bone marrow transplantation has been tried, resulting in an 86% event-free survival at 5 years after transplant (Bhetia and Walters, 2008).

Patients undergoing surgery with general anesthesia are at increased risk of hypoxemia, sickling, and sickle cell crisis. They should be transfused before surgery with packed RBCs to bring the HbA level to 50% or higher. This decreases the likelihood of sickle cell episodes.

Pregnancy increases the risk of vaso-occlusive crisis for the mother. There is a high incidence of fetal loss among women who have sickle cell anemia. Vaso-occlusive episodes in the placenta may result in lower-birth-weight infants or fetal death.

Sickle Cell Trait

Patients with sickle cell trait are heterozygous for the sickle gene and have a much lower likelihood of sickling than those who are homozygous. Most heterozygotes are asymptomatic throughout life. Patients with sickle cell trait, however, may develop complications if put into an extremely hypoxic environment such as high altitude, suffer heat stroke and dehydration, or acquire pulmonary infections.

Acquired Forms of Hemolysis

The acquired forms of reticuloendothelial or extravascular hemolysis are dominated by patients with acquired immune-mediated hemolytic disease. Patients with *autoimmune hemolytic anemia* (AHA) can present with severe anemia; this is usually associated with another disease such as a collagen vascular disease (e.g., rheumatoid arthritis, severe systemic

lupus erythematosus) or drugs, or it is idiopathic. AHA is uncommon but can be dramatic on presentation. About 50% of patients have no associated disease. The Coombs antiglobulin test, performed directly and indirectly determines the presence of antibody coating the patient's RBCs or free antibody in the plasma capable of binding to RBCs in AHA diagnosis. The autoantibodies may fix complement or may target the red cell for phagocytosis by the RES.

Therapy of AHA depends on the severity and causative mechanism. If the AHA is drug-induced, it is often sufficient to stop the drug and wait for the antibodies to clear, although this may take some time. Drug-induced hemolytic disease is uncommon and requires a specialized laboratory to make a precise diagnosis. AHA associated with collagen vascular diseases, lymphomas, or Hodgkin's disease may be controlled with treatment of the primary underlying condition. The mainstay of treatment of AHA is high-dose corticosteroid therapy, at least 1 mg/kg of prednisone daily; refractory cases may require up to 2 mg/kg/day. Patients who do not respond to steroid therapy may be candidates for splenectomy, because the spleen is the primary site of removal of antibody-coated RBCs. Other drugs used as second- and third-line therapies for their immunosuppressive effects include cyclophosphamide, chlorambucil, and intravenous immune globulin (IVIG).

A final mechanism of acquired extravascular hemolysis is *hypersplenism*. Typically, patients with hypersplenism have an enlarged spleen because of infiltrative disease of the spleen, or they have splenomegaly as a result of portal hypertension. Under these circumstances, the RBCs are trapped for an unusually long period in the splenic circulation. Splenectomy may be beneficial.

Polycythemia

Polycythemia (or *erythrocytosis*) is the overproduction of red blood cells (erythrocytes). The mechanism of action resulting in polycythemia may be primary or secondary. *Primary* polycythemia indicates that the disorder arises at the level of the hematopoietic stem cells (see later), whereas *secondary* polycythemia represents the overproduction of RBCs caused by the increased stimulation of the bone marrow by EPO.

Polycythemia is typically identified initially in the laboratory by Hb and Hct values that are substantially above normal, requiring an explanation. Hb values of 18 to 20 g/dL lie in a range in which it is unclear whether the elevated Hb is caused by increased RBC production or a decreased plasma volume. In the latter case, the elevated Hb and Hct levels are caused by a contraction of the plasma volume and not by an increase in the RBC mass, so-called spurious polycythemia (pseudopolycythemia), or Gaisbock's syndrome, and may not warrant therapeutic intervention. Typically, Hb level above 20 g/dL is unequivocally associated with increased RBC mass.

In the evaluation of patients with polycythemia or suspected polycythemia, it is important to first establish that the RBC mass has increased. This is achieved through direct measurement of the red cell mass using isotope dilution techniques, and the test can be performed at most large hospitals. Once that issue has been resolved, and assuming that there is evidence of RBC overproduction, it is important to determine whether the polycythemia is primary or secondary by measuring the circulating EPO level. If elevated, causes of

the increased EPO production to consider include heart or chronic pulmonary disease, in which there is desaturation of Hb as it leaves the lungs, or less common causes such as renal cysts, hepatic or cerebellar tumors, uterine leiomyoma, or impaired Hb function caused by heavy smoking, which results in elevated levels of carboxyhemoglobin, which is essentially inert as an oxygen transporter. Severe obstructive sleep apnea may cause enough desaturation to raise EPO levels, resulting in secondary polycythemia. Athletes using EPO, androgens, or blood doping may also present with secondary polycythemia.

Certain forms of polycythemia are inherited. These can be associated with mutations in the Hb molecule that increase Hb's affinity for oxygen, making it more difficult to offload oxygen within the tissues. These are referred to as "high-affinity mutants," and more than 20 have been identified. It is important to identify the various possibilities because different causative factors have different long-term consequences.

Primary polycythemia, or *polycythemia vera* (PV), is a disorder of the hematopoietic stem cell. It is acquired typically in midlife and thereafter and, when full-blown, is associated with an increase in the platelet count, white cell count, splenomegaly, and severe itching following hot showers or baths. Pruritus can be disabling and presumably results from degranulation of skin basophils. Unlike secondary forms of erythrocytosis, EPO level is in the normal or low-normal range.

Treatment of PV strives to reduce the RBC mass to normal. Because PV is usually associated with an increase in total blood volume, the goal of phlebotomy therapy should be Hb and Hct levels in the normal range. Eventually, repeated phlebotomies induce iron deficiency, which is a reasonable end point. For patients with more aggressive disease (e.g., a growing spleen, increasing white cell and platelet counts), hydroxyurea therapy is effective. The goal is to maintain blood counts as close to normal as possible, or at least in an acceptable range.

Myeloproliferative Disorders

Polycythemia vera is one of a group of conditions referred to as the myeloproliferative disorders. These include essential thrombocytosis (ET) and agnogenic myeloid metaplasia with myelofibrosis (AMM/MF), also known as idiopathic myelofibrosis. All these disorders are characterized by the overproduction of one or more cell types. In PV the clinical picture is dominated by the increased production of RBCs. In ET the clinical picture is dominated by increased numbers of platelets, which may reach values as high as $2 \times 10^6/\mu\text{L}$. With AMM/MF the clinical picture is dominated by various cytopenias associated with marrow fibrosis and splenomegaly. Splenomegaly, in this case, likely represents extramedullary hematopoiesis.

Many features of these diseases overlap. In PV, the spent phase may resemble myelofibrosis. Some patients with ET will eventually manifest an increased RBC mass. The occasional overlapping and thus confusing nature of these disorders has been partially explained by the recent demonstration of a very high frequency of a point mutation in a signaling molecule on the EPO signaling pathway (Kralovics et al., 2005). In several reports, almost two thirds to three quarters of patients with PV had this mutation in *JAK2*, with lower frequencies seen in patients with ET and AMM/MF. The mutation results in a constitutively activated pathway and the overproduction of bone marrow cellular elements.

It can be anticipated that this will become a useful molecular test in the differential diagnosis of these disorders and will almost certainly become a target for drug development.

In ET the peripheral smear reveals increased numbers of platelets of various sizes. Platelet counts may be high, in excess of 1 or $2 \times 10^6/\mu\text{L}$. There may be an associated leukocytosis, and Hb level is typically normal. The decision to treat such patients is not always easy. Generally, patients with platelet count approaching $1 \times 10^6/\mu\text{L}$ are treated, even with no associated symptoms or signs. Asymptomatic young women with ET require special consideration; watchful waiting is probably sufficient, although hydroxyurea plus aspirin is the most effective approach for patients who require treatment.

Patients with AMM/MF tend to run an indolent course. Usually, over time, the spleen continues to enlarge, and peripheral RBC destruction increases. There also may be varying degrees of thrombocytopenia caused by impaired bone marrow production and increased splenic sequestration. In all the myeloproliferative disorders, platelet function may be abnormal. Treatment of AMM/MF is largely symptomatic. The anemia can be treated with transfusions, or epoetin therapy can be attempted, although no good clinical trials support these approaches. In advanced cases of myeloid metaplasia, the spleen may grow to such a size that it may require removal to stabilize peripheral blood counts. Proper management of all the myeloproliferative disorders is associated with extended survival.

KEY TREATMENT

Different preparations of iron salts are equally well tolerated and effective in the treatment of iron deficiency anemia. Controlled-release iron preparations have fewer GI side effects but similar discontinuation rates, so they are no more effective (McDiarmid and Johnson, 2002) (SOR: A).

Pneumovax vaccine should be given to patients with sickle cell disease because they tend to undergo auto splenectomy (Nabel, 2009) (SOR: B).

Treatment of a sickle cell crisis consists of rest, hydration, and oral analgesics, such as NSAIDs, antihistamines, and oral morphine (Nabel, 2009) (SOR: B).

In severe cases of sickle cell, allogeneic (sibling) bone marrow transplantation results in an 86% event-free survival at 5 years (Bhetia and Walters, 2008) (SOR: B).

High-dose corticosteroid therapy is the treatment of choice for autoimmune hemolytic anemia (Nabel, 2009) (SOR: B).

White Blood Cells

Key Points

- Leukocytosis is WBC count 2 SD above the mean, generally higher than 11,000/ μL .
- Only 10% of all neutrophils are found in the peripheral blood, where they survive only 6 to 10 hours.
- Neutrophilia is caused by inflammation, stress, or steroid therapy.
- Infection is probable when band neutrophils are more than 20% of the total WBC count and Döhle bodies and toxic granulations are seen.
- The risk of severe infection does not usually occur unless the absolute neutrophil count is less than 500/ μL .

The white blood cells (WBCs, leukocytes) are made up of neutrophils, lymphocytes, eosinophils, basophils, monocytes, and plasma cells, although plasma cells are rarely found in the circulation. Most are produced in the bone marrow and some primarily in lymphoid tissue. The normal WBC count ranges from approximately 4300 to 10,000 cells/ μL with some variation, depending on the laboratory reference control samples. An abnormal WBC count can be defined as more than 2 SD from the mean of 7000 cells/ μL .

Leukocytosis is defined as a WBC count 2 SD higher than the mean, generally greater than 11,000 cells/ μL . WBCs are composed of two types of cells with different functions. *Phagocytic cells*, consisting of neutrophils, eosinophils, monocytes, and macrophages, are primarily responsible for the ingestion and killing of microorganisms. *Lymphocytes* are responsible for cellular-mediated immunity and humoral immunity expressed through the production of antibodies. Table 39-4 lists normal WBC values and ranges. White cells produce cytokines (interleukins and growth factors), vasoactive substances, and enzymes, which allow them to interact and formulate immune responses. This section focuses primarily on phagocytic cells and their disorders; lymphocytes and lymphocytic disorders are discussed in a later section. When a patient has an increasing number or severity of bacterial or fungal infections, or both, abnormalities of phagocytic cells should be suspected. Conversely, when any phagocytic cell line is increased, such as neutrophils or eosinophils, an infectious process should be suspected.

Types of White Blood Cells

See online text for discussion of granulocytes, eosinophils, and monocytes/macrophages.

Disorders of Neutrophils

Neutrophilia

Neutrophilia is defined as a WBC count higher than 10,000 cells/ μL plus an absolute neutrophil count more than 2 SD above the mean, or higher than 7000 cells/ μL . The *absolute neutrophil count* (ANC) can be calculated by multiplying the total WBC count by the percentage of polymorphonuclear neutrophil (PMN) leukocytes and bands (PMNs + bands)

Table 39-4 Normal White Blood Cell (WBC) Counts in Peripheral Blood

| WBC Type | Range (cells/ μL) | Range (%) |
|-----------------------|-------------------------------|-----------|
| All white cells | 4300-10,000 | 100 |
| Total neutrophils | 2000-7000 | 20-70 |
| Segmented neutrophils | 1500-6000 | 15-60 |
| Band neutrophils | 500-1000 | 5-10 |
| Lymphocytes | 1500-4000 | 15-40 |
| Monocytes | 100-900 | 1-9 |
| Eosinophils | 100-700 | 1-7 |
| Basophils | 0-150 | 0-1.5 |

in the WBC differential. There are two major categories of neutrophilia, primary and secondary. *Primary* neutrophilia is related to defects in the production or maturation of neutrophil precursors in the bone marrow, associated with conditions such as chronic myelogenous leukemia (CML) and PV. Rare genetic forms of neutrophilia include the type associated with Down syndrome infants, who may express intermittent leukemoid reactions. In the presence of an enlarged spleen, myelocytic precursors in the peripheral blood, increased levels of basophils and eosinophils, and a low leukocyte alkaline phosphatase (LAP) level, the diagnosis of CML is highly probable. Unless neutrophilia is caused by a myeloproliferative syndrome, treatment is usually not indicated.

Secondary neutrophilia is caused primarily by three major mechanisms: inflammation (or infection), stress, and steroid therapy. *Inflammation* can result from active inflammation or infection; cigarette smoking; burns, surgery, or trauma; and vaccination or snakebite. *Stress* may be caused by pregnancy and spontaneous or cesarean delivery; chronic anxiety state, panic disorders, posttraumatic stress disorder, and depression; vigorous exercise; splenectomy; and sickle cell disease.

The physician must consider the history and physical examination to determine the appropriate diagnosis for the cause of neutrophilia. *Severe* neutrophilia (30,000-50,000 cells/ μL and higher) is called a *leukemoid reaction* and is related to severe infections such as sepsis, hemorrhagic shock, and major tissue injury, but must be distinguished from acute or chronic leukemia. Infections and chronic inflammation may change the characteristics of neutrophils in the peripheral circulation. Increasing numbers of young cells, such as bands and metamyelocytes, the presence of Döhle bodies (residual endoplasmic reticulum), and toxic granulations are indicators of infectious and inflammatory causes of neutrophilia. Recognition allows the probable cause to be appropriately treated, particularly because treatment of chronic inflammation, infection, and stress is different.

A pseudoleukocytosis occasionally occurs, usually related to clumping of platelets in a blood sample, which alters the electronic determinations of WBC and platelet counts. Platelet clumping may be related to inadequate anticoagulation of the blood sample or the presence of abnormal proteins in a patient's blood, leading to platelet clumping. Cold, insoluble plasma proteins, known as cryoglobulins, may also cause increased WBC and platelet counts, particularly when the patient's temperature is 30° C (86° F) or lower.

The highest specificity for the presence of infection occurs when more than 20% of the total WBC count is made up of band neutrophils. The highest sensitivity for infection is the presence of Döhle bodies, toxic granulations, and cytoplasmic vacuoles when the peripheral smear is examined. The most accurate predictor of the presence of acute inflammation is a total WBC count higher than 10,500 cells/ μL (Neutrophilia, 2009).

Neutropenia

Neutropenia is defined as ANC less than 1800 cells/ μL , approximately 2 SD below the mean, and includes both mature PMN and band forms. Some ethnic populations, such as those of African descent or Yemenite Jews, may have a lower total WBC count and ANC that can be normal at 1000 neutrophils/ μL . The primary concern with neutropenia

is the risk of infection. Severe infection does not usually occur unless ANC is less than 500 cells/ μ L (Table 39-5). When severe neutropenia occurs, patients are at risk for serious infection from breaks in cutaneous or mucosal barriers in areas such as the GI tract or oropharynx. If they are taking corticosteroids, the risk of infection in the presence of neutropenia is greatly enhanced because of the steroidal effect on immune responsiveness.

As with RBC disorders, neutropenia can be classified as production disorders, maturation disorders, and increased destruction disorders (Box 39-4). Production disorders may be congenital or caused by genetic abnormalities, such as cyclic neutropenia, characterized by recurrent mouth infec-

Table 39-5 Relation of Absolute Neutrophil Count (ANC) to Risk of Infection

| ANC (cells/ μ L) | Risk/Management |
|----------------------|---|
| >1500 | None. |
| 1000-1500 | No significant risk of infection; fever can be managed on outpatient basis |
| 500-1000 | Some risk of infection; fever can occasionally be managed on outpatient basis. |
| <500 | Significant risk of infection; fever should always be managed on inpatient basis with parenteral antibiotics; clinical signs of infection present. |
| <200 | Very significant risk of infection; fever should always be managed on inpatient basis with parenteral antibiotics; clinical signs of infection may be late phenomena. |

Box 39-4 Classification of Neutropenia

Production disorders

Congenital neutropenia
Cyclic neutropenia
Chédiak-Higashi syndrome
Cancer drugs (cyclophosphamide, methotrexate, azathioprine)

Maturation disorders

Vitamin B₁₂, folate deficiencies
Myelodysplastic syndromes
Viral infections

Disorders of increased destruction

Immune induction agents
Postinfection disorders (HBV, EBV, HIV/AIDS, bacteria)

Autoimmune disorders

Felty's syndrome
Systemic lupus erythematosus
Acute respiratory disease
Hypersplenism
Rheumatoid arthritis
Transfusion reaction

tions and 21-day fluctuations in the neutrophil count. *Congenital neutropenia*, also known as infantile genetic agranulocytosis, is a chromosomal abnormality possibly related to a G-CSF receptor defect. *Chédiak-Higashi syndrome* is an autosomal recessive chromosomal abnormality characterized by recurrent infections, partial albinism, and lymphoproliferative features caused by defective neutrophil migration and bactericidal properties. Cancer chemotherapeutic agents (e.g., cyclophosphamide, methotrexate, azathioprine) also directly suppress neutrophil production, in a dose-dependent manner.

Maturation disorders include vitamin B₁₂ and folic acid deficiencies, myelodysplastic syndromes, and viral infections. Disorders of increased neutrophil destruction include those caused by antibodies to neutrophils induced by drugs such as antibiotics, antithyroid medications, and sulfa-containing compounds. Infections caused by hepatitis B, Epstein-Barr virus (EBV), human immunodeficiency virus (HIV), rickettsiae, and parasites may induce the production of antibodies that adversely effect the sequestration and destruction of neutrophils.

Autoimmune causes of neutropenia may also have an associated thrombocytopenia and hemolytic anemia. *Felty's syndrome* is the combination of rheumatoid arthritis, splenomegaly, and neutropenia, which is caused by antineutrophil antibodies. Similar antibodies can also be found in systemic lupus erythematosus and Sjögren's syndrome. Antineutrophil antibodies can occasionally be found in hyperthyroidism and Wegener's granulomatosis as well. Antibodies to G-CSF also play a role in some of these autoimmune disorders. Isoimmune neonatal neutropenia is a disorder in infants secondary to transplacental transfer of IgG antibodies that react with neutrophilic antigens. These antigens are inherited from the father of the infant, and the disease process is similar to that of Rh-hemolytic disease of the newborn. This disorder resolves spontaneously, but occasionally the administration of G-CSF is necessary.

Treatment

Treatment of neutropenia depends on its cause and relative severity. Chronic neutropenia will necessitate a careful family history, a chronology of the types and severity of infections, and recurrent findings, such as oral ulcers, cellulitis, and sepsis. A medication history is extremely important in determining the cause of recent-onset neutropenia. Bone marrow aspiration is indicated if a production deficit is suspected or if there is any question of a myelodysplastic or malignant cause. If a viral infection is suspected, serologic testing for infectious mononucleosis, hepatitis, HIV, EBV, and parvovirus may be indicated. When an autoimmune disorder is implicated, testing for antinuclear antibodies and rheumatoid factor is necessary. When neutropenia is found, a direct review of the peripheral blood smear using Wright-Giemsa stain not only confirms the relative absence or decreased number of neutrophils, but also can provide clues if there are toxic granulations, Döhle bodies, or changes seen in the maturation of the available neutrophils. If anemia or thrombocytopenia (or both) is found along with neutropenia, bone marrow aspiration and biopsy should be performed to determine the cause of this deficit in bone marrow production.

The Infectious Disease Society of America (IDSA; www.idsociety.org) and the American Society of Clinical

Oncology (www.asco.org) have developed evidence-based guidelines for the treatment of neutropenia associated with acute febrile episodes and those associated with cancer chemotherapy. These websites are kept current for use in clinical practice. **Box 39-5** provides guidelines for the management of febrile neutropenia.

Mild neutropenia in the absence of a recurrent or protracted infection is most likely benign and can be observed. The history of a recent viral infection or new medication is often associated with mild neutropenia. The patient should be examined carefully and ANC monitored until it returns to normal. Once the neutropenia resolves, CBC should be determined whenever a fever occurs. If the neutropenia continues for 8 weeks or longer, a bone marrow aspiration and biopsy may help determine the cause and prognosis.

In patients with *moderate to severe neutropenia* with recurrent infection, a more vigorous approach should be undertaken to determine the cause. Bone marrow aspiration and biopsy, appropriate serologic tests, and blood cultures are necessary. Determination of antinuclear antibodies, complement levels, and antineutrophil antibodies and serologic studies for entities such as HIV infection are needed. An acute episode of febrile neutropenia requires a careful history and examination for potential sites of infection; blood and body fluid samples should be tested, and immediate implementation of IV antibiotic therapy is required. If indicated, antibiotics should be adjusted after 3 days, depending on culture results. Low-risk patients and patients responding quickly may be switched to oral antibiotic therapy. If the patient is severely

ill and is not responding, treatment with antifungal agents and G-CSF should be considered.

Chronic neutropenia in Felty's syndrome may respond to splenectomy and regular doses of methotrexate. The long-term use of corticosteroids, gamma globulin injections, and splenectomy are generally not indicated in patients who have chronic neutropenia. Long-term antibiotics have no proven benefit in preventing infections in patients with chronic or recurrent neutropenia. Patients with fever and ANC higher than 1000 cells/ μ L can generally be managed on an outpatient basis with oral antibiotics.

The use of myeloid growth factors (G-CSF, GM-CSF) may be helpful for some neutropenic patients. These recombinant-manufactured products can correct neutropenia and reduce infectious morbidity, particularly in patients subject to recurrent infections, such as those with severe congenital neutropenia, cyclic neutropenia, HIV infection, and long-term bone marrow suppression from cancer chemotherapy. In controlled studies in patients with severe chronic neutropenia or HIV disease with low CD4+ cell count and ANC less than 1000/ μ L, administration of G-CSF reduced the incidence of infection by 30% to 40% (Jadersten et al., 2005). G-CSF is now recommended to be given in the first cycle of chemotherapy, when the incidence of febrile neutropenia is likely to be higher than 20%. Patients receiving G-CSF may have more intensive chemotherapy and better survival but a greater risk of leukemia (Dale, 2009). Patients older than 55 with neutropenia or with acute myeloid leukemia may benefit from the administration of CSFs after completion of induction therapy. These agents can be started 24 to 72 hours after chemotherapy and are continued until ANC reaches or exceeds 1000/ μ L.

Box 39-5 Guidelines for Management and Prevention of Febrile Neutropenia

Management

- Take careful history and conduct thorough physical examination of the patient.
- Examine patient carefully for portal for bacterial or fungal infections.
- Culture blood and other appropriate body fluids.
- Start antibiotics immediately.
- Treat with monotherapy (e.g., ceftazidime or imipenem) or dual therapy (e.g., aminoglycoside such as gentamicin, with β -lactam drug effective against *Pseudomonas*, such as piperacillin).
- Add vancomycin if there is a significant risk of gram-positive sepsis.
- Adjust antibiotic therapy after 3 days, depending on the results of cultures and the patient's clinical status.
- Switch low-risk patients to oral therapy.
- Continue broad-spectrum therapy for severely ill patients.
- Consider antifungal treatments.
- Consider colony-stimulating factors as an adjunct to antibiotics for febrile neutropenia in severely ill, high-risk patients.

Prevention

- Primary prophylaxis with granulocyte colony-stimulating factor (G-CSF) reduces the incidence of febrile neutropenia by about 50% when risk of febrile neutropenia is about 40%.
- Use G-CSF or granulocyte-macrophage colony-stimulating factor (GM-CSF) as a preventive strategy for patients who have had their cancer treatment reduced or experience a delay in treatment because of an episode of febrile neutropenia or a prolonged period of neutropenia.
- Consider reducing the intensity of chemotherapy.

Disorders of Neutrophil Function

Some patients have normal numbers of neutrophils but have recurrent, severe, or unusual infections and therefore have a neutrophil function disorder. Defects in function include neutrophil adherence, chemotaxis, degranulation, and metabolic problems. The evaluation is complex but involves family history, complete examination of peripheral smear, and determination of immunoglobulin and complement levels. Neutrophil function can be evaluated by the nitroblue tetrazolium (NBT) test and other assays. Chronic granulomatous disease and severe G6PD deficiency may be found in this evaluation. Referral to a specialist is usually necessary to investigate disorders of neutrophil function adequately.

Eosinophilia

Eosinophilia is an absolute eosinophil count greater than 700 cells/ μ L, with primary and secondary causes. Secondary eosinophilia may result from immunodeficiency, neoplasms, collagen vascular disease, and dermatologic disorders. When seen in a family medicine setting, allergic disorders and infections caused by parasites are more likely causes of eosinophilia. The primary form of eosinophilia is often called *hypereosinophilic syndrome* (HES). Characteristics of HES are an eosinophil count higher than 1500 cells/ μ L, longer than 6 months in duration, and evidence that eosinophils have infiltrated into tissues. Studies have shown that this may be a mutation in chromosome 4 that results in the linkage of

the *RHCE* and *PDGFR α* genes. Clinical features are a rash, fever, cough, dyspnea, peripheral neuropathy, diarrhea, and development of congestive heart failure, with valvular abnormalities and mural thrombi. The blood smear reveals many eosinophils with vacuoles and decreased numbers of granules. The total WBC count may range from 10,000 to 30,000 WBCs/ μ L, of which 30% to 70% are eosinophils. Care should be taken to eliminate severe allergic reactions, eosinophilic leukemias, and invasive parasitic infections before this diagnosis is firmly established. If there are cardiopulmonary problems, initial therapy with prednisone at high doses, followed by lower doses for up to 3 months or longer, is often successful. If this not helpful, hydroxyurea can be used to lower the WBC count to below 10,000 cells/ μ L.

Monocyte and Macrophage Disorders

These disorders are histiocytic syndromes in which macrophages and dendritic cells are abnormal, such as acute monocytic leukemia, monocytic sarcoma, nonmalignant disorders such as histiocytosis syndromes, and Hand-Schüller-Christian and Letterer-Siwe disease. Most of these are rare and infrequently seen in family medicine. Lysosomal storage diseases are enzymatic disorders that are usually congenital, such as lipid and polysaccharide storage diseases.

KEY TREATMENT

Patients with severe neutropenia and fever empirically need IV antibiotics started in an inpatient setting (e.g., cefepime, 2 g every 8 hours) (IDSA, 2008) (SOR: C).
In patients with severe chronic neutropenia or HIV disease with low CD4+ count and absolute neutrophil count less than 1000 cells/ μ L, G-CSF reduced the rate of infection by 30% to 40% (Jadersten et al., 2005) (SOR: A).

Platelets

Key Points

- Petechiae and bleeding do not usually occur until the platelet count is below 20,000 cells/ μ L.
- Platelet dysfunction should be considered in a patient with clinical evidence of hemorrhage and platelet count above 100,000 cells/ μ L.
- Primary marrow-related thrombocytosis is more likely to cause thrombosis.
- Aspirin irreversibly inactivates cyclooxygenase in platelets, whereas nonsteroidal anti-inflammatory drugs do not.

Platelet Origins

Platelets are produced by megakaryocytes, which develop from the same stem cells as leukocytes and red cells in the bone marrow. Production of megakaryocytes is under the control of thrombopoietin. Megakaryocytes are large cells with abundant cytoplasm that undergo division of the nucleus without concomitant cell division (endomitosis). As the cell matures, it develops a vacuolated blue-gray appearance with strands. Beads of the strands pinch off to become

platelets. The youngest platelets are the largest, as reflected in the mean platelet volume (MPV), which is an automatically determined parameter in the CBC. Smaller platelets are older, have less activity, and are less effective. Platelets live approximately 8½ to 10 days in the circulation, with a half-life of 4 days.

Although there is no reserve pool of platelets in the bone marrow, the marrow can increase its production of platelets sevenfold to eightfold above normal in response to stress (Fig. 39-6). From 30% to 40% of the platelet pool is in the spleen. Platelets freely move between the spleen and the circulation. (See further discussion online.)

Platelet Functions

The primary role of the platelet is to maintain the integrity of the endothelial lining of small vessels. This process is not completely understood but most likely indicates that platelets are constantly being recruited to repair submicroscopic rents between endothelial lining cells in small arterioles and venules. Thus, when the platelet count falls below a certain level, petechiae begin to appear, particularly in the dependent portions of the body such as the ankles and lower legs. Minor trauma may induce unusual bruising at these sites. (See discussion at www.expertconsult.com.)

Platelet Disorders

Disorders of platelets can be classified into three major categories: thrombocytopenia, thrombocytosis, and platelet function disorders.

Thrombocytopenia

Thrombocytopenia is a platelet count below the lower normal limit of 150,000 cells/ μ L and has two major causes, reduced platelet production and accelerated platelet removal. Bleeding does not generally occur until the platelet count falls below 20,000 cells/ μ L or the patient is an older adult, has coexistent diseases such as liver dysfunction or a connective tissue disorder, or is taking a drug that impairs platelet function.

Figure 39-6 Increased number of platelets seen on a peripheral blood smear. (From the American Society of Hematology Image Bank image #2695. Copyright 1996 American Society of Hematology, used with permission.)

Clinical signs of thrombocytopenia include the appearance of *petechiae*, small spots of pinpoint (millimeters) bleeding in the skin and subcutaneous tissue in which red blood cells leak from small capillaries or venules. Petechiae occur most frequently at sites in the lower extremities, around the mouth, or where there is constrictive clothing causing pressure on small vessels. Mucosal bleeding, recurrent nosebleeds, small bruises, and excessive menstrual bleeding are likely to be associated with von Willebrand's disease or discrete platelet disorders. If the clinical picture involves deep tissue bleeding into muscles or joints, a clotting factor disorder such as hemophilia is more likely.

Aspirin plays a key role in impairing platelet function and is used prophylactically in small doses to prevent coronary insufficiency syndromes and strokes. The investigation and treatment of thrombocytopenia are significantly affected by whether it is a solitary phenomenon or is associated with other cytopenias. Confirmation of a low platelet count should be done by repeating the CBC, because low platelet numbers can result from clumping caused by inappropriate anticoagulation of the blood sample or cold agglutinins. MPV can provide additional diagnostic information; low values suggest poor production and very old platelets, and high values suggest rapid production of new platelets. Bone marrow aspiration with biopsy may be important in the diagnosis of thrombocytopenia when the cause is unclear, because it may indicate aplasia, hypoplasia, drug toxicity, or bone marrow infiltration with leukemic cells or fibrosis.

Box 39-6 divides the causes of thrombocytopenia into production defects and accelerated platelet removal mechanisms. Platelets may not be produced in adequate numbers or may have dysfunctional characteristics if the marrow has been damaged by radiation or chemotherapeutic drugs or has been infiltrated by cancer or fibrous tissue. Drugs such as gold, sulfa products, thiazides, and ethanol can inhibit platelet production, and certain infections (e.g., HIV, rubella) or vaccines may cause deficits in production. Drug etiologies are more frequently related to drugs started within the previous 1 to 2 months. Deficiencies of vitamins (e.g., B₁₂, folic acid) may render the development of platelets ineffective.

Box 39-6 Classification of Thrombocytopenic Disorders

Platelet production defect

Pancytopenia, aplasia: Radiation, cancer drugs

Marrow infiltration: Fibrosis, cancer

Impaired platelet production: Infections (rubella, HIV) drugs; gold, sulfa compounds, alcohol

Impaired platelet development: Folate, vitamin B₁₂ deficiencies, alcohol

Accelerated platelet removal

Immune destruction: Autoantibodies—idiopathic thrombocytopenic purpura, systemic lupus erythematosus; infections (HIV, sepsis, mononucleosis); drugs

Nonimmune destruction: Disseminated intravascular coagulation, vasculitis, thrombotic thrombocytopenic purpura, HELLP syndrome*

Hypersplenism: Various causes

*Hemolysis (microangiopathic), elevated liver enzymes, and low platelets.

The most common phenomenon in accelerated platelet removal is *immune destruction*. Antibodies produced by the body may facilitate the enhanced removal of platelets from the circulation. Diseases involving immune platelet destruction include idiopathic thrombocytopenic purpura, systemic lupus erythematosus (SLE), drug-induced thrombocytopenia, infectious mononucleosis, HIV/AIDS, malaria, and even posttransfusion purpura. Diseases involving no immunologic mechanism, but in which platelets are removed from the circulation more rapidly than normal, include disseminated intravascular coagulation (DIC), preeclampsia, vasculitis, thrombotic thrombocytopenic purpura, and gram-negative septicemia. Also, a significantly enlarged spleen represents an increased platelet pool, thus lowering the platelet count.

Removal of drugs that could be causing production problems and replacement of vitamins (B₁₂ and folic acid) are probably the easiest remedies to address platelet production defects. Recombinant thrombopoietin is in development, but has not yet been approved for clinical use. Platelet counts greater than 50,000 cells/ μ L are generally safe for interventional procedures, except major surgery or epidural anesthesia. Childbirth and tooth extractions may occur safely with stable platelet levels (30,000-50,000) and no evidence of bleeding.

Accelerated Platelet Removal Caused by Immune Destruction

Idiopathic Thrombocytopenic Purpura

Formerly seen most often in young women, idiopathic thrombocytopenic purpura (ITP) is now seen more often in HIV-positive men. Associated illnesses or causes may include infectious mononucleosis, Graves' disease, thyroiditis, and other viral illnesses. ITP has an insidious onset, with the only physical finding being petechiae in the lower extremities. There may be some gingival bleeding with brushing or flossing of the teeth; splenomegaly is uncommon. ITP is characterized as an autoimmune disorder in which IgG antibodies are formed against the patient's own platelets. These antibodies attach to platelets, causing them to be identified as abnormal. The platelets are then removed by the RES, most often in the spleen. The bone marrow responds to the rapid destruction of platelets by increasing production, resulting in functionally large platelets, which accounts for the low incidence of bleeding in this disorder. The laboratory evaluation reveals a higher-than-normal MPV and the presence of few platelets on a peripheral blood smear (Bain, 2005); however, the platelets present are large and well granulated. If schistocytes or helmet cells are seen, this suggests a mechanical hemolytic process as well. The bone marrow reveals a plethora of megakaryocytes, whereas other test results for autoimmune diseases should be negative. Other, similar presentations might include a falsely low platelet count resulting from the anticoagulant used in the blood sampling (e.g., pseudothrombocytopenia caused by clumping), cold agglutinins, gestational thrombocytopenia, and myelodysplastic syndrome.

Treatment of ITP varies with the degree of bleeding, whether the patient is pregnant, CNS involvement, and to some extent, the patient's age. The goal is to prevent serious bleeding. The American Society of Hematology has made the

following evidence-based recommendations for the management of ITP (George et al., 1996):

1. Patients with platelet counts above 50,000 cells/ μ L do not require treatment routinely.
2. Treatment is indicated in patients with platelet counts of 20,000 to 30,000 and in patients with platelets below 50,000 with significant mucosal bleeding or risk factors for bleeding.
3. Patients with platelets below 20,000 need not be hospitalized if they are asymptomatic or if they have only mild purpura.

Patients in the second category who have mucosal bleeding with a platelet count between 20,000 and 30,000 cells/ μ L are often treated with prednisone, 60 to 100 mg/day, to reduce the amount of antiplatelet antibodies produced by lymphocytes in the marrow and spleen. When the platelet count rises after 2 to 3 weeks of therapy, the prednisone can be tapered over another 3 to 4 weeks. Long-term complete response occurs in probably 15% to 20% of patients. If the platelet counts remain below 30,000 after 6 to 8 weeks of therapy, or if the platelet count begins to fall after the steroids have been tapered, splenectomy should be considered. If splenectomy is planned, steroid therapy should be resumed to boost the platelet count to a more acceptable level. The lymphoid system in the spleen can respond best to immunizations, such as pneumococcal, *Haemophilus influenzae*, or meningococcal vaccine, which should be administered 1 to 2 weeks before surgery. If steroids do not raise the platelet level to an acceptable presurgical level, IVIG at 0.4 to 1.0 mg/kg may also be administered before surgery but will take 1 to 3 days to increase platelet counts to safe levels. CNS bleeding is a medical emergency in which hospitalization, large doses of prednisone, and IVIG are used as concomitant therapeutic measures.

Patients who go into remission and later relapse or fail to respond to these measures are considered to have refractory ITP. If the platelet count is above 30,000, the best course of action is to consider it an incomplete response and manage the patient conservatively, without further therapy. If therapy is indicated in these refractory cases, the physician can consider agents such as azathioprine or cyclophosphamide, plus prednisone. Referral of these patients to a hematologist is often necessary.

Other Disorders Caused by Immune Destruction

Immune-mediated thrombocytopenia may occur in patients with SLE or lymphoma; treatment is similar to that of ITP in other patients. If the ITP is associated with a hemolytic anemia, the clinical picture is that of Evans' syndrome. Treatment is similar to that for ITP without autoimmune hemolytic anemia. Patients with aggressively treated HIV may develop antibodies to the platelet GP-IIb/IIIa, causing thrombocytopenia; if platelet count is below 10,000, prednisone or splenectomy (or both) can be used. Patients treated with GP-IIb/IIIa antagonists may develop thrombocytopenia. Removal of the antagonist is usually effective. For platelet counts less than 10,000, one platelet transfusion is usually effective in restoring platelets to safe levels.

Approximately 5% of all pregnant women have a platelet count as low as 70,000 cells/ μ L. If the platelet count drops lower, preeclampsia should be ruled out before making a diagnosis of ITP. Splenectomy carries significant risks of

miscarriage, which can be reduced by administering corticosteroids or IVIG.

Multiparous women receiving a blood or platelet transfusion may have posttransfusion thrombocytopenia at a level of 10,000 cells/ μ L or lower. This is apparently the result of having previously been sensitized to blood and platelet antigens that induced an antibody not only to the foreign platelets in the transfusion, but also to endogenous platelets. This occurs 2 to 10 days after the transfusion and may last for as long as 4 weeks. Platelet transfusions are not effective. Therapeutic use of IVIG and sometimes high doses of corticosteroids are more likely to be effective.

Specific drugs can elicit immune-mediated platelet destruction that mimics ITP, including cocaine, gold, heparin, quinidine, and platelet glycoprotein antagonists (e.g., abciximab [ReoPro]). Removal of the offending drug is usually sufficient, along with time to allow the situation to resolve. A few cases of thrombocytopenia have occurred in patients taking a combination of naproxen and acetaminophen; their metabolism caused an immune reaction involving normal platelets, leading to their enhanced destruction.

Nonimmunologic-Enhanced Destruction of Platelets

A common theme in nonimmune platelet destruction is blood vessel wall injury, resulting in thrombin and platelet activation, with ensuing consumption of platelets and a reduction in the platelet count. Heparin-induced thrombocytopenia may result from heparin flushes used in settings where large, vascular access lines are needed.

Thrombotic Thrombocytopenic Purpura and Hemolytic Uremic Syndrome

One of the more serious entities in this category is thrombotic thrombocytopenic purpura (TTP) and the adult hemolytic uremic syndrome (HUS). These disorders may be stimulated by similar agents or factors, but their pathophysiology differ. In both, damage to the endothelium of small vessels triggers platelet deposition in small arterioles and capillaries, resulting in a thrombotic microangiopathy. TTP is characterized by five major clinical features: (1) microangiopathic hemolytic anemia with a high lactate dehydrogenase (LDH) level, (2) severe thrombocytopenia, (3) fever, (4) CNS symptoms and signs, and (5) renal compromise.

The physician should suspect TTP or HUS in the patient with thrombocytopenia and microangiopathic hemolytic anemia alone, with no other apparent cause. The blood smear in both disorders will show reduced platelets, helmet cells, and schistocytes, indicative of the microangiopathic hemolytic process. If assayed, bone marrow will reveal increased numbers of megakaryocytes. Renal disease will be more severe in HUS, whereas CNS symptoms may be more prominent in TTP. Not all patients have all five features on presentation. Differentiation must be made from other disorders such as Evans' syndrome, SLE, and leukemia. Hemolysis, leukocytosis, and a negative direct Coombs test are hallmarks of TTP and HUS. The absence of abnormal coagulation results essentially eliminates DIC. Causes of these syndromes may range from pregnancy to bone marrow transplantation, drugs, cancer, and in children, infection with *Escherichia coli* O157:H7. Treatment of this *E. coli* infection with antibiotics does not help and may make the disease worse. Various drugs may also cause TTP and HUS,

such as cancer chemotherapeutic drugs, immunosuppressive agents such as cyclosporine, antiplatelet drugs such as ticlopidine, oral contraceptives, and quinine.

A number of theories exist concerning the cause of these syndromes. Damage to the endothelial surface of small arteries may stimulate extensive platelet aggregation, thereby plugging up small vessels. Some investigators have found that there are abnormally large von Willebrand factor multimers in the circulation, suggesting that there is a deficiency in the enzyme (ADAMTS-13) that cleaves this blood-clotting factor. These large proteins then bind to platelets and cause plugging of small arterioles and capillaries.

A large, randomized clinical trial in Canada found that plasma exchange transfusions at 1.5 to 2 times the total body plasma volume were significantly more effective than simple plasma transfusions (Rock et al., 1991). This therapy must use a higher volume during the first 3 days and a lower volume over the next 4 to 5 days, for a minimum of 7 days. Other therapies, such as aspirin and steroids, have not been studied in randomized clinical trials. Splenectomy has been used occasionally, but only by experts seeing larger numbers of cases than normally seen in a family medicine setting.

HELLP Syndrome

The HELLP syndrome—*hemolysis (microangiopathic), elevated liver enzymes, and low platelets* ($\leq 100,000/\mu\text{L}$)—can occur in pregnant women between the 23rd and 39th weeks of gestation. This is a form of preeclampsia in which the patients are extremely ill. Treatment is delivery of the infant. The lowest platelet counts occur several days after delivery, although in some cases, thrombocytopenia does not present until after delivery. If a clinical picture of TTP emerges, plasma exchange should be strongly considered.

Thrombocytosis

Thrombocytosis can be a primary marrow-related disorder or secondary/reactive to a surgical or medical condition and is defined as a platelet count greater than 500,000/uL. Primary marrow related thrombocytosis may occur in the face of a chronic myeloproliferative or myelodysplastic disorder such as polycythemia vera (PV), primary myelofibrosis (MF), chronic myelogenous leukemia (CML) and essential thrombocythemia (ET). ET can be diagnosed by eliminating secondary causes and the other myeloproliferative disorders. (See earlier section: Myeloproliferative Disorders).

Secondary or reactive thrombocytosis can occur in the setting of infection, post surgical conditions with and without infection, cancer, postsplenectomy, acute blood loss or iron deficiency. Other situations, such as celiac disease, amyloidosis, rheumatoid arthritis, or rebound after alcohol- or drug-induced thrombocytopenia, can lead to thrombocytosis as well. Symptoms are more likely to be associated with primary rather than secondary thrombocytosis and include headache, lightheadedness, chest pain, visual disturbance, fingertip or toe paresthesia, and bleeding or thrombosis. Platelet morphology is also helpful. In most reactive thrombocytoses, the increased platelets on the peripheral blood smear are typically small and relatively uniform in size. In contrast, increased platelets of patients with myeloproliferative disorders may vary in size, including macrothrombocytes, misshapen platelets, and large patches of bluish-staining

material that may represent megakaryocyte cytoplasmic fragments. Patients with iron deficiency and increased platelets will have low serum ferritin levels, and splenectomized patients will have Howell-Jolly bodies in their RBCs and target cells on peripheral blood smears. C-reactive protein (CRP) should be elevated in inflammatory states and normal in primary marrow-induced thrombocytosis disorders. Diagnostic criteria for ET require platelet counts greater than 600,000. Patients with a primary marrow thrombocytosis have a mutation in *JAK2*.

Secondary thrombocytosis rarely causes thrombosis, and treatment is directed at the underlying disorder (e.g., infection, anemia). In primary marrow-related thrombocytosis, thrombosis is more likely. If thrombosis has occurred and the platelet count is greater than 800,000, prompt platelet apheresis is recommended. Chronically, the platelet count can be reduced with platelet-lowering agents (e.g., aspirin, hydroxyurea) with a goal of keeping the level below 400,000. Vasomotor symptoms may be controlled by low-dose aspirin (81 mg/day).

Platelet Function Disorders

Impaired platelet function may be acquired or inherited. Certain drugs are designed to interfere with platelet function and have proved useful in preventing recurrent strokes or other cardiovascular events, such as transient ischemic attacks (TIAs), in patients with established vascular disease. Particularly useful are drugs such as aspirin and nonsteroidal anti-inflammatory drugs (NSAIDs). An important distinction between aspirin and NSAIDs is that aspirin irreversibly inactivates cyclooxygenase in platelets, and aspirin-treated platelets will not normally contribute to clot formation. In contrast, NSAIDs reversibly interfere with platelet function. Clopidogrel inhibits platelet aggregation and selectively inhibits the binding of adenosine diphosphate (ADP) to its platelet receptor and the subsequent ADP-mediated activation of the GP-IIb/IIIa complex. Even more effectively than aspirin, clopidogrel reduces myocardial infarction, TIA, unstable angina, and other adverse events in patients with established arteriosclerotic cardiovascular disease.

Inherited disorders of platelet function are uncommon, although Glanzmann thrombasthenia may be seen most often. This congenital disorder has identified mutations in the GP-IIb/IIIa complex. ADP-induced platelet aggregation is abnormal, as is platelet contribution to clot retraction. Abnormalities involving impaired granular release or relative absence of granules characterize Bernard-Soulier and Wiskott-Aldrich syndromes; these rare disorders are also associated with thrombocytopenia. Von Willebrand's disease is an example of impaired platelet adhesion and aggregation caused by the deficiency of the von Willebrand factor, which significantly affects platelet function.

Unusual causes of acquired platelet dysfunction include liver disease and chronic renal failure. The role of the platelet function lesion in uremia or chronic liver disease is unclear, although the bleeding time may be prolonged in both disorders. The correction of the anemia with epoetin therapy in patients with end-stage renal disease appears to lessen the bleeding tendency in these patients.

Acquired platelet dysfunction can occur in myeloproliferative disease, uremia, liver disease, dysproteinemia, and drug-induced conditions. Some drugs that affect platelet

function include aspirin, NSAIDs, alcohol, dextrans, semi-synthetic penicillins, heroin, and GP-IIb/IIIa antagonists. Platelet dysfunction usually requires hematologic consultation and special laboratory testing to determine the cause.

KEY TREATMENT

Treatment starts with high-dose corticosteroids in ITP patients with platelet count less than 20,000/ μL and mucosal bleeding (Cines and McMillan, 2003) (SOR: B). Splenectomy is indicated in ITP patients in whom steroids fail to sustain platelet counts greater than 30,000/ μL (Nabel, 2009) (SOR: C). Patients should receive pneumococcal, *H. influenzae*, and meningococcal vaccines 1 to 2 weeks before splenectomy (Nabel, 2009) (SOR: C). Patients with TTP are best treated with plasma exchange transfusions (Rock et al., 1991) (SOR: A). Patients with chronic thrombocytosis can be treated with a platelet-lowering agent such as aspirin or hydroxyurea (Harrison et al., 2005) (SOR: A).

Lymphoid System

Key Points

- B lymphocytes produce immunoglobulins; T lymphocytes function as helper, suppressor, or cytotoxic cells; NK lymphocytes function as natural killer cells.
- Suspect malignancy for lymph node enlargement that is one sided, in the neck or mandibular region, in older patients with no evidence of infection.
- Biopsy reveals malignancy in 17% of patients with persistent lymph node enlargement from strictly primary care practices.

The lymphoid system is made up of the primary and secondary tissues or organs. The primary lymphoid system consists of the bone marrow and thymus and generates B and T lymphocytes. The secondary lymphoid system consists of the lymph nodes, spleen, tonsils, and special lymphocytic tissue in the GI and respiratory tracts. Lymphocytes reside in these tissues; B and T cells may be segregated but can interact. T cells are more localized between follicles and B cells more within follicles. Macrophages, histiocytes, dendritic cells, and endothelial cells form the supporting structures of lymphoid organs and facilitate interactions that allow lymphocytes to generate appropriate cellular and humoral immune responses. T cells make up 60% to 80% of the normal lymphocyte population, B cells 10% to 20%, and natural killer (NK) cells 5% to 10%. NK cells are related to T cells in that they both arise from thymic precursors.

Functions of Lymphocytes

See discussion online at www.expertconsult.com.

Lymphocyte Disorders

Lymphocytosis

The presentation of lymphocytosis varies somewhat with age. In those older than 12 years, the upper limit of normal is 4000 cells/ μL . Neonates and young children may have

normal absolute lymphocyte counts up to 8000 cells/ μL . The absolute lymphocyte count can be calculated by multiplying the WBC count by the percentage of lymphocytes in the differential. When an absolute lymphocytosis is encountered, the peripheral smear should be examined for atypical lymphocytes, granular lymphocytes, blastocytes (blasts), smudge cells, and other abnormalities of morphology and diversity.

Lymphocytosis can be classified as primary (malignant) or secondary (reactive). *Primary* lymphocytosis is defined in the context of an acute or chronic lymphoproliferative disorder, often caused by dysregulation of lymphocyte development and production. Leukemias (chronic lymphocytic, acute lymphocytic, hairy cell), lymphoma, and B-cell lymphocytosis are examples of primary or malignant lymphocytosis. *Secondary* lymphocytosis is defined as a lymphocytosis in a patient who does not have a known hematologic disorder and in whom the lymphocyte count is expected to return to normal in less than 2 months after cessation of the inciting condition. *Reactive* lymphocytosis can sometimes be mistaken for a primary or malignant lymphocytosis when examining the peripheral blood smear, particularly in infectious mononucleosis with a marked increase in larger, atypical, or transformed lymphocytes. Other causes of secondary lymphocytosis may generate small lymphocytes, as in pertussis. Viral infections are the most prevalent cause of secondary lymphocytosis, including Epstein-Barr, cytomegalovirus, herpes simplex, varicella, rubella, HIV, adenovirus, and hepatitis. Occasionally, toxoplasmosis and pertussis in children can cause a lymphocytosis that is extremely high, up to levels of 50,000 to 70,000 cells/ μL . Some forms of extreme stress can cause an increase in lymphocytes, such as cardiovascular collapse, septic shock, status epilepticus, surgery, or major hypersensitivity or allergic disorders. *Chronic* lymphocytosis may be seen in patients with cancer, sarcoidosis, and certain autoimmune disorders, as well as in cigarette smokers.

Lymphocytopenia

When a paucity of lymphocytes occurs, because most lymphocytes are T cells, it is preponderantly a reduction in the T-cell count. Lymphocytopenia is defined as a total lymphocyte count of 1000 cells/ μL or lower. Inherited causes of lymphocytopenia include severe combined immunodeficiency, ataxia-telangiectasia, Wiskott-Aldrich syndrome, and idiopathic CD4+ T-cell lymphocytopenia. Acquired causes of decreased lymphocyte counts include mostly viral infections, such as HIV, hepatitis, influenza, or respiratory syncytial virus (RSV), and unusual bacterial infections, such as typhoid fever or tuberculosis. Miscellaneous causes include aplastic anemia, autoimmune diseases, Hodgkin's disease, sarcoidosis, chronic alcohol ingestion, immunosuppressive agents, particularly corticosteroids, and radiation.

Lymphadenopathy

Enlarged lymph nodes, single or multiple, are a common problem seen by family physicians in ambulatory practice. Nodes may be enlarged as a reactive phenomenon to infection, inflammation, malignancy, or systemic generalized disease (Box 39-7). Most enlarged lymph nodes seen in younger patients are benign. Table 39-6 summarizes the four major determinants of significant lymphadenopathy:

Box 39-7 Causes of Lymphadenopathy**Infections**

Bacterial: Streptococci, staphylococci, cat-scratch fever, mycobacteria, tularemia

Viral: Infectious mononucleosis, adenovirus, HIV, herpes simplex

Chlamydial: *Chlamydia trachomatis*

Mycotic: Sporotrichosis, histoplasmosis

Protozoal: Toxoplasmosis

Rickettsial: Rocky Mountain spotted fever, typhus

Malignancies

Hodgkin's lymphoma, acute and chronic leukemias, lymphoma

Metastatic tumors and sarcoma

Immune system

Drug reactions

Insect stings

Connective tissue diseases

Serum sickness

Miscellaneous

Sarcoidosis, amyloidosis

Chronic granulomatous disease

Histiocytic disorders

Necrotizing lymphadenitis

age of patient, location of adenopathy, character of lymph node, and clinical settings in which enlarged lymph nodes can occur. For example, a relatively soft, small (<1 cm), movable node may be found in the submandibular or anterior cervical region in as many as 50% to 60% of those younger than 50 years. Inguinal nodes up to 1 to 2 cm may be found in normal healthy adults. Patients younger than 50 are much more likely to have lymphadenopathy from a benign or infectious process than patients older than 50, in whom only 40% of the causes of lymphadenopathy are of a benign or infectious nature.

Enlarged lymph nodes in the anteroposterior cervical regions or the occipital area in younger persons are generally benign, but this also depends on the character of the node and the clinical setting in which this enlargement occurs. If two distinct but separate lymph node groups are enlarged, a hematologic malignancy is more likely, such as chronic lymphocytic leukemia or lymphoma. Infectious processes such as infectious mononucleosis, viral hepatitis, secondary syphilis, histoplasmosis, toxoplasmosis, or cytomegalovirus infection are more probable when generalized lymphadenopathy is found. If one-sided lymph node enlargements without obvious infectious cause are discovered in the neck or mandibular region, and in older patients in the anterior scalene node region, malignancy deserves much greater consideration.

Virchow's node is an enlarged left supraclavicular node usually infiltrated with a metastatic tumor from below the diaphragm, especially of GI origin. An enlarged right supraclavicular node is more likely associated with a tumor of thoracic origin. A matted node that is enlarged could be caused by a local phenomenon such as an infection, bite, or trauma to the arm, but it may also represent a melanoma, lymphoma, or metastatic breast cancer in a young woman. Bilateral hilar adenopathy and enlargement of nodes in the femoral triangle are more likely to be seen with systemic disease, generalized infection, or occasionally lymphoma.

The character of the node, overall size, and relation to other lymph node groups help determine whether biopsy is indicated. When there is thoracic adenopathy, unilateral hilar adenopathy, or mediastinal adenopathy, particularly in older adults, lung cancer, sarcoidosis, or lymphoma must be strongly considered, depending on the clinical setting. Mediastinal adenopathy in young persons, however, may be associated with sarcoidosis or infectious mononucleosis. Enlarged nodes found in the abdomen or retroperitoneal space are more likely to be malignant and are characteristic of lymphomas or germ cell tumors in men.

Nodes that are enlarged, well circumscribed, rubbery, firm, mobile, and not particularly tender are more likely to be reactive lymph nodes related to infection. Some may also be painful, particularly if the rate of the growth has been rapid, caused by inflammation. Lymph nodes that are hard, nontender, nonmovable, and fixed to the underlying tissues are more likely to be infiltrated with metastatic tumor from a regionally proximate cancer.

The clinical setting is important. An older adult who smokes and has an enlarged supraclavicular or cervical lymph node may be more likely to have a cancer in the mouth, head and neck, or lung than a younger person with enlarged cervical lymph nodes accompanied by a fever and sore throat, indicative of infectious mononucleosis.

Table 39-6 Lymphadenopathy: Clinical Signs and Implications

| Considerations | Significance |
|---|---|
| Age of patient (yr) | |
| <30 | 80% lymphadenopathy benign, most often infectious |
| >50 | 40% benign probability |
| Location of node enlargement | |
| Cervical nodes, axillary nodes, epitrochlear nodes, bilateral hilar adenopathy | Benign, infectious |
| Generalized; unilateral, jugular, or mandibular areas; supraclavicular, scalene nodes; Virchow's node; thoracic, retroperitoneal; unilateral hilar adenopathy | Malignant |
| Characteristics of node enlargement | |
| Soft, mobile, tender | Benign |
| Rubbery, matted, nontender | Lymphoma |
| Hard, fixed | Chronic lymphocytic leukemia (CLL), metastatic |
| Clinical setting of patient* | |
| Older adult, smoker | Malignant |
| College student | Infectious with pharyngitis and fever |
| *In which solitary, nontender, enlarged cervical node occurs. | |

Auxiliary and supraclavicular nodes may increase in size in women with silicone breast implants. Patients with acquired immunodeficiency syndrome (AIDS) may have generalized lymphadenopathy indicative of a severe systemic infection or lymphoma. Associated symptoms such as fatigue and intermittent fevers are common.

When an enlarged lymph node or lymph node group that does not have striking hallmarks of malignancy is seen, and there are no other symptoms, it is appropriate to watch and observe the patient over several weeks. Nodes that do not become smaller or revert to a more benign appearance should be biopsied. In primary care practices, referral yielded a 17% prevalence of malignancy (Chau et al., 2003). Nodes that are difficult for the pathologist to read as reactive and lymph nodes diagnosed with follicular hyperplasia may have an occult lymphoma, and a second opinion might be beneficial. For a patient with repeated lymph node enlargements that have no clearly infectious cause, serologic studies for infections and repeat lymph node biopsies are indicated to establish a diagnosis. Most lymph node enlargements found by the family physician are benign and resolve within a short time. Those that do not resolve require further investigation and ultimately biopsy if no cause can be found.

Classification of Hematopoietic and Lymphoid Tissue Tumors

The World Health Organization (WHO) updated its classification of blood and lymphoid tissue tumors in 2008 by utilizing more molecular characteristics or markers instead of primarily morphologic changes seen in malignant cells. It includes genetic, morphologic, immunophenotypic, and clinical characteristics to formulate a diagnosis. Tumors of heme and lymphoid cells are divided into three main cell types: (1) myeloid cell neoplasms, originating in leukocytes and RBCs found in the marrow; (2) lymphoid neoplasms, from B-cell and T-cell lymphocyte precursors and mature forms; and (3) dendritic/histiocytic neoplasms, derived from precursors to dendritic cells or tissue microphages (Box 39-8).

Box 39-8 WHO Classification of Hematologic and Lymphoid Neoplasms

Myeloid Neoplasms

Acute myeloid leukemia (AML)
Myelodysplastic syndromes
Myeloproliferative disorders
Chronic myelogenous leukemia (CML)
Chronic neutrophilia leukemia
Polycythemia vera (PV)
Essential thrombocytopenia (ET)
Chronic eosinophilic leukemia
Mastocytosis
Myelodysplastic/myeloproliferative syndromes
Myelomonocytic leukemia: chronic/juvenile
Atypical CML

Lymphoid Neoplasms

Precursor lymphoid neoplasms (precursor B or T cell)
Leukemia/lymphomas
Mature B-cell neoplasms
Chronic lymphocytic leukemia
Follicular lymphoma
Diffuse large B-cell lymphoma
Plasma cell myeloma
Hairy cell leukemia
Hodgkin's lymphoma (HL)
Nodular lymphocyte-predominant HL
Classic HL
Mature T-cell or NK-cell neoplasms
Anaplastic large-cell lymphoma
Adult T-cell lymphoma/leukemia

Dendritic/Histiocytic Neoplasms

Tumors from precursors to dendritic cells
Tumors from tissue microphages

Leukemia

Urogenital health care concerns account for 4.4% of all ambulatory patient visits in the United States, more than half with primary care physicians (Schappert and Rechtsteiner, 2008). Disease in the urogenital system can be categorized as anatomic, functional, infectious, and neoplastic disorders. Although there is inevitable overlap between these categories, as in benign prostatic hyperplasia (neoplastic) causing out-flow obstruction and incontinence (functional), this framework is useful for characterizing urinary tract abnormalities.

Evaluation of the Urinary Tract

The urinary system includes the kidneys, ureters, bladder, and urethra; a system history most often focuses on *voiding*, its primary function. Other issues may include *sexual function* or areas of overlap with other systems (e.g., abdominal pain). Patients often present with, or are found to have, common concerns specific to the urinary tract (see later discussion). A thorough drug history is critical because many common medications have urologic side effects (Thomas et al., 2003) (see eTable 40-1 online).

Physical Examination

Physical examination is limited with urinary tract disorders, but special techniques are available. Many physical findings are helpful, if present, although their absence does not

imply normalcy. For example, a renal bruit may indicate arterial stenosis, but its absence does not rule out the condition. Variations in examiner skill and patient factors also limit the accuracy and reliability of physical findings.

The kidneys are retroperitoneal organs and are difficult to palpate, except in very thin persons and children. The right kidney sits more inferiorly than the left because of the liver. The ureters are nonpalpable but, as with the kidneys, may radiate pain to the flank area. The bladder is typically nonpalpable unless distended with at least 150 mL of urine, and percussion is preferred over palpation for diagnosing distention (Gerber and Brendler, 2007). In women an enlarged bladder may also be noted on bimanual examination.

Pelvic examination is useful for diagnosing *cystocele* in women. Two fingers can be placed in the introitus and opened to visualize the vaginal cavity. The patient then performs the Valsalva maneuver. The anterior wall dipping down into the vaginal cavity may signify a cystocele. More subtle cystoceles can be detected by placing a lubricated cotton swab in the urethral meatus and having the patient perform the Valsalva maneuver. If the swab moves upward (anteriorly), it may indicate movement of the bladder neck with straining.

Examination of the external genitalia in men may reveal penile lesions, regional adenopathy, or disorders of the scrotum and testicles. Uncircumcised men should have the foreskin retracted to rule out phimosis and visualize

the glans. Careful palpation of the testicular complex is needed to detect and differentiate masses and anatomic abnormalities. Digital rectal examination (DRE) can estimate prostate size and detect masses or inflammation. It is usually performed with the patient leaning forward on the examination table with his elbows bent. Prostate tenderness, warmth, or a boggy consistency suggests prostatitis. Prostate enlargement consistent with benign prostatic hyperplasia is typical in older men. Masses or asymmetry may indicate a tumor.

Laboratory Tests

Key Points

- Routine screening urinalysis is not recommended, even in pediatric prevention.
- Evaluate for sexually transmitted infections in patients with UTI symptoms, positive leukocyte esterase, and negative urine cultures.
- Do not use urine from a catheter bag for culture.
- Microalbuminuria screening is routine in diabetes care.

Urinalysis

Urinalysis is the most common office laboratory test, with dipstick urinalysis most often used (Cherry et al., 2007). Urinalysis is inexpensive, noninvasive, easily carried out, and could indicate a number of urinary and systemic conditions. Performing urinalysis in otherwise healthy people as a preventive health service is commonplace. However, screening is not recommended in asymptomatic adults for many of the conditions that urinalysis can identify (e.g., asymptomatic bacteruria, bladder cancer; see later). Routine urinalysis lacks evidence of benefit, and guidelines recommend against routine urinalysis as part of adult or child preventive care, suggesting it only be done if clinically indicated (Grenz et al., 2009a, 2009b; Stephens and Wilder, 2003). The American Academy of Pediatrics also no longer recommends urinalysis as part of routine pediatric prevention (AAP, 2007).

Although urinalysis can detect occult disease, most positive results will not yield this outcome; more patients would incur unnecessary or potentially dangerous medical evaluations than would benefit. Thus, the potential value is elusive while there is the possibility of harm. It is important, however, not to confuse broad population screening recommendations with those specific to certain patients or problems. For example, microalbuminuria screening is routine in diabetes care (ADA, 2009).

Physicians should be aware that there is a good chance of false-positive and false-negative results with dipstick tests. Thus, abnormal results are not necessarily indicative of disease and may need confirmatory testing (Gerber and Brendler, 2007; Simerville et al., 2005).

Specimen Preparation

A midstream clean-catch specimen is the recommended standard for urinalysis. Uncircumcised men should retract the foreskin before urinating. Urine should be examined immediately, if possible, and should be refrigerated if it will not be examined in 1 to 2 hours.

Inspection

Normal urine color varies from clear (dilute) to yellow to deep golden and cloudy. Many substances can cause urine color to appear abnormal (Table 40-1). Cloudy urine may be caused by infection (*pyuria*), but the most common cause is *phosphaturia*, in which phosphate crystals precipitate in alkaline urine. Microscopic analysis can differentiate these two entities. A strong or foul-smelling sample does not necessarily indicate infection. Urine odor may change because of dietary intake (e.g., asparagus), medications, illness, or concentration. Fecal odor suggests gastrointestinal-vesical fistula.

Dipstick Urinalysis

Specific Gravity

Urine specific gravity ranges from 1.001 to 1.035. It reflects the urine concentration and is a marker of hydration status. However, conditions affecting renal functions, such as chronic kidney disease and syndrome of inappropriate antidiuretic hormone secretion (SIADH), alter specific gravity and its relation to hydration. The glomerular filtrate has a specific gravity of 1.010, and urine with this fixed specific gravity may indicate renal dysfunction.

pH

Average urinary pH is usually acidic, ranging from 5.5 to 6.5. It reflects the serum pH except in patients with *renal tubular acidosis* (RTA) (Simerville et al., 2005). These patients have

Table 40-1 Factors Affecting Urine Color

| Color | Causative Factor |
|---------------|---|
| Colorless | Very dilute urine; overhydration |
| Cloudy, milky | Phosphaturia; pyuria; chyluria |
| Red | Hematuria; hemoglobinuria, myoglobinuria; anthocyanin in beets and blackberries; chronic lead and mercury poisoning; phenolphthalein (in bowel evacuants); phenothiazines (e.g., prochlorperazine [Compazine]); rifampin |
| Orange | Dehydration; phenazopyridine (Pyridium); sulfasalazine (Azulfidine) |
| Green-blue | Biliverdin; indicanuria (tryptophan indole metabolites); amitriptyline (Elavil); indigo carmine; methylene blue; phenols (e.g., IV cimetidine [Tagamet]; IV promethazine [Phenergan]); resorcinol; triamterene (Dyrenium) |
| Brown | Urobilinogen; porphyria; aloe, fava beans, rhubarb; chloroquine, primaquine; furazolidone (Furoxone); metronidazole (Flagyl); nitrofurantoin (Furadantin) |
| Brown-black | Alkaptonuria (homogentisic acid); hemorrhage; melanin; tyrosinosis (hydroxyphenylpyruvic acid); cascara, senna (laxatives); methocarbamol (Robaxin); methyl dopa (Aldomet); sorbitol |

alkaline urine because the kidneys cannot acidify urine. Type 1 RTA will always have alkaline urine, whereas urine in type 2 RTA may become acidic as the acidosis worsens. Urine infected with urease-producing organisms such as *Proteus* species becomes alkaline.

Blood

Dipstick urinalysis has a sensitivity of 91% to 100% and a specificity of 65% to 99% for microscopic hematuria (Grossfeld et al., 2001a). Myoglobin and hemoglobin can cause a false-positive dipstick reaction. Thus, heme-positive urine specimens require microscopic examination.

Glucose

Glucose in the urine (*glycosuria*) occurs when the glucose concentration of the glomerular filtrate exceeds the proximal tubule's ability to resorb it. The dipstick only reacts to glucose. A finding in uncontrolled diabetes mellitus, glycosuria occurs when the serum glucose level exceeds 180 mg/dL.

Ketones

Urinary ketone bodies are a main feature of diabetic ketoacidosis. They may also be found in starvation states and pregnancy. Dipsticks detect acetoacetic acid. False-positive results may occur with very concentrated or acidic urine.

Leukocyte Esterase

Leukocyte esterase is a substance produced by neutrophils that signifies possible pyuria. It is sensitive (72%-97%), but not very specific (41%-86%) for urinary tract infection (UTI). Urine contamination by vaginal cells is the most common reason for false-positive results. Patients with typical UTI symptoms, positive leukocyte esterase, and negative urine cultures should be evaluated for sexually transmitted infections (STIs) (Graham and Galloway, 2001).

Nitrite

The finding of nitrites in the urine is 92% to 100% specific for a UTI (Simerville et al., 2005). However, many patients with UTIs will not be nitrite positive (i.e., low sensitivity). Gram-negative coliform organisms convert urinary nitrates to nitrite, but not *Staphylococcus saprophyticus* or enterococci. The test loses accuracy with lower bacterial colony counts. The reagent is air sensitive, so a dipstick may yield false-positive results if strips in the container are not tightly sealed (Gallagher et al., 1990).

Protein

Urine dipsticks are very sensitive and specific for albuminuria. The reagent color change roughly corresponds to the protein concentration in the sample (Table 40-2). Very dilute, alkaline, or nonalbumin proteinuria may cause false-negative results. Microalbuminuria screening usually requires a separate dipstick designed specifically for this purpose. A urine protein electrophoresis is needed to evaluate nonalbumin proteinuria, such as globulinuria or Bence Jones protein.

Urobilinogen

Urobilinogen is a breakdown product of conjugated bilirubin. There is normally a small amount present, but elevations indicate possible hemolysis or liver disease. Conjugated bilirubinuria is abnormal and signifies hepatic disease or biliary

obstruction. Unconjugated bilirubin is not filtered by the glomerulus.

Urine Microscopy

To prepare a urine sample for microscopic analysis, centrifuge 10 mL of urine for 5 minutes at 2000 rpm. After centrifugation, pour off the supernatant and resuspend the remaining sample (0.5-1.0 mL). Place a drop of this sample on the slide and focus up to high power. Samples showing probable skin or vaginal contamination should be retested or a catheterized specimen obtained (Grossfeld et al., 2001a). Sediment counts should be estimated as the average number of elements viewed per high-power field (hpf).

Red Blood Cells

Urine specific gravity may affect findings, because red cells may lyse at values lower than 1.007 (Vaughan and Wyker, 1971). Normal-appearing red blood cells (RBCs) suggest a lesion in the urinary tract, whereas dysmorphic RBCs are probably of glomerular origin (Fig. 40-1). Red cell casts are typically found at the edges of the glass coverslip and are highly suspicious for renal parenchymal disease.

White Blood Cells

Normal urine samples may show some white blood cells (WBCs) on high-power examination (Fig. 40-2). For women, fewer than 5 WBCs/hpf is normal, and for men fewer than 2 WBCs/hpf is normal (Simerville et al., 2005). Values in excess of these limits constitute microscopic pyuria. Purulent, cloudy urine with WBCs too numerous to count describes gross pyuria.

White cells are inflammatory markers, so infection cannot be confirmed by their presence or ruled out by their absence. Common causes of sterile pyuria include STIs, kidney stones, prostatitis, and urinary tract neoplasms. In children, pyuria may occur during a febrile illness, even if a UTI is not present (Graham and Galloway, 2001).

Casts

RBC casts signify a nephritic or vasculitic process. WBC casts are often considered pathognomonic for pyelonephritis, but may be found in other types of nephritis. Granular and waxy casts signify renal parenchymal disease. Hyaline casts may

Table 40-2 Dipstick Protein Findings

| Dipstick Color | Estimated Corresponding Protein Level (mg/dL) |

be normal in concentrated specimens or a marker of renal infection or disease.

Crystals

Various crystal morphologies may be seen in urine samples (Fig. 40-3).

(From Gerber GS, Brendler CB. *Evaluation of the urologic patient*. In Wein AJ [ed]. *Campbell-Walsh Urology*, 9th ed, vol 1. Philadelphia, Saunders-Elsevier, 2007, p 108.)

Urinary Epithelial (Urothelial) Cells

Transitional epithelial cells are normally found in microscopic specimens. They are uniform in shape and have a large, central nucleus. In contrast, squamous cells have irregular borders and a small nucleus. Squamous cells indicate skin contamination.

Bacteria

Bacteria may signify bacteruria, although in women vaginal contamination is also likely. A urine Gram stain is also helpful for identifying bacterial characteristics in urine samples in which infection is suspected.

Fungi

Yeast seen in urine specimens most likely indicates contamination from the skin or vagina. However, it may signify systemic *Candida* infection if found in a catheterized specimen (Graham and Galloway, 2001).

Trichomonads

These motile organisms signify a common STI and may be seen in urine samples. Treatment with metronidazole (2 g as a single dose or 500 mg twice daily for 7 days) is effective. Patients should be evaluated for other STIs.

Urine Culture

Urine culture is the “gold standard” test for diagnosing UTIs. Many sources have emphasized the midstream clean-catch technique as necessary for preventing contamination, although the value of this practice is uncertain (Lifshitz and Kramer, 2000). Bladder aspiration and catheterization are invasive sampling techniques. Urine from a catheter bag should not be used for culture, because bacterial contamination is typical.

More than one bacterial isolate on culture suggests contamination. Controversy exists regarding the threshold colony counts that define bacteruria consistent with infection. Although more than 10^5 colony-forming units per milliliter (CFU/mL) is a well-known cutoff, lower values are meaningful in certain patients. In patients with typical UTI symptoms, counts as low as 10^2 CFU/mL signify infection if *Escherichia coli* or other enterobacteriaceae are isolated. A cutoff of 10^3 CFU/mL is appropriate in men with symptoms (Graham and Galloway, 2001).

Other Diagnostic Tests

Postvoid Residual Measurement

Postvoid residual measurement assesses the volume of urine in the bladder after voiding and can be performed in the office. One method is to have the patient void and then measure any residual urine by catheterization. Less than 50 mL of residual urine is normal, and 200 mL or greater is abnormal (Nitti and Blaivas, 2007). Portable ultrasound units can also estimate postvoid residual urine. *Urodynamics* refers to a battery of tests examining micturition, which may include postvoid residual measurement as well as various tests of bladder and sphincter pressures.

Endoscopy

Urinary endoscopy (cystoscopy) provides visual diagnosis and the opportunity for intervention. Rigid or flexible endoscopic procedures are available. Common interventional

techniques include stone retrieval, stent placement, tumor biopsy and resection, and laser treatment. Risks include infection, bleeding, urethral damage, and bladder perforation.

Imaging Studies

Key Points

- Ultrasound studies are ideal for evaluating renal parenchymal disease and testicular disorders.
- Computed tomography is a better choice for evaluating solid renal masses, renal infections, perirenal masses, and renal calculi.

Intravenous Urography

The standard method of upper urinary tract imaging is intravenous urography (IVU), also known as intravenous pyelography (IVP). It is widely available, has a low cost, and can detect upper tract urothelial tumors and renal calculi. However, it cannot distinguish solid from cystic masses. Thus, ultrasound studies are often required to evaluate abnormal findings. Ultrasound and IVU are limited in their ability to detect small renal masses, particularly those smaller than 3 cm. Further, IVU is only 52% to 59% sensitive for detecting renal calculi (Grossfeld et al., 2001b). IVU also requires administering radiographic contrast.

Ultrasound

Ultrasound has many applications for evaluating urinary tract disease. It is the method of choice for imaging renal cysts and the renal parenchyma as part of a renal disease workup. Ultrasound is also the test of choice for evaluating scrotal and testicular disorders. It can usually differentiate masses such as hydrocele, inguinal hernia, and varicocele. Furthermore, regular and color Doppler ultrasound are essential parts of evaluating acute scrotal pathology, such as epididymitis, orchitis, and testicular torsion.

Ultrasound is almost 100% sensitive for testicular tumors (Dogra et al., 2003). However, it does not provide tissue diagnosis. Rather, ultrasonography helps define the nature of the suspected lesion, differentiating it from the many other conditions that might mimic an intratesticular tumor.

Computed Tomography

Computed tomography (CT) is a better choice for evaluating solid renal masses, perirenal masses, and renal infections (Grossfeld et al., 2001b). CT is the test of choice for renal calculi (Lindbloom and Meadows, 2001). Other uses include CT angiography, trauma imaging, and cancer staging.

Other Techniques

Magnetic resonance imaging (MRI) is an option comparable with CT for detecting renal masses. MR urography is also available. MRI studies are more expensive than CT, however, and availability varies (Brehmer, 2002). Thus, this modality is often used when CT examination is equivocal or contraindicated. MRI is used for staging prostate cancers (Harisinghani et al., 2003).

Voiding cystourethrography (VCUG) uses contrast imaging of the bladder and urethra during urination. Contrast material is delivered via catheter, and the images are obtained while the patient voids. It is most often used to diagnose suspected vesicoureteral reflux. Nuclear medicine studies may also be used to examine possible vesicoureteral reflux, as well as renal function or suspected testicular torsion.

Common Urinary Tract Concerns

Key Points

- Dysuria most often indicates UTI, vaginitis, or STI.
- Gross hematuria requires aggressive evaluation.
- Urine microscopy is required to diagnose hematuria. In adults, risk factors for malignancy should be assessed; isolated hematuria is most common in children.
- Hematuria of renal origin often has dysmorphic red cells. Hematuria of bladder origin should show normal red cells.
- Nocturia is common in both genders and increases the risk of falling in older adults.
- The urine protein/creatinine (Upr/UCr) ratio correlates well with a 24-hour urine and is much easier to obtain.
- Proteinuria in children is most often orthostatic.

Dysuria

Urinary burning or pain most often represents UTI or vaginitis. It is common in middle-aged and/or sexually active women. In men, it is more likely to occur as they grow older (Bremnor and Sadovsky, 2002). Both voiding history and sexual history are essential. Questions regarding vaginal symptoms are important in women. Also, use of medications and personal hygiene products should be reviewed.

Dysuria significantly increases the chance that a patient has a UTI. However, there are many potential causes of dysuria (Box 40-1), and empiric treatment based on this symptom alone leads to unnecessary antibiotic use. Incorporating other symptoms increases the likelihood that a UTI is the

Box 40-1 Differential Diagnosis of Dysuria

cause (see Urinary Tract Infection) (Bent et al., 2002; McIsaac et al., 2002).

Flank Pain

Flank pain may be a presenting complaint indicating urinary tract disorder. It is typically not relieved by position changes and is colicky in nature. Nausea and vomiting may coincide. Obstruction (e.g., kidney stones) and inflammation (e.g., pyelonephritis) are the two most common causes. The location may help localize the underlying cause (Fig. 40-4). Tumors are less likely, because they are usually only symptomatic if they distend the renal capsule or obstruct the ureter.

Urinary Frequency

As a complaint, urinary frequency implies a deviation from a patient's normal urination pattern. Thus, it may either be truly abnormal or simply more than the patient's custom (but still normal). It may exist alone or in concert with other symptoms. For example, UTI often causes urinary frequency, urgency, and dysuria.

Adults typically urinate five to six times a day (Gerber and Brendler, 2007). Frequency usually represents an increased number of episodes with small volumes of urine as opposed to increased urine volumes, such as in polyuria. These factors help narrow the differential diagnosis (Box 40-2).

Hematuria

Hematuria is often an incidental finding on urinalysis, and evaluation depends on whether it is gross or microscopic and whether it occurs in adults, children, or adolescents. Most patients with hematuria do not have significant pathology, but this depends on the type of hematuria and underlying risk factors. One prospective study found that 61% of patients with hematuria had no finding after evaluation (Khadra et al., 2000).

Gross hematuria is blood in the urine visible to the patient or physician. Microscopic hematuria is the more

common entity. Various cutoff points exist; for adults, the American Urological Association (AUA) Best Practice Policy has defined *microscopic* hematuria as 3 or more (RBCs/hpf) (Grossfeld et al., 2001a). In children, clear consensus is lacking, although more than 5 RBCs/hpf found in at least two weekly urine samples is considered abnormal (Dodge et al., 1976; Vehaskari et al., 1979). The reasons for the different definitions may reflect a lower evaluation threshold in adults because of the larger spectrum of potential causes.

Dipstick urinalysis alone is insufficient for diagnosing hematuria, because certain substances (e.g., myoglobin) and test characteristics (e.g., specificity) can cause false-positive results. Thus, microscopic analysis is necessary and inherent in the definition.

Hematuria in Adults

Gross Hematuria

Gross hematuria is a common presenting symptom for patients with bladder or renal cancer (Yun et al., 2004). The sensitivity of gross hematuria for bladder cancer is 83%, and the positive predictive value (PPV) is 22% (Buntinx and Wauters, 1997). However, the studies generating these values were of low quality and based on referral populations. No studies are available on the likelihood that family medicine patients with this finding will have serious pathology. Pending this research, the approach to gross hematuria should remain aggressive (Khadra et al., 2000).

Confirmation of blood in the urine with dipstick and microscopy is needed in cases of red-tinted urine, because certain substances can discolor the urine (see Table 40-1). However, visible clots are unlikely to have a mimic. History should focus on signs and symptoms of infection, trauma, as well as risk factors for urinary tract malignancy (see Bladder Cancer). Physical examination should assess the external

genitalia and include a pelvic examination in women and a prostate examination in men. Urology consultation is appropriate, except when an obviously benign (e.g., menses) or treatable cause is found. Even when a treatable cause is identified (e.g., renal calculi), close follow-up with repeat urinalysis is needed because gross hematuria is frequently a harbinger of serious urinary tract pathology (Khadra et al., 2000).

Microscopic Hematuria

Asymptomatic hematuria potentially signals serious urinary tract disease, although there are many causes, often benign. Hematuria may occur in 9% to 18% of normal subjects (Grossfeld et al., 2001a). Most studies evaluating and defining this problem were not performed in typical family medicine populations or are of lower quality, or both. No prospective studies demonstrate an improved outcome from routine screening. For the general population, finding asymptomatic microscopic hematuria carries a predictive value of only 0.5% (Brehmer, 2002). Thus, benefit from routine microhematuria screening is unlikely (Kryszczuk et al., 2004).

Because routine screening is unhelpful, family physicians encountering microhematuria should consider patient risk characteristics and systematic laboratory testing and imaging (Fig. 40-5). The first step in approaching asymptomatic microscopic hematuria is to verify it is a consistent finding. Patients should have repeat urinalysis, and if two separate follow-up samples are normal, no further evaluation is needed. Transient hematuria is not unusual, and serious urinary tract pathology is unlikely in patients younger than 40 years. Furthermore, history or examination may reveal a benign cause—menses, sexual activity, vigorous exercise, viral illness, or trauma. If repeat examination is normal after these considerations, no further examination is needed. A caveat would be the patient at risk for bladder cancer, because intermittent hematuria can precede this finding, and more extensive follow-up may be warranted (Grossfeld et al., 2001b). Family physicians should be cautious not to misattribute certain causes as benign. For example, warfarin (Coumadin) may cause hematuria if the patient is excessively anticoagulated, but it should not cause hematuria within its goal international normalized ratio (INR) range. Hematuria in this setting is often a sign of urologic disease (Culclasure et al., 1994).

If hematuria is consistently found, the next step is to risk-stratify the patient based on history, physical, and baseline laboratory findings. Initial laboratory testing should include urinalysis, urine culture (if indicated), and serum creatinine level. If UTI is present, a repeat examination 6 weeks after treatment is appropriate. High-risk patients are those at increased risk for urologic malignancy—older than 40 years, tobacco history, analgesic abuse, pelvic irradiation, occupational exposures (see Bladder Cancer), prior urologic disease, irritative voiding symptoms, history of UTIs, and cyclophosphamide use (Grossfeld et al., 2001b). These patients should undergo a more thorough evaluation for the cause of their hematuria, whereas lower-risk patients can have a more limited testing battery (Grossfeld et al., 2001a). Hematuria of renal origin may be associated with microscopic red cell casts or dysmorphic RBCs. Other findings may include proteinuria, elevated serum creatinine, or a physical finding such as

hypertension or edema. These patients need evaluation for renal disease, including urine protein quantification. Some patients will have risk factors and findings for both renal and urologic disease or may already have a history of chronic kidney disease (CKD), so simultaneous evaluations for both causes may be necessary.

Patients whose initial evaluation does not suggest primary renal disease should undergo urologic evaluation based on their risk category. This includes upper urinary tract imaging, urine cytology, and cystoscopy. There are no prospective outcome data on the impact of imaging on asymptomatic microscopic hematuria. Thus, patient-oriented recommendations are unavailable, and family physicians should consider the advantages and disadvantages of the different techniques (see earlier Imaging Studies) when deciding on the appropriate method. IVU is widely available and less costly, and has a low chance of missing pathology when appropriate follow-up studies are used. CT is a good choice for a broad range of urinary tract disorders. Non-contrast-enhanced scans can be performed initially. If these show calculi in a low-risk patient, no further imaging is needed. Contrast studies can follow in all other cases (Grossfeld et al., 2001b). CT is the modality of choice when other techniques fail to reveal a cause (Lang et al., 2002). Deciding between IVU and CT is challenging because the lower cost of IVU may be offset by the eventual need for CT (McDonald et al., 2006). Radiation exposure must be considered as well. Kidney, ureter, and bladder (KUB) studies with ultrasound or MRI are alternatives for patients unable to receive radiographic contrast. However, in the case of CKD patients, the risk of nephrogenic systemic sclerosis from gadolinium contrast may also limit use of MRI.

Cystoscopy is necessary to rule out bladder cancer confidently because no imaging study is adequate for evaluation. Urine cytology is often performed with cystoscopy and has a sensitivity of 40% to 76% for bladder cancer. A positive finding is diagnostic, but a negative finding does not rule out disease. Thus, in high-risk patients, cytology is used adjunctively and in follow-up. Cystoscopy is optional in low-risk patients because it is unlikely to yield a definitive finding. These patients should undergo urine cytology. Furthermore, if they develop any high-risk characteristics, they should undergo cystoscopy (Grossfeld et al., 2001b). Urine tumor markers are available but not yet validated for routine use (Cohen and Brown, 2003).

A cause for hematuria is often not found even after a complete evaluation. Isolated hematuria is *asymptomatic microscopic hematuria* with a normal urologic evaluation and no signs of systemic disease or microscopic evidence of intrinsic renal disease (the definition slightly differs for children). The prognosis is good, although some studies indicate a high proportion of renal abnormalities (e.g., IgA nephropathy). Thus, surveillance for signs of renal disease is appropriate (Grossfeld et al., 2001b). Also, up to 3% of patients with initially negative workups are later found to have a urinary tract malignancy. High-risk patients should have periodic follow-up with focused history, blood pressure, urinalysis, and urine cytology for up to 3 years. This regimen can also be considered for low-risk patients (see Fig. 40-5). Evaluation and treatment of *symptomatic microscopic hematuria* is directed at the condition. However, family physicians should consider the underlying risk of urinary tract abnormalities when deciding

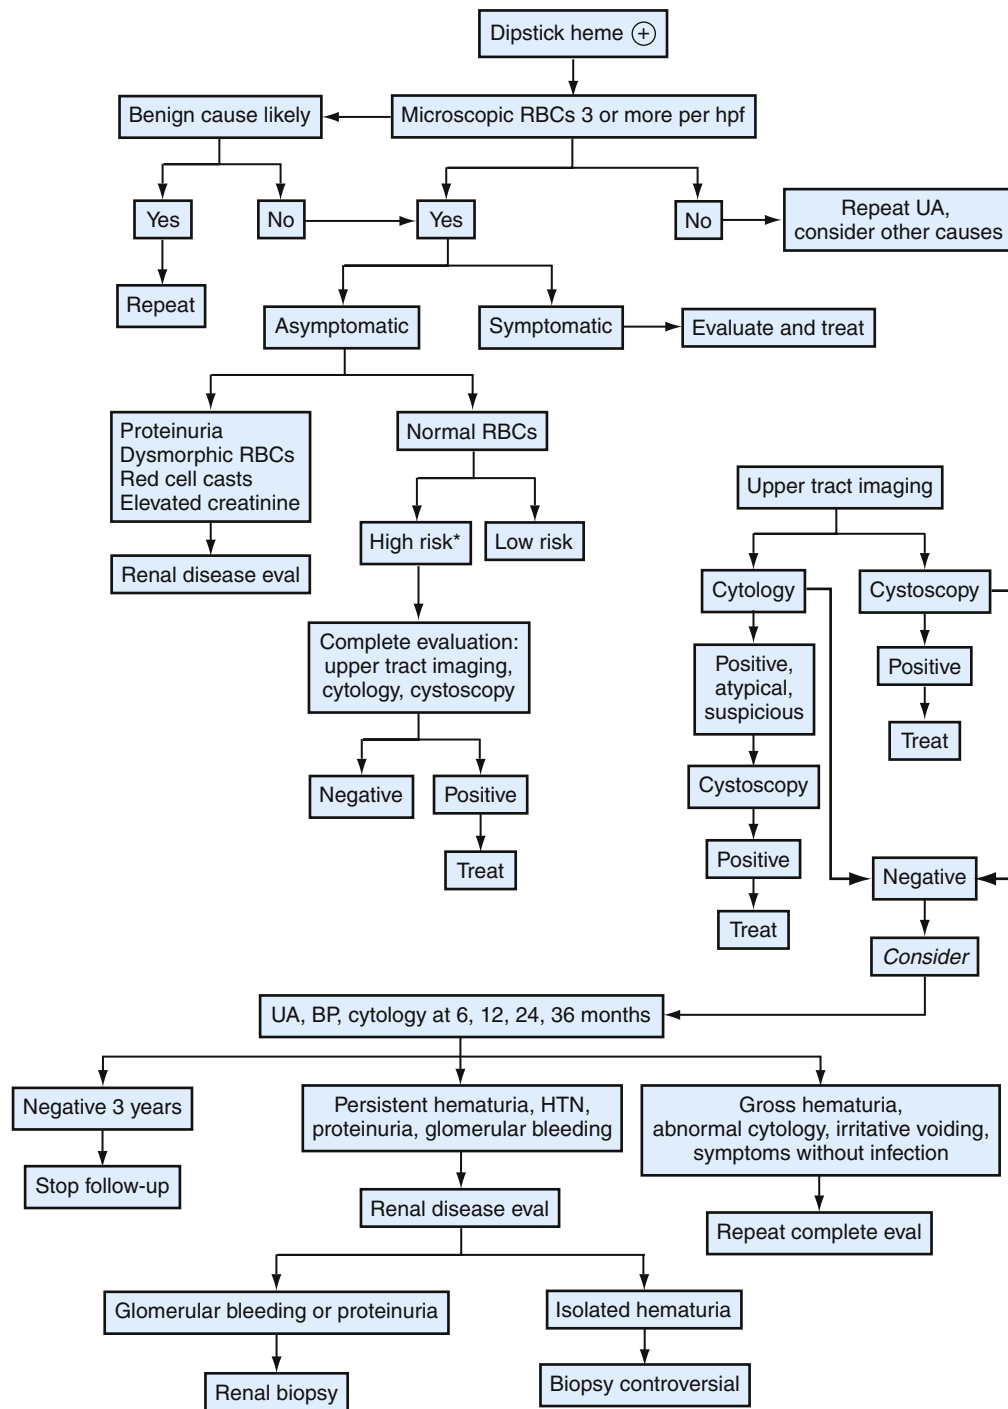

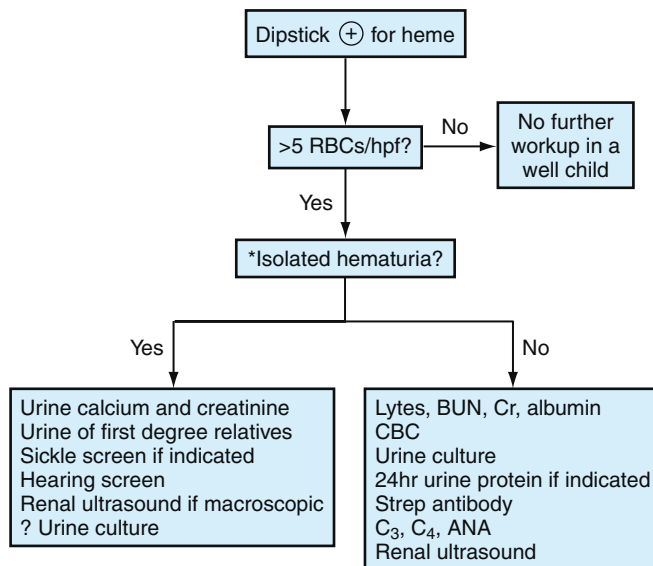

Figure 40-5 Evaluation and follow-up of asymptomatic microscopic hematuria. *BP*, Blood pressure; *HTN*, hypertension; *RBCs*, red blood cells; *UA*, urinalysis.

on follow-up. For example, a patient with a symptomatic kidney stone may have microhematuria. Although this provides the most likely explanation for the bleeding, if the patient has a background risk for malignancy (e.g., smoking) or renal disease, repeat urinalysis is needed to ensure resolution.

Hematuria in Children and Adolescents

Hematuria is a relatively common finding in children, with an estimated prevalence of 0.5% to 2% of asymptomatic school-age children (Dodge et al., 1976). Those with hematuria and proteinuria, particularly when associated with

hypertension, edema, or urinary casts, need aggressive evaluation for underlying glomerular disease or uropathy. The vast majority of children with hematuria, however, present with isolated hematuria. This is typically detected on a random urine sample obtained in the context of a routine physical examination but may also present as asymptomatic gross hematuria. In children, the term *isolated* refers to the complete absence of symptoms, significant past medical or family history, physical examination findings, or other abnormalities on urinalysis. This distinction often separates those children with benign processes from those with underlying pathology.

* Negative history, normal physical exam, and absence of symptoms, HTN, pyuria, proteinuria, or cellular casts

Figure 40-6 Approach to the child with hematuria. ANA, Antinuclear antibody; BUN, blood urea nitrogen; CBC, complete blood cell count; Cr, creatinine; RBCs/hpf, red blood cells per high-power field.

Once the diagnosis of hematuria has been confirmed and a complete history obtained and physical examination performed, a staged evaluation should ensue (Fig. 40-6). Significant underlying renal or urologic disease is highly unlikely in children with isolated microscopic hematuria (Bergstein et al., 2005). A more thorough evaluation is indicated for asymptomatic macroscopic hematuria.

The most common glomerular diseases associated with isolated hematuria are subclinical postinfectious glomerulonephritis, IgA nephropathy, and Alport's syndrome. In the absence of proteinuria or more advanced disease, there is no treatment given for these conditions. Yearly follow-up with blood pressure and urinalysis is indicated for all forms of persistent hematuria.

Hypercalciuria may or may not be associated with pain. The exact mechanism by which hypercalciuria causes hematuria is unproven but probably secondary to crystalluria (Stapleton, 1994). Hypercalciuria is generally defined by a urinary calcium excretion higher than 4 mg/kg/day or a random urine calcium/creatinine ratio higher than 0.2. Higher excretion rates are expected in infants and toddlers. Patients with documented hypercalciuria should undergo a renal ultrasound to rule out nephrocalcinosis or significant stone disease. The treatment is to increase fluid intake and restrict dietary sodium (<3 g/day) while maintaining the recommended daily allowance of calcium (Srivastava and Alon, 2005). This dietary intervention may lower the urine calcium concentration and ultimately result in resolution of the hematuria. A thiazide diuretic should be considered if there is evidence of nephrocalcinosis or nephrolithiasis.

Lower Urinary Tract Symptoms

Lower urinary tract symptoms (LUTS) are the symptoms traditionally associated with *benign prostatic hyperplasia* (BPH). Many subcategories of LUTS exist, but the two most

prominent are storage and voiding symptoms (Box 40-3). *Voiding* symptoms imply obstruction, but physical obstruction may not be responsible. In men with BPH, for example, detrusor overactivity, neurologic disorders, or age-related smooth muscle dysfunction may be the cause. Thus, LUTS should shift attention toward a larger symptom complex with many potential causes. This is particularly important when dealing with urinary tract disorders such as BPH, incontinence, and overactive bladder.

Nocturia

Nocturia describes waking at night to urinate. It is more common in older adults, but no population data define a normal range for any group; therefore the complaint implies a deviation from a perceived norm. Furthermore, the primary complaint often centers on the sleep disturbance rather than on urination. It may represent frequent nocturnal urination or excessive nocturnal urine production (nocturnal polyuria). Although often thought of as a prostatic symptom, it is common in both men and women. The many secondary causes in addition to local causes include prostatic hyperplasia and bladder dysfunction (Box 40-4). In patients with prominent lower urinary tract symptoms, the problem is compounded by urination difficulty. Furthermore, studies in older adults indicate that nocturia/LUTS increases risk of falling (Parsons, et al., 2009). Age-related variations in arginine vasopressin secretion may play a role in nocturnal polyuria (Weiss and Blaivas, 2000).

Treatment centers on the underlying cause, and a voiding diary may aid clinical decisions. Prostate hyperplasia or bladder dysfunction often receives first attention. Treating BPH may help, although BPH often does not result in true physical obstruction, and epidemiologic data have indicated that nocturia is common in men without prostatic obstruction. Thus, family physicians should consider the contribution of nocturnal polyuria. For example, patients with chronic heart failure and leg edema may benefit from fluid restriction and napping with leg elevation during the day. Treating obstructive sleep apnea helps alleviate the increased urine production resulting from increased atrial natriuretic peptide production. Behavioral

interventions include avoiding excess nighttime alcohol or fluid intake and afternoon napping. Adjusting diuretic doses so they are given earlier in the evening should negate medication effects during sleep (Weiss and Blaivas, 2000).

Proteinuria

The kidneys normally excrete a small amount of protein daily, usually glycoproteins. Only very small amounts of globulins, light-chain proteins, or albumin are released. Functional proteinuria may result from physiologic changes in glomerular filtration, as occurs with exercise (Venkat, 2004). However, consistent albuminuria implies glomerular or tubular dysfunction.

The urine dipstick is the most convenient measurement, but a more accurate test is the UPr/UCr ratio, obtained by dividing the random urine sample protein level by the urine creatinine level (both in mg/dL). This ratio has proven correlation with 24-hour excretion rates (Ginsberg et al., 1983). Thus, random urine samples are the best way to identify and follow proteinuria, and 24-hour collections are usually not needed (Levey et al., 2003) (Table 40-3). However, results from those with low or high levels of muscle mass may not correlate as well with 24-hour measurements (Venkat, 2004).

Proteinuria in Adults

Proteinuria is a marker of kidney disease in adults and may actually contribute to renal impairment. Patients with diabetes should be periodically tested for microalbuminuria. Others at risk for kidney disease, such as patients with hypertension, should also be tested.

Table 40-3 Proteinuria Values

| Test | Protein Value |
|---------------------|--|
| Dipstick | ≥1+ if urine specific gravity ≤1.015 or ≥2+ if urine specific gravity >1.015 |
| UPr/UCr* | Children >0.5 (age 6 mo to 2 yr) >0.25 (>2 yr) Adults: >0.2 |
| 24-hour urine assay | Children >4 mg/m ² /hr >100 mg/m ² /day Adults 30-300 mg/24 hr—microalbuminuria >300 mg/24 hr—albuminuria >3.5 g/24 hr—nephritic-range proteinuria |

*Urine protein/creatinine ratio.

Adults with proteinuria need their UPr/Ucr determined. Those with values outside the normal range should undergo an evaluation for CKD (see later). Patients with dipstick proteinuria but normal-range UPr/UCr values should be rechecked at periodic follow-up (Fig. 40-7).

Proteinuria in Children and Adolescents

Most proteinuria in children is transient when followed up with weekly urine sample testing. Persistent proteinuria found in at least two of three weekly urine samples warrants further evaluation to identify those children who may have chronic renal disease.

Proteinuria in children may be classified as functional, isolated, or symptomatic. *Functional* proteinuria may occur with fever or exercise. *Isolated* proteinuria is defined by the absence of abnormal history, physical examination findings, symptoms, or other urinary abnormalities. The most common cause of this form is *benign orthostatic proteinuria*, defined by normal protein excretion overnight or in the supine position. The initial evaluation for isolated proteinuria involves obtaining a first-morning urine sample for protein and creatinine as well as a formal urinalysis for microscopy review (Hogg et al., 2000). The absence of morning proteinuria, as evidenced by normal UPr/UCr, supports the diagnosis of benign orthostatic proteinuria. A more accurate assessment is a split 24-hour urine collection for protein. Benign orthostatic proteinuria may be transient or fixed and in either case has an excellent prognosis (Springberg et al., 1982). In contrast, *nonorthostatic* isolated proteinuria with a duration of 1 year or longer may represent significant renal pathology (Trachtman et al., 1994). Thus, these patients need yearly or twice-yearly clinical follow-up with assessment of blood pressure, renal function, serum albumin, urine microscopy, and urine protein.

Pathologic proteinuria, whether isolated or symptomatic, occurs in the setting of a variety of glomerular and tubulointerstitial diseases (Box 40-5). Some children may present with the *nephrotic syndrome* (proteinuria, hypoalbuminemia, edema). Depending on the degree of proteinuria and the results of the initial laboratory evaluation, a renal biopsy may be indicated (Fig. 40-8).

Anatomic Disorders

Key Points

- Prenatally identified hydronephrosis may be caused by underlying urinary tract obstruction. These infants need close follow-up with ultrasound in the first week of life.
- Hydroceles in infants often resolve by age 2 years. Hydroceles in adults may have a secondary cause.
- Reassure patients with Peyronie's disease that it is usually self-limited.

- Testicular torsion is a medical emergency. Torsion of the appendix testis is less severe and can be managed with supportive care.
- Undescended testes increase the risk for testicular cancer in the undescended as well as contralateral testicle.

Anatomic urinary tract disorders involve various congenital and acquired abnormalities, most notably of the external genitalia. Testicular disorders are seen more often than abnormalities of the penis, particularly undescended testes. Anatomic derangements of the bladder, ureter, and kidney are often only discovered incidentally or during an evaluation

for UTIs, voiding problems, CKD, or pain possibly related to the urinary tract. For example, posterior urethral valves cause vesicoureteral reflux and may contribute to recurrent UTIs (see Urinary Tract Infections in Children).

Scrotal masses are frequently encountered in family medicine. Anatomic causes of scrotal masses are not limited to the urinary tract, and neoplastic and infectious causes are also in the differential diagnosis (Table 40-4). Scrotal or testicular pain, the so-called acute scrotum, implies a more urgent or emergent cause (e.g., testicular torsion). Because the history and physical examination may not be adequate to differentiate certain conditions (e.g., epididymo-orchitis from testicular torsion), adjunctive imaging such as ultrasound is often used.

Fetal Hydronephrosis

With the pervasive use of fetal ultrasound, hydronephrosis is more often diagnosed prenatally. A dilated renal collecting system is often the only indication of a number of congenital uropathies (Ismaili et al., 2004). Two processes cause hydronephrosis, reverse urine flow (vesicoureteral reflux, VUR) and impaired forward urine flow (obstruction). VUR occurs as an isolated entity or can be associated with a more complicated uropathy, such as bladder outlet obstruction with VUR. Obstructive uropathy may occur at different sites along the urinary tract, most often the ureteropelvic junction (UPJ).

Infants with fetal hydronephrosis need an ultrasound in the first week of life. If normal, a repeat ultrasound should be done in 2 to 4 weeks because of the possibility of a false-negative study in the low urine flow state characteristic of the newborn (Becker and Avner, 1995). Once the diagnosis is confirmed, evaluation includes a urinalysis, urine culture, basic metabolic panel (if bilateral), and a VCUG. If the VCUG is normal, a furosemide renogram is needed to determine the presence and degree of obstruction.

Hydrocele

Hydroceles are fluid accumulations in the tunica vaginalis and can be *primary*, resulting from a failure of the processus vaginalis to close during development, or *secondary* to epididymitis, orchitis, testicular torsion, trauma, or tumors (Brenner and Ojo, 2004). Hydroceles typically transilluminate, whereas inguinal hernias do not. In young children, management is supportive, with the hydrocele often resolving by age 2 years. Hydroceles presenting beyond 2 years or those associated with inguinal hernias require surgical consultation. Also, some hydroceles are communicating; that is, fluid can pass from the peritoneal cavity into the hydrocele. These may change in size with activity or during the day and need surgical evaluation (Schneck and Bellinger, 2007). Hydroceles arising *de novo* in adults often have a secondary cause and require evaluation (Dogra et al., 2003).

Hypospadias

Hypospadias, in which the urethra opens on the underside of the penis, is infrequently seen (Fig. 40-9). However, it is important that hypospadias is recognized early, preferably at the initial newborn examination. It can occur with or

Table 40-4 Selected Differential Diagnosis of Scrotal Masses with Physical Findings

| Abnormality | Physical Finding |
|--------------------------------|---------------------------------------|
| Epididymitis, orchitis | Tender mass |
| Hydrocele | Transilluminates |
| Inguinal hernia | Does not transilluminate |
| Testicular torsion | Pain and loss of cremasteric reflex |
| Torsion of the appendix testis | Blue dot sign |
| Trauma | Tender scrotum, edema, trauma history |
| Tumor | Solid mass |
| Spermatocele | Nontender cystic mass |
| Varicocele | Bag of worms appearance |

without chordee (curvature). Circumcision should be withheld and a urology consultation obtained. Hypospadias must be differentiated from ambiguous genitalia, which implies an intersex disorder. *Epispadias*, in which the meatus is located on the dorsal surface of the penis, is uncommon and is usually associated with extrophy of the bladder.

Labial Adhesions

Labial adhesions may be seen in young girls and may be partial or complete (fusion) and asymptomatic. However, labial adhesions can be associated with difficult or abnormal urination and may contribute to the development of UTIs. It is important to perform an external genital examination in the female with her first UTI (Fig. 40-10). Retrospective data and case series support topical estrogen cream to the affected areas, with gentle traction until the adhesions have separated (Bacon, 2002). In a recent study, however, labial separation occurred more quickly and with less recurrence in patients treated with betamethasone than in those treated with estrogen cream (Mayoglou et al., 2009).

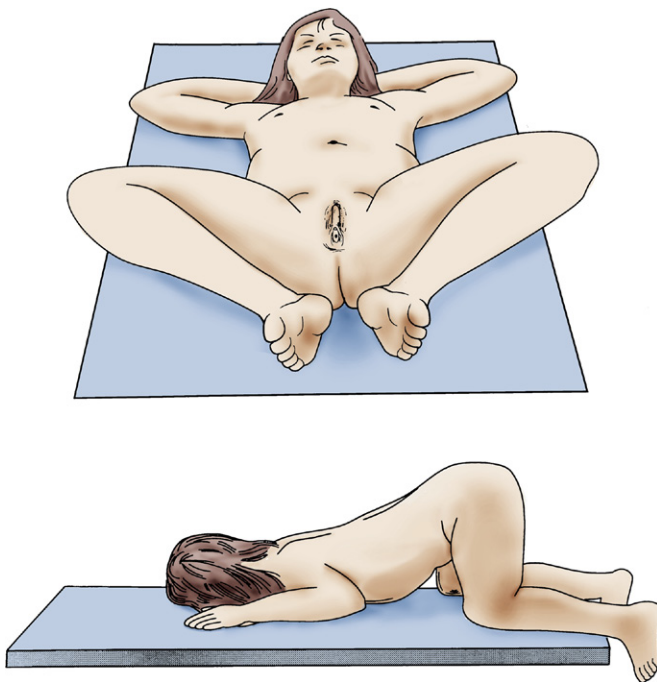

Figure 40-10 Techniques for pediatric female genital examination. (From Canning DA, Nguyen MT. *Evaluation of the pediatric urologic patient*. In Wein AJ [ed]. *Campbell-Walsh Urology*, 9th ed, vol 1. Philadelphia, Saunders, 2007.)

Peyronie's Disease

Peyronie's disease is characterized by formation of fibrosis in the tunica albuginea, with resulting penile deformity and pain. Symptoms include painful erection, physical penile deformity (often curvature), palpable penile plaque (fibrosis), and erectile dysfunction. Pain is typically transient, and most cases do not result in a deformity so severe that it impairs intercourse. Sexual history, counseling, and partner involvement are important, because Peyronie's disease can be disruptive to a relationship. Most patients do not require any treatment beyond reassurance and counseling. Nonsurgical treatments are available (e.g., colchicine, intralesional verapamil), but supporting evidence is limited, and urologic consultation should be considered before exploring treatment. Steroid injection is best avoided. Surgery is an option in severe cases (Lewis and Munarriz, 2007).

Phimosis and Paraphimosis

Phimosis (inability to retract foreskin over glans) and paraphimosis (inability to return retracted foreskin over glans) are possible complications seen in the uncircumcised male (Fig. 40-11). About 50% of boys typically are able to retract their foreskin by 1 year of age and 80% by age 3 (Anderson and Anderson, 1999). Topical estrogen therapy has been reported as successful, but no randomized trials support its use (Yanagisawa et al., 2000). However, low-potency topical corticosteroid therapy combined with daily prepuce retraction appears effective for phimosis (Zampieri et al., 2005).

Because vascular engorgement leads to necrosis of the glans, acute paraphimosis needs urgent medical attention. A dorsal slit procedure may be required if other reduction techniques are unsuccessful. Ice packs and plastic wrap may

Figure 40-11 Paraphimosis. (From Kleigman R, et al. *Nelson Textbook of Pediatrics*, ed 18. Philadelphia, Saunders-Elsevier, 2007, p 2256.)

reduce the edema enough to allow manual reduction (Choe, 2000). Circumcision is generally indicated after the reduction and edema resolution. Methods of reduction included manual, osmotic, puncture and aspiration (Little and White, 2004).

Spermatoceles

Spermatoceles (epididymal cysts) are painless cysts filled with sperm and can be palpated distinct from the testis. They transilluminate, are generally of no consequence, and do not affect fertility.

Testicular Disorders

Testicular Torsion

Although occasionally seen in the newborn male, testicular torsion is an acquired condition seen during puberty and is an emergency. It usually presents with abrupt onset of severe scrotal pain, at times waking the patient up in the early morning. Associated signs and symptoms include fever, nausea, vomiting, and abdominal pain. Intermittent testicular torsion has been described. On physical examination, the testis may lie in a more horizontal position, caused by a lack of normal attachment to the tunica vaginalis ("bell clapper" deformity), and demonstrate a loss of the cremasteric reflex. The diagnosis of testicular torsion can be made by physical examination or with the assistance of color Doppler ultrasound; however, physical examination is unreliable for ruling torsion in or out (Schmitz and Safranek, 2009). Timeliness of the diagnosis is critical, because testicular viability declines to 0% if detorsion occurs 24 hours after the onset of symptoms (Brenner and Ojo, 2004). Testicular torsion can occur in systemic illnesses, such as Henoch-Schönlein purpura, or can mimic the symptoms of other conditions, such as appendicitis or nephrolithiasis.

Torsion of the appendix testis presents similar to testicular torsion, although the symptoms are not as severe. The classic patient is a boy age 7 to 12 years. Palpation of the testis is normal except for a small, tender, palpable mass located on the superior or inferior pole. The cremasteric reflex is intact. The “blue dot” sign may be present and represents the compromised appendix testis as viewed through the scrotum. Diagnosis is generally made clinically and treatment is supportive, including analgesia and scrotal elevation. It is not unusual for the pain to last 5 to 10 days, but chronic pain may occur and warrants urology consultation.

Undescended Testis

Undescended testis (testes) occurs in 2.7% to 5.9% of full-term male infants, decreasing to 1.2% to 1.8% by age 1 year (Pillai and Bassner, 1998); the incidence is higher in premature infants. An undescended testis must be differentiated from a *retractile* testis, which may occur as the cremasteric reflex is developed. As opposed to an undescended testis, a retractile testis can be manually coaxed into the scrotum. In general, the patient with truly undescended testes needs urology evaluation. Failure to respond to human chorionic gonadotropin (hCG) is an indication for orchiopexy, especially if the testes have not descended by the first birthday. This should be accomplished before the child is 6 years old. The testicular examination should be taught to orchiopexy patients because of the slightly increased risk of cancer in either testicle (Altman, 1967).

Varicoceles

A varicocele is a collection of dilated and tortuous veins surrounding the spermatic cord. It is most often asymptomatic and left-sided. Varicoceles arise in adolescence and are estimated to occur in 10% to 15% of the male population (Schneck and Bellinger, 2007). Evidence that varicoceles cause infertility is limited, but they are found in 12% of men presenting with infertility and in mature adolescents with varicoceles, 26% had abnormal semen analyses (Brenner and Ojo, 2004; Biyani et al., 2009). The “bag of worms” appearance on scrotal examination is the hallmark of this diagnosis. Inferior vena cava obstruction should be considered if the varicocele is right sided, of acute onset, or occurs in a prepubertal boy.

Functional Disorders

Key Points

- Patients with proteinuria and elevated Upr/UCr should be evaluated for chronic kidney disease. The serum creatinine level may not correlate with glomerular filtration rate; GFR estimates are adequate to diagnose kidney disease; 24-hour urine testing is usually not needed.
- Patients with chronic kidney disease need systemic management.
- Enuresis typically resolves with age. A bed-wetting alarm is effective if treatment is needed.
- Erectile dysfunction has many causes and may be a marker of vascular disease.
- Pelvic floor muscle exercises are first-line treatment for stress and mixed urinary incontinence.

- Anticholinergic drugs and tiroprium are effective treatments for urge incontinence.
- Anticholinergic drugs for an overactive bladder may not have clinically significant benefits and often cause dry mouth.
- Men with recurrent kidney stones and idiopathic hypercalciuria should be on a low-sodium, low-protein diet. Low-calcium diets do not reduce stone formation.
- Non-contrast-enhanced CT is the test of choice for diagnosing kidney stones.

Chronic Kidney Disease

Renal disease is a significant public health burden, with almost 20 million persons in the United States having chronic kidney disease (Coresh et al., 2003). In 2002 the National Kidney Foundation issued guidelines on the evaluation and management of CKD. The centerpiece of this new approach is defining CKD as kidney damage or decreased kidney function for 3 months or longer (Levey et al., 2003).

Proteinuria is a clinical sign of kidney disease. Patients with proteinuria should be approached as described earlier. Patients with abnormal urinary protein values (e.g., UPr/UCr) or other markers of kidney damage should be assessed for CKD (Johnson et al., 2004). The primary measure of kidney function is the glomerular filtration rate (GFR), and the stages of CKD are based on GFR (calculated by Cockcroft-Gault or MDRD equation) (Table 40-5). The modification of diet in renal disease (MDRD) equation performs as well or better than measured creatinine clearance (Levey et al., 1999). However, physicians should be aware that the values obtained by the equations may differ slightly, and the

Table 40-5 Stages of Chronic Kidney Disease

| Stage | Defining Features | GFR [†] (mL/min/1.73 m ²) |
|-------|-------------------------------------|---|
| 1 | Kidney damage,* normal GFR | ≥90 |
| 2 | Kidney damage, mild decrease in GFR | 60-89 |
| 3 | Moderate decrease in GFR | 30-59 |
| 4 | Severe decrease in GFR | 15-29 |
| 5 | Kidney failure | <15 |

*Pathologic renal abnormalities; markers of damage: abnormal blood, urine, or imaging studies.

Calculators for office use are available from National Kidney Disease Education Program (NKDEP). http://www.nkdep.nih.gov/professionals/gfr_calculators/index.htm.

[†]Glomerular filtration rate (GFR) equations

Cockcroft-Gault equation:

$$C_{Cr}(\text{mL/min}) = \frac{[(140 - \text{Age}) \times \text{Weight}] / 72 \times S_{Cr}}{(\times 0.85, \text{if female})}$$

Abbreviated MDRD:

$$\frac{\text{GFR}(\text{mL/min}/1.73\text{m}^2)}{(0.742[\text{if female}] \times 1.210[\text{if black}])} = 1.86 \times (S_{Cr})^{1.154} \times (\text{Age})$$

C_{Cr} , Creatinine clearance; MDRD, modification of diet in renal disease study equation; S_{Cr} , serum creatinine level (mg/dL).

From Johnson CA, Levey AS, Coresh J, et al. Clinical practice guidelines for chronic kidney disease in adults. Part II. Glomerular filtration rate, proteinuria, and other markers. *Am Fam Physician* 2004;70:1091-1097.

Cockcroft-Gault equation is the primary measure used when validating recommended medication dosing adjustments for creatinine clearance. Slightly elevated (or even “normal range”) serum creatinine levels may correlate with impaired GFR, depending on factors such as age or race (Table 40-6). Thus, the serum creatinine level alone is an inadequate clinical marker for a patient’s risk for, or the presence of, renal impairment (Levey et al., 2003).

Workup of persons identified as having CKD (by GFR) includes a complete urinalysis, renal ultrasound, and determination of the serum creatinine and serum electrolyte levels and albumin/creatinine ratio. Patients should also be assessed for background risk factors that may worsen their disease. Particular emphasis should be placed on the most common problems—diabetes, hypertension, and tobacco use. Patients with class 1 CKD have evidence of renal disease (e.g., diabetes, proteinuria) but a normal GFR. Patients with type 2 diabetes and nephropathy clearly benefit from treatment with an angiotensin-converting enzyme (ACE) inhibitor or an angiotensin receptor blocker (ARB). Furthermore, blood pressure control is critical for preventing nephropathy

progression. The evidence is stronger for ARBs for preventing end-stage failure in patients with advanced nephropathy (Shlipak, 2009).

Management of patients with stage 1 or 2 CKD focuses on risk factors and preventing disease progression. Particular attention should be directed toward controlling diabetes and hypertension, if present. CKD has numerous complications requiring regular assessment. In stage 3 CKD, family physicians should assess for anemia, neuropathy, nutrition, and disorders of bone metabolism. Patients with a GFR less than 30 should be referred to a nephrologist. Stage 4 patients should be proactively prepared for dialysis or transplantation. Patients in stage 5 should be monitored for uremia and dialysis initiated at that point (Levey et al., 2003).

Chronic Nonbacterial Prostatitis

The term *prostatitis* means prostate inflammation but often also implies infection (infectious causes are discussed later). However, prostatitis encompasses many different clinical entities (Table 40-7). Chronic nonbacterial prostatitis, also

Table 40-6 Serum Creatinine Levels and Chronic Kidney Disease*

Table 40-7 NIH and NIDDK Classification System for Prostatitis

| Category | Name | Defining Characteristics |
|----------|---|--|
| I | Acute bacterial prostatitis | Acute prostate infection |
| II | Chronic bacterial prostatitis | Recurrent prostate infection |
| IIIa | Chronic nonbacterial prostatitis— <i>inflammatory</i> chronic pelvic pain syndrome | No infection; white cells evident in semen, prostatic secretions, or postprostate massage voided urine |
| IIIb | Chronic nonbacterial prostatitis— <i>noninflammatory</i> chronic pelvic pain syndrome | No infection; no white cells in semen, prostatic secretions, or postprostate massage voided urine |
| IV | Asymptomatic inflammatory prostatitis | No subjective symptoms; white cells in prostatic secretions or prostate tissue |

From McNaughton-Collins M, Joyce GF, Wise M, Pontari MA. Prostatitis. In Litwin MS, Saigal CS (eds). *Urologic Diseases in America*. US Department of Health and Human Services, Public Health Service, National Institutes of Health (NIH), National Institute of Diabetes and Digestive and Kidney Diseases (NIDDK). Washington, DC, US Government Printing Office, 2007; NIH Pub No 07-5512, p 13.

known as *chronic pelvic pain syndrome*, is poorly understood and better classified as a *functional* urinary tract disorder. Patients with chronic nonbacterial prostatitis can experience genital, ejaculatory, perineal, back, pelvic, or rectal pain; irritative voiding symptoms; and sexual dysfunction. Unlike those with category II prostatitis, however, patients with nonbacterial prostatitis do not experience recurrent UTIs (Stevermer and Easley, 2000). Physical examination may be normal or reveal a tender prostate.

Chronic nonbacterial prostatitis negatively affects quality of life and is associated with depression, anxiety, and somatization (McNaughton-Collins, 2003). A potentially helpful clinical tool is the validate National Institutes of Health (NIH) Chronic Prostatitis Symptom Index, which can help define a patient's symptoms (McNaughton-Collins et al., 2007). Treatment is problematic because the underlying pathogenesis is uncertain and the evidence base poor. Alpha-adrenergic blockers reduce pain and improve quality of life (Erickson et al., 2008). There is not enough evidence to recommend routine antibiotic use (McNaughton-Collins et al., 2001). Patients with NIH category IIIa prostatitis can receive a trial of a fluoroquinolone antibiotic for 2 to 4 weeks or a prolonged course (4-6 weeks total) if they benefit. However, antibiotics in categories IIIb and IV prostatitis appear ineffective (Erickson et al., 2008; Wagenlehner and Naber, 2003). Allopurinol, 5 α -reductase inhibitors, anti-inflammatory drugs, biofeedback, pentosan (Elmiron), prostate massage, thermotherapy and sitz baths are alternatives of uncertain effectiveness (McNaughton-Collins and Wilt, 2002). As in other somatic syndromes, patients benefit from a supportive physician relationship focused on quality of life rather than cure.

Enuresis

Nocturnal Enuresis

Enuresis is a common childhood complaint. Distinguishing *primary* enuresis (children who have never achieved a satisfactory period of nighttime dryness) from *secondary* enuresis (return of nighttime wetting after 6 months of nighttime dryness) is important; secondary enuresis indicates possible dysfunctional voiding or other pathologic condition. A child needs to be 5 years old to be considered enuretic, and children younger than 7 years may not exhibit the commitment necessary for treatment to be effective (Kiddoo, 2007). It is more common in boys and has a genetic tendency. The exact cause is unknown. Family background, life stressors, and psychological problems have not shown a causal relationship (Theidke, 2003). Enuresis typically resolves with age, although 1% of adults may have an average of two wet nights per week.

History should focus on birth and development, family history, voiding and defecation history, signs of abnormal voiding, and parental response to the problem. A voiding diary may be helpful (Theidke, 2003). Evaluation with a urinalysis and an age-appropriate neurologic examination, including gait and anal reflex (wink), as well as close examination of the lumbosacral area, is mandatory to determine the need for further evaluation in the patient with primary nocturnal enuresis. If the history, physical exam, and urinalysis are normal, usually no further workup is indicated.

Interventions found to be beneficial for managing nocturnal enuresis include dry-bed training with positive reinforcement, decreasing fluids at night, medications such as desmopressin and tricyclics, and conditioning therapy with nighttime bed-wetting alarms. Waking children age 4 to 5 years after 1.5 to 2 hours of sleep ("lifting") may help reduce the number of wet nights (vanDommelen et al., 2009). A bed-wetting alarm is the most effective treatment for nocturnal enuresis (Glazener et al., 2005b). Desmopressin is effective, but the effects are temporary, with a high relapse rate once discontinued (Glazener and Evans, 2002; Kiddoo, 2007). Tricyclic medications have proved efficacious for nocturnal enuresis, but side effects such as anorexia, drowsiness, and cardiac arrhythmias limit their use. A limited study found that reboxetine, a nonadrenaline reuptake inhibitor without apparent cardiac toxicity, successfully treated enuresis, especially in conjunction with desmopressin (Neveus, 2006). Because most children will be dry by 7 years old, reassurance may be most appropriate until that point (Kiddoo, 2007).

Dysfunctional Voiding

Dysfunctional voiding, a term used to describe impairments of micturition, encompasses a wide array of symptoms and can lead to significant morbidity. The typical patient is a school-age girl who may be enuretic or have recurrent UTIs. Parents will often give a history that the child "holds her urine" or demonstrates urgency with infrequent voiding. *Vincent's curtsy* is a well-known posture assumed by these girls to help alleviate the pressure of a full bladder, which can result in a non-neurogenic neurogenic bladder. The dysfunctional voiding scoring system (DVSS) is a validated tool instrument that can be used to diagnose and evaluate children with dysfunctional voiding (Farhat et al., 2000). Urodynamic studies, cystoscopy, and imaging studies are available in the workup of voiding dysfunction, if indicated by the history and physical examination. Treatment is designed to improve bladder tone by placing the patient on a timed voiding schedule.

Erectile Disorders

Erectile Dysfunction

Erectile dysfunction (ED) refers to "the inability to attain and/or maintain penile erection sufficient for satisfactory sexual performance" (NIH Consensus Development Panel on Impotence, 1993). Sexual function declines with age, and normal erectile function depends on a number of body systems—cardiovascular, endocrine, muscular, nervous, psychological (Lue, 2000). Disorders in any of these can lead to ED, although many factors often are involved.

As many as 30 million men have ED (Fink et al., 2003, 2002). Risk factors include diabetes, cardiovascular diseases (e.g., hypertension, coronary heart disease, hyperlipidemia), lifestyle (e.g., alcohol, obesity, smoking), depression, neurologic disease or damage, pelvic or vascular surgery, and medications, and other endocrine and urologic disorders (Fink et al., 2002). Medications such as antidepressants and anti-hypertensives are often implicated, and medications play a role in as many as 25% of cases (McVary, 2007) (see eTable 40-1). As many as two thirds of men with cardiovascular

Box 40-6 Erectile Dysfunction Treatment Options

Alprostadil* †
 Intracavernosal (Caverject, Edex)*
 Intraurethral (Muse)*
 Topical
 Apomorphine (sublingual)*
 Cognitive-behavioral therapy
 Ginseng
 Phosphodiesterase (type 5) inhibitors
 Sildenafil (Viagra)*
 Tadalafil (Cialis)*
 Vardenafil (Levitra)*
 Yohimbine (Yocon, Yohimex, generic)
 Papaverine‡ (alone or mixed with phentolamine or phentolamine and alprostadil)
 Penile prosthesis surgery
 Psychosexual counseling
 Therapeutic lifestyle changes—smoking cessation, weight loss, limited alcohol consumption
 Vacuum device*

disease experience ED before the onset of cardiac symptoms (Billups, 2005), suggesting clinical risk assessment in men presenting with ED.

Assessment should include a general health history, with particular focus on risk factors and psychosocial issues, such as substance use, libido, and partner relationship. Clinical survey tools such as the sexual health inventory for men (SHIM) can aid in diagnosis and treatment (Cappelleri and Rosen, 2005). Surgical and medication history is essential. The examination should focus on genitourinary, endocrine, and vascular function. Laboratory work includes urinalysis, blood count, and assessment of renal function and glucose, lipid, and serum testosterone levels. Hyperprolactinemia may cause ED, although this occurs in fewer than 2% of cases (Mikhail, 2005). Thus, determination of prolactin levels, along with free testosterone and luteinizing hormone (LH) levels, should be reserved for patients with signs or findings consistent with hypogonadism (e.g., low serum testosterone level) (Lue, 2000).

Alprostadil (intracavernosal, intraurethral), apomorphine, and phosphodiesterase type 5 (PDE-5) inhibitors are effective ED treatments (Box 40-6). Potentially beneficial alternative therapies include yohimbine and Korean red ginseng, with yohimbine having the stronger evidence base (Tharyan and Gopalakrishnan, 2009). Attention to lifestyle issues is important. For example, weight loss may improve sexual function in obese patients (Esposito et al., 2004). Discontinuing potentially causative medicines is an option, although risks and benefits of this choice and its effect on other conditions must be considered. The advent of oral treatment with PDE-5 inhibitors has made these medications the drugs of first choice (Table 40-8). Cardiovascular disease is a concern

with PDE-5 inhibitors because these patients may be taking nitrates or may experience cardiac symptoms from sexual exertion. The medicine itself does not cause ischemia. Furthermore, no increase in cardiovascular events or death was found in randomized trials (Fink et al., 2002). Patients with antidepressant-induced ED, primarily from selective serotonin reuptake inhibitors (SSRIs), may benefit from the addition of a PDE-5 inhibitor, a switch to a different antidepressant (e.g., bupropion), or a drug holiday (Rudkin et al., 2004; Sturpe et al., 2002). PDE-5 inhibitors may also be beneficial in patients with ED from diabetes or spinal cord injury.

One unintended consequence of widely publicized ED treatments is the negative emotions when these treatments fail, which they often do (Fink et al., 2002; Tomlinson and Wright, 2004). Psychosexual counseling and cognitive-behavioral may be beneficial, although evidence is limited for these interventions (Tharyan and Gopalakrishnan, 2009).

Premature Ejaculation

Although various definitions exist, premature ejaculation is “ejaculation that occurs sooner than desired, either before or shortly after penetration, causing distress to either one or both partners” (AUA, 2004). Sexual history, psychological history, and differentiation from ED are essential. Treatment should be tailored to the individual patient. Psychological interventions are options for willing patients. Although no medicines are U.S. Food and Drug Administration (FDA) approved for this problem, exploiting side effects of SSRIs and topical anesthetics is an option.

Incontinence

Urinary incontinence is defined by the involuntary loss of urine. Many systems for classifying incontinence exist, but the most widely accepted divides the problem into stress, urge, and mixed incontinence (Abrams et al., 2010). *Stress* incontinence is the loss of urine with effort, exertion, or the Valsalva maneuver (e.g., coughing). *Urge* incontinence is urine leakage preceded by an urge to void. *Mixed* incontinence describes patients with symptoms from both categories. *Functional* incontinence can be used to describe patients who have incontinence with clear functional causes and who do not fit the previous categories (e.g., spinal cord injury, bedridden patient).

Urinary incontinence negatively affects quality of life through social isolation, depression, sexual dysfunction, and impaired activities of daily living (SIGN, 2004). Women are more likely to experience incontinence at a younger age than men. Risk increases with age, increased weight, depression, hysterectomy, smoking, and childbirth (Melville et al., 2005, Onwude, 2009). Causes for men are not well defined but include prostate procedures. Women are less likely than men to seek medical advice for this problem (SIGN, 2004). In community-dwelling elderly persons the rates may approach 35%, up to 60% in those at long-term care facilities (Griebing, 2009).

Evaluation should address bowel and bladder history, symptom characteristics, surgical history, and medication review. A voiding diary may be helpful in characterizing the

Table 40-8 Oral Phosphodiesterase (PDE-5) Inhibitors for Erectile Dysfunction

| Drug | Doses, Duration | Dosing | Side Effects, Precautions, Drug Contraindications |
|----------------------|----------------------------------|---|--|
| Sildenafil (Viagra) | 25, 50, 100 mg 4 hr | 50 mg (25 mg if >65 yr); 100 mg/24 hr; take 0.5-4 hr before intercourse. | Common—headache, flushing, dyspepsia, nasal congestion, abnormal vision; serious—priapism Caution if sexual activity or exertion risky because of existing cardiovascular disease; caution with potent CYP3A4 inhibitors; caution in renal, hepatic impairment; caution in older adults (>65 yr); caution with α -blockers.* Nitrates |
| Tadalafil (Cialis) | 2.5, 5, 10, 20 mg Up to 36 hr | Daily use: 2.5 mg, may increase to 5 mg PRN use: 10 mg, 1 dose/24 hr; take before intercourse. | Common—headache, dyspepsia, back pain, myalgia, nasal congestion; serious—priapism Caution if sexual activity, exertion risky because of existing cardiovascular disease; caution with alcohol; caution in renal, hepatic impairment; caution in left ventricular (LV) outflow obstruction; caution with potent CYP3 inhibitors; caution in older adults (>65 yr); caution with α -blockers.* Nitrates |
| Vardenafil (Levitra) | 2.5, 5, 10, and 20 mg 4-5 hr | 10 mg (5 mg if >65 yr); 1 dose/24 hr; take 1 hour before intercourse. | Common—headache, flushing, dyspepsia, rhinitis; serious—priapism Caution in hepatic impairment; caution if sexual activity, exertion risky because of existing cardiovascular disease; caution in LV outflow obstruction; caution with potent CYP3A4 inhibitors; caution in older adults (>65 yr). α -Blockers, nitrates Avoid in patients with prolonged QT taking class IA or III antiarrhythmics. |

From Physicians' Desk Reference, 64th ed. Montvale, NJ, Thompson, 2010. www.pdr.net.

*PDE-5 inhibitors should be used with caution in patients taking alpha-adrenergic blockers. This is no longer a contraindication based on labeling, but a number of precautions are based on potential for additive vasodilation in concomitant use:

1. Patients should be on α -blocker therapy and stable before starting PDE-5 inhibitor.
2. Patients who already have hemodynamic instability on α -blockers are at increased risk of additive vasodilatory effects.
3. Use the lowest recommended dose to start.
4. If starting α -blocker in a patient on a PDE-5 inhibitor, use the lowest dose of α -blocker.
5. Other medications or volume status may also contribute to vasodilation and should be considered.

type of incontinence and possible overlap with syndromes such as overactive bladder. Genitourinary and neurologic examinations as well as urinalysis should be performed. A postvoid residual urine measurement is useful for men with obstructive symptoms or patients with voiding difficulty (SIGN, 2004). Urodynamic studies are of uncertain benefit. No studies have shown that these tests improve outcomes or predict who will succeed with surgical treatment (Glazener and Lapitan, 2002; Lemack, 2004). Urodynamics may be helpful if the cause of incontinence is uncertain (Lopez et al., 2002). Children who are thought to be incontinent—that is, those who cannot be categorized as simply enuretic or dysfunctional voiders—need more extensive evaluation.

Incontinence treatment should focus on improving quality of life. Stress and urge incontinence may be treated differently, depending on the underlying cause. Physical therapies, medications, alternative treatments, and surgery are options. Pelvic floor exercises are effective and a reasonable first choice for stress and mixed symptoms. It is unknown whether these are effective for urge symptoms (Hay-Smith et al., 2001). Bladder training is effective for urge incontinence (Teunissen et al., 2004). Other options include biofeedback and electrical stimulation (Onwude, 2009). Evidence does not currently support acupuncture treatment (SIGN, 2004).

Medications include alpha agonists, anticholinergics, estrogen, serotonin and norepinephrine reuptake inhibitors,

and tricyclic antidepressants (TCAs). Oral estrogen replacement therapy should not be used because of the underlying cardiac and cancer risk, as well as the finding that it worsens incontinence (Hendrix et al., 2005). Topical vaginal estrogen appears effective; however, data on long-term use and effects after treatment cessation are limited or lacking. Thus, short-term use is likely most prudent at present (Cody et al., 2009).

For stress incontinence, some evidence has shown that α -agonists are more effective than placebo, but the only available form in the United States is pseudoephedrine and side effects limit its use. TCAs are an option, but no randomized controlled trials (RCTs) have evaluated this use (SIGN, 2004). Duloxetine (Cymbalta) improves stress incontinence compared to placebo, but long-term data are lacking (Guay, 2005, Onwude 2009). Anticholinergic drugs such as oxybutynin, tolterodine, solifenacin, and darifenacin are effective for urge incontinence (Table 40-9). Trosipium, a quaternary ammonium compound, is also effective (Athanasopoulos and Perimenis, 2009). Preventing incontinence would be ideal. Methods such as pelvic muscle exercises are often recommended for women after childbirth, although evidence on effectiveness is insufficient at present (Hay-Smith et al., 2002). Episiotomy does not appear to reduce urinary incontinence in women (Hartmann et al., 2005).

Table 40-9 Medications for Urinary Incontinence

| Medication | Dosage |
|---|---|
| Stress Incontinence | |
| Duloxetine (Cymbalta)* | 40 mg twice daily |
| Pseudoephedrine | 30, 60 mg every 4-6 hr 120 mg SR daily |
| Estrogen* | Topical |
| Urge Incontinence/Overactive Bladder | |
| Tolterodine (Detrol, Detrol LA) | 1, 2 mg twice daily 2, 4 mg daily (LA) |
| Trospium (Sanctura, Sanctura XR) | 20 mg twice daily 60 mg daily (XR) |
| Solifenacin (Vesicare) | 5, 10 mg daily |
| Darifenacin (Enablex) | 7.5, 15 mg daily |
| Oxybutynin (Ditropan, Ditropan XL) | 5 mg twice daily 5, 10 mg daily (XL) |
| Oxybutynin transdermal (Oxytrol) | 3.9 mg transdermal patch twice weekly |
| Oxybutynin transdermal gel (Gelnique) | 100 mg/g topical daily |
| Imipramine (Tofranil)* | 10, 25, 50 mg at bedtime; max dose 150 mg |

Interstitial Cystitis

Interstitial cystitis is a chronic, noninfectious bladder disorder predominantly diagnosed in women. Symptoms mimic those of a UTI (urgency, frequency) with the addition of chronic pelvic pain, dyspareunia, or both and varying with bladder filling. Although not associated with cellular change, epithelial inflammation and prolonged symptoms can lead to epithelial damage (Kahn et al., 2005). Two forms are identified: "classic" interstitial cystitis, demonstrating inflammatory bladder wall changes identifiable on cystoscopy, and *painful bladder syndrome*, defined by the symptoms of interstitial cystitis in the absence of any objective cystoscopic findings (Marinkovic et al., 2009).

The main impact of interstitial cystitis is on quality of life. Patients often express somatization and depression or anxiety; as with other somatic pain syndromes, its pathogenesis is unclear. Differential diagnosis includes other somatic syndromes such as fibromyalgia, irritable bowel, and chronic pelvic pain, as well as UTI, overactive bladder, uterine fibroids, and endometriosis. Interstitial cystitis should be considered in any patient presenting frequently with UTI symptoms. There may also be association with autoimmune disorders.

Pentosan polysulfate sodium (Elmiron), 100 mg three times daily, is the only FDA-approved medication for interstitial cystitis. Adjunctive medications include antihistamines, TCAs, gabapentin, anticholinergics, prednisone, and cyclosporine (Marinkovic et al., 2009). Urologic consultation should be considered. Physical therapy, counseling, and bladder training may help (Kahn et al., 2005). Many dietary avoidance recommendations have focused on acidic, high-potassium foods and drinks with acid, caffeine, or alcohol. However, prospective data on dietary interventions are lacking, so such restrictions should be individualized to each patient.

Overactive Bladder

Overactive bladder describes a clinical syndrome characterized by lower urinary tract voiding dysfunction. The International Continence Society has defined overactive bladder as "urgency, with or without urge incontinence, usually with frequency and nocturia" (Wein and Rovner, 2002). The lack of specificity inherent in this definition creates potential for overlap with other urinary tract symptom complexes (e.g., LUTS) and diseases. The pathogenesis is uncertain, and urinary tract abnormalities that could cause symptoms should be ruled out. The primary dysfunction revolves around improper detrusor muscle activity and functional reductions in bladder volume. However, the definition does not exclude patients with the symptoms who do not have objective bladder hypercontractility. Furthermore, voluntary control of bladder contraction may be impaired so that the urge to void cannot be controlled (Herbison et al., 2003).

Neurologic conditions may contribute. For example, patients with multiple sclerosis, stroke, or diabetic neuropathy might manifest overactive bladder. This might be better described as *neurogenic detrusor overactivity*, whereas patients without cause or contributor might be described as having *idiopathic detrusor overactivity* (Herbison et al., 2003). Thus, overactive bladder is best viewed as a descriptive, symptom-driven complex rather than a disease.

Overactive bladder affects approximately 16% of adults, with equal gender distribution. However, women are more likely to experience urge incontinence as a feature (Stewart et al., 2003). Patients may plan their days around issues such as restroom access or avoiding social settings because of incontinence. Patients may be reluctant to discuss these symptoms because of embarrassment, so family physicians may not detect the true impact of these symptoms without specific inquiry.

Many pharmacotherapy options are available for overactive bladder (see Table 40-9). Bladder retraining is another option. There are no systematic reviews comparing these treatments, although incontinence data have suggested that physical therapies are a reasonable option. There are no important differences in effectiveness among medications. Systematic review of anticholinergic medications versus placebo shows statistically significant effectiveness. However, the clinical significance is uncertain, with the exception of side effects, and long-term treatment effects are unknown (Herbison et al., 2003). Anticholinergic treatment will likely result in one less leakage or voiding episode every 48 hours, but one third of patients experience dry mouth (Hay-Smith et al., 2005b).

Renal Calculi

Adults

Approximately 5% to 12% of adults will have a kidney stone, and the chance of a recurrent stone is 50% (Parmar, 2004; Teichman, 2004). Whites have the highest risk, particularly men. Family history increases the risk threefold and is present in 55% of recurrent stone formers (Teichman, 2004).

A classic history suggesting renal calculi is the abrupt onset of unilateral flank pain. It often radiates into the groin and may be accompanied by nausea and vomiting. Patients with kidney stones typically have great difficulty finding a comfortable position. On examination, there may be costovertebral angle or lower abdominal pain, and hematuria occurs in 90% of patients (Teichman, 2004). Patients may experience UTI symptoms such as dysuria, frequency, and urgency as the stone passes from the ureter into the bladder. However, patients with fever, microscopic signs of infection, or signs of systemic sepsis may have superimposed UTI. Complete obstruction and hydronephrosis can result in renal failure.

Helical non-contrast-enhanced CT is the test of choice for diagnosing renal calculi (Lindbloom and Meadows, 2001). Renal ultrasound and IV urography may be helpful for radiopaque stones and pregnant women (ultrasound only) (Sheafor et al., 2000). Stones larger than 5 mm found in the proximal ureter on more than one imaging study will probably need urology consultation and intervention (Grossfeld et al., 2001b). Stones smaller than 5 mm will likely pass without intervention (Teichman, 2004).

Treatment initially focuses on analgesia and relieving nausea and vomiting. Pain results from ureteral obstruction and renal capsular distention and/or hydronephrosis. Pain can be effectively managed with narcotic analgesics or nonsteroidal anti-inflammatory drugs (NSAIDs; ketorolac, indomethacin). Ketorolac (Toradol) is more effective than meperidine (Demerol) and probably as effective as narcotics (Larkin et al., 1999; Teichman, 2004). Alpha blockers such as terazosin or tamsulosin appear to increase the likelihood of a stone passing (DasGupta et al., 2009).

Two thirds of stones pass spontaneously. Stones that have not passed within 4 weeks are unlikely to pass (Teichman, 2004). Urine straining is important because a captured stone can be analyzed for content. Repeat imaging is needed when stone passage has not occurred or is uncertain.

It is debatable whether all patients should receive an evaluation for metabolic disorders after a first kidney stone. A reasonable workup includes an electrolyte panel, urinalysis, blood urea nitrogen (BUN), creatinine, calcium, parathyroid hormone (if calcium elevated), and stone analysis, if possible. Calcium oxalate is found in 60% to 80% of stones (Parmar, 2004). Patients with recurrent stones need a more extensive evaluation, including urine culture and a 24-hour urine study to determine calcium, oxalate, uric acid, citrate, phosphate, sodium, and creatinine levels (Teichman, 2004).

Proper hydration is essential in preventing stones. Patients should aim for urine output of 2 to 3 L/day (Parmar, 2004). Cost-effectiveness data suggest that dietary intervention is appropriate for first episodes (Lotan et al., 2004). Patients with recurrent stones need dietary intervention, a metabolic evaluation, and potassium citrate measurement. Hypercalciuria is an indication for prophylaxis with thiazide diuretics, which effectively reduce recurrence of calcium oxalate

stones. Evidence is less clear for other treatments, such as citrate (Pearle et al., 1999). Men with recurrent stones and idiopathic hypercalciuria will have fewer stones on a low-sodium, low-protein diet than men on a low-calcium diet (NNT = 5.5 for 5 years). Low-calcium diets do not reduce stone formation (Borghesi et al., 2002).

Patients with uric acid stones respond to urinary alkalization with potassium citrate (Teichman, 2004).

Children

Although usually considered an adult problem, children are not immune to urolithiasis. Older children present with typical symptoms, and younger children may have signs mimicking those of colic. About 15% of children presenting to the emergency department who were ultimately diagnosed with urolithiasis by CT did not have hematuria (Persaud et al., 2009). Metabolic disorders are often the cause of pediatric stones, most often hypercalciuria (Peitrow et al., 2002).

The mainstay of treatment is a high fluid intake. Urinary alkalization inhibits cystine and uric acid stones. For calcium-based stones, a diet low in sodium and oxalate and high in potassium is recommended. Excess intake of vitamins D and C is discouraged. Thiazide diuretics are also a treatment option. Gated and ungated shock wave lithotripsy has been successful treatment in children, with minimal morbidity (Shouman et al., 2009).

KEY TREATMENT

Use ACE inhibitors and angiotensin receptor blockers for nephropathy prevention in diabetes (Shlipak, 2009) (SOR: A).
 Antibiotics are ineffective for chronic nonbacterial prostatitis (category IIIb, IV) (Erickson et al., 2008) (SOR: A).
 Enuresis alarm helps manage nocturnal enuresis (Kiddoo, 2007) (SOR: A).
 Pelvic floor muscle exercises are used for stress incontinence (Onwude, 2009) (SOR: B).
 Duloxetine is effective for stress incontinence (Onwude, 2009) (SOR: A).
 Anticholinergics (oxybutynin, tolterodine, solifenacin, darifenacin) and trospium are effective for urge incontinence (Athanasopoulos and Perimenis, 2009) (SOR: A).
 PDE-5 inhibitors (sildenafil, tadalafil, vardenafil) are used for erectile dysfunction (Tharyan and Gopalakrishnan, 2009) (SOR: A).

Infectious Disorders

Key Points

- *Neisseria gonorrhoeae* and *Chlamydia trachomatis* cause most cases of urethritis and typically coexist.
- Identifying and treating asymptomatic bacteriuria are only important in pregnant women.
- Evaluate for urethritis, prostatitis, or both in men with UTI symptoms.
- Women with dysuria and frequency without vaginal symptoms have a 90% chance of UTI.
- Both antibiotic prophylaxis and cranberry juice prevent recurrent UTI.
- The ideal evaluation of children with UTIs is controversial.

Balanitis

Balanitis refers to inflammation of the glans penis (Fig. 40-12). It may occur as a local infectious process, as part of a urethritis syndrome (e.g., Reiter's syndrome), or as a skin disease (e.g., lichen sclerosis). In uncircumcised men, yeast balanitis may result from poor hygiene. Consideration should be given to dermatologic conditions and immunodeficiency in circumcised men.

Epididymitis

Epididymitis (epididymo-orchitis) often presents with testicular pain or swelling. It is usually unilateral, with a palpable, tender epididymis and possibly hydrocele. Risk factors include STI, insertive anal intercourse, invasive urinary tract procedures, and anatomic urinary tract disorders. Anatomic abnormalities are the most likely explanation in children. Epididymitis may occur as an STI in men during insertive anal intercourse or in men older than 35 who have undergone invasive procedures (e.g., cystoscopy). The differential diagnosis includes trauma, infarction, testicular cancer, and testicular torsion. Testicular cancer can be misdiagnosed as epididymitis. Thus, family physicians should emphasize close follow-up.

Chlamydia trachomatis and *Neisseria gonorrhoeae* cause most cases in men younger than 35 and usually coexist with asymptomatic urethritis (CDC, 2006). Other causative organisms include gram-negative enteric bacteria. Fungi and tuberculosis are other possible infectious causes.

Treatment includes antibiotics, analgesia, and scrotal elevation. In patients in whom gonorrhea or chlamydia is the likely cause, ceftriaxone (single dose, 250 mg IM) and doxycycline (100 mg twice daily for 10 days) is the treatment of choice. In patients who are allergic to these, or likely to have an enteric organism as the cause, 10 days of treatment with ofloxacin or levofloxacin is appropriate (CDC, 2006; del Rio, 2007).

Prostatitis

Prostatitis is a fairly common urinary tract disorder in men (Krieger et al., 2003) (see Table 40-7). Categories I (acute) and II (chronic) prostatitis are treated as infectious disorders.

Figure 40-12 Circinate balanitis in a patient diagnosed with Reiter's syndrome (arthritis, conjunctivitis, urethritis). (From the CDC Public Health Image Library image 5806. Courtesy Susan Lindsley and Dr. M. Rein.)

The four-glass method for diagnosing and localizing prostatitis is often recommended but has not been prospectively validated (Stevermer and Easley, 2000).

Acute Bacterial Prostatitis

Acute bacterial prostatitis should be suspected in men presenting with symptoms of UTI. Age and immunodeficiency contribute to men having UTIs, so prostatitis is more likely in otherwise healthy men with these symptoms (Lipsky, 1999). Patients may have UTI symptoms (e.g., dysuria, frequency, urgency) and typically systemic symptoms of acute illness, such as fever, chills, and myalgias. Local discomfort in the form of pelvic or back pain is also typical. Examination reveals a tender, boggy prostate. Most experts have recommended against prostate massage in acute prostatitis because it would be very uncomfortable and theoretically could disseminate the infection (Benway and Moon, 2008; Wagenlehner and Naber, 2003).

Urine culture is typically positive for the causative organism. Treatment is empiric pending the results. Depending on the degree of illness, patients may need an IV broad-spectrum penicillin or third-generation cephalosporin, possibly with an aminoglycoside, or a fluoroquinolone (Wagenlehner and Naber, 2003). Less severe cases can be managed with oral antibiotics. Options include fluoroquinolones and trimethoprim-sulfamethoxazole (TMP-SMX) (Lipsky, 1999). An alternative when STI is likely is intramuscular (IM) ceftriaxone followed by oral doxycycline. Antibiotic therapy is typically 10 to 14 days, although some recommend 4 weeks because of concerns about antibiotics poorly penetrating prostatic tissue. Obstructive uropathy may result from prostatic enlargement; thus, assessment for this clinically or with postvoid residual assessment should be considered (Benway and Moon, 2008).

Chronic Bacterial Prostatitis

Chronic bacterial prostatitis may manifest with irritative voiding symptoms, prostatic obstruction, or recurrent UTIs (Lipsky, 1999). Patients may have microscopic pyuria but negative cultures. Other symptoms include hemospermia, penile discharge, and systemic symptoms.

Longer courses of antibiotics are generally considered standard practice. Options include TMP-SMX and fluoroquinolones for 4 to 6 weeks (Lipsky, 1999). Alpha-adrenergic blockers have limited evidence of benefit when added to antimicrobials for category II prostatitis (Erickson et al., 2008). Patients with recurrent symptoms may need longer antibiotic courses, urologic consultation, or reconsideration of their diagnosis.

Sexually Transmitted Infections

Chancroid

Chancroid is caused by infection with *Haemophilus ducreyi*. A clinical syndrome of painful genital ulcers and adenopathy (patient does not have syphilis; ulcers are herpes negative) allows for presumptive diagnosis (Fig. 40-13). Many treatment options exist (Table 40-10).

Gonorrhea and Nongonococcal Urethritis

Urethritis may present as a urethral discharge or simply dysuria. Family physicians should suspect urethritis in patients with symptoms of UTI, pyuria, presence of leukocyte esterase, and negative urine culture. *N. gonorrhoeae* and *C. trachomatis* are the most important causative organisms. Gonococcal urethritis is typically symptomatic. Chlamydia causes most cases of nongonococcal urethritis (CDC, 2006). Various treatment options exist (see Table 40-10). Fluoroquinolones are no longer recommended as a treatment option due to resistance rates (del Rio et al., 2007). Patients with gonorrhea who are not ruled out for chlamydia should be treated for it because co-infection is common (CDC, 2006).

Herpes Genitalis

Herpes simplex virus type 2 (HSV-2) causes most genital herpes infections, although HSV-1 causes 50% of first cases (CDC, 2006). An estimated 20% of those older than 12 years have it, and infection is often asymptomatic (USPSTF, 2005). Symptoms, if present, may present as multiple,

Figure 40-13 Chancroid: penile lesions and inguinal adenopathy. (From the CDC Public Health Image Library image 4419. Courtesy Pledger.)

small, painful ulcers or vesicles (Fig. 40-14). Causative virus is prognostically important, so confirmatory testing is recommended. Polymerase chain reaction testing is sensitive, whereas a Tzanck test is not (CDC, 2006). Serologic tests for herpes IgG are available but do not differentiate acute from remote infection. The U.S. Preventive Services Task Force (USPSTF, 2005) recommends against routine screening for HSV in asymptomatic adults because there is no evidence that this decreases disease transmission or reduces morbidity. Antiviral medications can treat acute outbreaks and be used as prophylaxis to prevent recurrent outbreaks.

Human Papillomavirus

Human papillomavirus (HPV) may cause symptomatic genital warts, although most patients do not manifest them. HPV types 6 and 11 cause most visible warts (CDC, 2006). Certain HPV types are associated with genital squamous neoplasia. Patients with penile plaques suspicious for warts can be examined by placing an acetic acid solution on the plaque and looking for an acetowhite change. Untreated warts will regress, remain stable, or spread. Symptomatic relief is the main treatment goal. Treatment options include podofilox 0.5%, imiquimod (1%, 5%), topical interferon, cryotherapy, office-based chemical treatments (acetic acid), or surgery (Buck, 2007; CDC, 2006).

Syphilis

Primary *Treponema pallidum* infection manifests as a painless genital ulcer known as a *chancre* (Fig. 40-15). Diagnosis is typically confirmed with a combination of nontreponemal screening tests (rapid plasma reagin [RPR], Venereal Disease Research Laboratories [VDRL]) and a treponema-specific test (fluorescent treponemal antibody absorption [FTA-ABS]). *T. pallidum* is difficult to culture, so darkfield microscopy or fluorescent antibody testing of a tissue specimen provides definitive diagnosis. Primary syphilis is treated with a single dose of penicillin, 2.4 million units IM in adults and 50,000 to 2.4 million U/kg IM in children) (CDC, 2006).

Table 40-10 Treatment for Selected Sexually Transmitted Infections (STIs)

| STI | Medication | Dose | Route* | Duration |
|-------------------|-------------------|---------------|--------|------------------------------|
| Chancroid | Azithromycin | 1000 mg | PO | Single dose |
| | Ceftriaxone | 250 mg | IM | Single dose |
| | Ciprofloxacin | 500 mg | PO | Twice daily for 3 days |
| | Erythromycin base | 500 mg | PO | Three times daily for 7 days |
| Chlamydia | Azithromycin | 1000 mg | PO | Single dose |
| | Doxycycline | 100 mg | PO | Twice daily 7 days |
| Gonorrhea | Cefixime | 400 mg | PO | Single dose |
| | Ceftriaxone | 125 mg | IM | Single dose |
| Syphilis, primary | Penicillin | 2.4 million U | IM | Single dose |

*PO, Oral; IM, Intramuscular.

Doxycycline and tetracycline are alternatives for penicillin-allergic patients.

Urinary Tract Infections

Urinary tract infections are the most common urologic issue encountered by family physicians and one of the most common diagnoses overall (Stange et al., 1998). Most are uncomplicated lower UTIs, such as cystitis.

Asymptomatic Bacteriuria

Approximately 5% of reproductive-age women have asymptomatic bacteriuria (Bent et al., 2002). It is also common in older adults. This is important for understanding the community risk of UTI when evaluating a patient with UTI symptoms. However, although asymptomatic bacteriuria may conceptually place a patient at risk for UTI, identification and treatment do not appear to affect morbidity or mortality (Gartlehner et al., 2004; Lin and Fajardo, 2008). Thus, bacteriuria screening is not recommended (USPSTF, 2008a).

In contrast, pregnant women do benefit from screening. Testing with urine culture should be done in all pregnant women at 12 to 16 weeks of gestation (USPSTF, 2008a). Urine culture is the best method, because dipstick testing

and microscopy are not accurate enough tests to predict this condition.

Uncomplicated Cystitis

Most UTIs manifest as acute uncomplicated bacterial cystitis, and women experience most of these episodes. *Escherichia coli* causes up to 90% of cases, with the rest probably caused by *Staphylococcus saprophyticus*. Other causative organisms include *Proteus mirabilis*, enterococci, and *Klebsiella* (Fihn, 2003). To have “uncomplicated cystitis,” women must have no underlying urinary tract abnormalities or immune compromise (Bent et al., 2002).

Dysuria, frequency, and urgency are the classic clinical triad. The condition most commonly mimicking UTI is vaginitis. Other conditions have been described (see Dysuria). Patients may also experience back or flank pain and suprapubic abdominal pain. Dipstick urinalysis may show leukocyte esterase or nitrite or may be heme positive. Microscopic analysis should assess for pyuria, hematuria, and bacteriuria. The gold standard for diagnosis is urine culture.

Women presenting with at least one UTI symptom have a 50% chance of having a UTI. The combination of dysuria and frequency without vaginal symptoms increases the chance to 90% (likelihood ratio, 24.6). Four symptoms significantly increase the chance of UTI—dysuria, frequency, hematuria, and back pain (Bent et al., 2002). Nitrite-positive or leukocyte esterase-positive dipsticks are the most accurate tests, but cannot rule out a UTI.

Antibiotics are the mainstay of treatment, usually for 3 days (Table 40-11). A shorter duration is as effective as longer therapy for most women, including older adult women (Lutters and Vogt, 2002; Milo et al., 2005). In the southeastern and southwestern United States, there is growing *E. coli* resistance to TMP-SMX, leading some to recommend that this should no longer be first-line treatment for UTI. However, many women treated with TMP-SMX who have a resistant organism on culture achieve clinical cure (Fihn, 2003). Compared with quinolones’ propensity for resistance, TMP-SMX is still a reasonable first choice for many patients, and family physicians should base treatment choices on documented local resistance patterns. If resistance to TMP-SMX exceeds 20%, an alternative treatment should be employed (Nicolle, 2008).

Figure 40-15 Chancre of primary syphilis. (From CDC Public Health Image Library image 6803. Courtesy Dr. M. Rein.)

Complicated Infection

Complicated UTIs are characterized by signs and symptoms of upper tract (i.e., renal) involvement or by factors that predispose to upper tract involvement. UTIs with signs of renal or systemic involvement are also called *pyelonephritis*. Most cases of pyelonephritis are caused by ascending bacterial infection from the bladder (Ramakrishnan and Scheid, 2005).

Symptoms include fever, flank pain, nausea, vomiting, and costovertebral angle tenderness. Findings such as pyuria are typical, and urine culture is usually positive. White cell casts may be present on urine microscopy. Hospitalized patients with UTIs are best managed based on culture results. *E. coli* is the typical pathogen for uncomplicated outpatient UTIs and pyelonephritis. *E. coli* is still the most common isolate in hospitalized patients, but now to a lesser extent, as

Table 40-11 Treatment Options for Acute Uncomplicated UTIs

| Medication | Dose | Regimen | Duration |
|--|--------------|---------------|-------------------------|
| Trimethoprim/sulfamethoxazole (Bactrim DS, Cotrim DS, Septra DS) | 160/800 mg | Twice daily | 3 days |
| Trimethoprim (Primsol) | 100 mg | Twice daily | 3 days |
| Nitrofurantoin macrocrystals (Macrochantin) | 50 or 100 mg | 4 times daily | 7 days |
| Nitrofurantoin monohydrate macrocrystals (Macrobid) | 100 mg | Twice daily | 7 days |
| Ciprofloxacin (Cipro) | 250 mg | Twice daily | 3 days |
| Gatifloxacin (Tequin) | 400 mg | Daily | 1 single dose or 3 days |
| Lomefloxacin (Maxaquin) | 400 mg | Twice daily | 3 day |
| Levofloxacin (Levaquin) | 250 mg | Once daily | 3 days |
| Norfloxacin (Noroxin) | 400 mg | Twice daily | 3 day |
| Fosfomycin (Monurol) | 3 g | Single dose | Single dose |

From Fihn SD. Acute uncomplicated urinary tract infection in women. *N Engl J Med* 2003;349:259-266.
 UTIs, Urinary tract infections; DS, double strength.

Enterococcus, *Pseudomonas*, and *Staphylococcus* species become more likely (Graham and Galloway, 2001; Scholes et al., 2005). Blood cultures do not necessarily change management (Ramakrishnan and Scheid, 2005). Imaging, such as renal ultrasonography, is sometimes recommended, but it also does not necessarily change management and thus can be employed at clinical discretion (Nicolle, 2008).

Outpatients can be managed with an oral fluoroquinolone. Hospitalized patients should receive a fluoroquinolone, an aminoglycoside with or without ampicillin, or an extended-spectrum cephalosporin with or without an aminoglycoside. Patients with cultures showing gram-positive cocci should receive ampicillin-sulbactam with or without an aminoglycoside (Warren et al., 1999). Treatment for 7 to 14 days is usually adequate. Resistant bacteria and renal calculi are the most common causes of treatment failure (Ramakrishnan and Scheid, 2005).

Recurrent Infections

Recurrent UTI can be defined as three episodes in 1 year or two episodes in 6 months (Sen, 2008). Self-diagnosis has an 84% PPV in women with recurrent UTIs (Bent et al., 2002). Cultures are helpful in guiding antibiotic choice (Table 40-12). Prophylactic antibiotics are effective for the subset of women with recurrent symptomatic UTI, although choice of patient and duration is uncertain. Because sexual activity

Table 40-12 Antibiotics for Uncomplicated UTI Prophylaxis

| Drug | Pediatric Dose | Adult Dose* |
|----------------|----------------------------------|---|
| Amoxicillin | 10 mg/kg, once daily | N/A |
| TMP-SMX | 2 mg/kg, once daily based on TMP | Single strength (80/400 mg), half-tablet at night or three times weekly |
| Trimethoprim | N/A | 100 mg nightly |
| Nitrofurantoin | 1-2mg/kg, once daily | 50 or 100 mg nightly |
| Norfloxacin | N/A | 200 mg nightly |

Postcoital prophylaxis options: TMP-SMX, nitrofurantoin, fluoroquinolones.
 TMP-SMX, Trimethoprim-sulfamethoxazole; N/A, not applicable.

is associated with developing UTIs, many physicians recommend that women void immediately after intercourse. However, the poor-quality study examining this practice found no significant effect (Beisel et al., 2002). Thus, no evidence supports recommending this practice to patients. In contrast, postcoital antibiotic prophylaxis reduces the incidence of cystitis (Sen, 2008). Furthermore, it may be as effective as continuous prophylaxis at reducing recurrence, because women in one RCT comparing these methods showed no difference in UTI rates (Albert et al., 2004). In postmenopausal women, topical estrogen is often proposed, but this too lacks good supporting evidence (Sen, 2008).

Cranberry juice has potential as a preventive treatment for recurrent UTI. Its effect is likely caused by chemicals that inhibit bacterial adherence to uroepithelial cells rather than urinary acidification (Raz et al., 2004). RCTs support its use in community-dwelling women. Ingesting pure cranberry juice, from 200 mL daily to 250 mL three times daily, or taking cranberry concentrate tablets (1:30) resulted in a 12% to 20% absolute reduction in symptomatic UTIs (NNT = 58). The type of juice is likely a factor, although type and amount have yet to be well defined (Jepson and Craig, 2008; Sen, 2008).

Urinary Tract Infections in Children

An estimated 3% to 8% of girls and 1% to 2% of boys will have a UTI (Foxman, 2002; Hellstrom et al., 1991). *Pyelonephritis* is a clinical diagnosis and is the most common documented serious bacterial infection in febrile infants. *Cystitis* is common in school-age children and adolescents and, as a general rule, is not a condition of infants or pre-toilet-trained toddlers. Risk factors for UTI range from constipation and dysfunctional voiding to congenital uropathies. Presenting symptoms vary with age and site of infection and may be nonspecific in younger children. *Pyelonephritis* in infants, for example, may present with fever, irritability, vomiting, diarrhea, poor feeding, or failure to thrive. School-age children and adolescents may present with fever, vomiting and flank pain. Symptoms of cystitis are more common after age 2 years and may include dysuria, frequency, urgency, and low-grade fever (<38.3° C).

As with adults, the gold standard test in children is an appropriately obtained urine culture. In neonates and young infants, a suprapubic aspiration is the ideal collection method. Catheterization is otherwise preferred until the

child is old enough to collect a midstream clean-catch specimen. Bag urine collections are unreliable and increase the number of ambiguous cultures (Schroeder et al., 2005). Many elements of the urinalysis have been viewed as tools for aiding diagnosis of UTI. Inadequate sensitivity and specificity continue to support use of urine culture (AAP, 1999). Furthermore, no RCTs have evaluated clinical empiric treatment versus awaiting culture results (Larcombe, 2004). However, pyuria (>5 WBCs/hpf) and a positive Gram stain are helpful in making the decision to initiate early antibiotic therapy, pending culture results.

Treatment remains somewhat controversial, particularly the choice between parenteral and oral antibiotics in the setting of pyelonephritis. For children with pyelonephritis, therapeutic goals include treating or preventing systemic complications of bacteremia, preventing renal sequelae, and ameliorating acute symptoms. Historically, parenteral antibiotics have been the preferred option, particularly in younger children with pyelonephritis. This remains true for infants younger than 4 weeks, who should be hospitalized and receive parenteral therapy. This is also true for older infants and children assessed at high risk because of a septic appearance, vomiting or inability to take oral fluids and medications, dehydration, or concerns regarding compliance. Choice of parenteral antibiotic includes ampicillin in combination with gentamicin or cefotaxime for neonates and third-generation cephalosporin alone for older children. In these cases, transition to oral therapy follows once culture results and sensitivities are known and signs of systemic infection have resolved. Follow-up urine cultures to test for cure are unnecessary in patients with good clinical response (AAP, 1999). Prolonged parenteral therapy is indicated for septic infants. For children 1 month and older not assessed as high risk, it now appears that oral antibiotics are equally effective not only regarding course of illness but also in preventing renal scarring (Montini et al., 2007). Options for initial oral therapy would include amoxicillin-clavulanic acid, TMP-SMX (>2 months), and cephalosporins. Because of the increasing incidence of UTI with ampicillin-resistant *E. coli*, amoxicillin is no longer the preferred initial choice. The recommended length of therapy is typically 7 to 10 days for an uncomplicated UTI (i.e., cystitis) and 10 to 14 days for pyelonephritis (Larcombe, 2007).

The most appropriate evaluation after first UTI is controversial (Layton, 2003). Traditionally, children have undergone a complete evaluation for underlying urologic abnormalities that would increase the risk of further infections and renal scarring. This includes renal ultrasound and VCUG. In 309 children younger than 24 months with their first febrile UTI, ultrasound was of limited value because it did not change management, and other tests may be obviated by routine cultures for children with a febrile illness after a prior UTI (Hoberman et al., 2003). However, 29% of 390 children under age 5 years with a first-time febrile UTI had abnormal renal ultrasound findings (Huang et al., 2008).

The most common uropathy associated with pediatric UTI is *vesicoureteral reflux* (VUR), occurring in 30% to 40% of cases. Reflux is diagnosed by VCUG and graded on a scale of 1 to 5, with grade 5 being the most severe. The degree of VUR is directly proportional to the incidence of renal scarring. In addition to the standard fluoroscopic VCUG, radionuclide cystography may be performed. This test has the advantage of less radiation exposure but is lacking in anatomic detail

and is most often used for follow-up studies. The traditional approach to the patient with VUR has been prophylactic antibiotics, with surgical intervention reserved for complicated patients with breakthrough UTIs and evidence of renal injury (see Table 40-12). “Deflux” is a newer, less invasive procedure performed using cystoscopy and is proving to be highly effective in the treatment of reflux. However, the management of VUR is a rapidly evolving field and remains controversial. Evidence supporting prolonged antibiotic prophylaxis is weak because of a lack of properly designed RCTs (Williams et al., 2005). Also, evidence that surgical repair reduces negative outcomes in children with normal renal function is weak or absent (Larcombe, 2007). The Randomized Intervention for Children with Vesicoureteral Reflux (RIVUR) is a multicenter, randomized, double-blind prospective study currently in progress in the United States designed to assess the efficacy of prophylactic antibiotics in the treatment of grade 1 to 4 VUR in children age 2 months to 6 years. If emerging evidence supports withholding antibiotic prophylaxis, the need for routine VCUG will be obviated. Renal scintigraphy (dimercaptosuccinic acid [DMSA] scan) has been recommended to help diagnose pyelonephritis. This is also controversial because false-negative results could lead to undertreating children with pyelonephritis. DMSA scanning has shown promise in predicting higher grades of reflux in older infants and children (Lee et al., 2009), but this has not been true in neonates (Siomou et al., 2009). DMSA scans are not recommended routinely in children with UTI (AAP, 1999). The prudent course with evaluation is to await more evidence-based management guidelines, which appear to be forthcoming.

The ultimate goal in the approach to patients with UTI is to prevent morbidity. Renal scarring may ultimately manifest as hypertension, proteinuria, or both. The incidence of renal scarring in patients with UTI is increased in children younger than 3 years, presence of VUR proportional to grade of reflux, recurrent UTI, and delayed or inadequate therapy.

KEY TREATMENT

Continuous or postcoital antibiotics are equally effective for recurrent UTI (Sen, 2008) (SOR: A).
Ceftriaxone and cefixime are used for gonorrhea (CDC, 2006) (SOR: C).
Fluoroquinolones should not be used to treat gonorrhea (CDC, 2006; del Rio, 2007) (SOR: C).
Treat for chlamydia and gonorrhea if treating urethritis presumptively (CDC, 2006) (SOR: C).

Neoplastic Disorders

Key Points

- Benign prostatic hyperplasia affects most men by age 80 years. Lower urinary tract symptoms vary and may not correlate with prostate size. Other factors such as detrusor dysfunction contribute to LUTS.
- Alpha-adrenergic antagonists and 5 α -reductase inhibitors are effective for BPH and LUTS.
- Smoking is the top risk factor for bladder cancer, and hematuria is the most common presenting sign.

- Prostate cancer is the most common cancer in men and second most common cause of male cancer death.
- There is no PSA value that is both sensitive and specific for prostate cancer.
- When ordering a PSA test, family physicians should discuss the risk, benefits, and uncertainties with patients and make a shared decision about whether to screen.
- The value of testicular self-examination is unknown.

Benign Neoplasia: Benign Prostatic Hyperplasia

Benign prostatic hyperplasia is a common problem for men. More than 50% of men older than 60 years have BPH, and this reaches 80% by 80 years of age (Dull et al., 2002; Thorpe and Neal, 2003). The exact pathogenesis of BPH is uncertain, but it is characterized by epithelial and stromal cell proliferation in the periurethral prostate tissue.

The LUTS syndrome (see earlier) overlaps with BPH because up to 30% of men have lower urinary tract symptoms (Thorpe and Neal, 2003). The symptoms defining LUTS were once thought to be solely indicative of BPH. However, LUTS may arise from other disorders (e.g., detrusor dysfunction), and there is a lack of symptomatic correlation with prostate size. However, outflow obstruction from an enlarged prostate may contribute to the development of detrusor dysfunction and urinary retention, referred to as LUTS-BPH.

Diagnosis focuses on patient history, rectal examination, and impact on quality of life. Symptoms can vary over time, even without treatment; however, the course is typically progressive, and 1% to 2% of men with BPH experience acute urinary retention annually (Webber, 2006). Various measures exist for measuring symptom severity. The most widely used and well validated is the International Prostate Symptom Score. This scoring system can discriminate the severity of symptoms and treatment response. However, it does not correlate with anatomic findings or objective measures of urinary flow (Barry and O'Leary, 1995). Prostate-specific antigen (PSA) values may increase with prostate hyperplasia, but the overlap with prostate cancer makes this of limited use in managing BPH (Barry, 2001).

Medical therapies have overtaken surgical as the most common treatments. Alpha-adrenergic blocking drugs improve urinary symptoms in BPH (Wilt et al., 2008). Alpha-adrenergic antagonists block adrenoceptors in the prostate and bladder neck (Table 40-13). They may also induce prostate epithelial apoptosis (Thorpe and Neal, 2003). Side effects, particularly blood pressure effects, are important, because these drugs will most often be used in older adults (Schulman, 2003). The α -blocker tamsulosin has recently been implicated in association with serious postoperative ocular complications in patients undergoing cataract surgery (Bell et al., 2009).

Prostate tissue is androgen responsive throughout life. 5α -Reductase inhibitors inhibit the conversion of testosterone to dihydrotestosterone, leading to glandular atrophy and reduced prostate volume (20%-30%) (Thorpe and Neal, 2003). It takes many months for these medicines to become effective. Sexual side effects are the most prominent. These drugs also reduce PSA by up to 50%. Based on the Prostate Cancer Prevention Trial, family physicians should discuss potential benefits and harms of 5α -reductase inhibitors (see Prostate Cancer) when using these medications for BPH and LUTS (Kramer et al., 2009). Prostate enlargement can progress

Table 40-13 Pharmacotherapy for Benign Prostatic Hyperplasia

| Drug | Dosage | Adverse Effects |
|---|--------------------|--|
| Alpha-Adrenergic Blockers | | |
| Alfuzosin (Uroxatral) | 10 mg daily | Cardiovascular: dizziness, postural hypotension, syncope Sexual: ejaculatory dysfunction Systemic: asthenia, drowsiness, fatigue, headache |
| Doxazosin (Cardura, generic) | 1-8 mg daily | |
| Terazosin (Hytrin, generic) | 1-10 mg at bedtime | |
| Tamsulosin (Flomax)* † | 0.4 mg daily | |
| 5α-Reductase Inhibitors | | |
| Dutasteride (Avodart) | 0.5 mg daily | Sexual: impotence, decreased libido, ejaculatory dysfunction |
| Finasteride (Proscar) | 5 mg daily | |
| <small>From Schulman CC: Lower urinary tract symptoms/benign prostatic hyperplasia: Minimizing morbidity caused by treatment. <i>Urology</i> 2003;62:24-33; Schwinn DA, Price DT, Narayan P: α_1-Adrenoceptor subtype selectivity and lower urinary tract symptoms. <i>Mayo Clin Proc</i> 2004;79:1423-1434; and Thorpe A, Neal D: Benign prostatic hyperplasia. <i>Lancet</i> 2003;361:1359-1367. *Alpha-1 adrenoceptor selective. †Associated with postoperative complications from cataract surgery.</small> | | |

enough to obstruct the bladder outlet completely, leading to acute urinary retention. If this occurs, catheterization is warranted. The addition of an α -blocker may aid in voiding once the catheter is removed (Thorpe and Neal, 2003). A randomized, double-blind trial of doxazosin and finasteride over 4 years showed that combining these two medications significantly slowed symptomatic progression and reduced the risk of urinary retention and invasive treatment. Treatment was safe, and the effect of combined treatment on symptom scores was greater than the effect of either agent alone (McConnell et al., 2003). In addition to prescription medicines, a number of alternative therapies are available. Saw palmetto extract (*Serenoa repens*) is one of the most studied herbal medicines (Buck, 2004). Earlier studies found it is as effective as tamsulosin or finasteride for BPH. Other herbal medicines include β -sitosterols (promising), pygeum (African plum, *Prunus africanus*), and rye grass pollen (cernilton), with efficacy of the latter two uncertain (Webber, 2006).

Malignant Neoplasias

With the exception of prostate cancer, urologic malignancy is relatively uncommon in the general population. After prostate cancer, which is the most common cancer diagnosed in men, the next most common cancers are bladder and renal cell cancers (American Cancer Society, 2009). Testicular cancer is relatively common in young men compared with other cancers in that age group.

Bladder Cancer

Bladder cancer occurs in approximately 38.4 per 100,000 men and 9.8 per 100,000 women. Its incidence in white men is twofold higher than in black men (ACS, 2009). The

incidence increases with age, with 80% of new cases occurring in patients older than 60 (National Cancer Institute, 2009a).

Cigarette smoking is the most prominent risk factor, increasing the risk fourfold to sevenfold. Aminobiphenyl is a cigarette carcinogen linked to bladder cancer. Smoking cessation decreases risk, although it still remains twofold higher 10 years after cessation. Other risk factors include exposure to the aromatic amines used in the dye and rubber industry, benzidine production, dry cleaning, garment manufacturing, and rope and twine manufacturing, as well as exposure to gases and soot from coal. Medical risks include cyclophosphamide, radiation, and prolonged exposure to foreign bodies (e.g., catheter). Finally, aristolochic acid, found in certain weight loss supplements and traditional Chinese herbal compounds containing *Aristolochia fangchi*, may increase risk. Banned in many western countries, this is still available in the United States (NCI, 2009a).

Hematuria is the most common sign of bladder cancer (NCI, 2009a), and diagnosis is most often made by direct bladder visualization (cystoscopy) and biopsy. Positive urine cytology is essentially diagnostic, although false-negative results limit the usefulness of this approach alone. No imaging test can reliably detect bladder cancers.

The USPSTF (2004a) recommends against routine screening of asymptomatic persons for bladder cancer. The prevalence of bladder cancer is low, and most patients with hematuria do not have bladder tumors. Most positive screening tests yield false-positive results, prompting unnecessary evaluation.

Penile Cancers

Penile cancers are rare; with 1250 new U.S. cases in 2010 (ACS, 2010). Penile cancers are most often squamous cell, and there may be a connection to HPV infection. As expected from this cell type, lesions may appear as a superficial plaque or ulcer. Biopsy or consultation is appropriate in the evaluation of a suspicious penile lesion.

Prostate Cancer

Prostate cancer is the most common cancer diagnosed in men and is the second most common cause of cancer death in men after lung cancer. The gap between the annual numbers of diagnoses (217,730) and deaths (32,050) is wide (ACS, 2010). Major risk factors include age, African American race, and family history. Most cases occur in men older than 65. African Americans have a 60% higher incidence compared with whites and experience a disproportionate share of prostate cancer deaths (Harris and Lohr, 2002).

Dietary factors may play a role, including the proandrogenic effects of dietary fat, carcinogenic compounds in grilled meats, and antioxidants in vegetables (Nelson et al., 2003). Dietary antioxidants such as lycopene show epidemiologic links (mostly related to tomato consumption) supporting a preventive effect, with possible mechanisms including androgen inhibition (Wertz et al., 2004). However, an RCT using vitamin E and selenium, alone or in combination, failed to show any preventive effect. Given these results and prior disappointing results of other antioxidant trials, clinicians should not recommend supplements for prostate cancer prevention (Lippman et al., 2009).

Prostate cancer is most often indolent, with symptoms typically arising later in the disease course. Physical examination is most often unrevealing. A firm nodule on DRE may indicate a tumor. However, DRE accuracy depends on the performing physician and is imprecise. An abnormal DRE predicts prostate cancer in 18% to 28% of cases (Schwartz et al., 2005). Further, up to 25% of biopsy-detected cancers after an abnormal DRE occur on the side opposite the palpated nodule (McNaughton-Collins et al., 1997).

Tumors are most often diagnosed after biopsy for an abnormal screening result. The Gleason score grades cellular differentiation of the two most common patterns seen in a biopsy specimen. Scores range from 2 to 10, with higher scores indicating a more poorly differentiated tumor (Schwartz, 2005). The risk of prostate cancer death is higher with poorly differentiated cancer. Men with low Gleason scores (2 to 4) have a low risk of death, whereas those with higher scores (8 to 10) had a high probability of dying from prostate cancer within 10 years (Albertson et al., 2005).

Treatment options for prostate cancer include watchful waiting, brachytherapy, external beam radiation, radical prostatectomy, androgen ablation, and combinations of these options. High-grade tumors receive aggressive treatment, but the ideal treatment for intermediate-grade tumors (Gleason score of 5 to 7) is controversial. Low-grade tumors are candidates for watchful waiting. Treatment for localized disease, regardless of method, carries the risk of persistent negative effects on quality of life, such as sexual, urinary, and bowel dysfunction (Smith et al., 2009). An RCT of prostatectomy versus watchful waiting for low-grade tumors in Scandinavian men found little difference in outcomes during early follow-up, but at 10 years, the prostatectomy group had a lower risk of metastasis or progression and a slightly lower overall mortality (Bill-Axelsson et al., 2005; Holmberg et al., 2002).

Prostate-specific antigen is a glycoprotein produced by prostatic epithelial cells. Its level increases with prostate adenocarcinoma, hyperplasia, inflammation, procedures, ejaculation, and massage. However, clinical DRE should not affect the PSA level (Barry, 2001). The most widely accepted upper limit of normal for total PSA is 4.0 ng/mL. The Prostate Cancer Prevention Trial, using a biopsy standard, indicated that as PSA levels increase, sensitivity declines and specificity increases, and at no point is there a good balance between the two. Thus, cancer appears ubiquitous—men with normal-range PSA levels may have prostate cancer; 15% of men with a PSA less than 4.0 ng/mL have cancer, 15% of which are high-grade tumors (Thompson et al., 2004). Furthermore, although some studies have concluded that a lower abnormal PSA cutoff level would detect more cancer (Punglia et al., 2003), these findings indicate that more men would have unnecessary biopsies. Thus, PSA testing suffers from both a high false-positive rate and false negatives as (Harvey et al., 2009).

It is unknown whether PSA screening reduces all-cause mortality. Two large, randomized screening trials, the Prostate, Lung, Colorectal, and Ovary (PLCO) trial, and the European Randomized Study of Screening for Prostate Cancer (ERSPC), were initiated to evaluate the impact of screening on mortality. The ERSPC study did show a 20% reduction in prostate cancer death; 1410 men would need to be screened and 48 prostate cancer cases treated to prevent

one death in 10 years. Overdiagnosis of clinically insignificant prostate cancer was a problem (Schroder et al., 2009). In contrast, interim reports from the ongoing PLCO trial found no differences in prostate cancer mortality between the test and control groups (Andriole et al., 2009).

Should screening prove beneficial, African American men and patients with first-degree family histories (age <65) may be most likely to benefit, beginning at age 45 years (ACS, 2009b). Although older men have a higher risk, competing causes of death and the low chance of progression make screening men with less than 10 years in remaining life expectancy of little benefit (Fisher, 2002; Ilic et al., 2006).

Preventing prostate cancer with prophylactic measures can be considered (Unger et al., 2005). The Prostate Cancer Prevention Trial showed that finasteride significantly reduced cancer compared with placebo in an RCT (absolute risk reduction, 6% at 7 years). However, patients taking finasteride had an increased risk of high-grade cancer (Thompson et al., 2003). The American Society for Clinical Oncology and American Urological Association joint guideline recommends clinicians consider discussing the risks and benefits of 5 α -reductase inhibitors for men with PSA values less than 3.0 who either undergo regular PSA screening or are planning to do so. The impact on PSA values and how PSA screening is interpreted must also be considered (Kramer et al., 2009).

Because PSA testing will detect cancers early, patients may live longer with the disease but not actually live longer lives (lead-time bias). Also, some patients treated for PSA-detected cancer may not have aggressive tumors. Treating them may artificially elevate treatment success and survival rates (length-time bias). Thus, mortality rate reductions may reflect the success of screening, misattribution of cause of death, research bias, improved treatments, or changing disease patterns. The most significant challenge remains that there is no way to differentiate patients with aggressive disease from those with clinically unimportant disease using current screening tools. Until this is resolved, controversy surrounding prostate cancer screening is likely to persist.

Despite any clear evidence showing that screening saves lives, over half of U.S. men are regularly screened with PSA testing (Thompson et al., 2005). PSA testing is a well-known test, with men possibly believing that being screened is beneficial and responsible behavior (Chapple et al., 2002). Furthermore, the PSA test has accuracy problems, which makes reassuring patients with normal-range results difficult. The controversies surrounding screening are reflected in the disparate prostate cancer screening guidelines (Box 40-7). However, one consistency emerges—family physicians should engage in an informed-consent discussion with their patients before screening. The risks, benefits, and limitations should be discussed so that patients are fully informed and can incorporate their personal preferences into the screening decision. Thus, although screening remains debatable, it appears inappropriate to order PSA testing routinely without this type of discussion.

As with any screening method, false-positive test results have potential for physical and psychological harm. Prostate biopsy carries procedural risks as well as the risk of discovering and treating a cancer that would not be significant in the patient's lifetime.

Box 40-7 Prostate Cancer Screening Recommendations

U.S. Preventive Services Task Force (USPSTF)

Evidence insufficient for recommendation in men younger than 75 years.

Recommend against PSA screening in men 75 and older.

American Cancer Society

Routine screening should not occur without an informed consent discussion.

Asymptomatic men with a life expectancy greater than 10 years should have the opportunity to make an informed decision on screening. Men with an average risk should have this at age 50; African-Americans or men with a first-degree relative with prostate cancer at age 45; and men with multiple affected relatives at age 40.

Men with less than a 10 year life expectancy should not be offered screening.

If screening is chosen, then PSA with or without DRE is the method.

For men who choose screening:

- PSA < 2.5 ng/mL may be screened every 2 years.
- PSA > 2.5 ng/mL should be screened every year.
- PSA > 4.0 ng/mL should be referred for biopsy. Consider individual risk for prostate cancer in men with PSA between 2.5 and 4.0 ng/mL.

Does not support routine testing.

Offer PSA testing and DRE annually beginning at age 50 years for men with at least 10-year remaining life expectancy as part of risk/benefit discussion; African Americans, and those with family history in one or more first-degree relatives diagnosed at an early age, should begin at 45 years.

American Academy of Family Physicians

Recommends against screening men 75 and older.

American Urological Association

Offer DRE and PSA testing to asymptomatic men 40 years or older with remaining life expectancy more than 10 years.

Modified from American Academy of Family Physicians. Recommendations for clinical preventive services; American Cancer Society guideline for early detection of cancer; American Urological Association. Prostate-specific antigen: best practice statement: 2009 update; US Preventive Services Task Force. Screening for prostate cancer: recommendation statement. *Ann Intern Med* 2008;149:185-191. DRE, Digital rectal examination; PSA, prostate-specific antigen.

Renal Cancers

Renal cancers are twice as common in men as in women; more than 57,000 cases are diagnosed annually in men (ACS, 2010). Risk factors are less well understood than for other urologic cancers. Heavy tobacco use (>20 packs/year) is a risk factor in men, and severe obesity is a risk in both genders. Risks from occupational or medication exposure are less certain (Dhote et al., 2004).

Diagnosis of renal cancer is often incidental to an imaging study (e.g., ultrasound) obtained for another reason. Hematuria is also a clinical sign that may lead to the diagnosis. Although renal cell cancers are curable if localized (88%-100%), overall survival rates (40%-60% at 5 years) are not as encouraging as in other urologic cancers (Dhote et al., 2004; NCI, 2009d).

Testicular Cancer

Approximately 8400 men were diagnosed with testicular cancer in 2010 (ACS, 2010). It is unusual in that it occurs mostly in young men (15-35 years) and is the most common

cancer in this group. Orchiopexy in children with cryptorchidism does not necessarily prevent cancer, so these patients should be followed closely (NCI, 2009e).

Most testicular tumors are initially discovered by patients. Typical presentations include painless testicular lumps or scrotal pain, edema, or hardness. Symptoms can mimic those of epididymitis, and tumor should be in the differential of this condition (Kinkade, 1999). Ultrasound is the initial study of choice for suspected testicular masses. Most tumors are germ cell neoplasms. Thus, serum tumor markers (β -hCG, lactate dehydrogenase, alpha-fetoprotein) are important in the diagnosis, prognosis, and monitoring aspects of care. However, normal values do not rule out cancer in patients with a mass, and they are not appropriate as screening tools, so they should not be used to decide whether a confirmed mass is cancerous (Kinkade, 1999). Patients are typically followed for many years for treatment failure or recurrence, and family physicians play an important role in ensuring that patients participate adequately with follow-up.

Testicular self-examination or clinical examination might detect cancer at an earlier stage but is highly unlikely to have a significant impact on testicular cancer mortality, with

survival rates already so high. Thus, USPSTF (2004b) does not recommend testicular cancer screening in the general population.

Wilms' Tumor

Wilms' tumor presents in childhood as an abdominal mass. It is a rare cancer, with approximately 500 cases annually. Wilms' tumor has good cure potential, with survival rates greater than 90% at 4 years (NCI, 2009f).

KEY TREATMENT

Use of 5 α -reductase inhibitors is effective for benign prostatic hyperplasia (BPH) (Kramer et al., 2009; Thorpe and Neal, 2003) (SOR: A).
Alpha-adrenergic blockers are also used to treat BPH (Wilt et al., 2000) (SOR: A).
5 α -Reductase inhibitors are used for prostate cancer prevention (SOR: B).
Surgical treatments may be needed for BPH (SOR: A).

Patients present to the family physician with a limited set of symptoms, often with subtle differences to indicate mild or serious ocular conditions. To decide when to treat patients and when to refer them to an ophthalmologist, the family physician must possess a complete appreciation of these subtle differences. Knowledge of the basic anatomy of the eye is essential in determining these diagnostic differences (Fig. 41-1).

Red Eye

The family physician frequently encounters patients who complain of a “red eye.” Usually, the condition causing the red eye is a simple disorder, such as conjunctivitis or subconjunctival hemorrhage. These conditions improve spontaneously or are readily treated. A red eye, however, may be a symptom of a more serious disorder, such as herpetic dendritic ulcer, iritis, acute angle-closure glaucoma, ophthalmia neonatorum, or congenital glaucoma. These conditions must be clearly distinguished from the much more common conjunctivitis and subconjunctival hemorrhage because *immediate referral* to the ophthalmologist is paramount. To evaluate the red eye, the family physician needs to have available a penlight, magnifying glasses, visual acuity chart, fluorescein dye, anesthetic drops, and tonometer.

Evaluation

Symptoms and Signs

Patients who complain of a red eye generally can tell the physician whether the eye irritation occurred rapidly or progressed slowly. This information is important because a small foreign

body, such as a grain of sand, lodged in the conjunctival sac produces a rapid hyperemia, whereas a viral or allergic conjunctivitis, or an iritis, generally produces a slowly progressive redness. Ocular pain is an important symptom (Table 41-1). Irritation of the superficial layer of the cornea, as caused by a small foreign body, is accompanied by a superficial “grain of sand” sensation in the eye. Deeper inflammatory processes, such as iritis or iridocyclitis, or a deeper penetrating foreign body in the cornea, present with more severe, dull pain in the eye.

Abnormal light sensitivity (photophobia) is a third danger symptom that must be elicited by the family physician. Photophobia occurs with corneal inflammation, iritis, and angle-closure glaucoma. Patients who have conjunctivitis usually do not have abnormal light sensitivity (Box 41-1).

Patients who complain of a red eye often complain of discharge from the eye (Table 41-2). If they do not complain of eye discharge spontaneously, the physician must inquire about the presence, type, and quantity of discharge. Purulent (creamy white or yellow watery) discharge suggests a bacterial cause. A serous or clear discharge suggests a viral cause. Scanty, white, stringy exudate occurs most often with allergic conjunctivitis. The absence of discharge indicates an unusual cause for red eye, such as iridocyclitis, ultraviolet (UV) light keratitis (snow blindness), or acute angle-closure glaucoma. A complaint of diminished visual acuity is a serious danger sign and must be elicited in the history.

Physical Examination

It is important to examine both eyes because many patients with conjunctivitis in one eye have clear signs of early conjunctivitis in the other. The type of infection must be closely

Figure 41-1 Anatomy of the right eyeball. (From Scheie HG, Albert DM. *Textbook of Ophthalmology*, 9th ed. Philadelphia, Saunders, 1977.)

Table 41-1 Red Eye: Differential Diagnosis

| Parameter | Conjunctivitis, Bacterial | Iritis | Keratitis | Acute Glaucoma |
|------------------------|---|--|---------------|-----------------------------------|
| Vision | Normal | Blurred | Blurred | Marked blurring |
| Pain | None | Moderately severe; intermittent stabbing | Sharp, severe | Severe; sometimes nausea/vomiting |
| Photophobia | None | Moderate | Moderate | Moderate |
| Discharge | Usually significant with crusting of lashes | None | None to mild | None |
| Conjunctival injection | Diffuse | Circumcorneal | Circumcorneal | Diffuse |
| Appearance of cornea | Clear | Clear | Cloudy | Cloudy |
| Pupil size | Normal | Constricted | Normal | Dilated |
| Intraocular pressure* | Normal | Normal or low | Normal | Elevated |

*Caution: Do not measure IOP with discharge present.

inspected; *conjunctival* infection is characterized by individually visible vessels in the conjunctiva branching from the sclera toward the cornea, whereas *ciliary* infection appears as a red ring surrounding the cornea in which individual vessels are not clearly visible. The significance of ciliary infection is that the deep ciliary vessels are involved, indicating a much more serious inflammatory condition of the eye, such as a deep corneal infection, iritis, or iridocyclitis. Inspect the palpebral conjunctiva carefully with magnification to determine whether lymphoid hyperplasia (cobblestone appearance) exists. The type and quantity of discharge are assessed by pulling down the lower lid. The appearance of the punctum should be examined to determine whether pus is coming out

of the tear duct. Palpation of the tear sac on the upper portion of the nose (lacrimal crest) demonstrates tenderness in cases of acute dacryocystitis.

Carefully examine the cornea. Normally, the cornea is perfectly transparent. Excessive fluid within the stroma of the cornea results in partial opacification that can be observed by direct illumination with a penlight. A diffuse corneal haze can occur with congenital glaucoma and angle-closure glaucoma. After inspection with a penlight under magnification, perform corneal staining with fluorescein using sterile filter paper strips. The stained part of the strip is moistened with water and touched to the conjunctiva away from the cornea. With blinking, the fluorescein

Box 41-1 Approach to Patient Presenting with Red Eye (No History of Trauma)

1. Check for the following symptoms or signs.
 - a. Reduced vision
 - b. Pain
 - c. Photophobia
 - d. Corneal staining
 - e. Corneal edema
 - f. Unequal pupils
 - g. Elevated intraocular pressure
2. Refer to ophthalmologist if any of these signals are present.
3. If none of the above is present, the diagnosis is probably conjunctivitis.
4. The triad of a red eye, pain, and loss of vision should *always* alert the examiner to a potentially blinding condition.

Table 41-2 Conjunctivitis Clues

| Finding | Cause |
|-------------------------------------|-----------|
| Purulent discharge | Bacterial |
| Serous or clear discharge | Viral |
| Stringy, white discharge | Allergic |
| Preauricular lymph node enlargement | Viral |

spreads over the cornea. A UV light source enhances fluorescence. Areas of bright-green staining denote absent or diseased epithelium. Corneal staining readily demonstrates a corneal abrasion and helps identify corneal foreign bodies and infectious epithelial defects, such as herpetic dendritic keratitis (Fig. 41-2).

Examine the pupils carefully for size and shape. In most people the pupils are of equal size; a small percentage have congenital variation in the size of the pupils (anisocoria). These patients are often aware that their pupils are unequal. In patients with previously equal pupils, inequality of the pupil may indicate iritis, typically with the affected pupil partially constricted. In acute angle-closure glaucoma the pupil is usually partially dilated and may not be round. Unequal pupil size is an important sign of significant ocular trauma or third nerve palsies.

Estimate the anterior chamber depth by side illumination with a penlight. If the anterior chamber is normal or deep, the entire surface of the iris is well illuminated. When the anterior chamber is shallow, the iris on the more distant side of the pupil is in shadow. A shallow anterior chamber in a red eye may indicate acute angle-closure glaucoma or ocular trauma. The anterior chamber appears deep in patients with congenital glaucoma.

If the red eye does not have an obvious infection, measure the *intraocular pressure* (IOP) with a tonometer. IOP is normal in most patients with red eye, except for those with acute angle-closure glaucoma. With iritis and traumatic, perforating ocular injuries, IOP is generally low. Sterilize the tonometer before and after application to a red eye, preferably by heat sterilization.

Preauricular lymph node enlargement is a frequent sign of viral conjunctivitis and usually is not present with acute bacterial conjunctivitis (see Table 41-2).

Red Eye in Infants**Key Points**

- Red eye in infants requires special attention to differentiate ophthalmia neonatorum, congenital glaucoma, conjunctivitis, and dacryocystitis.
- Cultures should be obtained in neonates with symptoms suggestive of ophthalmia neonatorum.
- Febrile children with acute dacryocystitis should have cultures tested to direct management.
- Infants with symptoms of congenital glaucoma should be promptly referred to an ophthalmologist.
- For chronic dacryocystitis, the best age for surgical intervention is 6 to 12 months.
- Infants with a dacryocystocele require prompt ophthalmologist referral and systemic antibiotics.

Several conditions occur specifically during the first year of life. They include ophthalmia neonatorum, acute and chronic dacryocystitis, bacterial conjunctivitis, and congenital glaucoma.

Ophthalmia Neonatorum

Ophthalmia neonatorum is an infection or inflammation of the conjunctiva that occurs during the first 4 weeks of life. Possible causes include chemical conjunctivitis, *Neisseria gonorrhoeae*, and chlamydial infection. The increased incidence of venereal disease and shortcomings in silver nitrate prophylaxis are significant factors in the constantly evolving clinical picture. Ophthalmia neonatorum frequently is a manifestation of a systemic infection, requiring determination of the exact cause in all but the most transient cases. Table 41-3 outlines the management of the various types of ophthalmia neonatorum. At present, erythromycin is the medication of choice. Povidone-iodine ophthalmic solution (0.5%) is less toxic, inexpensive, and effective, but is not generally used because of confusion over povidone solution versus povidone soap.

Silver nitrate has been replaced by erythromycin, so the incidence of chemical conjunctivitis has decreased significantly. Before the neonatal prophylaxis, gonorrhea was a common cause of ophthalmia neonatorum. Half of patients with *gonococcal* conjunctivitis develop corneal clouding, a major cause of blindness. Gonococcal conjunctivitis still occurs, despite erythromycin prophylaxis. Frequently, the infant with gonococcal conjunctivitis presents with swollen lids, purulent exudates, beefy-red conjunctiva, and conjunctival edema. The gonococcal organism can rapidly penetrate the intact corneal epithelium and produce corneal perforation if recognition and treatment are delayed. When gonococcal conjunctivitis is suspected, referral to an ophthalmologist is critical. Patients may also have systemic involvement, with associated central nervous system (CNS) signs. Both parents should be examined for venereal disease and treated, if necessary.

Figure 41-2 Corneal abrasion. The patient had a fingernail injury caused by the daughter (*left*). Characteristic fluorescein staining is displayed in the adjacent photomicrograph (*right*).

Table 41-3 Management of Ophthalmia Neonatorum

| Disease | Diagnosis | Treatment |
|--------------------------------|--|--|
| Gonococcal conjunctivitis | Gram-negative intracellular diplococci <i>plus</i> Growth on chocolate agar or Thayer-Martin agar <i>plus</i> Fermentation glucose negative and maltose negative | Ceftriaxone, 125 mg IM single dose <i>plus</i> one of the following: Oral tetracycline, 500 mg qid Oral doxycycline, 100 mg bid Oral erythromycin, 500 mg qid Ophthalmology consultation |
| Other bacterial conjunctivitis | Gram stain <i>plus</i> Growth on blood agar or chocolate agar | Gram positive: erythromycin ointment qid, or fluoroquinolone qid, for 2 wk Gram negative: gentamicin, tobramycin, or fluoroquinolone, qid for 2 wk |
| Chlamydial conjunctivitis | Giemsa stain—basophilic intracytoplasmic inclusion bodies <i>plus</i> Chlamydial culture | Tetracycline, 500 mg qid for 3-4 wk Erythromycin, 250-500 mg for 3 wk Doxycycline, 100 mg bid for 2 wk Azithromycin, 1 g (one dose) |

IM, Intramuscularly; *bid*, twice daily; *qid*, four times daily.

A recommended regimen for ophthalmia neonatorum prophylaxis is a single application of silver nitrate 1% aqueous solution, erythromycin 0.5% ophthalmic ointment, or tetracycline 1% ophthalmic ointment (CDC, 2002b).

Chlamydial Infection

Chlamydial infections are a leading cause of ophthalmia neonatorum. There is a high incidence of this type of infection because of the frequent exposure to the newborn during delivery and the lack of effective prophylaxis. The onset of infection can occur at any time. The typical picture is a mild unilateral or bilateral mucopurulent conjunctivitis with moderate

lid edema, chemosis, and conjunctival injection. Systemic involvement may include rhinitis, vaginitis, and otitis media.

Treatment is with tetracycline ointment or erythromycin four times daily for 4 weeks. In addition, both parents should be treated with oral tetracycline or azithromycin. Alternative treatments include oral erythromycin or doxycycline for 3 weeks. Systemic tetracycline should be avoided in breastfeeding women with this infection.

Conjunctival cultures are indicated in all cases of suspected infectious neonatal conjunctivitis (CDC, 2002).

Bacterial Conjunctivitis

The most common gram-positive bacteria that are causative agents of conjunctivitis include *Staphylococcus aureus*, *Streptococcus pneumoniae*, and group A and B streptococci (Fig. 41-3). Gram-negative organisms include *Haemophilus influenzae*, *Escherichia coli*, and *Pseudomonas aeruginosa*. Bacterial conjunctivitis can occur at any age from the first day of life. Chemosis (edema of bulbar conjunctiva), purulent discharge, lid edema, and injection are common signs. Associated systemic septicemia can occur, especially with *Pseudomonas* infection. Cultures should be prepared on blood and chocolate agar.

A topical fluoroquinolone often provides effective treatment for severe cases before culture results (Leibowitz, 1991). Gram-negative organisms are best treated with tobramycin or a topical fluoroquinolone. Systemic antibiotics are recommended when there is evidence of systemic disease. Physicians should use caution with gentamicin, neomycin, and sulfacetamide eye medications, because these drugs may cause a toxic chemical conjunctivitis and complicate management. Patients with mild conjunctivitis generally respond to erythromycin or bacitracin ointment.

Acute Dacryocystitis

Neonates may present with acute dacryocystitis, an inflammation of the lacrimal sac (Fig. 41-4). Pain, tearing, redness, and discharge usually occur. If the child is febrile, culture testing and Gram staining should be done. *S. pneumoniae* and *S. aureus* are the most common pathogens. Systemic antibiotics are indicated for the acute stage. The ophthalmologist should be consulted immediately, because irrigation and probing may be necessary to establish drainage as quickly as possible. Severe cases may progress to a dacryocystocele, sepsis, meningitis, or even death, especially in young infants.

Figure 41-3 Purulent conjunctivitis may indicate infection with *Staphylococcus*, *Haemophilus influenzae*, *Streptococcus*, or *Pseudomonas*. (From American Academy of Ophthalmology. *The Red Eye*. San Francisco, AAO Professional Information Committee, 1986 [AAO. *The Red Eye*].)

Figure 41-4 Acute dacryocystitis in a neonate with fever and malaise. Lacrimal sac massage and systemic antibiotics relieved the acute infection.

Chronic Dacryocystitis and Nasolacrimal Duct Obstruction

Infants with chronic dacryocystitis usually present to the physician with a chronic history of tearing and crusting with a chronic yellow discharge. Topical antibiotics, such as a fluoroquinolone four times daily, should be used. The mother should be taught to compress or massage the lacrimal sac four to six times daily. Approximately 80% of these inflammations resolve spontaneously by age 6 to 12 months. If treatment is not successful or if dacryocystitis persists, the patient should be referred and the nasolacrimal duct system irrigated between 6 and 10 months of age. Before age 14 months, a single probing is curative in about 90% of cases.

Congenital Glaucoma

Congenital glaucoma is a potentially blinding condition with an incidence of 1 per 10,000 births. It is often confused with chronic dacryocystitis. About two thirds of these cases are bilateral. These patients, similar to those with dacryocystitis, present with excessive tearing. The infants usually are light sensitive (photophobic) and frequently bury their head in a pillow or blanket. These infants often have intense

Figure 41-5 Congenital glaucoma in a 2-month-old infant who presented with a cloudy cornea involving the right eye. Intraocular pressure was elevated. The diagnosis was congenital glaucoma.

blinking or lid spasm (blepharospasm). An enlarged cornea or corneal clouding can be detected clinically and measured with a plastic ruler (normal, ≤ 12 mm) (Fig. 41-5). Corneal edema is the result of elevated IOP, which causes breaks in the inner corneal layers (Descemet's membrane) and intrusion of anterior chamber fluid into the corneal stroma. Increased IOP causes significant optic nerve damage, which can lead to blindness. Whenever glaucoma is suspected, immediate consultation is indicated. Surgical treatment of congenital glaucoma is successful in approximately 90% of cases. These patients must be followed by an ophthalmologist for life as a precaution against recurrent IOP elevation and amblyopia.

KEY TREATMENT

Newborns should be prophylactically treated with erythromycin 0.5% or tetracycline 1% ophthalmic ointment to reduce the risk of ophthalmia neonatorum (CDC, 2002) (SOR: A).

Ciprofloxacin 0.3% ophthalmic solution is effective empiric treatment of bacterial conjunctivitis (Leibowitz, 1991) (SOR: A).

A broad-spectrum antibiotic for 5 to 7 days is generally effective for most cases of bacterial conjunctivitis (American Academy of Ophthalmology [AAO], 2008) (SOR: A).

Children with nasolacrimal duct obstruction may undergo nasolacrimal duct surgery between 6 and 12 months of age, or sooner if clinically indicated (Katowitz et al., 1987) (SOR: C).

Children with congenital glaucoma should be promptly referred to a pediatric ophthalmologist or glaucoma specialist (AAO, 2008) (SOR: A).

Red Eye in Adults and Older Children

Key Points

- Red eye in adults and older children requires careful evaluation to differentiate the various causes of inflammation.
- Purulent conjunctival discharge warrants culturing and broad-spectrum antibiotics.
- Allergic conjunctivitis generally responds well to topical treatment; symptoms may manifest or worsen on initiation of systemic antihistamines.

Figure 41-6 Seborrheic blepharitis is characterized by greasy, dandruff-like scales on the lashes. (From AAO. *The Red Eye*.)

Figure 41-7 Acute hordeolum, or stye. The swollen, tender, red eyelid includes an acute, boil-like lesion. Treatment includes warm compresses and topical antibiotics. (From AAO. *The Red Eye*.)

- Orbital cellulitis requires prompt computed tomography and systemic antibiotics. Cultures should be obtained from the nasopharynx, conjunctiva, and blood.
- Iritis is characterized by pain, photophobia, miosis, and circumciliary injection and generally occurs after blunt trauma.
- A red eye in a contact lens wearer requires prompt evaluation for a corneal ulcer.
- Acute angle-closure glaucoma is an ocular emergency and requires immediate treatment by an ophthalmologist.

Blepharitis

Blepharitis is a chronic lid inflammation that involves abnormalities of the glands surrounding the eyelashes. The two most common types are chronic staphylococcal infections of the lid and seborrheic blepharitis (Fig. 41-6). *Staphylococcal blepharitis* is the most common inflammation of the external eye. It is frequently asymptomatic initially, but as the disease progresses, the patient complains of foreign body sensation, matting of the lashes, and burning. Lid crusting, discharge, redness, and loss of lashes are observed. *Seborrheic blepharitis* is associated with seborrhea of the scalp, lashes, eyebrows, and ears, characterized by greasy, dandruff-like scales on the lashes. Blepharitis is not associated with skin ulcerations.

Figure 41-8 Chalazion of right upper eyelid in 10-year-old girl. (From AAO. *The Red Eye*.)

Treatment of both these conditions is long and laborious. Lid hygiene is recommended for both conditions. Topical antibiotics are prescribed for staphylococcal blepharitis. Both conditions are recurrent and require repeated therapy.

Stye

A stye is the most common localized infection of one of the glands of the eyelid margin (Fig. 41-7). It is an acute boil-like lesion, and the patient usually has a swollen, tender, red eyelid. There may be a moderate amount of conjunctival injection. Treatment includes warm compresses for 15 minutes four times per day and topical antibiotics. Systemic antibiotics are usually not indicated unless there is a preseptal cellulitis component. Generally, the stye drains spontaneously within several days. If resolution does not occur within 2 weeks, the patient should be referred.

Chalazion

A chalazion is a chronic swelling of the eyelids not associated with conjunctivitis (Fig. 41-8). The chalazion, a granulomatous inflammatory reaction, may persist for weeks or even months. Chalazia are generally not amenable to oral or topical antibiotics, unless the lesion is secondarily infected. Chalazia are usually rubbery, cystic, and nontender on palpation. When the upper lid is involved, vision may be temporarily blurred. If the chalazion persists for more than 4 to 6 weeks, it may require incision and curettage. Recurrent chalazia may be caused by an underlying sebaceous carcinoma, so the lesion should be biopsied and sent for pathologic testing.

Bacterial Conjunctivitis

All common bacteria may cause acute conjunctivitis. Presently, *S. pneumoniae*, *H. influenzae*, *S. aureus*, and *P. aeruginosa* are the most common pathogens. The most frequent

causes of hyperacute conjunctivitis are *N. gonorrhoeae* and *N. meningitidis*. Risk factors for bacterial conjunctivitis include contact lens wear, exposure to infectious persons, compromised immune systems, nasolacrimal duct obstruction, and sinusitis. In the presence of a severe purulent discharge, culture of the conjunctiva is mandatory (see Fig. 41-3). Subconjunctival hemorrhage may occur with bacterial conjunctivitis and is especially common with *H. influenzae* conjunctivitis.

Treatment of conjunctivitis is with a topical antibiotic, such as erythromycin or bacitracin. Tobramycin ophthalmic ointment may be used for many gram-positive and gram-negative conjunctivitis cases. Ciprofloxacin and ofloxacin also provide effective broad coverage of most types of conjunctivitis. Gonococcal and *Haemophilus* conjunctivitis require systemic and topical therapy. If the conjunctivitis does not improve within 2 to 3 days or the worsening symptoms develop, the patient should be referred to an ophthalmologist.

Ciprofloxacin and ofloxacin provide effective broad coverage of most causative organisms. Newer fluoroquinolones such as gatifloxacin and moxifloxacin provide more potent coverage and better penetration for gram-positive organisms than earlier types of fluoroquinolones. Topical steroids or antibiotic-steroid combinations for conjunctivitis or other causes of red eye should not be used unless the patient is under the care of an ophthalmologist.

Topical corticosteroids have four potentially serious ocular side effects and are contraindicated for conjunctivitis, as follows:

1. Steroids can facilitate penetration of an undetected corneal herpetic infection to the deeper corneal layers and cause corneal perforation.
2. Prolonged local use of the corticosteroids (usually >2 weeks) can cause chronic open-angle glaucoma.
3. Prolonged use of topical corticosteroids can cause cataracts.
4. Topical corticosteroids are capable of potentiating the development of fungal corneal ulcers.

In general, topical steroids should be reserved for patients under the care of an ophthalmologist.

KEY TREATMENT

Cultures of the conjunctiva are indicated in all cases of suspected infectious neonatal conjunctivitis (AAO, 2003) (SOR: A).

Viral Conjunctivitis

Viral conjunctivitis, in contrast to bacterial conjunctivitis, has a less prominent discharge that is usually watery. The condition is highly contagious, and handwashing is important to avoid infection. When infected, hospital personnel, daycare workers, and institutional personnel should avoid contact with others. Palpable preauricular lymph nodes frequently are present with viral conjunctivitis and represent an important sign that can differentiate it from bacterial conjunctivitis. An associated upper respiratory infection may occur. In advanced cases, true photophobia and blurred vision caused by corneal involvement may be present and require consultation. However, most viral conjunctivitis is self-limiting, and no specific treatment is indicated. Topical

steroids are contraindicated. Most viral infections resolve within 10 to 14 days, and specific serologic diagnosis is not necessary. If the conjunctivitis persists or there is any pain or change in vision, the patient should be referred.

Allergic Conjunctivitis

Allergic conjunctivitis is frequently found in pediatric patients and adults. It is usually seasonal, most often the spring and fall. Although often associated with allergic rhinitis, allergic conjunctivitis may occur without systemic symptoms. There is an increase in itching, redness, and swelling, which is variable from day to day. Seasonal allergic conjunctivitis is related to tree and grass pollens, each of which has a distinct season and severity. The condition may be asymmetric. Chronic allergic conjunctivitis is most often related to various indoor allergens, including dust mites, animal dander, molds, and cockroaches. Cats are especially irritating to the eye for the allergic patient.

Treatment for allergic conjunctivitis involves avoidance procedures for outdoor allergens, keeping windows closed at night during allergy season, and eye protection (even sunglasses can reduce exposure to allergens). Washing the face after coming indoors, washing the hair when showering, and keeping the patient's hands away from the eyes can reduce allergen exposure. Bed linens should be washed weekly. Occasionally, allergy testing and allergy shots may be necessary in severe recalcitrant cases.

Symptomatic treatment of allergic conjunctivitis includes cool compresses, artificial tears, and over-the-counter (OTC) antihistamines. Topical antihistamine-decongestant combinations include naphazoline hydrochloride/antazoline phosphate (Vasocon-A) and naphazoline hydrochloride/pheniramine maleate (Naphcon-A), which are reasonably safe and effective. However, rebound vasodilation can occur and cause chronic hyperemia and conjunctival injection.

Cromolyn sodium 4% and olopatadine hydrochloride (Patanol) are effective mast cell stabilizers. Ketorolac tromethamine (Acular), azelastine hydrochloride (Optivar), and lodoxamide tromethamine (Alomide) are also reasonable options for managing allergic conjunctivitis. Systemic allergy medications may cause allergic conjunctivitis to manifest because of reduced tear film production.

Subconjunctival Hemorrhage

A patient may present with a bright-red eye, normal vision, and no pain. Usually, no obvious cause exists, but in some patients there is a history of coughing, sneezing, or straining before the hemorrhage is present. The patient should be reassured that it is nothing more than hemorrhage of the conjunctiva. There is no therapy, except reassurance that the blood will clear within 2 to 3 weeks. Hematologic blood coagulation studies are usually of limited value in patients with subconjunctival hemorrhages unless there is a history of recurrence. Additionally, it is unusual for a hemorrhage to involve the relatively avascular sclera. If trauma is suspected, the patient should be referred to an ophthalmologist to rule out more serious injuries, such as perforation, contusion, or occult rupture of the globe. Subconjunctival hemorrhage may indicate that the patient is a battered child or adult, and other signs of bodily trauma should be investigated.

Corneal Herpetic Infections

Herpetic infections of the eye can produce conjunctivitis, corneal inflammation (keratitis), and uveitis (inflamed iris, ciliary body, and choroid). The herpes simplex virus (HSV) is the most common cause of corneal opacification in temperate-zone countries. The human is the only natural host for this DNA virus. Approximately 90% of the population has systemic antibodies to HSV. The incubation period of HSV infection is 2 to 12 days. HSV type 1 (HSV-1) is the most common cause of ocular infection, but transmission of HSV-2 also can occur. Although classically HSV-1 is the oral type and HSV-2 is the genital type, current epidemiologic studies indicate that either type may be the source of corneal infection, and therefore cultures and viral titers are often sent for both types.

Primary Herpes Simplex Infection

Primary ocular infection in a nonimmune subject usually presents as conjunctivitis with a clear watery discharge, skin vesicles on the lids, and preauricular nodes. Associated vesicles and ulcers on the oral mucosa and skin are common. Corneal involvement also may occur with single or multiple dendrites. If dendrites are present, the patient should be referred for treatment. Particular attention should be given to inspecting the nose for possible lesions. A lesion at the tip of the nose indicates involvement of the cornea through the nasociliary branch of cranial nerve V. Treatment generally involves trifluridine 1% (Viroptic) drops five times daily for 10 to 14 days. If other regions are involved, oral acyclovir is added to trifluridine, as in eyelid or corneal involvement. These patients should be managed by an ophthalmologist.

Recurrent Corneal Herpetic Infections

At the time of the primary herpetic infection, the virus gains access to the CNS, where it resides in a latent state in the trigeminal and other ganglia. Recurrent attacks occur when the latent state is reversed. The virus travels via the sensory nerves to target tissues, one of which is the eye. Recurrent corneal involvement also includes the development of single or multiple dendritic ulcers. After a brief period, the plaque of epithelial cells desquamates to form a linear branching ulcer (dendrite). When a corneal dendrite is detected by corneal staining with fluorescein, the patient should be referred.

Preseptal Cellulitis

Preseptal cellulitis involves the eyelid and periorbital soft tissues and is characterized by acute eyelid erythema and edema. The infection usually occurs in the setting of an upper respiratory tract infection, external ocular infection, or trauma to the eyelids. Patients may have a mild fever and tend to complain of epiphora, conjunctivitis, and localized tenderness. However, the signs of orbital cellulitis are generally absent, unless a preseptal cellulitis evolves into an orbital cellulitis. Treatment is initiated empirically in most cases with cefuroxime, ceftriaxone, or nafcillin.

Orbital Cellulitis

Orbital cellulitis, most frequently caused by an extension of infection from the ethmoid sinus, can occur in adults and children (Fig. 41-9). It is the most common cause of

Figure 41-9 Orbital cellulitis in 3-year-old patient. (From AAO. *The Red Eye*.)

exophthalmos in children. It may be difficult to differentiate a periorbital or anterior lid cellulitis from a true posterior orbital cellulitis. With a true orbital cellulitis, the child or adult has pain on movement of the eye, conjunctival edema, and limited extraocular movements. The most common causative organisms are *S. aureus*, *Streptococcus*, and *H. influenzae*. Cultures should be obtained from the nasopharynx, conjunctiva, and blood.

Immediate hospitalization and ophthalmic consultation are necessary. Emergent computed tomography (CT) should be performed to rule out orbital cellulitis. If orbital cellulitis is diagnosed, immediate hospitalization with intravenous (IV) antibiotics and ophthalmologic consultation should be undertaken. Appropriate systemic antibiotic treatment depends on the causative organism. Cavernous sinus thrombosis, meningitis, and blindness are serious complications of orbital cellulitis.

Iritis

Iritis is an inflammatory process of the anterior chamber, often associated with blunt trauma or infection. Redness, pain, and photophobia occur with iritis. No discharge is seen, and the pupil is constricted. Circumcorneal (ciliary) injection may occur. IOP is normal or low. Initial treatment may include dilation with homatropine and loteprednol etabonate (Lotemax) for patient comfort, with immediate referral to an ophthalmologist. Consultation should be obtained for all such patients as soon as possible.

Corneal Ulcers

The most common causes of corneal ulcers include gram-positive organisms, such as staphylococci and streptococci; and gram-negative organisms, such as *Pseudomonas aeruginosa* and Enterobacteriaceae. Less common gram-negative

organisms include *Bacteroides*. Risk factors for corneal ulcers include patients with corneal erosions, persistent epithelial defects, impaired immunologic mechanisms, contact lenses, chronic topical or systemic steroid use, diabetes, and alcoholism. Corneal ulcers require consultation with an ophthalmologist for appropriate culture and antibiotic therapy.

Angle-Closure Glaucoma

Acute elevations in IOP can occur when the outflow of aqueous humor is suddenly blocked. The condition is more common in Asians but may occur in any patient. An acute angle-closure attack may follow an episode of emotional or physical stress, dilation of the pupil in dim lighting, or rarely, after instillation of dilating eyedrops. A patient having an acute attack usually has severe ocular pain, redness, blurred vision, rainbow-colored halos around lights, and sometimes nausea and vomiting. On examination, the eye is usually red, pupil mid-dilated and poorly reactive, and IOP greatly elevated. Generally, only one eye is affected at a time. Corneal clouding or corneal edema may be present in advanced cases.

An acute episode of angle-closure glaucoma is an ocular emergency and requires immediate treatment to lower IOP by medical treatment. Once IOP is under control, yttrium-argon-garnet (YAG) or argon laser peripheral iridectomy is performed.

Ocular Trauma and Other Emergencies

Key Points

- Chemical burns require immediate evaluation and treatment to stabilize the ocular surface.
- Central retinal artery occlusion requires immediate intervention to return oxygenation to the retina. Patients should be thoroughly evaluated to determine the source of the retinal artery occlusion.
- Hyphema should be carefully managed with bed rest, shielding the injured eye, and appropriate pharmacologic or surgical treatment to minimize potential complications. Patients with hyphema and angle recession require lifelong evaluation for possible glaucoma.
- Ocular foreign bodies of the surface can be conservatively managed with removal of the foreign material and appropriate antibiotic ointment. Care should always be taken to rule out an occult ruptured globe.
- The early signs of a retinal detachment include an increase in floaters or flashing lights. Retinal detachments warrant careful evaluation and prompt intervention.

Emergencies

True emergencies can be classified as those for which therapy should be instituted within minutes. Two true emergencies in the eye are chemical burns of the cornea and central retinal artery occlusion.

Chemical Burns

Most acids produce the extent of their damage immediately on contact—the more concentrated the acid, the more severe the immediate effect. Alkali burns are more devastating to

the eye because they continue to cause damage long after the initial chemical contact. Corneal melting can lead to perforation, and severe chronic glaucoma can occur as a later complication. Burns of the eye by acids or alkalis are true ocular emergencies. An alkaline substance, such as lye, can cause permanent and irreversible blindness.

The immediate treatment of chemical burns must be continual irrigation of the eyes, with up to 1000 mL of normal saline (NS) or lactated Ringer's (LR) solution. If these solutions are not available, water from a shower, spigot, bathtub, or drinking fountain is appropriate. The conjunctival pH should be assessed after irrigation and again 30 minutes later to confirm stabilization of the ocular surface; pH value should be 7.5 to 8. If the pH remains abnormal, irrigation should be repeated until the pH is normal. Patients are managed with aggressive antibiotic ointment therapy and lubrication following a chemical burn. After the initial ocular irrigation, ophthalmologic consultation must be immediate.

KEY TREATMENT

Chemical burns of the ocular surface should be washed with at least 1 liter of fluid and tested until the pH returns to normal. An ophthalmologist should evaluate the affected eye within 24 hours after treatment (AAO, 2007) (SOR: C).

Central Retinal Artery Occlusion

With an incidence of about 1 in 10,000 people, central retinal artery occlusion is generally not the result of trauma. Risk factors include atrial fibrillation, mitral valve disease, atherosclerosis, a hypercoagulable state, and hypertension. Additionally, prolonged intraorbital swelling can cause occlusion of the central retinal artery. Such situations occur particularly in patients who are having surgery in the face-down position. The characteristic fundus appearance with central retinal artery occlusion is narrow arterioles and a pale optic disc. In addition, there is diffuse retinal whitening. A cherry-red spot occurs only several hours after the initial retinal artery occlusion (Fig. 41-10).

Treatment of central retinal artery occlusion must be immediate, including breathing into a small paper bag to help increase the patient's carbon dioxide level. Emergency paracentesis is a rapid method to decompress the eye and may actually provide immediate restoration of vision. However, most physicians are reluctant to perform paracentesis on a patient within a few minutes. Ocular massage is another means of decompressing the eye. Some centers have hyperbaric oxygen available, which may also be helpful in restoring retinal perfusion for some patients. Treatment should be instituted within 90 minutes if any realistic hope of possible visual recovery can be expected. Patients with central retinal artery occlusion should be thoroughly evaluated for cardiac and carotid disease.

Urgent Situations

Urgent situations include those for which therapy should be instituted within minutes or a few hours. They include penetrating injuries of the globe, acute angle-closure glaucoma,

Figure 41-10 Central retinal artery occlusion of left eye with Hollenhorst plaque in right eye. Patient has a characteristic cherry-red spot involving the macula of left eye (*left*). Hollenhorst plaque with a retinal arcade in right eye suggests bilateral carotid disease and cardiovascular disease (*right*).

papillary block, orbital cellulitis, corneal ulcer, corneal foreign body, gonococcal conjunctivitis, ophthalmia neonatorum, and acute iritis. In addition, trauma with retinal tears, vitreous hemorrhage, retinal detachment, and hyphemas constitute urgent situations.

Ocular Foreign Body and Other Eye Injuries

The most common eye injury encountered in family practice is a foreign body in the eye. The most common causes of a foreign body in the conjunctival sac or one embedded in the cornea are particles blown in by the wind, occupational or work-related injuries, and metallic foreign bodies that may fly into the eye, such as after a person hits a metal object with a hammer. It is important to evaluate the location of the foreign body and, in the case of corneal foreign bodies, the depth of penetration. Symptoms may be helpful; superficial foreign bodies in the cornea generally present with the complaint of a dust particle in the eye. Foreign bodies that have penetrated deeper into the corneal stroma produce a dull, aching pain perceived in or behind the eye.

On examination, it is important to look carefully at the inflammatory response of the eye. A purely localized conjunctival inflammation pattern is generally associated with superficial foreign bodies. Ciliary injection is a warning sign that a deep penetration may have taken place, and an ophthalmologic consultation should be sought immediately. Examine the eye after the instillation of ophthalmic local anesthetic to avoid blepharospasm and evasive eye movements. Inspect the cornea with a penlight or ophthalmoscope in a darkened room. Use of the slit on the ophthalmoscope can help visualize irregularities in the corneal surface. Staining with fluorescein demonstrates abrasions and helps identify otherwise transparent foreign bodies.

The family physician may elect to remove a foreign body in the conjunctival sac by irrigation with a sterile solution or after eversion of the upper lid with a moistened cotton swab. In the case of superficial corneal foreign bodies, a physician may attempt to remove it with a moist sterile swab, but embedded foreign bodies should be referred to an ophthalmologist.

Corneal Abrasions

Corneal abrasions are often caused by foreign bodies underneath the upper lid or inadvertent injury from a finger or small object. Evert the lid and examine for conjunctival foreign bodies. To evert the lid, the patient is seated and asked to look downward. The upper lid is grasped by its central lashes and pulled downward and slightly outward. The examiner then depresses the upper lid with a cotton applicator proximal to the upper tarsus margin. Gentle pressure is maintained until the upper lid is flipped into the everted position. Frequently, the foreign body is observed and can be removed with a cotton applicator or forceps. Corneal abrasions generally can be treated with an antibiotic ointment. Small abrasions often do not require patching. Large corneal abrasions may require pressure patching or bandage contact lens.

If the conjunctival or corneal foreign body is not easily removed with a cotton applicator, the family physician should obtain ophthalmologic consultation. If the abrasion is not healed within 24 hours, an ophthalmic consultation should be obtained. Corneal abrasions should also be carefully inspected for other ocular injury. Any irregularity of the pupil in the presence of a corneal abrasion could signify an underlying occult penetrating injury. In such cases, the patient should be immediately directed to an ophthalmologist for further evaluation.

Contact Lens Overwear

Patients suffering from contact lens overwear syndrome have worn their lenses longer than usual and typically awaken during the early-morning hours with severe pain and tearing. In response to prolonged wear, the cornea becomes swollen and develops epithelial defects. Patients need reassurance that the condition is usually not serious, even though the pain is severe. However, occasional contact lens-induced corneal abrasions, especially those associated with soft lenses, can rapidly progress to severe corneal infection. Patients should be seen the next day and referred if they have not improved. Contact lens wear may be resumed only after the corneal epithelium is well healed.

Metallic Foreign Bodies

Metallic foreign bodies, if allowed to stay in the eye for a number of hours, frequently leave a “rust ring” that is clearly visible after removal of the foreign body. Rust rings irritate the cornea and result in long-lasting inflammatory changes in the eye. Follow-up should be daily, with staining of the cornea to demonstrate the expected rapid healing. If healing does not take place over 24 to 48 hours, suspect an infection in the corneal stroma and obtain consultation. Topical antibiotic ointments are used after removal of foreign bodies in an attempt to prevent this complication.

Corneal and Scleral Lacerations

Corneal and scleral lacerations fall within the realm of the ophthalmologist and should be referred immediately after a shield is placed over the eye. Frequently, signs of corneal and scleral lacerations include unequal pupils, decreased IOP, iris prolapse, and hyphema, and a corneal laceration often also involves the lens. It is important to consider posterior injuries to the globe, including retinal detachment, retinal tear, and vitreous hemorrhage (Fig. 41-11). Patients can often be managed as outpatients with oral antibiotics. Intravitreal antibiotics may be given at ruptured-globe repair. Some patients are hospitalized for IV antibiotics, although current intravitreal penetration of many antibiotics is often comparable. Corneoscleral lacerations should be principally repaired at the presenting institution when possible with available ophthalmology services. Hospital transfers delay wound closure or risk wound extension or prolapse of intraocular contents.

Blunt Eye Injuries

Blunt eye injuries are common and may result from relatively trivial injuries or high-velocity impact projectiles. An exact history of the trauma must be obtained to assess the velocity involved, which in turn may indicate the extent of ocular damage. Inquiry must be made to determine whether visual acuity changes occurred immediately after the injury. Flashing lights are often seen at the instant of injury and indicate irritation of the retina, because any message to the brain from the retina is perceived as light. Persistent blurred vision is indicative of a more serious injury. It may indicate blood in the anterior chamber that is suspended in the aqueous humor. Free-floating blood in the anterior chamber is generally not appreciated by direct ophthalmoscopy. A slit-lamp examination is necessary to observe the suspended red blood cells in the anterior chamber.

Black Eye (Eyelid Contusion)

A black eye may be serious or relatively minor. If accompanied by severe pain, bleeding, or constant blurred vision, more serious eye trauma must be considered. In such patients, orbital CT scan and ophthalmologic consultation may be necessary to rule out a ruptured globe.

Red Eye

Almost all ocular trauma cases include bleeding or dilation of blood vessels on the surface of the eye (subconjunctival hemorrhage). This may be observed with any degree of eye

Figure 41-11 Corneal leukoma in 6-year-old boy. Diagnosis was ocular trauma and penetrating corneal laceration.

injury. For example, a subconjunctival hemorrhage may be spontaneous and often indicates minor injury. In the presence of other findings, a subconjunctival hemorrhage suggests more serious injury, particularly if a concomitant hyphema or vitreous hemorrhage is present.

Pupillary Change

Blunt trauma to the eye may result in lacerations of the sphincter muscle of the pupil. These are manifested by traumatic mydriasis. Unlike the unequal pupils seen with congenital anisocoria, traumatic mydriasis is characterized by recent onset of unequal pupils and by the irregularity of the dilated pupil. Although traumatic mydriasis by itself is not harmful, it suggests severe blunt trauma and is an indication for a careful assessment of other ocular structures, including the vitreous and retinal periphery.

Traumatic Hyphema

Blunt trauma to the eye may cause injury to the iris, angle structures, and other intraocular structures. Hemorrhage into the anterior chamber, or *hyphema*, is most often found in children. The agent producing the hyphema is usually a projectile that strikes the exposed portion of the eye. A great variety of missiles and objects may be responsible, including balls, rocks, projectile toys, air gun, paint balls, bungee cords, and the human fist. With the increase of child abuse, fists and belts have started to play a prominent role. Boys are involved in 75% of cases.

Rarely, spontaneous hyphemas occur and may be confused with traumatic hyphemas. *Spontaneous* hyphemas are secondary to neovascularization, ocular neoplasms (retinoblastoma), and vascular anomalies (juvenile xanthogranuloma). Vascular tufts that exist at the pupillary border have been implicated in spontaneous hyphema. A *traumatic* hyphema may be graded by measuring the height of the layered hyphema in the anterior chamber in millimeters. A hyphema is an ocular emergency and should be referred immediately.

Cataract, choroidal rupture, vitreous hemorrhage, angle recession glaucoma, and retinal detachment are often associated with traumatic hyphema and compromise the final visual acuity prognosis. It is important to recognize that the prognosis for visual recovery from traumatic hyphema is directly related to three factors: (1) amount of associated damage to other ocular structures (e.g., choroidal rupture or macular scarring), (2) presence or absence of secondary hemorrhage, and (3) presence or absence of complications

of glaucoma, corneal blood staining, or optic atrophy. With treatment, most hyphema patients have a good visual outcome. (See the discussion of hyphema grading and complications, as well as treatment and prognosis, online at www.expertconsult.com.)

KEY TREATMENT

Hyphemas are generally well managed with bed rest, shielding of the injured eye, and medical control of the hyphema and intraocular pressure (Crouch et al., 2009) (SOR: A).
If IOP remains elevated or hyphema occupies more than 50% of the anterior chamber, surgical evacuation of the clot may be required to lower IOP, preserve corneal clarity, and reduce optic atrophy (Sheppard et al., 2009) (SOR: A).

Nonaccidental Inflicted Neurotrauma (Formerly “Shaken Baby Syndrome”)

The true incidence of nonaccidental inflicted neurotrauma is unknown because of the difficulty collecting statistical data. An estimated 1300 children in the United States experience fatal head trauma from child abuse annually (JAMA, 2003). The findings of nonaccidental inflicted neurotrauma involve repetitive, violent, unrestrained, acceleration-deceleration, head and neck movements. Neurotrauma can occur without blunt head trauma. Cases primarily occur in children under 3 years old, usually during the first year of life. Typically, patients present with fracture and intracranial or intraocular hemorrhages; not all findings are required to establish the diagnosis. An ophthalmologic consult should be obtained for all patients with suspected nonaccidental inflicted neurotrauma, with carefully documented retinal drawings or preferably fundus photography. Approximately 20% of cases are fatal within the first few days of presentation. Traumatic *retinoschisis*, if present, is highly specific for nonaccidental inflicted neurotrauma, particularly if the child is younger than 5 years.

Retinal Detachment

An increase in previous floaters or the onset of new floaters may occur in a retinal detachment. Traumatic detachment of the retina can be observed after blunt eye injury, especially in older adults. Retinal detachment may also occur spontaneously, especially in patients with high myopia. The patient may complain of reduced overall brightness in the involved eye or may have continuous light flashes, indicating retinal traction. After eye trauma, it is imperative to inspect not only the central portions of the retina, but the peripheral portions as well. This examination should be performed in a darkened room after instillation of a short-acting mydriatic agent. Any questionable findings should be referred to an ophthalmologist immediately.

Other serious injuries are traumatic tears of the iris, subluxation or dislocation of the lens that occasionally displaces into the anterior chamber, and blowout fracture of the orbit, with impaired upward eye movement caused by entrapment of the inferior rectus muscle. These injuries are usually readily identified.

Pediatric Ophthalmology

Key Points

- Children should be screened at birth, birth to 3 months, 3 to 6 months, 6 to 12 months, 3 years, 5 years, and then every 1 to 2 years.
- Amblyopia and strabismus are distinct but may be associated. Children can have amblyopia without having strabismus. All children with amblyopia or strabismus should be referred to a pediatric ophthalmologist.
- Cataracts are an important cause of amblyopia in children and require prompt intervention.
- Pediatric cataracts may be a sign of a metabolic disorder, TORCH infection (*toxoplasmosis*, other agents, rubella, cytomegalovirus, herpes simplex), or chromosomal abnormality.
- Leukocoria warrants further investigation; significant causes include cataracts, *Toxocara canis* infection, retinal disease, and retinoblastoma.

Evaluation of Vision within First 4 Months of Life

Parents may report that their baby does not appear to look at them. This statement requires the physician to document a history of prematurity, fetal distress, anoxia, or birth trauma carefully. A failure to reach developmental milestones may indicate neurologic abnormalities. A history of seizure disorder, cerebral palsy, or chromosomal abnormalities helps identify potentially serious causes. In this case, visual acuity or the child's ability to fixate must be assessed. Normal newborns follow faces. By age 2 or 3 months, infants normally follow light and high-contrast objects. Assessment of vision can be achieved by using an optokinetic nystagmus drum. Oculomotor disturbances may be the underlying cause of the child's apparent visual inattention. Bilateral cranial nerve III palsy, congenital fibrosis syndrome, or partial cranial nerve III palsy may give this impression as well.

Searching or roving eye movements are a form of profound nystagmus, with little foveal perception. Nystagmus is an important sign of decreased vision, indicating visual acuity often in the range of 20/200. The onset is usually at birth or shortly thereafter. The nystagmus can be a jerk or pendular nystagmus. The direction should be characterized as horizontal, vertical, or rotary.

Abnormalities of the anterior portion of the eye can cause profound visual loss and are easily visible with a +10 magnification. They include corneal opacities (leucoma) caused by congenital glaucoma, *Peter's anomaly* (abnormal cornea and lens), and *leukocoria* (white pupil) related to congenital cataracts, inflammatory disease, or retinal disease.

Evaluation of the posterior aspect of the eye, including examination of the red reflexes, may indicate an early retinal detachment or retinoblastoma. Optic nerve abnormalities may be associated with midline CNS defects, such as an absent septum pellucidum, agenesis of the corpus callosum, or hypopituitarism. Optic nerve abnormalities such as optic nerve hypoplasia are associated with nystagmus. CT or magnetic resonance imaging (MRI) can identify these abnormalities. Electroretinography (ERG) may be

helpful for determining the cause of decreased visual acuity. An abnormal ERG is seen with Leber's congenital amaurosis, congenital achromatopsia, and congenital stationary night blindness. Visual-evoked potential testing may be necessary to determine whether vision is intact.

Some infants who have a completely normal eye examination but demonstrate poor fixation may actually have a delay in maturation of the visual system. Normally, the initial visual system development matures by 4 to 6 months of age. Visual-evoked potential acuities are about 20/400 during the first few days of life and improve to about 20/40 by 6 months of age. In some patients, visual-evoked responses and clinically assessed visual function may be abnormal, only to improve between 4 and 12 months of age. Although incompletely defined, in delayed visual maturation the vision is decreased, but the ocular examination appears normal, including brisk pupillary response to light. Typically, there is no nystagmus, and ERG is normal.

Vision Screening and Ocular Examination

Appropriate vision screening is one of the most important factors in pediatric eye care. Because focused visual stimuli are critical to normal development, early detection and correction of visual problems reduce serious vision impairment or blindness. The American Academy of Ophthalmology (AAO), American Academy of Pediatrics (AAP), and American Association of Pediatric Ophthalmology and Strabismus (AAPOS) strongly support the goal of early detection and treatment of eye problems in children. In particular, vision screening is needed to detect four major conditions: strabismus, amblyopia, ocular disease, and refractive errors. Family physicians are ideal vision screeners because of their ability to detect abnormalities at an early age. Essential components of vision screening are age, testing format, testing procedures, efficacy, and referral criteria. On a practical level, vision screening must be cost-effective and time-efficient. The testing devices must be readily available and relatively easy to use. High sensitivity is essential to keep overreferrals and underreferrals to a minimum.

Four Stages of Screening

The AAO and AAPOS recommend that children be examined for eye problems in the following four stages (Table 41-4):

1. In the newborn nursery, physicians should examine all infants. Ophthalmologists should be consulted to examine patients at high risk for conditions such as retinopathy of prematurity (ROP), cataracts, congenital defects, and other ocular pathology.
2. At 6 months
3. At 3 years
4. At 5 years and older

The AAO statement recommends that family physicians establish a close working relationship with a local ophthalmologist who is familiar with children's eye problems. The collaboration can help clarify questions about vision screening and the need for referral. (See online content for specific information on different stages of vision screening.)

Also, special groups may need additional vision screening. The following children should also be screened, even if they are not due to be examined by their age: all children

Table 41-4 Recommended Vision Screening by Family Physicians

| Age | Examination | Referral Criteria |
|----------|---|---|
| Newborn | Penlight examination of cornea Rule out nystagmus Red reflexes | Any ocular pathology Nystagmus Abnormal red reflexes or white reflex |
| 6 months | Fixation to light and small toys Penlight examination Corneal light reflex test, cover test Red reflexes | Object to occlusion Nystagmus; any ocular pathology Strabismus Abnormal red reflexes or white reflex |
| 3 years | Visual acuity: Snellen letters, tumbling E, or HOTV wall chart Corneal light reflex test, cover test Fundus examination | Acuity of 20/40 or less in one or both eyes Strabismus Any ocular pathology |
| ≥5 years | Visual acuity: Snellen letter, tumbling E, or HOTV (see online text) Corneal light reflex test, cover test Fundus examination | Acuity of 20/30 or less in one or both eyes Strabismus Any ocular pathology |

at high risk of having vision disorders, including those who are mentally retarded or who have trisomy 21 or cerebral palsy; and all children who show signs or symptoms of visual problems, experience school failure, or have reading difficulties or other learning problems (e.g., dyslexia). It is important to note that children with learning disabilities such as dyslexia have the same incidence of ocular abnormalities (strabismus, refractive error) as children without such disabilities. Dyslexia involves interpretation by cortical processing centers and does not generally indicate any ocular pathology. Eye defects do not cause letter, number, or word reversal.

Testing Visual Acuity

Several diagnostic tests are used to detect strabismus, amblyopia, ocular disease, and refractive errors. These include visual acuity and fixation preference tests, corneal light reflex test, cover test, simultaneous red reflexes test, fundus examination, stereoscopic tests, and photorefractive techniques.

The best way to screen for possible visual loss caused by amblyopia is to measure the visual acuity or fixation preference of each eye separately. The covered eye should be firmly occluded during the assessment to avoid any peeking. When there is no apparent sign of amblyopia, the only clue to poor vision may be the child's objection to having the better eye occluded. Additionally, the child may demonstrate a fixation preference of the better-seeing eye, with an inability to fixate on distance objects in the amblyopic eye. Both are common signs of amblyopia that may be caused by a refractive error, media opacities, retinal or optic nerve abnormality, or cortical processing problem.

Equipment required for testing children older than 42 months consists of standard wall charts containing Snellen letters, Snellen numbers, tumbling Es, and HOTV monitors, as well as some means of occluding the nontested eye, ideally, occluder patches (Opticlude, Coverlet).

Stereoscopic and Photorefractive Tests

The visual acuity test is the most widely used vision screening test, but use of this test alone will underrefer many patients with amblyopia and undiagnosed strabismus. Stereoscopic tests such as the random dot E stereogram are relatively inexpensive, fairly accurate, and easy to use. Stereopsis tests are complementary and offer additional information regarding a patient's visual health.

The use of photorefractive apparatus is relatively new. Reproducible results of photography of the red reflex can screen the nonverbal infant or child. The sensitivity is high (95%) for refractive error in the range of 1.00 to 2.00 diopters. A problem with this technique is that cycloplegia is usually required to prevent obtaining false-positive results, especially for myopia. In addition, two photographs are needed to avoid missing an astigmatic refractive error. The technology offers great promise, but it must be cost-effective. As newer, more rapid and accurate vision tests are developed, these may be incorporated into the screening process.

Strabismus and Amblyopia

Strabismus and amblyopia are two of the most common visual problems affecting children. Strabismus occurs in 4% and amblyopia in 4% of the population. Half of all amblyopia patients have a concomitant strabismus. Conversely, half of all amblyopia patients will have no demonstrable strabismus.

Movements of the eyes horizontally and vertically are controlled by the six muscles attached to the sclera of each eye. Movement of both eyes in unison allows vision of singular images. Through a blending process called *fusion*, the brain combines the two images into a single, three-dimensional image. As long as the eye muscles are able to work together, the brain can process incoming visual information. When the eye muscles are not coordinated, one eye deviates inward, outward, or upward, and the other eye remains straight. When this occurs, the brain receives a different image from each eye and cannot combine the two disparate images into a single image frame.

Misalignment of the eye muscles results in strabismus. In addition to a breakdown or absence of fusion, the causes of strabismus may include refractive errors, anatomic anomalies, and abnormal tonic innervation. Adults with acquired strabismus frequently develop double vision, but children with strabismus quickly learn to ignore or suppress the image seen by the deviated eye. As a result of suppression, the straight eye takes over most of the work of seeing, and the crossed eye develops reduced central vision because of lack of use. There are various types of strabismus and may be horizontal, vertical, or rotational (cyclotorsional). (See online text for additional information on specific types of strabismus.)

Loss of vision in a relatively normal eye is called *amblyopia*. The phrase "lazy eye" should not be used in diagnosing patients because it can be confused with amblyopia and strabismus. As mentioned earlier, these two distinct clinical entities

Figure 41-12 Amblyopia. This 5-year-old patient also required patching of the better-seeing eye to improve vision in the amblyopic eye.

are associated with each other in only 50% of cases. In children younger than 4 years, amblyopia is the most frequent cause of unilateral vision loss (Fig. 41-12). The condition is usually unilateral, although bilateral high myopia, hyperopia, or astigmatism may occur. Unless treatment begins early, loss of vision in the affected eye may be permanent. Amblyopia is usually treatable if detected at age 3 to 4 years but is generally considered irreversible after 13 years; however, treating amblyopia in patients older than 13 years has had some success. The earlier treatment begins, the better the prognosis for the patient. The primary treatment of amblyopia includes the use of patches, glasses, or both. The better eye is occluded, and underlying conditions such as cataracts or refractive errors are treated.

Testing for Strabismus

The corneal light reflex test, cover test, red reflex, and extraocular rotations are four basic tests for strabismus. To perform the corneal light reflex test, project a penlight onto the cornea of both eyes simultaneously while the child looks straight ahead. Compare the placement of the two corneal reflections. When the eyes are straight, the light appears at the same point on each cornea. If a muscle deviation is present, the reflected light appears slightly off center in one eye. Figure 41-13 illustrates the placement of corneal reflections as they would appear for each direction of deviation. In part A, note that the light is centered on the cornea of the left eye but is displaced laterally, or outward, on the right cornea, indicating that the right eye is turned inward, or is *esotropic*. In B, note that the light is centered again on the left cornea but is displaced medially, or inward, on the right cornea, demonstrating an outward-turning, *exotropia* of the right eye. In part C the light indicates that the right eye is turned upward, or is *hypertropic*, and the left eye is straight.

The cover test is performed by having the child look straight ahead at an object 20 feet away (Fig. 41-14). An eye chart is usually used to test children older than 3 years. For younger children, it is helpful to use a colorful, moving object or toy. As the child looks at the target, cover the child's right eye and look for movement of the uncovered eye. If the left eye moves to pick up fixation, it was deviated before placing the cover over the right eye. Repeat the procedure for the left eye, and watch for any movement in the uncovered right eye. If the eye moves inward to pick up fixation, the eye is exotropic. If the eye moves outward to pick up fixation, the eye is esotropic.

The third test involves simultaneous examination of the pupillary red reflexes. This is a useful test to assess ocular

Figure 41-13 Strabismus of right esotropia (A), right exotropia (B), and right hypertropia (C). (From American Academy of Ophthalmology. *The Child's Eye: Strabismus and Amblyopia*. American Academy of Ophthalmology, Professional Information Committee, San Francisco, 1982 [AAO. *The Child's Eye*].)

alignment and rule out abnormal ocular media, such as cataracts. The test should be performed in a darkened room with the examiner approximately 18 to 24 inches from the patient. Both red reflexes should be simultaneously assessed and compared using the direct ophthalmoscope. If an abnormality exists in the ocular media, the red reflex will be asymmetric or a white reflex may be present. An abnormal reflex may also signify a high refractive error or a small strabismus. The red reflexes should be equal and symmetric. Ophthalmoscopy also permits direct visualization of the fundus and optic disc. The fourth test checks the extraocular movements in the cardinal positions of gaze (Fig. 41-15). The results of these tests provide a good basis for determining whether there is any misalignment present. This is an important screening for all family physicians to learn, because early intervention can help improve the overall visual and binocular status of the patient.

Table 41-5 lists several forms of strabismus. For congenital esotropia, surgery is the primary treatment for this condition and is performed between 6 and 12 months of age (Fig. 41-16). Esotropia may also be related to refractive error and managed with spectacle correction (Figs. 41-17 and 41-18). Large deviations of exotropia and hypertropia are also managed surgically (Figs. 41-19 to 41-23). (See online text for further discussion.)

Pseudostrabismus

A common misconception is that children with cross-eye (esotropia) outgrow the condition, but this is generally not the case. This belief stems from confusion between true strabismus and what is known as pseudostrabismus, or false strabismus.

Figure 41-14 Cover-uncover test. Evaluate the unoccluded eye for strabismus. (From AAO. *The Child's Eye*.)

A child with pseudostrabismus has broad folds of skin that partially cover the top of each eye and a flat nasal bridge that creates the illusion of crossed eyes. As the child ages and the skin fold becomes less apparent, the condition becomes less noticeable. When a child's eyes are truly crossed, it is always a serious condition and requires the care of an ophthalmologist.

Other Causes of Strabismus

Acute strabismus may be brought on by a viral upper respiratory tract infection, which can cause acute cranial nerve VI palsy. With the advent of antibiotics, middle ear infections with associated petrositis and cranial nerve VI palsies are relatively uncommon. Sudden-onset strabismus may also indicate underlying neurologic disease. Another cause is spasm of the near reflex. A hallmark of spasm of convergence is a constricted pupil. Paralytic or mechanical causes of strabismus occur with trauma and Duane's syndrome. In addition, neurologic trauma accounts for paralysis to cranial nerves III, IV, and VI (Fig. 41-24).

The proper corrective treatment for strabismus includes nonsurgical treatment, such as patching and glasses, and surgical treatment, when indicated. Eye muscle surgery is performed when nonsurgical methods cannot correct the misalignment, as well as with worsening misalignment, no effect on the deviation or stereopsis, or progressive loss of fusion. Four aspects of strabismus surgery should also be stressed, as follows:

1. The surgery is safe and effective.
2. The eyeball is never removed from the orbit to perform the surgery.
3. More than one procedure may be required to establish alignment.
4. Both eyes may require surgery to correct the strabismus.

The goals when treating strabismus include the ability to provide and maintain equal vision in both eyes, enable the eye to work together rather than independently, and improve depth perception, whenever possible.

KEY TREATMENT

Surgical and nonsurgical treatment of strabismus is beneficial to appropriate visual development, reduction of amblyopia, and rehabilitation of sensorimotor function or depth perception (AAO, 2007) (SOR: A).

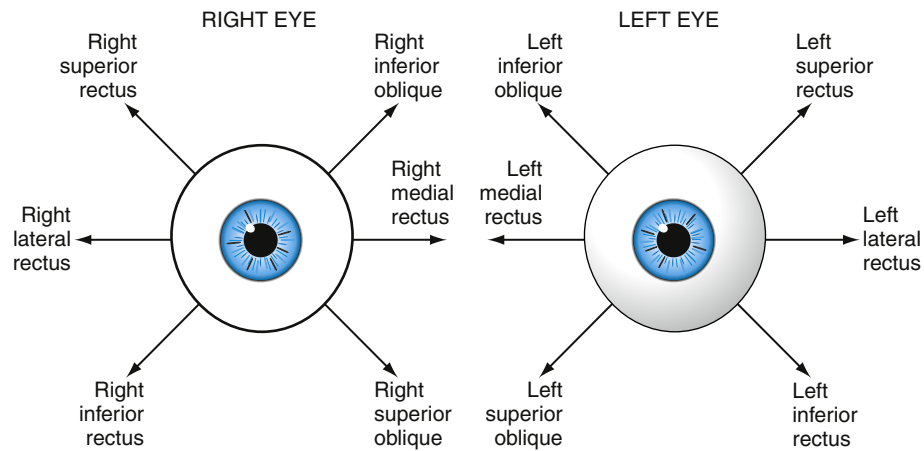

Figure 41-15 Ocular muscle movement in cardinal fields of gaze.

Table 41-5 Classification of Strabismus

| Type | Cases (%) | Age of Onset |
|---------------------------------------|-----------|---|
| Congenital or infantile esotropia | 20 | Birth to 6 mo |
| Accommodative esotropia | 45-50 | 6 mo to 7 yr (usually 2 yr) |
| Nonaccommodative (acquired) esotropia | 10 | Variable, depending on cause |
| Exotropia | 20 | Variable (usually during infancy to 4 yr) |
| Hypertropia | <5 | Variable, depending on cause |

Figure 41-16 Clinical esotropia in 12-month-old infant. With the right eye fixing, there is a left esotropia.

Refractive Errors and Color Vision

Some eyes are either too long or too short and need help focusing light onto the retina. If an eye is too long, the light rays focus in front of the retina and the image is blurred; the person can move things closer to see better or can wear glasses. This condition is called nearsightedness (*myopia*). With farsightedness (*hyperopia*), the light focuses behind the retina because the eye is too short and causes a blurred image. Both conditions are corrected by glasses or contact lenses. *Astigmatism*, another common error in the eye's focusing abilities, is caused by unequal curvature of the front surface of the cornea. Corrective glasses are necessary if it

Figure 41-17 Accommodative esotropia and anisometropic amblyopia in 5-year-old patient who has unequal refractive errors between the two eyes as well as accommodative esotropia.

Figure 41-18 Accommodative esotropia in 3-year-old patient uncorrected (top) and corrected by hyperopic (farsighted) glasses (bottom). (From AAO. *The Child's Eye*.)

causes blurred vision or discomfort. Unless there is a marked amount of myopia (nearsightedness), hyperopia (farsightedness), or astigmatism, or a significant refractive difference between the eyes, eyeglasses can adequately compensate for these problems. Refractive errors requiring eyeglasses affect almost 20% of the pediatric population before full growth is attained.

Figure 41-19 Exotropia in 8-year-old patient with right exotropia.

Figure 41-20 Positive angle kappa, which appears similar to exotropia, in 8-year-old patient. Actually, this patient has retinopathy of prematurity, with bilateral dragged maculas.

Figure 41-21 Patient with diagnosis of Crouzon's syndrome presented with proptosis, amblyopia, and left exotropia.

Color vision defects rarely result in significant visual difficulties. About 8% of white males have some red-green color deficiency, whereas less than 1% of females are affected. In isolation, this defect rarely results in any real drawback to normal function, especially during childhood. Although the identification of such defects can be helpful in a classroom situation, emphasis should not be placed on these minor abnormalities at this age. Color vision testing is not required unless a retinal dystrophy or optic nerve disease is suspected, the family history is positive, or the family specifically requests it.

Figure 41-22 Positive head tilt in 4-year-old child could indicate a vertical deviation, especially superior oblique palsy. (From AAO. *The Child's Eye*.)

Figure 41-23 Ocular torticollis in 34-year-old patient. Note the abnormal head tilt.

Headaches

Headache is one of the most common conditions of humans, and children seem to complain less about headaches than adults. Most headaches are not serious and frequently are caused by tension. Many people believe incorrectly that eye

Figure 41-24 Chief presenting complaint of underaction of the left lateral rectus muscle and left esotropia after upper respiratory infection in 14-month-old patient, who actually had cranial nerve VI palsy related to the viral syndrome.

strain and the need for glasses are common causes of headaches, although this is certainly possible. Headaches caused by eye disease are usually felt in the eye or in the brow on the same side as the involved eye. Frequently, these headaches are associated with some other symptom, such as blurred vision, halos around lights, or extreme sensitivity to light. Most headaches are related to stress.

Learning Disabilities and the Eye

Although reading may be easier and faster when sight is clear, visual problems generally do not cause learning disabilities, and eye defects are not responsible for reversal of letters. In the past, reading problems were blamed on the eyes, although children with a learning disability have no greater incidence of eye problems than the rest of the population. Other issues, such as dyslexia, attention-deficit hyperactivity disorder, social issues, or family problems are often found to be contributing to a child's poor attention in class or learning difficulties.

It is important that a thorough medical eye examination be performed. The presence or absence of visual defects can be diagnosed and corrected. Once vision is corrected, no other examinations or therapies involving the eyes diminish a learning disability. Meta-analysis shows that children with learning disabilities do not benefit from visual training, muscle exercises, perceptual training, or hand-eye coordination exercises (AAO/AAP/AAPOS Policy Statement, 2009). It may be difficult to diagnose a learning disability definitively before a child is 6 to 7 years old. However, once a diagnosis is made, educational assistance is needed promptly.

Pediatric Cataracts

Approximately 40% of acquired pediatric cataracts are secondary to trauma, and as many as approximately one third of pediatric cataracts are inherited. The basic approach to the patient with pediatric cataracts is to determine whether the cataract is an isolated finding, part of a systemic abnormality, or associated with ocular disease. When several members of the same family are affected by congenital cataracts, a hereditary origin may be assumed. Autosomal dominant hereditary patterns are the most frequent mode of transmission.

X-linked cataracts are rare and occur primarily with the oculocerebrorenal syndrome. Congenital or infantile cataracts have been described in association with a large number of congenital anomalies. (See online content for additional information on pediatric cataract differential.)

History and Ocular Examination

In patients with pediatric cataracts, the physician should determine the age when the cataract or decreased vision occurred. A detailed history of maternal intrauterine infections should include rubella, toxoplasmosis, herpes simplex, cytomegalovirus, and varicella. Drug and medication use during pregnancy and birth trauma should be ruled out.

A complete ocular examination should be performed, including visual acuity assessment using fixation and following responses. Infants with complete bilateral congenital cataracts usually demonstrate decreased visual interest and may have delayed development. Nystagmus results from early visual deprivation and is an ominous sign of poor vision. Ocular fixation and following movements may be decreased or absent. In some cases, strabismus is a presenting sign, especially in children with monocular cataracts.

Glaucoma and other ocular disorders must be ruled out. Examination of the red reflexes by retinoscopy can reveal even minute lens opacities. Direct ophthalmoscopy or retinoscopy through the child's nondilated pupil is helpful for estimating potential vision in an eye harboring a cataract. Any central opacity or surrounding cortical distortion larger than 3 mm can be visually significant. Generally, the more posterior lens opacity carries more visual significance. The presence of retinal detachment, retinoblastoma, or other ocular pathologies that preclude good visual outcome must be ruled out by indirect ophthalmoscopy or ultrasonography.

Most *anterior polar cataracts* are small, less than 1 to 2 mm, and are usually not progressive. Surgery is seldom required for small, anterior polar cataracts, and the visual prognosis is excellent. If the cataracts increase in size, visual acuity may be compromised and may require surgical intervention.

Nuclear cataracts are typically congenital, dense axial opacities 3 mm or larger. Nuclear cataracts are frequently associated with microphthalmos and are inherited as autosomal dominant traits. Visual results are generally only fair, even if surgery is done early, and poor if done late. Aphakic glaucoma has a much higher incidence in these patients. *Rubella cataracts* may occur as a manifestation of the classic rubella syndrome—the triad of cardiac defects, hearing impairment, and cataracts.

Partial Lens Opacities

The evaluation of partial lens opacities is related to the location of the cataract. *Anterior cataracts* include anterior lenticonus, polar cataracts, persistent pupillary membrane opacities, and those occurring with anterior segment dysgenesis. *Posterior cataracts* include posterior polar, posterior lenticonus, persistent hyperplastic primary vitreous, and posterior subcapsular lens opacities. Posterior subcapsular cataracts are typically associated with corticosteroid use, atopic dermatitis, or inflammatory diseases and are generally bilateral.

Traumatic and Posterior Lenticonus

Traumatic cataract, the most common cause of unilateral cataract in children, is caused by penetrating or blunt trauma. Posterior lenticonus cataracts are the second most common cause of unilateral acquired cataract in children. *Posterior lenticonus* is a circumscribed oval or round bulge in the infant's or child's posterior lens capsule and cortex, restricted generally to a 2 × 7-mm axial diameter. The bulge increases progressively, and cataractous changes occur in the cortex surrounding the posterior lenticonus. Generally, there is a reduced red reflex initially with posterior lenticonus, and cataractous changes occur in the surrounding cortex. In 21 patients with posterior lenticonus, only two had bilateral posterior lenticonus. The interval between the "oil drop-let" posterior lenticonus and cataract development is variable. The eyes are normal in size, and visual results are good with surgery. Posterior lenticonus cataracts occur as early as 3 months of age or as late as 15 years. If the vision becomes worse than 20/70, the cataract should be removed by specialized instrumentation, followed by contact lens fitting or an intraocular lens.

Complete Lens Opacities

Workup for complete cataracts includes systemic evaluation, ocular ultrasonography, metabolic evaluation, serum chemistry, and chromosomal analysis. Congenital cataract causes include intrauterine infection, metabolic disorders, chromosomal anomalies, and systemic syndromes. Workup for congenital cataracts includes urinalysis for reducing substances and amino acids. Serum chemistry for calcium, phosphorus, glucose, and blood urea nitrogen (BUN) levels and TORCH (*toxoplasmosis, other agents, rubella, cytomegalovirus, herpes simplex*) titers should be obtained. When warranted, genetic and pediatric consultations should be requested. Radiologic imaging, including CT or MRI, may be needed.

Surgical Issues

Prompt clearing of the visual axis with immediate optical correction offers the best chance for visual recovery in pediatric patients with unilateral or bilateral cataracts. The surgical procedure recommended depends on the patient's age, risk of amblyopia and expected ocular growth, and reactivity to surgery. In patients younger than 6 months to 2 years old, the best option is to clear the visual axis and have it remain clear throughout the critical period of vision development with a lensectomy-vitreotomy procedure and 6-mm posterior capsulectomy with anterior vitrectomy. This procedure eliminates reopacification of the posterior capsule, which occurs in more than 90% of pediatric patients younger than 2 years. In children older than 2 years, lensectomy with vitrectomy and a 4-mm posterior capsulectomy are performed. Most of these children can be fitted with contact lenses, although an intraocular lens is indicated for some traumatic cataract patients. Traumatic unilateral cataracts present the least controversial situation in which intraocular lenses are considered in young children. Advances in intraocular lenses and surgical techniques have afforded significant improvements in pediatric cataract management.

The prognosis for children with monocular and binocular congenital and pediatric cataracts has improved markedly. Ongoing clinical studies will determine the best indications and procedures for use in pediatric cataract patients.

KEY TREATMENT

The decision for cataract surgery with intraocular lens implantation depends on the degree of vision loss and potential for amblyopia. Among newborns and infants with cataracts, visually significant cataracts should be removed and corrected with intraocular lens, aphakic contact lens, or aphakic spectacles (AAPOS, 2007) (SOR: C).

The decision for cataract surgery with intraocular lens implantation in older children depends on the degree of vision loss, comorbidities, and systemic disease (AAPOS, 2007) (SOR: C).

Retinoblastoma

Retinoblastoma is the second most common primary intraocular malignancy in all age groups (melanoma is most common in adults) and is the most common intraocular malignancy of childhood. Its incidence is approximately 1 in every 14,000 births. Generally, there are 250 to 300 new cases in the United States annually.

The tumor occurs bilaterally in as many as 40% of cases. It is generally diagnosed between 14 and 18 months of age, and more than 90% of the tumors are diagnosed by the age of 3 years. Familial retinoblastoma accounts for 6% of patients, but 15% of unilateral cases are carriers for the retinoblastoma gene. The remaining 94% of cases are sporadic. Germinal mutations account for 25% of retinoblastoma cases and somatic mutations for 75%. Most bilateral cases are caused by germinal mutations. The disease is inherited through an autosomal recessive tumor suppressor gene; thus the phenotype appears similar to that of autosomal dominant inheritance with incomplete penetrance. It is difficult, if not impossible, to differentiate the genetic mutations clinically and to determine which tumors will be passed on to offspring. There are occasional rare cases of retinoblastoma related to chromosomal abnormalities (partial deletion of long arm of chromosome 13). It has also been associated with trisomy 21.

The diagnosis of retinoblastoma is made by the patient presenting with a white pupil (leukocoria) in 61% of cases, strabismus in 22% of cases, and sometimes with a retinal detachment, red painful eye, or spontaneous hyphema (Fig. 41-25). Generally, patients with small retinoblastomas have problems with vision or strabismus. More advanced lesions present with leukocoria and occasionally secondary glaucoma. The advanced lesions may metastasize to the orbit and produce proptosis through the orbital spread. In addition, patients with retinoblastoma may have systemic metastases to the CNS, skull bones, lymph nodes, and other organs.

The treatment of retinoblastoma is generally enucleation for patients with advanced retinoblastoma involving more than 50% of the eye. If the second eye is involved, treatment depends on the size of tumor and whether there is extraocular extension. External beam irradiation treatment may be performed on the second eye or bilaterally, when necessary. Photocoagulation and cryotherapy are equally effective for small retinoblastomas confined to the retinal periphery. Newer

modalities are incorporating chemoreduction and radioactive plaque therapy for localized retinoblastoma and possible vision preservation. Systemic chemotherapy may be indicated after enucleation for advanced unilateral or bilateral cases.

KEY TREATMENT

Patients with retinoblastoma should receive long-term follow-up for evaluation of associated systemic cancers (Children's Oncology Group, 2006) (SOR: C).
Surgery for retinoblastoma requires specialist services and should be referred to supraregional centers when possible (National Collaborating Centre for Cancer, 2005) (SOR: C)

Adult Ophthalmology

Key Points

- Refractive errors in adults may be corrected with glasses or contact lens or more recent advanced techniques in refractive surgery. Risks and benefits associated with each option vary considerably.
- Patients with an acquired unilateral ptosis should be evaluated for Horner's syndrome, myasthenia gravis, and cranial nerve III palsy.
- Patients with recurrent anterior uveitis should be evaluated for ankylosing spondylitis, inflammatory bowel disease, sarcoidosis, juvenile rheumatoid arthritis, Reiter's syndrome, herpetic keratitis, and Lyme disease. Patients should be seen by an ophthalmologist for further evaluation.
- Common causes of posterior uveitis include toxoplasmosis, sarcoidosis, cytomegalovirus, Epstein-Barr virus, Behçet's disease, and *Bartonella* infection.
- Ocular medications, particularly antiglaucoma medications, are well known for having a variety of systemic side effects. Medications such as β -blockers may have implications for patients with heart or lung disease.

Figure 41-25 Total retinal detachment and advanced retinoblastoma in 23-month-old infant who presented with leukokoria (white reflex).

Correction of Refractive Errors

Contact Lenses

A major use of contact lenses is to correct myopia, aphakia, and astigmatism. It is critical to have a well-motivated patient who will wear contacts successfully. The many types of contact lenses mainly fall into four groups: (1) daily-wear hard lenses, (2) daily-wear soft lenses, (3) rigid, gas-permeable lenses, and (4) extended-wear soft lenses. Hard lenses have generally been constructed of polymethyl methacrylate. The material absorbs less fluid than soft contact lenses. Soft contacts may become 80% or more hydrated. New materials for hard and soft lenses continue to be developed. Complications of contact lenses, particularly extended-wear contacts, include infection, ocular allergies, follicular conjunctivitis, contact lens opacification, corneal edema, and corneal vascularization. Therefore, patients wearing contacts and complaining of red eyes require urgent evaluation.

Refractive Surgery

The latest treatment option for myopia, hyperopia, and astigmatism is laser refractive surgery with the excimer laser. Photorefractive keratectomy (PRK) and laser-assisted in situ keratomileusis (LASIK) use the excimer laser to remove corneal tissue to flatten the cornea or make it steeper. In the PRK procedure, the laser cuts through the surface cornea. Myopia of -1.00 to -10.00 diopters can be successfully corrected with PRK. This procedure does not involve a corneal flap, unlike LASIK, and has good visual recovery response. However, it is more painful than LASIK. The LASIK procedure is performed under a corneal flap. A 6-mm zone is cut with a microkeratome and the laser treatment directed to the exposed stromal tissue. LASIK is the preferred procedure for more than 6 to 8 diopters of myopia; its benefits are greater accuracy with the laser, reduced postoperative complications, quicker recovery of vision, and predictable healing. Some studies have suggested that LASIK has a slightly higher retreatment rate.

Hyperopia and astigmatism can now also be corrected with laser refractive surgery. The LASIK procedure is the preferred treatment for these conditions; PRK and LASIK are widely available. In the past several years, refractive surgery for myopia, hyperopia, and astigmatism has been considered instead of contact lenses or glasses. Recently, conductive keratoplasty has been advanced for treating presbyopia. However, there may be a compromise in balancing distance and near-vision postoperatively. Potential surgical complications include infections, epithelial ingrowth, halos, and loss of contrast sensitivity. In a patient with moderate cataracts, cataract surgery is more advisable than refractive surgery, because the patient will often have only a few years of vision correction before needing cataract surgery.

Decisions regarding refractive surgery procedures should be based on surgeon expertise, patient refraction, and available equipment. The patient should be informed about the possible options. For patients who are not candidates for laser refractive surgery, other surgical methods can correct refractive error. For example, implantable collamer lenses (ICLs) are particularly useful for high myopic patients, are generally well tolerated, and have a lower incidence of postoperative symptoms (e.g., halos).

Ocular Medications

Ocular medications may have significant systemic side effects, such as many of the glaucoma medications. Glaucoma medications can generally be classified into β -blockers, prostaglandins and prostamides, carbonic anhydrase inhibitors, α -blockers, and older medications, such as epinephrine and pilocarpine.

Systemic absorption of beta-adrenergic blockers, such as timolol (Timoptic), may exacerbate asthma. β -Blockers may also cause problems with breathing, bradycardia, and hypotension. These medications are contraindicated in patients with heart block, congestive heart failure, asthma, or obstructive lung disease.

Carbonic anhydrase inhibitors, such as methazolamide (Neptazane), lower IOP and decrease aqueous production. Carbonic anhydrase inhibitors, such as acetazolamide (Diamox), cause increased urination, decreased appetite, headache, nausea, malaise, and kidney stones. Additionally, these medications lower the serum potassium level, particularly in patients taking diuretics. Potassium supplements should be prescribed to prevent hypokalemia.

Alpha-adrenergic agonists, such as brimonidine tartrate (Alphagan), can lower blood pressure as well as intraocular pressure. Side effects include dry mouth and fatigue. Additionally, brimonidine can cross the blood-brain barrier and produce somnolence. Apraclonidine (Iopidine) induces allergy in 20% to 25% of patients and is found to be ineffective in about 25% of all patients.

A newer class of glaucoma medications includes the prostaglandins and prostamides. These medications, such as latanoprost (Xalatan), travoprost (Travatan), and unoprostone isopropyl (Rescula), are associated with increased eyelash growth and increased pigmentation of the iris, conjunctiva, and eyelids. Additionally, these medications can induce conjunctival hyperemia and can increase the risk of postoperative retinal edema.

Other ocular medications include antibiotics, anti-inflammatory agents, and steroids. Patients are occasionally given an antibiotic-steroid combination, such as tobramycin-dexamethasone (TobraDex), that may increase IOP, cause cataracts, or potentiate fungal ulcers. Steroid glaucoma is a form of open-angle glaucoma. If the condition is undetected and the patient continues to refill the medication, damage may occur to the optic nerve, including glaucomatous optic atrophy. Generally, IOP is lowered once the steroids have been discontinued. However, it may take several months for IOP to return to a normal level. Vision loss that occurs during this period may be permanent. Because of the relative frequency of steroid glaucoma, cataract, and exacerbations of viral infections, topical corticosteroids should be avoided for minor ocular inflammations. Generally, ocular conditions that warrant the use of topical steroids also warrant consultation with an ophthalmologist.

Ophthalmic Conditions in Older Adults

The most important causes of central and peripheral visual impairment in older adults include glaucoma, cataract, diabetic retinopathy, and macular degeneration. Most of these conditions can be controlled or, as in the case of cataracts, vision can be restored to a significant level to improve the

Figure 41-26 Blepharospasm in 68-year-old woman with a history of uncontrollable lid spasm resulted in her being unable to drive.

quality of life. Glaucoma and macular degeneration progression may be slowed with proper treatment. Regular eye examinations for older adults can detect early signs of ocular abnormalities and ensure that proper treatment is initiated. Generally, adults older than 40 years should have a complete examination at least every 3 years. After age 65, the examination should be at 1- to 2-year intervals.

Diseases of the Eyelid

Entropion is a turning in of the eyelid margin so that there is a rubbing of eyelashes or cilia, with resultant ocular irritation. An *ectropion* is a turning out of the eyelid margin so that the eye builds up excessive tears and becomes inflamed. Both conditions are more common in the older adult population. Entropion and ectropion can cause symptoms of irritation and corneal changes.

Basal cell carcinoma is much more common in older adults. It occurs more often on the lower lid. Generally, basal cell carcinomas have pearly edges and a central depression that becomes ulcerated.

Dermatochalasis, or baggy eyelids, may interfere with vision, covering part of the eye. This condition is caused by atrophy of the eyelid skin and elasticity changes. Dermatochalasis causes no permanent damage to vision.

Blepharospasm is a chronic spasm of the eyelid in older adults (Fig. 41-26). It may interfere with reading and driving. Botulinum toxin (Botox) injection in small doses is presently the treatment of choice.

Herpes Zoster and Herpes Simplex

Herpes zoster occurs more frequently in the older adult population. When the skin lesions involve the eyelids and tip of the nose, the ophthalmologist should be consulted for evaluation. Corneal dendrites and ulcers can occur with herpes zoster virus and HSV infection (Fig. 41-27). HSV infection is more frequently associated with uveitis. Herpes simplex infection responds to trifluridine (Viroptic) eyedrops, whereas HSV infection requires topical steroids.

Ptosis

Ptosis can occur in a number of forms, including congenital ptosis, pseudoptosis, and acquired ptosis (Fig. 41-28). Congenital ptosis can occur as a unilateral or bilateral ptosis. A Marcus Gunn, jaw-winking ptosis results from a misdirected

Figure 41-27 Herpes zoster keratitis. Photomicrograph shows pseudodendrites.

Figure 41-28 Congenital ptosis in 4-year-old patient with congenital bilateral ptosis.

cranial nerve III. Acquired forms of ptosis include *myogenic* forms, such as myasthenia gravis and progressive external ophthalmoplegia, and *neurogenic* forms, such as Horner syndrome and cranial nerve III palsy (Fig. 41-29). *Pseudoptosis* is caused by conditions giving the appearance of a ptosis. It is particularly common with microphthalmia (small eye, or phthisis bulbi). Pseudoptosis may also be secondary to hypotropia.

Congenital ptosis generally is corrected with bilateral fascia lata brow suspension or a levator resection in patients with good levator function. Treatment of adult forms of ptosis includes correction with a tarsoconjunctival resection, strengthening of the levator aponeurosis, and levator resection.

Myasthenia Gravis

Myasthenia gravis is an autoimmune disease. It can occur at any age and is more common in women. There are some genetic associations, but usually it is sporadic. In myasthenia gravis, acetylcholine receptor antibodies decrease postsynaptic receptor activity at the neuromuscular junction. The muscle cannot receive the message propagated by the action potential. The clinical effect is muscle weakness, which may be variable, chronic, localized, or diffuse. The immunologic component (B and T cells produced in thymus) plays a role. About 75% of patients have thymic abnormalities, and 10% have thymomas.

Figure 41-29 Ptosis of left upper lid in 8-year-old patient who had ocular myasthenia and subsequently developed ptosis of right upper lid and exotropia.

Common ocular findings include unilateral or bilateral ptosis, which is usually asymmetric lid fasciculations, and lid retraction. Patients with myasthenia gravis frequently have eye muscle deviations with double vision. Systemic manifestations include involvement of the jaw and neck, inability to hold the body erect because of weakness of the spinal muscles, and limb weakness. In addition, symptoms may include choking on food and shortness of breath, which is considered a *myasthenic crisis*. Speech difficulties may also occur. A neurologist usually prescribes treatment for myasthenic patients. The prognosis is generally good in patients who present with ocular abnormalities initially.

Strabismus in Adults

Adult strabismus results in both visual and psychosocial disabilities. Adults with strabismus may not be offered appropriate surgical treatment because of misconceptions regarding surgical and nonsurgical correction. Successful strabismus surgery can relieve diplopia and visual confusion, restore or establish depth perception, expand the visual field, eliminate an abnormal head posture, and improve psychosocial function and employability.

Adults with strabismus should be referred to an ophthalmologist who specializes in surgical and nonsurgical correction of adults. Patients should understand the management of strabismus, if possible, and can be educated regarding the relative risks and benefits of surgery.

KEY TREATMENT

The surgical and nonsurgical treatment of strabismus in adults results in improved binocular visual function, visual rehabilitation of sensorimotor system, and improved psychosocial benefits (AAO, 2007) (SOR: A).

Dry Eye (Keratitis Sicca)

Tears, because of their lubricating and bacteriostatic properties, are essential for maintaining a healthy cornea and conjunctiva. A deficiency in tear production may result in a dry eye, also known as keratitis sicca. *Keratoconjunctivitis sicca* is an acquired disorder seen frequently during the fifth decade

of life that occurs more often in women. Initial symptoms include a foreign body sensation, dryness, and burning, which often worsens as this condition progresses. Paradoxical tearing from reflex stimulation of the lacrimal gland occurs. Symptoms usually exceed the signs of this common condition. Examination reveals a lack of corneal and conjunctival luster, with punctate erosions. With a decrease in aqueous tears, there is an attempt to compensate by an increase in mucin production, leading sometimes to a stringy, ropelike discharge.

Some cases of keratoconjunctivitis sicca are related to an autoimmune cause, particularly those patients with dryness of other mucous membranes. It also often occurs with rheumatoid arthritis, systemic lupus erythematosus, and Sjögren's syndrome. Initial treatment includes lubrication with artificial tears and ointments to supplement or replace the tear film deficit. In moderate or severe cases, an ophthalmologist may need to occlude the eyelid punctum surgically and perform a tarsorrhaphy to protect the corneal surface. Moisture chambers may also be prescribed. Topical antibiotics are required only if secondary infection occurs. Cyclosporine 0.05% (Restasis) is also useful in addressing inflammatory components of tear film insufficiency, when other treatments are insufficient.

Exposure keratitis is a condition symptomatically similar to dry eyes that is caused by incomplete eyelid closure during blinking or with sleep. It may result from Bell's palsy, scarred or malpositioned eyelids, or thyroid exophthalmos. Management involves the use of ophthalmic lubricating solutions and ointments. Mechanical measures designed to assist normal eyelid closure may be necessary, including frequent manual massage of the lids during the day to assist closure, forceful blinking exercises to elicit Bell's reflex, and taping the lids shut at night. Merely patching the eye should be avoided because of an increased risk of corneal abrasion if the lids do not cover the eye underneath the patch.

Thyroid Eye Disease (Thyroid Orbitopathy)

Hyperthyroidism may induce an orbitopathy in some patients. In such cases, there is diffuse hyperplasia of the thyroid and infiltrative ophthalmopathy. Thyroid eye disease is seen in association with thyroid dysfunction, although thyroid function test results may be normal. With thyroid orbitopathy, the extraocular muscle becomes infiltrated; this may occur even when the disease appears to be under good systemic control. The precise extraocular mechanism is unknown and the genetic predisposition uncertain.

Graves' ophthalmopathy occurs in approximately 95% of patients with Graves' thyroid disease, but is only rarely seen with Hashimoto's thyroid disease. The diagnosis of *euthyroid* Graves' ophthalmopathy is primarily a clinical diagnosis, confirmed with orbital CT imaging. Clinical characteristics include hypotropia, esotropia, or a combination of vertical and horizontal strabismus. Many patients are euthyroid at diagnosis, but there may be a history of previous thyroid dysfunction. Thyroid myopathy is a common cause of acquired vertical deviation in adults but relatively uncommon in children. Werner has classified eye involvement in Graves' disease by the NO-SPECS mnemonic: *n*o signs of symptoms, *o*nly signs of lid retraction or gaze palsy with or without lid

lag or proptosis, signs and symptoms of soft tissue involvement, *p*roptosis, *e*xtraocular muscle involvement, *c*orneal involvement with corneal drying, and *s*ight loss with optic nerve involvement.

The total muscle volume of the extraocular muscles increases as the disease worsens. The volume can be computed by averaging serial CT sections. Indications for treatment of thyroid ophthalmopathy include diplopia, abnormal head position, a large horizontal or vertical strabismus, and loss of vision. Generally, the preferred treatment is orbital decompression if loss of vision is threatened. Nonsurgical management of the patient includes prisms to alleviate the diplopia in primary position. Eye muscle surgery can be performed with adjustable sutures.

Ocular Changes with Aging

Arcus senilis, or corneal arcus, is a hazy, white or yellow arc or deposit in the peripheral cornea. It has many causes and is more common in older adults. The deposit is composed of cholesterol and other lipids and does not generally indicate an underlying systemic abnormality. It does not interfere with vision or eye function. In white patients, this finding may indicate lipid abnormalities and an increased propensity for cardiovascular disease. No such clear correlation has been identified in African Americans, who are much more likely to have an arcus. The pupil becomes miotic and does not respond well to dilation or darkness. The vitreous body detaches from the retina, resulting in the perception of flashing lights secondary to retinal traction. The retinal pigment epithelium atrophies, making the choroidal vessels more visible. The lens becomes progressively stiffer with age. Symptoms begin in the mid-40s, with increasing difficulty in near-vision focusing. By age 60, most patients have had a major reduction in accommodative amplitudes. The universal stiffening of the lens with age causes the well-known symptoms of presbyopia, requiring the use of reading glasses.

Cataracts

A cataract is a condition that affects a large percentage of the population. As a result, cataract surgery is the most common U.S. surgery performed. Currently, cataracts affect approximately 40 million people in the United States. Generally, the normal aging and cataractous changes in the lens are related to its metabolic activity. *Acquired cataracts* may be caused by penetrating trauma, irradiation, heat, or blunt trauma. Metabolic cataracts occur particularly in association with diabetes. Changes in the blood glucose concentration may alter the refractive power of the lens. With hyperglycemia, glucose byproducts enter the lens, causing it to swell and inducing a myopic shift. *Nuclear sclerosis cataract* is the most common cause of lens opacity seen by the ophthalmologist; an increased central density makes lens power stronger. As a result, frequent changes in the eyeglass prescription are necessary to correct the changing lens power. This type of cataract develops slowly, and surgery may not be necessary for several years.

The decision for cataract surgery with intraocular lens implantation depends on the degree of vision loss and the daily requirements of the patient. In patients with

cataracts, indications for surgery include the patient's preference and needs, functional disability by Snellen visual acuity test and visual field testing, and concomitant ocular problems.

Cataract surgery involves removal of the cataractous lens and insertion of an intraocular lens. Generally, the procedure is performed under local anesthesia, although the patient may have general anesthesia. Modern cataract surgery primarily entails removing the lens through an extracapsular technique, which can be done en bloc or through a small corneal incision with phacoemulsification. In children, cataracts are generally soft and often require aspiration equipment.

Phacoemulsification is a technique that uses ultrasonic energy to break up the lens material so that it may be withdrawn through a small needle. Unfortunately, phacoemulsification has been confused with laser treatment for cataract removal. It is important to emphasize to patients that the laser is not used to remove the cataractous lens. Part of the confusion lies in the fact that secondary cataracts or opacification of the posterior capsule can be eliminated using the YAG laser. With the YAG laser there is photodisruption of the capsule, which creates an opening and provides good visual acuity. Cataract removal is one of the most successful operations performed. Generally, adult patients are treated with intraocular lenses after cataract removal. If the patient has bilateral aphakia, contact lenses or cataract spectacles may be worn. However, moderate visual distortion occurs with aphakic spectacles, as well as restriction of peripheral vision. Routine preoperative testing does not improve clinical outcomes for healthy patients undergoing cataract surgery.

Uveitis

A red painful eye with photophobia and increased tearing often occurs with the presentation of anterior uveitis. In addition, the patient may have decreased vision. *Vascular injection*, a circumcorneal injection involving the deep vessels of the sclera, is one of the primary signs of anterior uveitis. Generally, uveitis patients are moderately light sensitive. In addition, the inflammatory process may hinder aqueous production and reduce intraocular pressure.

Patients suspected of an *anterior uveitis* should be referred to an ophthalmologist for consultation and treatment. The most common cause of anterior uveitis is idiopathic; other common causes include ankylosing spondylitis, inflammatory bowel disease, sarcoidosis, juvenile rheumatoid arthritis, Reiter's syndrome (urethritis, polyarthritis, and ocular inflammation), herpetic keratitis, and Lyme disease.

Patients with *posterior uveitis* usually present with a reduction in vision and vitreous floaters. They may have clinical signs of retinal vasculitis, retinal ischemia, optic nerve edema, and exudative retinal detachment. On careful inspection, cells may be visible floating in the vitreous. Common causes of posterior uveitis are toxoplasmosis, sarcoidosis, cytomegalovirus, Epstein-Barr virus, Behçet's disease, and *Bartonella* infection. *Toxoplasmosis* accounts for up to 30% of cases and may destroy the macula or other important visual structures. Characteristically, there is an exudation in the retina caused by an inflammatory process. *Toxocara canis* may also present as uveitis.

Diseases of the Retina and Optic Nerve

Key Points

- Glaucoma is a leading cause of blindness and is managed medically and surgically.
- Choroidal melanoma is the most common intraocular malignancy.
- Posterior vitreous detachment is a common cause of vitreous floaters but may present similar to retinal detachment.
- Age-related maculopathy represents a significant cause of central vision loss in older adults.
- Some patients with macular degeneration may benefit from advances in therapeutic laser treatments.
- Vitamin supplements have been shown to be beneficial for some patients with macular degeneration.
- Routine funduscopy should be performed to evaluate for hypertensive retinopathy and diabetic retinopathy.
- Diabetic retinopathy is the most common cause of blindness in Americans age 20 to 74.
- Giant cell arteritis generally occurs in patients 55 and older, with headache, scalp tenderness, jaw claudication, malaise, fatigue, and amaurosis fugax.
- Carotid artery disease is an important cause of transient ischemic attacks; 50% of patients with TIA involving carotid artery disease have a major stroke within 1 month of first attack.
- About 75% of women and 34% of men with optic neuritis will develop multiple sclerosis within 15 years.

Retinal diseases account for 10% to 15% of blindness. Common retinal diseases include macular degeneration, diabetic retinopathy, retinal detachment, and retinal vascular disease. Sudden loss of vision can have various causes; four common causes are retinal detachment, temporal arteritis, ischemic optic neuropathy, and optic neuritis (Table 41-6).

Vitreous Floaters

The vitreous gel degenerates during middle age and forms microscopic strands within the eye. An increase in previous floaters, acute flashing lights, or the appearance of a veil or curtain over a patient's vision may signify a retinal detachment. Posterior vitreous detachment is a common cause of vitreous floaters. The sudden onset of vitreous floaters can be alarming for the patient. Generally, they are simply the result of the normal aging process. Vitreous floaters may interfere with clear vision, particularly reading. Although generally benign, posterior vitreous detachments can create retinal hemorrhages and are associated with retinal tears and detachments.

Melanoma

Choroidal melanoma, a pigmented elevated mass in the choroid, is the most common intraocular malignancy. As the tumor spreads, it may produce a retinal detachment. In addition, retinal pigment epithelial alterations can occur in the form of *drusen* or *lipofuscin* (Fig. 41-30). The differential diagnosis of choroidal melanoma includes choroidal nevus, retinal detachment, and metastatic tumor to the choroid. All patients with intraocular tumors should have an extensive physical examination and laboratory testing to exclude metastatic spread of the neoplasm. Many ocular melanomas have already metastasized at diagnosis. Treatment modalities generally

Table 41-6 Systematic Approach to Patient Presenting with Rapid or Sudden Loss of Vision

| Presentation | Symptoms | Signs | Treatment |
|---|---|---|---|
| Painful Acute narrow, angle-closure glaucoma | Pain, tearing, headache | Shallow anterior chamber | Refer immediately. |
| | Halos around light with intermittent blurring of vision | Sudden rise of intraocular pressure | If no ophthalmologist available, begin oral glycerin (1 mL/kg), intramuscular acetazolamide (500 mg), and topical pilocarpine (1%-4%) every 15 min. |
| | Nausea, vomiting | Circumcorneal injection Cornea edematous and cloudy | |
| Painless Central retinal artery occlusion | Sudden unilateral visual loss (may be preceded by transient blurring) | Cherry-red spot in macula | Digital ocular massage |
| | | Narrowed arteries Pale optic nerve head Edematous retina | Elevation of blood CO ₂ level through rebreathing into paper bag or breathing 95% O ₂ and 5% CO ₂ (carbogen) if available |
| Painless Cranial (giant cell) arteritis | Sudden unilateral visual loss preceded by vague migrating joint pains Low-grade fever, depressed appetite No localized pain in eyeball but scalp pain; severe, boring headaches | Enlarged and painful temporal artery Increased erythrocyte sedimentation rate is key to diagnosis. | Refer immediately. Definitive treatment is high doses of systemic corticosteroids. Involvement of other eye in relatively short time; therefore, immediate referral is imperative. |
| Retinal detachment | Usually rapid loss of vision but <i>may vary</i> Frequently preceded by flashing lights and floaters; more common in patients with myopia; after cataract extraction; after blunt trauma | Retinal elevation on ophthalmoscopic examination | Refer to ophthalmologist promptly. |

Figure 41-30 Choroidal melanoma. Increased pigmentation involves the choroid, with characteristic lipofuscin overlying the lesion, which is slightly elevated with bowing of the overlying vessels. This melanoma was locally treated.

Figure 41-31 Age-related maculopathy in 73 year-old woman who demonstrated evidence of geographic atrophy with her macular degeneration.

involve radioactive plaques, and enucleation is performed less frequently. When a small, melanotic lesion is detected, observation is indicated in older adults with slow-growing lesions.

Macular Degeneration

Age-related macular degeneration (ARMD) is the most common form of breakdown in the macular area, accounting for 70% of all cases. *Age-related maculopathy*, formerly called "macular degeneration," leads to loss of fine or central vision but not side vision. Laser treatment is of benefit in select

patients. Macular degeneration begins with nonexudative changes (Fig. 41-31). However, many people with macular degeneration have an abnormal vascularization that is not always amenable to laser therapy (Fig. 41-32). The condition occurs in the other eye within 1 year in 10% of cases. Another form of macular degeneration is *exudative macular degeneration*, which accounts for 10% of cases.

Normally, the macula is protected by thin tissue that separates it from the fine blood vessels that nourish the posterior aspect of the eye. When these blood vessels break or leak, scar

Figure 41-32 Age-related maculopathy with choroidal neovascularization. Abnormal blood vessels have formed in the area of macular degeneration and require further studies to determine whether laser treatment is indicated.

tissue may form, often leading to abnormal growth of new blood vessels (neovascularization). These new vessels are particularly fragile, and leakage and bleeding may occur. If macular degeneration involves both eyes, near activities become difficult. If an individual loses central vision related to macular degeneration, generally the peripheral vision is unaffected.

An ophthalmologist can confirm the diagnosis of macular degeneration; assessment includes color vision testing, ophthalmoscopy, and fluorescein angiography, when indicated. Examination reveals an accumulation of membranous debris on the posterior aspect of the retinal pigment epithelium, presence of drusen, and atrophy of the retinal pigment epithelium. In addition, there may be detachment of the retinal pigment epithelium and choroidal neovascularization.

There is no cure for patients with ARMD. Ophthalmic laser surgery may be beneficial in reducing the spread of the exudative macular degeneration, but it is successful only in the early stages. Laser therapy and anti-VEGF (vascular endothelial growth factor) medications have been helpful in treating membranes and neovascularization. Advanced cases of macular degeneration have been treated with macular translocation with some success. At present, use of multivitamins with beta-carotene and vitamin E may delay progression for many patients with ARMD. However, beta-carotene supplements in smokers have been associated with an increase in lung cancer. Vitamin supplements have no impact on cataract formation.

KEY TREATMENT

Patients with intermediate age-related macular degeneration had a 25% reduction in the progression of ARMD with the following vitamin and mineral supplements: vitamin C (500 mg), vitamin E (400 IU), beta-carotene (15 mg [25,000 IU]), zinc oxide (80 mg), and cupric oxide (2 mg) (AREDS Research Group, 2001) (SOR: A). Management options for macular degeneration include observation, antioxidant vitamin and mineral supplements, intravitreal injection of anti-VEGF agents, PDT, and laser photocoagulation surgery (AAO Preferred Practice Patterns, 2008) (SOR: A).

Hypertensive Retinopathy

Routine ophthalmoscopy in hypertensive patients affords the physician a direct view of the arterioles and helps assess the long-term duration and severity of the hypertension as well as evidence of accelerated or malignant hypertension. In the vascular system, arterioles serve as the resistance vessels, and the overall cross section of the arteriolar bed determines peripheral resistance. With the fundus examination, the physician can directly observe the degree of spasm in arterioles and the effects of long-term hypertension on the arteriolar wall. Severe hypertensive retinopathy can lead to profound vision loss, although usually the patient is completely asymptomatic.

The normal arteriolar wall is transparent, and the visible image is of the blood column as it passes through the arteriolar lumen. An additional anatomic consideration is that at the point of crossing of the arteriole and venule, the vasculature shares a common adventitial layer. Therefore, when arteriolar thickening occurs, the venule is compressed, resulting in arteriolar-venous (A-V) nicking. It is practical to divide the changes in the fundus seen in hypertension into two scales, a hypertensive scale and an arteriole-sclerotic scale (see online text, Hypertensive Retinopathy Grading).

Diabetic Retinopathy

Diabetic retinopathy is the most common cause of blindness in Americans 20 to 74 years old. Diabetic patients are at 25 times greater risk of becoming blind from diabetic retinopathy than nondiabetic persons of becoming blind from all other causes. Diabetic retinopathy is more common in women, but men appear to develop a more complicated and severe proliferative retinopathy. Findings have shown that in type 1 diabetes mellitus, it is unusual to detect diabetic retinopathy before 5 years after onset of disease. After 15 years from diagnosis, most patients with type 1 diabetes have some diabetic retinopathy, with incidence of proliferative disease greater than 40%. In type 2 diabetes, with onset after age 30, diabetic retinopathy is often detectable at the initial diagnosis. Diabetic patients requiring insulin have a higher incidence of diabetic retinopathy and proliferative disease.

The precise pathogenesis of diabetic retinopathy remains unclear, but the target tissue is the retinal capillary. Localized ischemia has been shown to increase levels of vascular endothelial growth factor (VEGF) and result in a corresponding area of vascular proliferation. The vascular complications evolve through states defined by ophthalmoscopic findings.

The first stage is called *nonproliferative* or "background" retinopathy (Fig. 41-33). Capillaries leak and later become occluded. The retinal findings include aneurysms, hard exudates, intraretinal hemorrhages, and macular edema. In the nonproliferative stage, patients will only experience visual loss if there is macular involvement. Visual loss from macular edema is present in 5% to 20% of diabetic patients, depending on the type and duration of disease. With progression, patients will develop *preproliferative* diabetic retinopathy. This stage frequently progresses to proliferative diabetic retinopathy. The most readily recognized abnormality of preproliferative retinopathy is the cotton-wool spot, a white opacity with feathery edges indicative of localized retinal infarct of the nerve fiber layer.

Proliferative diabetic retinopathy (PDR) is responsible for most serious vision loss in patient with diabetes. As a result

of continued retinal ischemia, new blood vessels form in the area of the optic disc or elsewhere on the retinal surface (Fig. 41-34). Without laser photocoagulation, these vessels typically progress to retinal detachment and form vascularization within the vitreous cavity. Neovascularization results in vitreous hemorrhage and retinal traction. Once fibrous proliferation has detached the retina, surgical repair can be challenging. Prophylactic laser photocoagulation is the best way to avoid this complication for diabetic patients with proliferative diabetic retinopathy.

Screening Recommendations.

Screening eye examinations for patients with type 2 diabetes reduce the chance of vision loss (FPIN, 2004) (SOR A, 1).

Type 1 diabetic patients should have their first eye examination 5 years after onset.

Type 2 diabetic patients should have their first eye examination at diagnosis.

Figure 41-33 Nonproliferative diabetic retinopathy of left eye. There is extensive nonproliferative disease with macroaneurysms, hemorrhages, and exudates. Although there is no neovascularization, this patient is at risk of developing proliferative disease.

Diabetic patients should have a baseline eye examination before becoming pregnant or early in the first trimester. On initiation of ophthalmic screening, all diabetic patients should have annual dilated fundus examinations by an ophthalmologist, or sooner if poor diabetic control or visual symptoms develop (AAO, 2007) (SOR A, 1).

Retinal Detachment

Retinal detachment is separation of the retina from its blood supply. It usually follows a tear or hole in the retina. Retinal tears may be caused by trauma or retinal disease, but the cause of most tears is unclear. When the retina is detached, vision is lost from the involved area of the retina. If the macula detaches, irreversible loss of vision may occur unless the detachment is treated within 24 hours. Anatomic reattachment of the retina is successful in up to 90% of cases.

Giant Cell Arteritis (Temporal Arteritis)

Temporal arteritis is a systemic autoimmune disorder. Pathologically, there is a granulomatous inflammation of large and medium-sized arteries. It generally occurs in patients older than 55 years, with no gender predilection. Involvement may occur in any organ system. Ocular involvement is generally associated with inflammation of the posterior ciliary arteries. General symptoms include amaurosis fugax, headaches, scalp tenderness, jaw claudication, occasional ear pain or arthralgias, pain and tenderness on one or both temples, malaise, and intermittent fevers. Ocular symptoms include loss of vision, diplopia, pain, red eye, and ocular-ischemic syndrome. The workup of patients suspected to have giant cell arteritis includes a careful history of non-visual symptoms, examination, and laboratory studies to include erythrocyte sedimentation rate (ESR), C-reactive protein, and complete blood count with differential. Using the Westergren method, the value for a normal ESR is 30 mm/hr for a 60-year-old man; for women, top of normal range is age plus 10 divided by 2, so 35 mm/hr is the upper range of normal for a 60-year-old woman. The differential diagnosis of sudden vision loss also includes emboli, central retinal artery occlusion, and retinal detachment.

The visual loss of giant cell arteritis is caused by an ischemic process in the optic nerve. Central retinal artery occlusion

Figure 41-34 Proliferative diabetic retinopathy. Patient has severe disease, with diffuse retinal hemorrhages in all quadrants and evidence of neovascularization, and requires urgent panretinal photocoagulation. There is evidence of neovascularization of the optic disc in the left eye.

may also occur with giant cell arteritis. It is important to diagnose giant cell arteritis as early as possible. Without corticosteroid treatment, patients often develop permanent vision loss bilaterally. When one eye is involved with giant cell arteritis, the second eye loses vision in 65% of untreated patients. Generally, involvement of the second eye occurs with 10 days of onset. When the diagnosis is suspected on the basis of clinical symptoms and signs, temporal artery biopsy is necessary to confirm the diagnosis. The ESR is often greatly elevated, although it may be normal for age. If there is any doubt regarding the diagnosis, a temporal artery biopsy is warranted.

Once the diagnosis is established, steroid therapy should be instituted immediately. Up to 100 mg of prednisone (1.0-1.5 mg/kg/day) should be given orally if giant cell arteritis is suspected. Some physicians recommend IV steroids. Patients often require treatment for several months pending a positive biopsy or strong suspicion of giant cell arteritis. Steroids should not be delayed because of the temporal artery biopsy. Biopsy results will remain positive for up to 1 week after beginning steroid therapy. The patient can be monitored by symptoms occurring after institution of treatment and by ESR. Because of the severe systemic effects of giant cell arteritis, the patient should be followed closely.

KEY TREATMENT

Giant cell arteritis should be promptly treated with oral or intravenous steroids before obtaining a temporal artery biopsy; treatment should not be delayed for laboratory confirmation (Turbin et al., 1999) (SOR: A).

Glaucoma

Glaucoma is responsible for at least 10% of people with blindness in the United States. Glaucoma is four times more common in African Americans, who are also eight times more likely to develop blindness from glaucoma. Glaucoma appears to increase with age in the United States and decreases with age in Japan. Diabetic patients also have an increased risk for developing glaucoma.

The most common form of glaucoma in the United States is primary *open-angle glaucoma*, which accounts for about two thirds of all cases. In Asia the most common form of glaucoma is *angle-closure glaucoma*. Open-angle glaucoma tends to be genetically based, with multifactorial inheritance or as an autosomal recessive trait, with a high prevalence of carriers. Glaucoma is bilateral and occurs predominantly after age 50, although incidence is significant during the 30s and 40s, and it may even occur during the teenage years. Glaucoma is more severe in the African American population. Current incidence of glaucoma is 2% in the United States. The family physician can measure intraocular pressure using tonometry to detect elevated IOP. Tonometry can be performed with a Schiøtz tonometer, Perkins applanation tonometer, Tono-Pen XL tonometer, or Goldmann applanation tonometer held horizontally. This test should be performed at least every 3 years, beginning at age 35 years.

The damage to vision caused by glaucoma is irreversible. If the glaucoma can be detected early, it can usually

be controlled and is curable by medical treatment, laser surgery, trabeculectomy, or some other filtering procedure. It is important to emphasize that glaucoma may occur at any age. Causes include congenital glaucoma, chronic open-angle glaucoma, narrow-angle glaucoma, or other forms of glaucoma, including pigmentary glaucoma.

One of the most common forms of secondary glaucoma is *steroid glaucoma*, which occurs in a substantial number of patients who use corticosteroid eyedrops or ointment for several weeks or longer. This condition also may occur with oral or systemic corticosteroid use, although it is rare. Steroid glaucoma is a form of open-angle glaucoma and, like primary open-angle glaucoma, can be effectively treated if detected early. If IOP is not lowered in time, there may be permanent damage to the optic nerve. Treatment for this type of glaucoma is discontinuation of corticosteroids and initiation of topical glaucoma medications. The IOP elevation is reversible once the steroids have been discontinued, but it may take 2 to 3 months or longer for pressure to return to a normal level. Any visual loss that occurs during this period may be permanent. There is no reliably safe dose of topical steroids that can ensure the prevention of steroid glaucoma. Even topical medications that consist of a combination of steroids and antibiotics or other type of medication can increase IOP. Because of the relative frequency of steroid glaucoma, as well as other ocular complications resulting from steroid use (e.g., cataract, exacerbation of viral infections), topical steroids should not be used for minor ocular inflammations, except in special circumstances.

Secondary glaucoma also may be caused by ocular trauma, intraocular inflammations, intraocular tumors, and carotid vascular disease. Regardless of cause, any patient suspected of having secondary glaucoma should be referred to an ophthalmologist as soon as possible for further evaluation and therapy. Management depends on the cause of the disease and character of the IOP elevation. Some medications can also result in glaucoma and include a warning related to developing angle-closure glaucoma. Additionally, topiramate (Topamax) is associated with an idiosyncratic acute glaucoma caused by uveal effusions.

With increased IOP, damage to the optic nerve and visual field abnormalities can occur. Almost all elevated pressures are caused by an obstruction to the outflow of aqueous humor. *Aqueous humor*, formed inside the eye in the ciliary body, circulates around the lens and through the pupil into the anterior portion of the eye. The aqueous humor exits through the anterior angle structures (trabecular meshwork and Schlemm's canal) (Fig. 41-35). About 10% of glaucoma cases occur in the setting of normal IOP, suggesting that these eyes are particularly susceptible to pressure changes. Glaucoma management involves more than controlling IOP. Possible sources of damage to the optic nerve involve mechanical factors affecting the optic nerve, decreased optic nerve perfusion, and blockage of axoplasmic flow in the lamina cribrosa. Carotid artery stenosis can also cause problems because of decreased perfusion to the optic nerve. Occasionally, elevations result from impeded outflow caused by elevated venous pressure, such as in patients with Sturge-Weber syndrome.

The most serious consequence of elevated IOP is damage to the optic nerve (Fig. 41-36). As IOP rises, retinal nerve

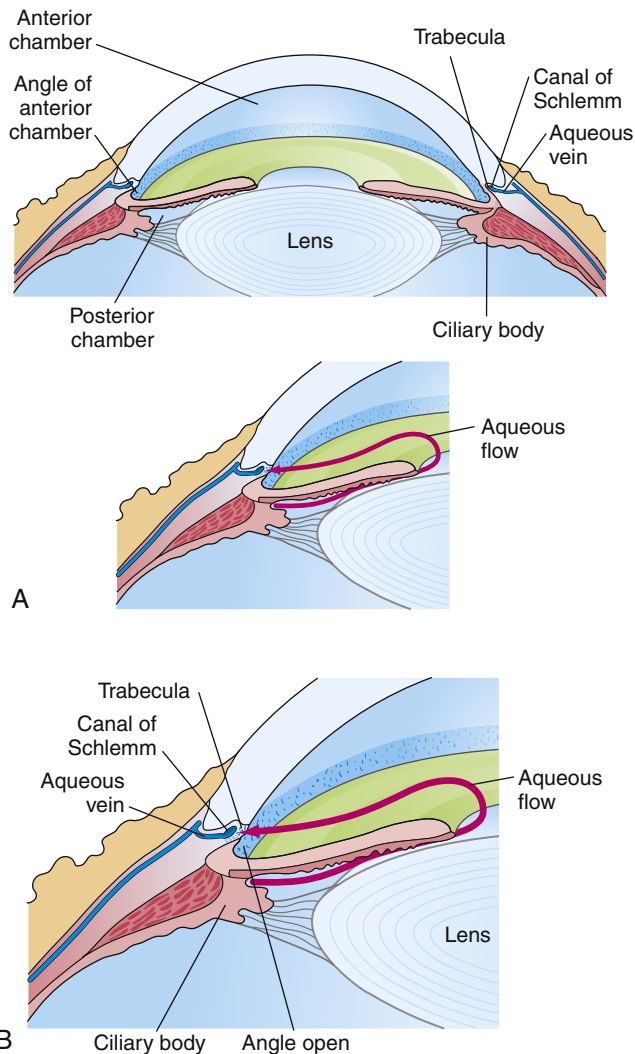

Figure 41-35 **A**, Flow of aqueous from the ciliary body, leaving the eye through the trabecula and canal of Schlemm via a normal, open, wide angle. **B**, Chronic open-angle glaucoma. (From Scheie HG, Albert DM. *Textbook of Ophthalmology*, 9th ed. Philadelphia, Saunders, 1977.)

fibers are destroyed at the optic nerve head, resulting in permanent visual loss. Peripheral vision is usually affected first, followed by progressive visual loss involving the entire visual field (Fig. 41-37).

KEY TREATMENT

Long-term monitoring is essential for successful management of glaucoma (AAO, 2000) (SOR: A).
 For chronic open-angle glaucoma, initial treatment is topical medications (AAO, 2000) (SOR: C).
 For uncontrolled chronic open-angle glaucoma, surgical treatment should be considered (AAO, 2000) (SOR: C).
 For acute angle-closure glaucoma, medical treatment and surgery (laser or incision) should be implemented as soon as medically possible (Saw et al., 1993) (SOR: A).

Anterior Ischemic Optic Neuropathy

The clinical characteristics of ischemic optic neuropathy include age at onset generally older than 60 years, painless vision loss, and afferent pupillary defect (Marcus Gunn pupil). These patients also usually have a visual field abnormality. Examination of the optic disc reveals edema in almost all cases. Pathology appears to be related to a diseased ciliary circulation. It is generally difficult to determine whether the disc edema will result in a mild peripheral (side) visual field defect and good visual acuity, or reduced central acuity and a significant visual field defect. Giant cell arteritis must be ruled out in these patients. A general physical examination and associated blood work are indicated. No treatment prevents the progression of ischemic optic neuropathy, including steroids and anticoagulants.

Transient Ischemic Attacks in Carotid Artery Disease

Transient ischemic attacks are neurologic deficits lasting less than 24 hours and are reversible. The most common ophthalmologic TIA is *amaurosis fugax*, which is a fleeting monocular blindness caused by an embolic event. There is a sudden graying or reduction of vision, often moving from the peripheral vision to the center to cover the entire visual field within a few seconds. After 1 to 5 minutes, the central vision

Figure 41-36 Bilateral glaucoma in 60-year-old man. Patient also had history of diabetes mellitus. The glaucoma is characterized by prominent optic nerve cupping. **A**, Enlarged optic nerve cup, right eye. **B**, Enlarged optic nerve cup, left eye. Note thinning of optic nerve rim.

Figure 41-37 Testing peripheral fields by confrontation. (From *American Academy of Ophthalmology. The Athlete's Eye. San Francisco, AAO Professional Information Committee, 1986.*)

begins to return first. Other causes of TIAs include chronic disc edema (in which vision loss lasts seconds, not minutes), chronic papilledema with bilateral blackouts based on optic nerve disease (often also lasting a few seconds and caused by postural changes), and basilar artery insufficiency. TIAs related to basilar artery insufficiency are usually bilateral blackouts lasting seconds or minutes, often with changes in the posterior circulation.

The most important mechanisms involving carotid TIAs with stroke are embolization from the carotid artery or its branches, reduced perfusion caused by carotid stenosis or occlusion, or a combination of the two. In most patients (up to 90%), the site of the obstruction is the carotid sinus. Hollenhorst plaques are bright-yellow cholesterol emboli that may occlude the retinal arterioles (see Fig. 41-10). Fibrin platelet emboli can occur near retinal arterioles and produce visual symptoms. A cholesterol or fibrin platelet embolus is indicative of ulcerative disease in the carotid arteries and is associated with a high incidence of ischemic heart disease, peripheral vascular disease, stroke, and aortic abdominal aneurysm. A rarer form of carotid TIA is related to valvular heart disease, particularly with a prolapsed mitral valve or

cardiac arrhythmia. Approximately 30% to 50% of patients with TIAs and carotid artery disease have a major stroke within 1 month of the first attack.

Optic Neuritis

Optic neuritis is localized inflammation of the optic nerve sheath, resulting in reduced neuronal transmission and decreased visual acuity. Generally, there is a loss of color vision and red desaturation noticed by the patients. The symptoms generally worsen during the first few days and progressively improve over several weeks. In children, optic neuritis has various causes, typically associated with viral infections. In young adults, optic neuritis has a high association with multiple sclerosis (MS). Approximately 75% of women and 34% of men with optic neuritis will develop MS within 15 years of the onset of optic neuritis. Patients should undergo MR neuroimaging to investigate for plaque formations. They should be questioned regarding constitutional symptoms of fatigue, weakness, difficulty moving or seeing after strenuous activity, and previous attacks.

Intravenous methylprednisolone (1 g/day for 3 days) followed by oral prednisone (1 mg/kg/day for 11 days) reduced the rate of MS development for 2 years (Optic Neuritis Study Group). Patients at high risk had a 44% reduction in the rate of developing MS when treated with interferon (Controlled High Risk Avonex Multiple Sclerosis Trial, CHAMPS). Newer treatments with interferon beta-1a (Avonex) and interferon beta-1b (Betaseron, Copaxone) have shown significant improvement in quality of life for patients and reduction in relapses. The Optic Neuritis Treatment Trial recommendations included giving patients with optic neuritis IV methylprednisolone (1 g/day) for 3 days, followed by 11 days of oral prednisone (1 mg/kg/day) (Beck et al., 1993). The dose is generally modified for children with 1 mg/kg/day whether using IV or oral steroids. Patients who receive oral rather than IV steroids for the first 3 days generally have more relapsing of their symptoms. Additionally, although corticosteroids hasten visual recovery, administration of steroids does not affect the overall visual acuity. The main benefit is delay of onset of multiple sclerosis.

Family physicians regularly encounter and manage a range of neurologic conditions. Many are fairly common in certain age groups, such as febrile seizures in children and Alzheimer's dementia in older adults. Other conditions, such as dysautonomia, are less common but present first to the primary care physician. This chapter discusses the neurologic disorders that family physicians are most likely to encounter, with guidelines for assessment and management.

Neurologic Examination

The neurologic examination begins with information obtained from the neurologic history, which is similar to a general medical history. The chief complaint is determined by asking open-ended questions. Analysis of the chief complaint should include the following:

- Date of onset
- Character and severity
- Location and extension
- Time relationship (acute, subacute, or chronic)
- Associated complaints
- Aggravating and alleviating factors
- Previous treatment and effects

The sequence of the events and their progression is helpful in localizing the lesion and developing a differential diagnosis. A brief neurologic review of systems should include questions about headaches, visual changes, weakness, sensory changes, gait disturbances, and bowel and bladder function. The past medical history, social history, and family history are reviewed as well.

Much of the initial neurologic examination, including cranial nerve testing, carotid artery auscultation, and reflex and sensory assessment, can be conducted with the patient

seated in a chair, on the bed, or on the examination table. Superficial reflexes, tests for meningeal irritability, and rectal examination are performed with the patient lying down. Gait, strength, and coordination can subsequently be evaluated with the patient standing. Traditionally, the neurologic examination is divided into five major areas: mental status, cranial nerves, motor system, sensory system, and reflexes.

Mental Status Examination

The mental status examination assesses appearance and behavior (including level of consciousness), speech and language, mood, thoughts and perceptions, and cognition. Speech abnormalities can interfere with the initial history. Abnormalities of speech include hearing deficits, aphasia (problems with understanding, thought, and word finding), and dysarthria (problems with articulation). *Aphasia* results from damage to the dominant hemisphere. *Wernicke's* aphasia refers to poor comprehension, with fluent but often meaningless speech. In *Broca's* aphasia, comprehension is preserved, but speech is nonfluent. Repetition, naming, reading, and writing are impaired in Wernicke's and Broca's aphasia. With *conductive* aphasia, there is a loss of repetition but preserved comprehension. Reading comprehension is thus relatively preserved, but reading aloud and writing are impaired. *Dysarthria* refers to difficulties with the production of speech caused by injury to the vocal cords, larynx, palate, tongue, or facial muscles. It is also seen with extrapyramidal or cerebellar lesions. Cognitive function is often assessed by tools such as the Mini-Mental State Examination, a simple, quick screening test for cognitive function. Errors in copying several simple drawings can be indicative of organic brain damage, particularly in those with dementia or parietal lobe damage.

Cranial Nerve Examination

The cranial nerve examination usually evaluates all cranial nerves, with the exception of CN I. CN I testing is generally reserved for patients with complaints of loss of smell or a closed-head injury. Smell can be decreased or lost in degenerative diseases, such as Parkinson's or Alzheimer's disease.

Cranial Nerve II (Optic Nerve)

The principal function of the optic nerve is vision. Testing of the optic nerve includes assessment of visual acuity and visual fields, funduscopic examination, and pupillary light reflex. Visual acuity is assessed in each eye individually. Visual fields are evaluated by confrontation. When performing the funduscopic examination, look for papilledema, hemorrhages, cholesterol emboli, and atrophy. Atrophy is characterized by a small, pale disc. Pupillary function assesses CNs II and III as well as sympathetic activity. The direct and consensual responses require CNs II and III to work correctly. If CN II is damaged, an afferent pupillary defect is often present. If the optic nerve is damaged, the light reflex is sluggish.

Cranial Nerves III (Oculomotor), IV (Trochlear), and VI (Abducens)

The principal functions of these nerves include ocular rotation, lid elevation (III), and pupillary constriction. CN III innervates the medial, inferior, and superior rectus muscles; the inferior oblique, which allows inward and upward gaze; and the levator palpebrae superioris muscle, which raises the upper eyelid. It also innervates the pupillary constrictor muscle. CN IV innervates the superior oblique muscle, which causes the eye to look inward and down. CN VI innervates the lateral rectus muscle.

To test ocular rotation, the patient should first be examined by looking straight ahead, to note any imbalances between the eyes. Next, ocular rotation of each eye is tested separately. First, abduction is tested with the patient following the examiner's finger horizontally; this tests the lateral rectus muscle. The patient then looks laterally and upward, to test the superior rectus, and downward, to test the inferior rectus. Adduction of the eye tests the medial rectus muscle. With the eye adducted, the patient looks up, to test the inferior oblique, and downward, to test the superior oblique.

The pupils should be observed for symmetry. Most unequal pupils (anisocoria) are congenital and not clinically significant. The light reflex, direct and consensual, is checked by shining a bright light directly into the pupil. The response to light should be brisk.

Cranial Nerve V (Trigeminal)

The principal functions of the trigeminal nerve include control of the muscles of mastication and sensation in the face, anterior half of the scalp, and mucous membranes of the mouth, nose, and sinuses. The nerve also mediates the afferent arc of the corneal reflex. The three sensory divisions are ophthalmic, maxillary, and mandibular. Each division is tested by light touch, pinprick, and temperature. The motor division of CN V can be assessed by palpating the jaw as the patient bites down. CN V is the afferent limb of the corneal

reflex, and CN VII is the efferent limb. This reflex is tested by lightly touching the cornea with a wisp of cotton; the reflex, integrated through the pons, results in brisk, bilateral eye closure.

Cranial Nerve VII (Facial)

The principal functions of the facial nerve are control of the muscles of facial expression and provision of taste for the anterior two thirds of the tongue. It also innervates the lacrimal, sublingual, and submaxillary glands. To test the facial nerve, the patient is asked to smile, close the eyes tightly, and wrinkle the forehead. Taste is tested on each side separately using bitter and sweet substances.

Cranial Nerve VIII (Vestibulocochlear Nerve)

The principal functions of the vestibulocochlear nerve are hearing and vestibular function. Hearing is tested one ear at a time. Testing of hearing can be done by comparing each side with a finger rub, watch tick, or vibration of a tuning fork. The Rinne test compares bone conduction with air conduction on both sides. A tuning fork is placed on the mastoid process to assess bone conduction and then in front of the ear to assess air conduction. Air conduction should be louder than bone conduction. The Weber test evaluates middle ear conduction. A vibrating tuning fork is placed on the forehead. With normal hearing, there should be equal sound in both ears. Sound lateralized to one side indicates a conductive loss on that side or a neural loss on the opposite side. Vestibular function is not routinely tested.

Cranial Nerve IX (Glossopharyngeal)

The principal function of CN IX is to supply sensation to the pharynx and tonsillar fossa and taste to the posterior one third of the tongue. Clinical testing is done by eliciting a gag reflex. It should be done on both sides of the pharynx.

Cranial Nerve X (Vagus)

The principal functions of the vagus nerve are motor control to the pharynx, palate, and larynx and parasympathetic innervation of the thoracic and abdominal viscera. Motor control is tested by observing for symmetric elevation of the palate. The uvula should not deviate. Vocal cord paralysis can present with hoarseness or dysphonia and can occur with injury to the recurrent laryngeal branch.

Cranial Nerve XI (Spinal Accessory)

The principal functions of this nerve are to allow turning of the head and assist in shrugging of the shoulders. It innervates the sternocleidomastoid and upper trapezius. Strength is tested by shrugging the shoulders and turning the head to both sides against resistance.

Cranial Nerve XII (Hypoglossal)

The principal function of the hypoglossal nerve is innervation of intrinsic muscles of the tongue. To test this nerve, ask the patient to protrude the tongue. It should be midline.

If not, it protrudes to the paretic side. Also, observe for atrophy or fasciculations of the tongue.

Motor Examination

The motor examination includes assessment of body position, strength, tone, involuntary movements, coordination, and gait. Strength is graded as follows:

5—Normal.

4—Weak but can overcome gravity plus some additional resistance.

3—Can overcome gravity but not additional resistance.

2—Can move joint but cannot overcome the force of gravity.

1—Muscle contracts, but with little or no joint movement.

0—No muscle contraction.

Muscle tone is tested by passively flexing and extending the arm or wrist. Abnormal responses include spasticity, rigidity and flaccidity. *Spasticity* refers to increased muscle resistance when the muscle is passively stretched. This is seen with lesions to the cortical spinal tract. *Rigidity* or *cogwheeling* is observed with extrapyramidal lesions and Parkinson's disease. *Flaccid* refers to the absence of muscle tone.

Muscular weakness can result from upper motor neuron (UMN) lesions, lower motor neuron (LMN) lesions, muscle disease, neuromuscular junction disorders, or functional weakness. UMN disease is characterized by increased tone and reflexes, whereas LMN disease presents with wasting, fasciculations, decreased tone, and absent reflexes. With neuromuscular junction disorders, the patient complains of fatigable weakness but has normal or decreased tone and normal reflexes. A patient with functional weakness has normal tone, normal reflexes without wasting, and erratic power. The motor examination also includes observation for any abnormal movements, including tremors, choreiform movements, myoclonus, and dystonia.

Gait should be examined, even if assistance is needed. Assessment includes stride length, arm swing, posture, and turning, starting and stopping. Watch for specific gait abnormalities, such as *hemiplegia*, which is seen with unilateral UMN damage; *spasticity*, in which both legs have UMN lesions; *steppage*, in which there is footdrop; *waddling*, caused by weakness of the trunk and pelvic girdle; and *parkinsonism*, characterized by a stooped posture, short steps, and flexed arms with decreased arm swing.

Balance is maintained by the cerebellum, proprioceptive system, basal ganglia, and vestibular system. The Romberg sign is tested with the patient standing with feet together and then with eyes closed. If the patient falls with eyes closed, the test is considered positive. A positive test indicates proprioceptive loss, which can be from a peripheral cause or a posterior column lesion. The Romberg test can be positive with cerebellar or vestibular disease. Postural stability can be checked by gently pushing the patient while the feet are together.

Coordination can be tested with simple tests. For the finger-to-nose test, ask the patient to extend the arm, touch the tip of the nose, and then touch the examiner's index finger. This is repeated after the examiner has moved the index finger several times. The heel-knee-shin test is performed by asking the supine patient to slide one heel smoothly down the opposite leg from knee to shin. Two other tests of

coordination are finger tapping and rapidly alternating hand movements. Injury to the cerebellar hemisphere impairs smooth coordination of limb movements on the same side of the body. With cerebellar lesions, these tests will be inaccurate, will have increased amplitude, and will be initiated more slowly.

Sensory Examination

The sensory examination requires an alert and cooperative patient. Sensory testing includes light touch, pinprick, proprioception, and vibration. Start by testing for light touch using a wisp of cotton or tissue on the major dermatomes of the extremities and trunk. Observe for dermatomal losses or a distal-to-proximal gradient. The same areas are then tested for superficial pain with a pin. Temperature is mediated by the same pathway as pain, so any deficits of pain sensation should have a corresponding deficit in temperature sensation. Vibration is tested by placing a 128-cycles/sec tuning fork on the bony prominences of the extremities and asking the patient to identify when it stops vibrating. Comparisons are made side to side. If there is a question of myelopathy, a vibration level may be noted as the tuning fork is moved up the spinous processes. Position is best tested using the great toe and distal phalanx of the thumb or another finger. The digit is grasped on the sides and moved up and down. Even a very slight movement of a finger should be detected. Proprioception, vibration, and light touch are functions of the dorsal column, and pain, temperature, crude touch, and pressure are functions of the spinothalamic tract.

Stereognosis, graphesthesia, and touch localization are integrated cortical sensations and are difficult to test if primary sensations are impaired. To test *stereognosis*, several small familiar objects are placed in the patient's hand and the patient is asked to identify them. To test *graphesthesia*, the examiner writes numbers on the patient's palm and asks the patient to identify them.

Reflexes

The reflex examination includes the deep tendon reflexes (DTRs) and the pathologic reflexes. In testing the deep tendon reflexes, it is important to look for symmetry. DTRs are graded using the following scale:

0—Absent

1—Present but diminished

2—Normal

3—Normal, but brisker than average

4—Increased and pathologic, with one or more beats of clonus

The DTRs assist with localization of a lesion because these reflexes are integrated at different levels of the spinal cord. DTRs help in distinguishing whether a lesion is a UMN lesion with pathologic hyperreflexia or possibly an LMN lesion with hyporeflexia. Table 42-1 summarizes the most important reflexes and their nerve root innervations.

The Babinski sign, or extensor toe sign, is tested by stroking the sole of the foot with a sharp object. A normal response is toe flexion. A pathologic response is extension of the great toe and flaring of the other toes. A positive response is always abnormal in patients older than 3 years and is a sign of pyramidal tract disorder.

Table 42-1 Nerve Root Innervations and Main Reflexes

| Root | Movement | Reflex |
|--------|--|-----------|
| C5 | Shoulder abduction, elbow flexion | Biceps |
| C6 | Elbow flexion | Supinator |
| C7 | Finger extension, elbow extension | Triceps |
| C8 | Finger flexors | Finger |
| T1 | Small muscles of hand | None |
| L1, L2 | Hip flexion | None |
| L3, L4 | Knee extension | Knee |
| L5 | Extension of great toe | None |
| S1 | Hip extension, knee flexion, plantar flexion | Ankle |

C, Cervical; T, thoracic; L, lumbar, S, sacral.

Neurologic Conditions

Headaches

Key Points

- More than 90% of men and women will have at least one headache each year.
- If there is a history typical of a particular primary headache with a normal examination, neuroimaging and electroencephalography are not necessary.
- Prophylactic treatment of migraine headaches is recommended when they occur with increasing frequency and there appears to be a potential overuse of acute therapies.
- Giant cell or temporal arteritis is a serious headache to consider in older adults and can be associated with blindness.

Headaches are a common problem encountered by family physicians. More than 90% of men and women will have at least one headache each year, and as many as 4.5 million Americans will experience recurrent headaches. The International Headache Society established a system for the classification of headaches to assist in diagnosis and treatment with a standard of care for family physicians. Migraine with aura, migraine without aura, tension, and cluster headaches constitute most primary headaches. Secondary headaches are symptoms of organic disease (Sarchielli, 2004). The initial evaluation of a patient with headache requires a complete history and physical examination with the following information:

- Age at onset
- Location, frequency, and duration
- Intensity and character
- Associated symptoms
- Triggering and ameliorating factors
- Medications
- Associated physical and neurologic symptoms
- Impact on work and family
- Psychological symptoms

- History of head trauma
- Previous imaging results
- Family history

Features of the history that should warn of an ominous cause for headache include the following:

Sudden onset of first headache

Worst headache ever

Late onset of new headache (after age 50 years)

Headache associated with fever, rash, or stiff neck

Progressively worsening headache

Headache associated with neurologic signs and symptoms other than aura

Headache associated with mental status changes

Headache associated with papilledema

Headache with exertion, sexual activity, coughing, or sneezing

The physical examination of a patient first presenting for evaluation of headache should include vital signs, cardiac examination, cervical spine examination, including nuchal rigidity, and ophthalmologic examination, including the optic fundi, pupils, and visual fields. The neurologic examination should include an assessment of cognitive function, motor function, reflexes, plantar response, cranial nerves, coordination, and gait.

If there is a history typical of a particular primary headache with a normal examination, neuroimaging and electroencephalography (EEG) are not necessary. A lumbar puncture, after neuroimaging, is recommended only if there is suspicion of subarachnoid hemorrhage, infection, or idiopathic intracranial hypertension (pseudotumor cerebri). Routine EEG is not indicated but may be useful in evaluating patients with associated mental status or consciousness changes, a history of head injury, or a history of syncope.

Migraine

Migraine headaches include migraine without aura, migraine with aura, and other migrainous disorders. Women suffer from migraines three times as often as men, and 90% of migraine sufferers have a positive family history. Migraines can begin in childhood, and as many as 4% to 10% of school-age children have migraines. The International Headache Society has developed diagnostic criteria for these types of headaches (Sarchielli, 2004). To establish a diagnosis of *migraine without aura*, there must have been at least five attacks fulfilling the following criteria:

1. Headache attacks lasting 4 to 72 hours
2. Headache with at least two of the following characteristics:
 - a. Unilateral location
 - b. Pulsating quality
 - c. Moderate or severe intensity (inhibits or prohibits daily activities or causes avoidance of routine)
 - d. Aggravated by physical activity such as walking or climbing
3. During the headache, at least one of the following occurs:
 - a. Nausea and vomiting
 - b. Photophobia and phonophobia

Migraine with aura has comparable diagnostic criteria but includes an aura. *Auras* can be a visual, sensory, motor, or speech aura. Visual changes include parallel zigzag lines and are often associated with scotomatous defects. Sensory

deficits can involve an ipsilateral arm or paraorbital numbness or tingling. The tongue may be involved in some patients. The sensation has a marching characteristic. Motor deficits can be similar to sensory in that the deficits spread from one area to another. Speech problems may manifest as a mild dysphasia.

Other migraine types include basilar-type migraine, retinal migraine, status migrainosus, and migrainous infarction. *Basilar-type migraine* aura symptoms are referable to the brainstem or bilateral hemispheres, including dysarthria, vertigo, tinnitus, diplopia, and bilateral paresthesias. Reversible monocular, positive or negative visual disturbances associated with migraine are characteristic of *retinal migraine*. A diagnosis of *status migrainosus* requires an ongoing migraine of at least 72 hours in duration. Neuroimaging evidence of a cerebral infarct associated with a migraine is indicative of *migrainous infarction*.

Treatment

Migraine headache management includes acute analgesia, pharmacologic prophylaxis, and nonpharmacologic management. Factors to consider before starting prophylactic medications include frequency, severity, and lack of response or contraindications to analgesic medications. Nonpharmacologic management includes identification and avoidance of triggering factors, stress management, regular sleep and exercise, and physical therapy. Factors that can aggravate or trigger migraines include alcohol, oral contraceptives, hormonal replacement, caffeine or caffeine withdrawal, stress, changes in weather, strong scents, foods (nitrates, dairy products, chocolate, aged cheese), and fasting or missing meals.

The goal of pharmacologic treatment is to reduce the patient's disability and maintain an acceptable quality of life. The choice of abortive drug therapy depends on the severity of the patient's symptoms. A plan can be developed with the patient to use some medications for mild to moderate attacks and other medications for more severe attacks. For mild attacks, combination medicines, such as aspirin, acetaminophen, and caffeine (Excedrin or generic equivalent) are effective. For more severe headaches, the triptans are the drugs of choice (the triptans are not indicated for basilar migraines or hemiplegic migraines) (Polizzotto, 2002).

Dihydroergotamine (DHE) and other ergotamine compounds are useful. Aqueous lidocaine applied intranasally is another option. Briefly, 0.5 mL of a 4% aqueous solution of lidocaine is slowly dripped into one nostril with the patient supine, head hyperextended 45 degrees, and rotated 30 degrees toward the side affected by the headache (Maizels et al., 1996). Antiemetics, such as metoclopramide or chlorpromazine, can be used in conjunction with most abortive medications (Table 42-2).

Prophylactic treatment of migraine is recommended when headaches occur with increasing frequency and the patient may be overusing acute therapies. The daily use of symptomatic medications, including acetaminophen and nonsteroidal anti-inflammatory drugs (NSAIDs), can cause liver and kidney injury. Also, regular use of certain medications (e.g., propoxyphene, butalbital, ergotamines, triptans) can result in habituation or rebound headaches. Preventive treatment is also recommended for patients who have

Table 42-2 Symptomatic Migraine Medications

| Drug Name | Dose Range | Adverse Effects |
|--|--|--|
| Acetaminophen, 325 mg; isometheptene, 65 mg; and dichloralphenazone, 100 mg (Midrin) | 2 capsules at onset, then qh for 3 hr | Liver toxicity, dizziness |
| Lidocaine 4% aqueous solution for nasal spray (Xylocaine) | 0.5 mL to nostrils, repeat after 2 min | None known |
| Ergotamine, 1 mg with caffeine, 100-mg oral tablets (Cafergot) | 2 tablets, then 1 every 30 min four times | Nausea, vasoconstriction, fetal harm |
| Ergotamine, 2 mg with caffeine, 100-mg suppository (Cafergot) | 1 rectally, up to 2 per attack | |
| Parenteral agents | | |
| Dihydroergotamine, 1 mg/mL (D.H.E. 45) | 0.5-1 mg IM, SC, or IV qh for 3 hr (2 hr for IV) | Nausea, vasoconstriction |
| Dihydroergotamine, 0.5 mg/mL (Migranal) | 0.5 mg spray in each nostril, repeat in 15 min | |
| Ketorolac (Toradol) | 15-30 mg IM or IV q6h | Gastrointestinal upset, renal toxicity |
| Selective Serotonin (5-HT) Agonists | | |
| Sumatriptan (Imitrex) | | |
| Autoinjector | 6 mg qh 12 mg/day | Chest and neck discomfort |
| Nasal spray | 5 or 20 mg q2h 40 mg/day | |
| Tablet | 50 mg q2h 300 mg/day | |
| Naratriptan (Amerge) | 2.5 mg q4h 5 mg/day | |

Table 42-3 Preventive Antimigraine Therapy

| Type of Drug | Dose Range | Adverse Effects |
|----------------------------------|-----------------|---|
| Beta-Adrenergic Blockers | | |
| Propranolol (Inderal) | 40-240 mg/day | Bronchospasm, bradycardia, hypotension, fatigue, depression |
| Timolol (Blocadren) | 10-30 mg/day | Bronchospasm, bradycardia, hypotension, fatigue, depression |
| Calcium Channel Blockers | | |
| Verapamil (Calan) | 240-480 mg/day | Hypotension, constipation, edema |
| Tricyclic Antidepressants | | |
| Amitriptyline (Elavil) | 10-150 mg/day | Sedation, dry mouth, weight gain, tremor, cardiac arrhythmias, difficulty voiding |
| Nortriptyline (Pamelor) | 10-150 mg/day | Sedation, dry mouth, weight gain, tremor, cardiac arrhythmias, difficulty voiding |
| Anticonvulsants | | |
| Divalproex sodium (Depakote) | 250-1000 mg/day | Nausea, fatigue, weight gain, hair loss, tremor, liver toxicity, fetal harm |
| Gabapentin (Neurontin) | 100-3600 mg/day | Fatigue |
| Topiramate (Topamax) | 25-200 mg/day | Fatigue, paresthesias, weight loss, memory loss, nephrolithiasis |
| Cyproheptadine | 4-16 mg/day | Drowsiness, dizziness, constipation, urinary retention |

frequent attacks, often four or more, throughout the month or when headaches are so severe that acute treatment is no longer completely effective. The overall goal of preventive treatment is to reduce the frequency and severity of migraine attacks. Prophylactic agents include beta-adrenergic blockers, calcium channel blockers, selective serotonin reuptake inhibitors (SSRIs), tricyclic antidepressants (TCAs), and anti-convulsant medications (Table 42-3). Beta blockers such as propranolol have proven efficacy in this role (Polizzotto, 2002).

Tension-Type Headaches

Tension-type headaches can be episodic or chronic. There is a slight female preponderance, and the prevalence may be directly related to socioeconomic status. Chronic tension headaches can sometimes develop in migraine patients and are frequently associated with overuse of analgesics. The International Headache Society has further subdivided

tension-type headaches into those with and without *pericranial tenderness* (Sarchielli, 2004). Headaches can be classified by cause, such as temporomandibular joint dysfunction, psychosocial stress, and analgesic overuse. Tension-type headaches require a comprehensive assessment to determine whether any comorbid conditions exacerbate the headache. The diagnostic criteria for episodic tension-type headaches include at least 10 previous headache episodes fulfilling the following criteria:

- Headaches lasting for 30 minutes to 7 days, with at least two of the following pain characteristics:
 - Pressing or tightening (nonpulsating) quality
 - Mild or moderate intensity
 - Bilateral location
 - No aggravation by walking, climbing stairs, or similar routine physical activity
- Both of the following:
 - No nausea or vomiting
 - Photophobia and phonophobia—both absent, or only one present

Frequently, the initial symptoms of a tension headache are described as a bandlike, squeezing, or tight pressure sensation. It is generally diffuse, often concentrated in the occipital region or in the temples. This can also be associated with depression or anxiety and aggravated by stress. No neurologic abnormalities should be noted in the history or physical examination.

A chronic tension headache requires that the pain be present for 15 days/month for more than 3 months. The other criteria are the same as those for episodic tension-type headaches.

The treatment for tension-type headaches is generally difficult. There is always the concern of analgesic abuse. Amitriptyline is frequently a reasonable drug choice, 10 to 100 mg daily. Muscle relaxants can be helpful as a short-term intervention when the pain extends into the shoulder trapezius muscles. In addition to therapeutic options, it is beneficial to use relaxation therapy, physical therapy, and stress management programs. Improvement of posture, stretching exercises, and even traction can be beneficial. On occasion, relief can be obtained with injections or occipital nerve blocks.

Medications can be used for abortive treatment and can include NSAIDs and analgesics with caffeine. The choice of medication depends on the severity and frequency of the headaches. Care needs to be used when prescribing butalbital-containing compounds, because their addiction potential is high. In addition, there is always the problem of analgesic overuse, which could lead to the development of chronic daily headaches.

Cluster Headaches

Cluster headaches are less common than migraines, and almost 80% of patients are male. Cluster headaches present with unilateral pain. Attacks may last 15 to 180 minutes and can occur every other day, up to eight times daily. The cycle may last for 4 to 12 weeks. These headaches frequently are triggered by alcohol, with some nausea. They tend to occur at a similar time during the day or night. The pain is frequently in the orbital or periorbital region. It is an extremely sharp, continuous, incapacitating pain.

The criteria for diagnosis include at least five attacks with the following elements:

1. Severe unilateral orbital or supraorbital pain lasting 15 to 180 minutes
2. Headache associated with at least one of the following ipsilateral signs in addition to the headache:
 - a. Conjunctival infection
 - b. Lacrimation
 - c. Nasal congestion
 - d. Miosis, ptosis
 - e. Eye edema
 - f. Forehead and facial sweating
 - g. Sense of restlessness or agitation
3. Frequency from every other day to eight times a day

Cluster headaches are unusual in that they may come at certain intervals throughout the year. Headaches may last for a few weeks and then disappear, or can become chronic and persist throughout the year.

Medications for the treatment of cluster headaches include some of the same drugs used for abortive treatment for migraines: DHE, ergotamines, intranasal 4% aqueous lidocaine solution, and triptans. The nasal and injectable forms have a more rapid onset of action than the oral preparations. Cluster headaches are also unusual in that they may respond to oxygen. Inhaled 100% oxygen can relieve an attack within 10 to 15 minutes.

For headaches that are intense, do not respond to abortive treatment, or require excessive use of abortive treatment, prophylaxis is recommended. Divalproex (Depakote) can be used for the treatment of the chronic cluster headache. Doses range up to 1000 mg/day in divided doses. A pulse dose of steroids can also be effective, as can verapamil.

Medication Overuse Headaches

Headache sufferers can begin to experience daily or almost daily headaches when medication doses are excessive or too frequent. Rebound can occur with opioids, acetaminophen, aspirin, analgesic-codeine or analgesic-barbiturate combinations, NSAIDs, ergotamines, and triptans. Characteristics of rebound headaches include a diffuse, bilateral, almost daily headache, often aggravated by mild physical or mental exertion. The headache is frequently present on waking and can be associated with restlessness, nausea, forgetfulness, and depression. Tolerance develops to abortive medications, and there is decreased responsiveness to preventive medications.

Treatment of rebound headaches can be difficult. The causative medications must be identified, and there may be some psychological as well as physical dependence. The key to treatment is to discontinue the overused medication and thus break the cycle. Stopping the medication may result in withdrawal symptoms and an initial period of increased headaches, with subsequent improvement. Patients may need to be hospitalized to stop the medication. Specific limits need to be set for the use of analgesics, ergotamines, and triptans to reduce the likelihood of rebound headaches.

Miscellaneous Headaches

Episodic and chronic *paroxysmal hemicrania* is an unusual headache that tends to occur in women. The attacks are short, and the pain is similar to that of a cluster headache.

These headaches respond to indomethacin, with a maximum of 150 mg/day in divided doses.

Posttraumatic headaches can follow a head injury, with presentation similar to migraine headache. No clear correlation appears to exist between intensity of the head trauma and development of headache. These headaches may be associated with dizziness and impaired concentration. Treatment is difficult, but many of the migraine compounds are effective.

Trigeminal neuralgia is described as a piercing, sudden, severe pain that can last for seconds to minutes in the area of the cheek or jaw and can be aggravated by chewing or talking. Treatment options include carbamazepine, oxcarbazepine, baclofen, and gabapentin. Surgical intervention is an option when medical treatment fails.

Headaches in Older Adults

A serious headache that presents in the older adult population is *giant cell arteritis*, or temporal arteritis. The pain can be bimodal or unilateral, moderate to severe in intensity, and is diffuse, not always throbbing, and persists throughout the day and often worsens at night. This headache is often associated with systemic complaints (e.g., weight loss, joint tenderness) and can be aggravated with jaw movement. It is important to treat giant cell arteritis because it can be associated with blindness. The Westergren erythrocyte sedimentation rate (ESR) is frequently elevated. If temporal arteritis is suspected, a diagnostic temporal artery biopsy is performed. It is important not to delay treatment while waiting for the biopsy. Steroid treatment can be initiated up to 2 weeks before the biopsy without compromising the results. The patient with headache of giant cell arteritis requires high doses of prednisone, usually for several months or longer.

Ophthalmic zoster is another type of head pain in the older adult. The pain is described as a burning, constant, piercing, shocklike pain. It follows the distribution of the trigeminal nerve. This is a difficult headache to treat, but it responds well to anticonvulsants, particularly carbamazepine and gabapentin.

Glaucoma can cause a migrainelike headache, with severe pain around the affected eye.

Stroke (Cerebrovascular Accident)

Key Points

- Strokes usually occur without warning, and less than 20% of CVAs are preceded by a warning TIA.
- Stroke risk factors include hypertension, smoking, atrial fibrillation, internal carotid artery stenosis, and diabetes.
- The time-related cellular death in areas of hypoperfusion requires reperfusion to reverse the ischemic penumbra.
- Both dipyridamole (plus aspirin) and clopidogrel are reasonable first-line antiplatelet agents for secondary stroke prevention.
- During the first day after an ischemic stroke, most patients with elevated blood pressure should not be treated unless systolic is consistently higher than 220 or diastolic is consistently higher than 120 mm Hg.

Cerebrovascular accident (CVA, stroke) is the third leading cause of death in the United States and the leading cause of significant disability in adults. About 750,000 new cases of

stroke occur each year. Despite a decline in ischemic stroke rate (which accounts for most strokes), the absolute number of strokes in the United States continues to rise. This continued annual increase is the result of an increase in the mean age of the population. Current projections predict 1 million strokes each year in the United States by 2050. The mortality rate for CVA is about 15%, and only slightly less than one third of patients who suffer a stroke regain normal cerebral function. Furthermore, the recurrence rate for patients who survive a stroke is about 10% per year. Thus, CVA remains a major public health problem in the United States (Benavente and Hart, 1999; Hart and Benavente, 1999).

Stroke is generally defined as the rapid onset of a neurologic deficit involving a certain vascular territory that lasts longer than 24 hours. A *transient ischemic attack* (TIA) is similarly characterized by the rapid onset of a neurologic deficit, but it generally lasts for less than 24 hours, and usually for only minutes. CVAs may be of ischemic or hemorrhagic origin, whereas TIAs are generally ischemic events. Statistically, most patients have ischemic rather than hemorrhagic strokes. About two thirds of ischemic strokes are caused by thrombosis, and slightly less than one third are caused by embolus. *Ischemic* strokes result from many causes, including intracranial atherosclerosis, cervical carotid artery stenosis, and occlusive disease of the small, penetrating arteries, leading to lacunar infarcts. *Hemorrhagic* strokes are generally related to intracranial or subarachnoid hemorrhage, with intracranial hemorrhages being more common. No specific cause is identified in as many as 30% of patients with stroke; patients with cryptogenic CVA are often younger.

Strokes usually occur without warning, and less than 20% are preceded by a warning TIA. Patients with a previous TIA or CVA have a 4.5% to 6.6% annual risk for subsequent stroke. The risk for CVA after a retinal TIA (amaurosis fugax) is much lower than that after a hemispheric TIA.

Risk Factors

Hypertension

Patients with a systolic blood pressure (SBP) higher than 160 mm Hg or a diastolic blood pressure (DBP) higher than 95 mm Hg have a fourfold increased risk of stroke compared with the general population. Decreasing DBP by as little as 5 mm Hg reduces the relative risk of CVAs by 43%, and a decrease of 10 mm Hg results in a 50% relative risk reduction. Treatment of older adults with isolated SBP elevations higher than 160 mm Hg reduces their risk of stroke and is usually well tolerated if approached carefully.

Smoking

Cigarette smoking is an independent risk factor for CVA. The risk of stroke is almost twice as high for smokers, and the relative risk of subarachnoid hemorrhage is almost three times as high as for the general population.

Atrial Fibrillation

Clinical trials continue to demonstrate the benefits of warfarin for primary and secondary stroke prevention among high-risk patients with nonvalvular atrial fibrillation. The CVA risk in patients with atrial fibrillation is reduced by about two thirds when they are treated with warfarin

adjusted to achieve a target international normalized ratio (INR) of 2 or 3.

Hypercholesterolemia

The role of cholesterol reduction in stroke prevention is not clear. Large observational studies have failed to implicate increased cholesterol as an independent risk factor for CVA. Statins are effective for the primary prevention of ischemic stroke for patients with a history of occlusive arterial disease, coronary artery disease (CAD), or diabetes, without a history of cerebrovascular disease. Statins reduce the risk of ischemic stroke in hypertensive patients with multiple cardiovascular risk factors and nonfasting cholesterol levels lower than 250 mg/dL, reduce CVA risk for patients with CAD or equivalent (e.g., diabetes, peripheral artery disease), and prevent recurrent ischemic stroke in CAD patients (Busch et al., 2004). Statins have also been shown to reduce the incidence of CVA and TIA in patients without preexisting CAD (Amarenco et al., 2006).

Carotid Artery Stenosis

Patients with internal carotid artery stenosis of less than 75% have an annual risk of stroke of approximately 1.3%. In contrast, patients with internal carotid stenosis greater than 75% have annual TIA risk of 7.2% and annual CVA risk of 3.3%. Patients with asymptomatic carotid stenosis have a relatively low rate of ipsilateral stroke, probably about 2% per year (Norris et al., 1991). Select patients with asymptomatic carotid stenosis may benefit from carotid endarterectomy. The Asymptomatic Carotid Atherosclerosis Study (ACAS) showed a benefit from endarterectomy in patients with a stenosis more than 60%, although the overall benefit was relatively small (Young et al., 1996). A low perioperative complication rate is crucial if endarterectomy is to offer asymptomatic patients a beneficial option. Carotid angioplasty and stenting are emerging as viable alternatives to carotid endarterectomy but are limited to patients at high risk for endarterectomy. When used with an embolus protection device, the safety and efficacy of carotid stenting has been established and its noninferiority compared with endarterectomy has been demonstrated. When medical management is elected, it should include control of hypertension, smoking cessation, education regarding the symptoms of TIA, efforts to identify and treat existing CAD, antiplatelet therapy, statin therapy, and serial carotid ultrasound studies to monitor the progression of carotid stenosis.

The management of symptomatic carotid artery stenosis—that is, cervical carotid stenosis associated with ipsilateral focal ischemic events—is less controversial. Clinical trials consistently demonstrate the benefits of carotid endarterectomy for patients with high-grade (70%) cervical carotid stenosis who are symptomatic. Conversely, symptomatic patients with mild (<50%) carotid stenosis do not benefit from surgery. Patients with moderate stenosis obtain a moderate benefit from surgery. These patients may be appropriately treated with surgery or medical therapy, depending on the clinical judgment of the treating physicians. Physicians should remember that women have a lower incidence of subsequent stroke than men with similar degrees of carotid stenosis. Women also have higher rates of perioperative complications than men.

Diabetes

Diabetic patients who suffer stroke tend to be younger and have a higher incidence of intracerebral bleeding. There is no evidence that controlling the hyperglycemia decreases the incidence of stroke.

Acute Intervention

When oxygen deprivation occurs, neuronal cellular death occurs within minutes. Thus, in nonperfused areas of the brain, necrosis results in minutes. These areas of necrosis are typically surrounded by areas of decreased blood flow. This diminished blood flow may be barely enough to keep the neurons in these areas alive. Such areas of hypoperfusion are electrically silent and are referred to as the *ischemic penumbra*. If timely reperfusion of the ischemic penumbra occurs, these neurons can recover. However, failure to reperfuse the ischemic penumbra promptly results in time-related neuronal cell death and transformation of an area of hypoperfusion into an area of frank infarction. Resuscitation of the ischemic penumbra is therefore a primary goal of acute stroke management. Because of the time-related cellular death that occurs in areas of hypoperfusion, interventions aimed at reperfusing the ischemic penumbra must be instituted expeditiously if maximal benefit is to be realized.

Many agents and interventions have been under investigation for the treatment of acute stroke. Although therapeutic options for acute stroke management are expanding, *tissue plasminogen activator* (t-PA) is currently the only specific medication validated for this purpose by clinical trials and labeled for this use by the U.S. Food and Drug Administration (FDA). The National Institute of Neurologic Disorders and Stroke recommends t-PA for acute intervention in select stroke patients (NINDS, 1995). The t-PA trials showed substantial improvement in long-term functional outcome for patients treated with t-PA within 3 hours of ischemic stroke onset, compared with the placebo group (NINDS, 1997). For every 100 patients given t-PA, 12 more experienced complete neurologic recovery than those receiving placebo. However, there was an approximately 6% increase in intracerebral hemorrhage in t-PA recipients, not all of which are symptomatic. This risk of intracerebral hemorrhage increased significantly if computed tomography (CT) demonstrated early infarction changes. More recently, the European Cooperative Acute Stroke Study III has demonstrated that the time window for administration of t-PA can be safely and effectively extended to 4.5 hours in select patients. Those older than 80, those with a history of stroke and diabetes, those taking oral anticoagulants, and those with NIH Stroke Scale greater than 25 are excluded from this extended timeframe.

The administration of t-PA for the treatment of acute stroke requires strict adherence to established eligibility criteria, emergency CT capability with experienced interpretation, and 24-hour intensive care unit monitoring (Box 42-1). The limit from stroke onset to treatment with t-PA must be respected, whether the patient meets criteria for the 3-hour time window or the 4.5 hour time window. If a patient wakes from sleep with a neurologic deficit, the stroke must be assumed to have had its onset at the time sleep commenced. If the exact time of stroke onset is in question, t-PA should not be given. Patients and their families should understand that although treatment of acute ischemic stroke with t-PA

Box 42-1 Criteria for t-PA Use in Patients with Thromboembolic Stroke

Considering t-PA as Treatment Option

Age \geq 18 years
 Noncontrast CT without evidence of hemorrhage
 Time since onset of symptoms clearly $<$ 3 hours (4.5 hours for select patients) before t-PA administration would begin

Excluding t-PA as Treatment Option

Historical and Clinical Findings

Clinical presentation suggests subarachnoid hemorrhage, even if CT is normal:

- Sudden, severe headache, often with loss of consciousness at onset

- Vomiting common

Active internal bleeding, increased risk of bleeding, or known bleeding diathesis, including:

- Recent use of warfarin with prolonged INR

- Use of heparin within 48 hours with prolonged aPTT

- Platelet count $<$ 100,000 cells/mm³

- History of intracranial hemorrhage

- Known arteriovenous malformation or aneurysm

- GI or GU bleeding in past 21 days

- Arterial puncture in past 7 days at noncompressible site

Recent lumbar puncture

Stroke, intracranial surgery, or head trauma in previous 3 months

Major surgery or serious trauma in preceding 14 days

Persistent systolic blood pressure $>$ 185 or diastolic $>$ 110 mm Hg

Seizure at stroke onset

Rapidly improving neurologic signs

Isolated, mild neurologic deficits

Acute myocardial infarction (MI)

Post-MI pericarditis

Blood glucose $<$ 50 mg/dL or $>$ 400 mg/dL

Patient pregnant or lactating

CT Findings

Evidence of intracranial hemorrhage

Hypodensity or effacement of the sulci in one third of the region of the middle cerebral artery

t-PA, Tissue plasminogen activator (alteplase [Activase]); aPTT, activated partial thromboplastin time; CT, computed tomography; INR, international normalized ratio; GI, gastrointestinal; GU, genitourinary.

is potentially beneficial, there is an approximately 1 in 15 chance of suffering a serious cerebral hemorrhage, even if t-PA is used in accordance with strict guidelines. They should also understand that although patients with severe ischemic strokes have the most to gain from t-PA, they also have a higher risk of t-PA-associated intracerebral hemorrhage. Finally, the CT must not demonstrate intracranial bleeding if t-PA is to be given, and some experts recommend withholding t-PA if the CT demonstrates evidence of early infarction.

In some referral centers, intra-arterial thrombolysis is also a treatment option. Such intervention extends the treatment window to 6 hours, principally because of the lower dose of t-PA administered and the ability to deliver the agent directly into the clot. Additionally, mechanical removal of intra-arterial thrombus is also a treatment option, using a

corkscrew-like mechanism (Merci device) or a suction mechanism (Penumbra device) to extract the clot and thereby reestablish blood flow to the ischemic penumbra.

Pharmacologic Therapy

Published studies to date overwhelmingly support the ability of *aspirin* to reduce stroke incidence and death in patients who present with TIA or CVA. Aspirin and other agents that affect platelet function are frequently used for long-term secondary stroke prevention. It therefore seems reasonable, after hemorrhage has been excluded by CT, to begin aspirin therapy in the setting of acute stroke, provided the patient does not have a contraindication to aspirin therapy. Aspirin doses between 50 and 1300 mg/day have been shown to be effective for stroke prevention. In the absence of convincing evidence favoring a specific dosage, most clinicians prescribe 81 or 325 mg/day. The FDA recommends that aspirin doses of 50 to 325 mg/day be used for stroke prevention.

Clopidogrel (Plavix) inhibits platelet function by irreversibly binding to adenosine diphosphate receptors. Compared with aspirin, clopidogrel significantly decreases the constellation of CVA, myocardial infarction (MI), and vascular death and has a toxicity comparable with that of aspirin. Thrombotic thrombocytopenic purpura (TTP) has been reported after the initiation of clopidogrel, often within the first 2 weeks of therapy (Bennett et al., 2000).

Dipyridamole (Persantine) was widely used in combination with aspirin in the early 1980s for the prevention of stroke until critical analysis cast doubt on its efficacy. A European study found high-dose sustained-release dipyridamole plus aspirin to be superior to aspirin alone for the prevention of stroke (Diener et al., 1996). The side effects of this therapy included headache and required discontinuation in approximately 6% of patients.

Selection of the appropriate antiplatelet agent for stroke prevention can become complicated, especially for patients with comorbid cardiovascular disease. Both extended-release dipyridamole plus aspirin (Aggrenox) and clopidogrel (Plavix) are reasonable first line antiplatelet agents for secondary stroke prevention, shown to be more effective than aspirin alone. Randomized controlled trials (RCTs) have shown no additional benefit of the combination of clopidogrel and aspirin, which only increase the risk of hemorrhage.

The use of *heparin* therapy for the prevention of recurrent TIA or stroke progression is limited. Progression of CVA is common, occurring in 15% to 20% of carotid-distribution strokes and 35% to 40% of vertebrobasilar CVAs. Even in patients with angiographically minimal or absent cerebral artery occlusion, clinical worsening of neurologic findings frequently occurs. Furthermore, heparin has not been shown in adequate clinical trials to improve clinical outcome among patients with stroke. The International Stroke Trial (IST, 1997) reported that patients receiving subcutaneous heparin had fewer recurrent ischemic strokes, but this improvement was offset by an increase in hemorrhagic strokes. There was no net benefit. Trials with heparinoids have also failed to demonstrate a clear benefit and have shown an increased risk of non-central nervous system (non-CNS) bleeding. Studies have also failed to demonstrate a clear benefit for low-molecular-weight (LMW) heparin.

Box 42-2 Cardiac Conditions Substantially Associated with Embolism

| |
|--|
| Atrial fibrillation |
| Mitral stenosis |
| Mechanical cardiac valves |
| Recent myocardial infarction |
| Left ventricular thrombus, especially if mobile and protruding |
| Atrial myxoma |
| Infective endocarditis |
| Dilated cardiomyopathy |
| Marantic (nonbacterial thrombotic) endocarditis |

Currently, *warfarin* (Coumadin) cannot be recommended as initial therapy for most patients with stroke of primarily cerebrovascular origin. In two large-scale RCTs of warfarin compared with aspirin in the prevention of recurrent stroke (SPIRIT, WARSS), warfarin was not superior to aspirin for patients without cardioembolic disease or operable carotid stenosis (Sacco et al., 2006). Furthermore, the hemorrhagic risk with warfarin was higher than with aspirin. In contrast to ischemic stroke, there is good evidence that warfarin is beneficial for patients with several major cardiac disorders predisposing them to embolic stroke. Box 42-2 summarizes cardiac conditions that are substantially associated with cardioembolic stroke and often warrant prophylactic therapy with warfarin. Other cardiac conditions, such as mitral valve prolapse with or without myxomatous changes, severe mitral annular calcification, and calcific aortic stenosis, have a low or uncertain risk of embolism, and warfarin therapy is generally reserved for secondary prevention.

Management of Acute Stroke

Initial Management in Emergency Department

Patients suspected of having suffered an acute stroke should be stabilized in accordance with usual emergency management, which focuses initially on basic cardiopulmonary resuscitation (CPR) and support. All patients should have a thorough but timely physical examination, looking especially for head and neck trauma and cardiovascular abnormalities, followed by neurologic evaluation, including assessment of mental status, cranial nerve function, cerebellar function, and motor and sensory function, using the NIH Stroke Scale. Initial laboratory studies should generally include determination of a complete blood count (CBC) with differential and platelet count, prothrombin time and partial thromboplastin time (PT/PTT), electrolyte, blood urea nitrogen (BUN), creatinine, and glucose levels, oxygen saturation by pulse oximetry, and a metabolic panel. Depending on the clinical history, some patients should have studies for possible altered coagulation or connective tissue diseases. A CT scan of the head should be obtained expeditiously to evaluate for hemorrhage. Most patients should have additional studies, including electrocardiography (ECG), chest radiography, echocardiography, and carotid duplex ultrasonography. Consultation with neurology, speech therapy, physical therapy, occupational therapy, and social services should be considered (Box 42-3).

Box 42-3 Initial Treatment Considerations for Stroke Patients**Provide Initial Care.**

Stabilize the patient, secure the airway, and provide adequate oxygenation.

Assess level of consciousness, language, visual fields, eye movements, and pupillary movements.

Obtain history and perform physical examination.

Perform CT of head without contrast.

Obtain CBC with platelets and differential, electrolytes, creatinine, BUN, glucose, PT/PTT, and oxygen saturation.

Consider Toxicology Screen.

Consider special coagulation studies such as antiphospholipid antibodies, factor V Leiden assay, protein C and protein S, antithrombin III, ANA, fibrinogen, RPR, homocysteine, serum protein electrophoresis, prothrombin gene 20210.

Consider Acute Intervention with T-PA.**Consider the Following with Admission Orders:**

Transesophageal echocardiography

Carotid duplex ultrasonography

Telemetry

Supplemental oxygen and appropriate oxygen saturation monitoring

Antiplatelet therapy

Fluid restriction if infarct is large, to reduce cerebral edema

Close monitoring of intake and output

Regular determinations of blood glucose levels to avoid hyperglycemia
NPO until there is certainty about the gag reflex pending swallowing evaluation

Elevate head of bed 20 to 30 degrees to reduce cerebral edema.

Bed rest for first 24 hours with fall precautions, then advance as appropriate.

Vital signs and neurologic checks every 2 hours \times 4, then every 4 hours for 24 hr

Prophylaxis for DVT while immobile

Speech therapy consultation to evaluate swallowing

Neurology, physical therapy, occupational therapy, nutrition, and social services consultations

ANA, Antinuclear antibodies; BUN, blood urea nitrogen; CBC, complete blood count; CT, computed tomography; DVT, deep vein thrombosis; NPO, nothing by mouth; PT/PTT, prothrombin time/partial thromboplastin time; RPR, rapid plasma reagin; t-PA, tissue plasminogen activator.

Elevated Blood Pressure

During the first day after an ischemic stroke, elevated blood pressure (BP) should not be treated unless systolic is consistently higher than 220 mm Hg or diastolic is consistently higher than 120 mm Hg. There are exceptions to this recommendation. Patients who have received t-PA should have BP maintained below 185/110 mm Hg, and patients with MI, heart failure, aortic dissection, or renal failure should have more aggressive BP control. Areas of cerebral ischemia lose their normal autoregulatory capacity, and tissue perfusion becomes directly linked to mean arterial pressure. When cerebral ischemia occurs, BP elevations are often transient and spontaneous declines common. Overzealous BP treatment can therefore convert an area of ischemia that retains the potential for recovery into an area of frank infarction with no potential for recovery.

Box 42-4 Antihypertensive Agents for Patients with Acute Stroke**Labetalol (Normodyne)**

10 mg intravenously (IV) over 1 to 2 minutes; may repeat or double dosage every 10 to 20 minutes until blood pressure controlled or maximum dose of 300 mg has been reached.

100 mg orally twice daily

Nicardipine (Cardene)

5 mg/hr IV, titrated upward as necessary, typically to a maximum of 15 mg/hr

Sodium nitroprusside (Nipride)

0.3 μ g/kg/min IV, titrated upward as necessary, typically to a maximum of 10 μ g/kg/min

When antihypertensive agents are used shortly after CVA, one with rapid action and predictable response, such as nicardipine (Cardene), labetalol (Normodyne), or sodium nitroprusside, should be chosen (Box 42-4). Nicardipine is currently considered first-line treatment in this setting. Labetalol is preferable to sodium nitroprusside because of nitroprusside's ability to cause cerebral vasodilation, which can worsen cerebral edema in some patients. Sublingual calcium channel antagonists should be avoided because of their ability to cause precipitous BP declines, which could significantly reduce cerebral blood flow and result in further ischemic damage.

Cerebral Edema

Cerebral edema usually peaks within 2 to 4 days after a stroke. It is seldom a problem during the first 24 hours, except in cases of large cerebellar CVAs. Steroids are not used to treat cerebral edema related to thromboembolic strokes. Steroids are generally ineffective and may exacerbate hyperglycemia and raise BP. Cerebral edema related to thromboembolic stroke is first treated by raising the head of the bed 20 to 30 degrees. Hyperventilation can work rapidly to reduce *intracranial pressure* (ICP) but has only a transient effect. Mannitol can be given to lower ICP at 0.25 to 0.5 g/kg intravenously (IV) over 30 minutes, but its use is controversial because of possible pooling in the area of ischemia and potential worsening of edema. Mannitol can rapidly lower ICP and can be repeated every 6 hours. The maximum dose of mannitol is 2 g/kg IV. Hypertonic saline has also been used to reduce cerebral edema in this context. Hemicraniectomy with durotomy is performed for malignant MCA-distribution infarct in select cases and has been shown to improve survival and functional outcome.

Other Management Issues

Hypoxia should be avoided. Any circumstance that is likely to impair oxygen delivery to the ischemic penumbra needs to be avoided. Patients with acute stroke should therefore have their oxygen saturation monitored, and supplemental oxygen provided if desaturation occurs.

The use of subcutaneous heparin for the prevention of *deep venous thrombosis* (DVT) in nonhemorrhagic stroke patients has been well accepted. Heparin should be dosed based on weight. LMW heparin is a reasonable alternative in this setting. Intermittent pneumatic compression stockings are the best prophylactic alternative for patients unable to receive

anticoagulants. Patients able to ambulate 50 feet daily are at low risk for venous thromboembolism.

Fever is seen quite often after an acute stroke. Regardless of cause, fever should be reduced, because ischemic cerebral insults accompanied by even mild elevations in body temperature have been associated with less favorable outcomes in both experimental models and clinical studies.

Hyperglycemia can be harmful for the ischemic penumbra because it permits anaerobic metabolism, which results in local generation of lactic acidosis. Serum glucose levels should generally be maintained below 150 mg/dL. Nevertheless, it should be recognized that controlling blood glucose has not been shown to improve stroke outcome in humans.

Patients who suffer a *seizure* after a stroke have a higher mortality. Some believe that such patients should receive anticonvulsant therapy indefinitely, whereas others note that a trial off medication after several years without seizure activity seems reasonable.

Delirium

Key Points

- A confused older adult patient should generally be assumed to have delirium until proved otherwise.
- Delirium is a transient, global disorder of cognition and consciousness; changes in consciousness typically develop quickly and fluctuate during the day.
- Underlying dementia is a significant risk factor for delirium.
- The history, physical examination, and test results usually suggest a cause for delirium.
- Delirium is best managed by correction of the causative disturbances.

Delirium is a common problem encountered in patients seen by family physicians, especially in the hospital or skilled nursing facility. Delirium is characterized by a change in cognition and attention that develops rapidly, usually over hours to days, and fluctuates throughout the day. It may present as *hyperactive delirium*, with agitation, disorientation, and delusions; *hypoactive delirium*, demonstrated by the lethargic patient who is difficult to arouse and engage in conversation; or a mixed-type delirium with features of both. Hypoactive delirium is the most common encountered form of delirium, which may explain why it goes unrecognized in up to 70% of patients experiencing delirium (Gillis et al., 2006). Because of this, any confused older adult patient should generally be assumed to have delirium until proved otherwise. Delirium is a serious condition that has long-term ramifications, including increased hospital length of stay, increased mortality, failure to return to baseline cognitive and functional status, and increased need for prolonged, skilled nursing facility care. **Box 42-5** summarizes risk factors for the development of delirium. Two thirds of delirium cases occur in patients with underlying dementia, placing these patients at significant risk when being treated for other health problems (Cole, 2004).

The mainstay of treatment for delirium is to identify and correct the underlying cause. This cause can usually be determined through a thorough history, physical examination, and evaluation of selected laboratory tests. **Box 42-6**

Box 42-5 Risk Factors for Development of Delirium

- Age >65 years
- Chronic kidney disease
- Dehydration
- Dependence with activities of daily living
- Hearing impairment
- Infection
- Malnutrition
- Multiple comorbid conditions
- Polypharmacy
- Underlying dementia
- Vision impairment

Box 42-6 Common Causes of delirium

- Dehydration
- Electrolyte abnormalities
- Infection
- Myocardial infarction
- Heart failure
- Neurologic disorder (stroke, seizure)
- Hypoxia
- Medications (anticholinergics, antihistamines, antidepressants, benzodiazepines, narcotics)
- Intoxication
- Environmental changes (change in location or caregiver, overstimulation)
- Pain
- Sleep deprivation
- Surgery
- Urinary catheter
- Urinary retention
- Fecal impaction

summarizes some of the common causes that should be considered. Special attention should focus on recently started medications. Although almost any medication can precipitate delirium, analgesics, antiarrhythmics, antidepressants, Parkinson's medications, and anticholinergic medications such as antihistamines, benzodiazepines, β -blockers, calcium channel blockers, steroids, diuretics, clonidine, and digoxin are common culprits. A targeted laboratory evaluation should be undertaken, including a CBC, determination of electrolytes, BUN, creatinine, glucose, calcium, magnesium, phosphate, and liver function tests (LFTs). Oxygenation should be assessed by oximetry or arterial blood gases (ABGs). ECG should be considered, especially for patients with angina, dyspnea, or a cardiac history. A chest x-ray film and urinalysis to evaluate for occult infection, especially in older-adult patients, should also be considered.

If this evaluation does not elicit a likely cause for a patient's delirium, further testing may be necessary. Additional laboratory studies to consider include thyroid function tests, human immunodeficiency virus (HIV) testing, rapid plasma reagin (RPR) test, drug levels, toxicology screening, serum ammonia level, and serum vitamin B₁₂ level. Lumbar puncture is usually reserved for patients with fever and signs

suggesting meningitis. Neuroimaging may be indicated for patients with new neurologic signs or a history of head trauma. EEG may be helpful in the evaluation of patients with a suspected seizure disorder or to differentiate delirium from a functional psychiatric disorder.

Delirium can be treated with both nonpharmacologic and pharmacologic measures. Environmental modifications should be instituted early, before pharmacologic intervention or mechanical restraint is considered. A supportive and familiar environment should be created for the patient. Family members should be encouraged to remain nearby as much as possible. The staff should visit the patient frequently or move the patient to be near them. The room should be well illuminated, with a large, easily read clock and calendar. The family should bring familiar items from home to be placed in the patient's room. Whenever possible, normal sleep hygiene patterns should be maintained with minimal interruptions during the night hours.

Pharmacologic management of delirium should be considered when the previous treatments have failed to control agitation and should involve the use of antipsychotic medications. Among the antipsychotic agents, haloperidol (Haldol) at 1 to 2 mg orally every 4 hours as needed, or 0.25 to 0.5 mg orally every 4 hours for elderly patients, is recommended (American Psychiatric Association, 1999). Other antipsychotic medications, such as risperidone (Risperdal), 0.5 to 1 mg orally daily, and olanzapine (Zyprexa), 2.5 to 5 mg orally daily, may also be used; as yet, no RCTs have established the safety and effectiveness of one antipsychotic medication over another for the management of delirium symptoms (Seitz et al., 2007). Risperidone and olanzapine do not work as quickly as haloperidol, often require slow titration, and can be associated with significant orthostasis. More recent studies have also demonstrated a potentially elevated risk of mortality in older adults with dementia who were treated with atypical antipsychotics (Schneider et al., 2005). Therefore, these risks must be considered when initiating pharmacologic treatment for delirium. Further recommendations for initiating antipsychotics for the treatment of delirium include using the lowest possible doses, frequent reassessments to limit the duration of antipsychotic use, and a baseline ECG to rule out susceptibility to an arrhythmia from a prolonged QT interval (Seitz et al., 2007). Lorazepam (Ativan), a benzodiazepine, has also been used for the treatment of agitation associated with delirium, although a Cochrane review concluded that benzodiazepines cannot be recommended for the treatment of non-alcohol-related delirium (Lonergan et al., 2009). Physical restraints should be a last resort, reserved for the protection of patients who do not adequately respond to environmental and pharmacologic interventions.

Dementia

Key Points

- Dementia is a gradual, progressive impairment of memory and other cognitive functions that is severe enough to impact work, social activities, and relationships.
- Dementia can be divided into four categories: Alzheimer's disease (60% of cases), dementia with Lewy bodies (15%), vascular dementia (15%), and all other causes (10%).

- Comprehensive, longitudinal, well-coordinated care delivered by the family physician for both the patient and the caregiver is the cornerstone of effective management of patients with dementia.
- The cholinesterase inhibitors are effective in slowing the progression of cognitive and functional decline and may be used in conjunction with memantine (NMDA receptor antagonist) to treat moderate to severe dementia.

Dementia is characterized by the development of an acquired impairment in memory associated with impairment in one or more cognitive domains, including executive function, language (expressive or receptive), *praxis* (learned motor sequences), or *gnosis* (ability to recognize objects, faces, or other sensory information). The impairments are severe enough to interfere with work, social activities or relationships (American Psychiatric Association, 1994). The course is usually one of gradual, progressive decline and causes impairment in the ability to perform activities of daily living (ADLs). The incidence of dementia increases with age. By 75 years, 10% to 15% of people have dementia, increasing to 35% to 50% for those over 85.

Classification and Pathophysiology

Dementia is usually divided into four main categories. Dementia of Alzheimer's type accounts for approximately 60% of cases; dementia with Lewy bodies, 15%; and vascular dementia, 15%. The remaining category includes multiple other forms, including mixed dementias that exhibit components of both Alzheimer's and vascular dementia and dementias resulting from CNS trauma, Parkinson's disease, Pick's disease, Creutzfeldt-Jakob disease, and Huntington's disease.

Alzheimer's disease patients have brains that demonstrate atrophy with ventricular and sulcal enlargement. They reveal evidence of neuronal loss as well as the presence of amyloid plaques and neurofibrillary tangles. Amyloid plaques are composed of misfolded β -amyloid that initiates a pathogenic cascade resulting in neurotoxicity and nerve cell death.

Dementia with Lewy bodies is similar to Alzheimer's disease, but visual hallucinations and motor symptoms similar to parkinsonism develop early in the course of the disease. Histologically, Lewy bodies are present, cytoplasmic inclusions found in the temporal, parietal, and paralimbic regions of the brain.

Vascular dementia is usually subdivided into multi-infarct dementia and subcortical vascular dementia. *Multi-infarct dementia* should be suspected when focal, asymmetric neurologic abnormalities accompany dementia. Neuroimaging may show multiple strokes. *Subcortical vascular dementia* should be suspected if the patient manifests significant problems with gait early in the course of the dementia. The CT or magnetic resonance imaging (MRI) scan is usually normal in these patients, except for increased signal in the deep white matter, a nonspecific sign.

Evaluation

The diagnosis of dementia is still made clinically, so evaluation of a patient with suspected dementia begins with a complete history and physical examination. The history should include questions regarding the time frame surrounding

symptom progression. The relation to any recent vascular events such as stroke should be noted. Risk factors for vascular disease (hypertension, diabetes, hyperlipidemia, atrial fibrillation, smoking history) should be reviewed. Changes in the ability to perform ADLs should also be addressed. The patient's ability to perform dressing, eating, ambulating, toileting, and bathing tasks should be recorded as independent, requiring assistance, or dependent. The physical examination should include a thorough neurologic examination for signs of underlying vascular disease and stroke. Cognitive testing should be done, ideally with the Mini-Mental State Examination, which allows for quantification of cognitive impairment over time (Table 42-4). A score less than 24 is considered abnormal, but because of educational bias, highly educated patients may have inflated scores and those with limited education artificially low scores (Tombaugh, 1992).

When considering which tests to perform as part of the evaluation of a patient with dementia, physicians have traditionally been taught to search for reversible causes of dementia. It is now recognized that reversible dementia rarely occurs (Sloane, 1998). Current recommendations for laboratory testing generally recommend that all patients be evaluated with a CBC, thyroid-stimulating hormone (TSH), serum calcium, electrolytes, and fasting glucose, as well as a serum B₁₂ level. Selective testing based on the presenting medical history, physical examination, and cognitive testing may include a red blood cell (RBC) folate level, RPR for syphilis screening, and HIV antibodies. Testing for

homocysteine levels and genetic testing for apolipoprotein E gene is not recommended (Feldman, 2008). Although neuroimaging is not recommended for all patients in the workup of dementia, selective use of CT or MRI is recommended for patients with suspected tumor, subdural hematoma, or normal-pressure hydrocephalus (NPH) (Feldman et al., 2008).

Management

Comprehensive, longitudinal, well-coordinated care delivered by the family physician for both the patient and the caregiver is the cornerstone of effective management of patients with dementia. Patients should be seen regularly in the office, and the physician should be readily available by telephone. The family should maintain frequent contact with the patient and physician. The family physician should update vaccinations, monitor visual acuity and hearing, and address other appropriate health issues. Families should be counseled regarding behavioral and environmental modifications that may be helpful, including reducing hazards in the home for falls and injuries. A discussion regarding the timing of cessation of driving should be undertaken early in the course of treatment. Decisions regarding advanced directives and planning for the later stages of the disease should begin early in the process as well. The patient should legally designate a durable power of attorney for health care. The discussion of the placement of feeding tubes should begin before difficulties with feeding develop. Families should be aware that feeding tubes do not prolong life, are associated with discomfort and medical complications, and are generally not recommended for patients in the final stages of a dementing illness (Li, 2002). The role of palliative care and hospice care should also be discussed early in the course of the illness, when the patient has the opportunity to participate in the decision-making process.

Pharmacotherapy

The cholinesterase inhibitors donepezil (Aricept), galantamine (Razadyne), and rivastigmine (Exelon) have received FDA approval for the treatment of patients with Alzheimer's disease. Tacrine (Cognex), which is associated with elevated liver transaminase levels in about 30% of patients, is rarely used. The cholinesterase inhibitors act by blocking acetylcholinesterase breakdown of acetylcholine, believed to increase acetylcholine in affected areas of the brain. All these agents show comparable response rates, and choice is therefore individualized according to patient and caregiver needs as well as the drug's side effect profile. Pharmacologic effectiveness is measured by a slowing of the decline in cognitive and global functioning over 6 to 12 months. The cholinesterase inhibitors are generally well tolerated, although side effects include nausea, vomiting, diarrhea, dyspepsia, anorexia, weight loss, bradycardia, and agitation. When these medications are discontinued, the patient may experience a rapid decline in global functioning.

Another medication, memantine (Namenda), an *N*-methyl-D-aspartate (NMDA) receptor antagonist, has been FDA approved for the treatment of moderate to severe dementia as monotherapy or in combination with a cholinesterase inhibitor (Reisberg, 2003). Memantine appears to have fewer

Table 42-4 Mini-Mental Status Examination

| Max Score* | Task |
|------------|--|
| 5 | Orientation: Year, season, date, day, and month. |
| 5 | Orientation: State, county, town, building, and floor (as applicable) |
| 3 | Registration: Name three objects. Record the number of trials required to learn. |
| 5 | Attention and calculation: Serial 7 subtraction: Subtract from 100 by 7 (stop after 5 answers) or Spell the word "world" backward (score number of correct letters in correct location). |
| 3 | Recall: Recall the three objects registered above. |
| 2 | Language: Name two objects (pencil and watch). |
| 1 | Repeat "No ifs, ands, or buts." |
| 3 | Follow a three-step command. |
| 1 | Read and obey: "Close your eyes" written in print large enough for patient to see clearly. |
| 1 | Write a sentence. |
| 1 | Copy a picture of intersecting pentagons. |

*Total possible score: 30.

side effects than the cholinesterase inhibitors, although dizziness, insomnia, and hallucination may be seen. Alternative agents such as *Ginkgo biloba*, nicotine, vitamin C, and vitamin E could be beneficial in the treatment of Alzheimer's disease. At present, however, no other prescribed medication, supplement, or herbal preparation can be recommended for the cognitive or functional manifestations of dementia (Hogan et al., 2008).

Seizures

Key Points

- Febrile seizures usually occur between age 3 months and 5 years and represent the most common convulsive disorder of young children (2%-5%).
- Risk factors for a first febrile seizure include family history, developmental delays, high fever, and child care attendance.

One in 11 Americans who lives to the age of 80 years experiences at least one seizure. About 1% of the U.S. population have epilepsy or recurrent unprovoked seizures. Treatment of patients with epilepsy reduces the risk of recurrent seizures while optimizing quality of life. This requires minimizing the adverse effects of antiepileptic medications and maximizing the patient's ability to engage in normal activities and responsibilities (Scheuer and Pedley, 1990).

Seizures are a manifestation of disturbed neurologic function and therefore often associated with acute neurologic disorders such as meningitis. In some patients the seizures are self-limited and resolve when an acute neurologic disturbance resolves. In others the seizures persist and result in a diagnosis of epilepsy. Some patients who appear medically and neurologically normal after appropriate evaluation may experience a single seizure and the cause never determined. Such patients do not have epilepsy.

Seizures are typically classified as partial or generalized. *Partial*, or *focal*, seizures arise in a portion of one cerebral hemisphere and are accompanied by focal EEG abnormalities, whereas *generalized* seizures appear to involve simultaneously all or large parts of both cerebral hemispheres from their onset. Partial seizures are subclassified according to whether consciousness is preserved (simple partial seizures) or impaired (complex partial seizures). Generalized seizures are subclassified by their associated patterns of convulsive movements (Box 42-7).

It is not always possible to classify accurately a seizure based exclusively on clinical observations. A seizure with generalized convulsive activity may have a focal onset with rapid generalization. Such a seizure would best be classified as a partial seizure with secondary generalization, rather than as a generalized tonic-clonic seizure. Accurate classification of such a seizure could not be accomplished, however, without EEG. Also, not every paroxysmal event that appears to be a seizure is a seizure. Movement disorders, psychological disorders, and sleep disorders can produce activity that is similar to seizure activity. Thus, accurate seizure diagnosis often requires both clinical observation and corroborative EEG. Because EEG is usually done in the absence of seizures, certain steps should be taken to increase its diagnostic yield. Both sleep and sleep deprivation increase the likelihood of recording epileptiform abnormalities by EEG. Obtaining

multiple recordings can also increase the diagnostic yield. In some cases, accurate diagnosis can be accomplished only with continuous video and EEG monitoring. A small number of patients with seizure disorders have normal interictal EEG recordings, despite efforts made to record epileptiform abnormalities.

Febrile Seizures

Febrile seizures are seizures without a definite cause that are associated with fever. Febrile seizures, by definition, do not include seizures occurring in patients with an intracranial infection, such as meningitis or encephalitis, toxic encephalopathy, or any other neurologic illness. The definition also excludes seizures associated with fever that occur in patients who have a history of a previous nonfebrile seizure. Febrile seizures usually occur in children between the ages of 3 months and 5 years and represent the most common convulsive disorder of young children, affecting 2% to 5% of U.S. children. The most common age of onset is in the second year of life, and boys are affected slightly more often than girls (Freeman and Vining, 1995; Hirtz, 1997).

Risk factors for a first febrile seizure include a family history of febrile seizures, developmental delays, very high fever, and child care attendance. Approximately one third of children who experience a first febrile seizure will experience at least one more. The younger the child when the first febrile seizure occurs, the more likely the child is to have another febrile seizure. Most recurrences occur within 1 year. A family history of febrile seizures also increases the likelihood of recurrence. Fortunately, less than 5% of children who experience a febrile seizure develop epilepsy.

Febrile seizures can be of any type, but are most often tonic-clonic. Febrile seizures are usually shorter than 6 minutes, and fewer than 8% last longer than 15 minutes. Most children therefore do not come to the attention of the family physician until after the seizure is over. Although it is commonly believed that the rate of fever increase is an important factor in the development of febrile seizures, no data support this as being more important than fever severity.

Box 42-7 Seizure Classification

Partial Seizures

Simple (consciousness is preserved)

Complex (consciousness is impaired)

Secondarily generalized

Complex partial seizures evolving to generalized tonic-clonic

Simple partial seizures evolving to complex partial, then to generalized tonic-clonic

Generalized Seizures

Tonic-clonic

Absence

Atypical absence

Myoclonic

Tonic

Atonic

The evaluation of a child who has had a febrile seizure should begin with a careful history and physical examination. The history should include symptoms of infection, medication use, toxic ingestions, developmental and health problems, prenatal/birth and family history, and detailed description of the seizure by witnesses. The physical examination should pay particular attention to signs of severe illness, including petechiae, meningismus, tense or bulging fontanelle, Kernig's and Brudzinski's signs, and signs of neurologic abnormality, including decreased alertness or cognition and deficits of motor strength or tone. Even in children with a previous history of febrile seizures, a seizure associated with fever may be a sign of an intracranial infection. If intracranial infection is suspected, a *lumbar puncture* (LP) should be performed. Otherwise, LP is not necessary. Children older than 18 months who have meningitis or encephalitis usually demonstrate typical clinical signs and symptoms. Many of these children lack histories, symptoms, or signs suggesting meningitis and thus do not require LP. However, children younger than 12 to 18 months may lack the typical clinical signs and symptoms of intracranial infection and are more likely to require LP. If a child is already taking antibiotics and experiences a seizure associated with fever, partially treated meningitis should be considered. The presence of a source of infection, such as otitis media, does not exclude the possibility of meningitis. Other features in the history that should also raise suspicion of meningitis in children with seizures and fever include evaluation for illness by a physician within the past 48 hours, a seizure that occurs in the office or emergency department (ED), or a focal seizure.

Most children with febrile seizures do not require routine laboratory testing. The only laboratory studies needed are those that will assist in evaluating the source of the child's fever. Radiography of the skull, neuroimaging studies such as CT and MRI, and EEG are not usually indicated. Children who are diagnosed with a febrile seizure should be observed in the ED or physician's office for several hours. These children may then be sent home, provided (1) they demonstrate satisfactory clinical improvement and are alert, (2) their fever has been appropriately evaluated and treated, and (3) close outpatient follow-up is possible. If there is any question about intracranial infection, if a child does not demonstrate expected clinical improvement during observation, or if follow-up cannot be ensured, hospital admission is recommended.

One of the most important components of outpatient management of children with febrile seizures is education of the parents. Seizures are frightening events for most parents. They should be reassured that febrile seizures do not result in brain damage and that the risk of epilepsy is very low. Slightly more than one in six children, however, experience another seizure within 24 hours, and about one in three experiences another febrile seizure at some point. If another seizure occurs, parents should be advised to place the child on his or her side or face down on the abdomen. Contrary to common belief, they should not attempt to place anything between the child's teeth during a seizure. The parents should carefully observe the child, and if the seizure does not spontaneously resolve after 10 minutes, they should call 9-1-1. Parents may have concerns about routine vaccinations for children with a history of febrile seizures. The diphtheria and tetanus toxoids and pertussis (DTP) and measles,

mumps, and rubella (MMR) vaccinations are most likely to produce fever associated with seizure. If a febrile seizure is going to occur after vaccination, it is most likely to occur within 48 hours of the DTP vaccination or within 10 days of the MMR vaccination.

Initial Diagnostic Evaluation of a First Seizure in Adults

A careful history and physical examination, along with routine blood work, can detect many medical problems that may be associated with seizures. Such problems include infection, electrolyte and glucose abnormalities, impaired hepatic or renal function, and cardiopulmonary disease. Most patients with new-onset seizures should have a CBC with platelet count and differential, toxicology screen, thyroid function testing, PT/PTT, determination of serum transaminase, electrolyte, calcium, magnesium, phosphorus, BUN, creatinine, glucose, ABGs, or pulse oximetry. If cardiopulmonary disease is suspected, ECG and chest radiograph should be obtained. Meningitis or encephalitis suspected clinically indicates LP, which is otherwise not necessary. Patients usually recover rapidly after a first seizure, and their clinical progress can be gauged after several hours of observation. Hospitalization is not usually necessary after a first seizure unless an underlying illness is suspected or there are concerns about the patient's clinical progress, inadequate social support or observation, or patient's ability or motivation to complete outpatient follow-up.

Patients with new-onset seizures should be scheduled for appropriate EEG and neuroimaging studies. MRI and CT are important complements to EEG because of their ability to identify structural abnormalities that may be related to the development of seizures. MRI is preferable to CT because of its superior ability to identify cortical architectural abnormalities, visualize the temporal lobes, detect gliomas, and identify cavernous malformations. CT, however, is appropriate in the emergency setting because it is readily available and can detect hemorrhages acutely. If the patient is seen in the office shortly after a first seizure, neuroimaging does not need to be performed immediately unless the history and physical examination suggest focal brain injury or marked cognitive impairment. In contrast to MRI and CT, positron emission tomography (PET) and single-photon emission CT (SPECT) can provide functional views of the brain. These studies can identify areas of relative hypoperfusion or hypometabolism that appear to be structurally normal but might play an important role in the development of partial seizures. Although such studies can be useful, especially for patients with conditions such as localization-related epilepsy, they are not routinely obtained or widely available.

Pharmacologic Therapy

Whether antiepileptic drug therapy should be initiated after a first seizure remains a topic of debate. The data regarding the likelihood of recurrent seizures after a first seizure are wanting or questionable, and estimates of the rate of recurrence after a single unprovoked seizure range widely. Certain findings and characteristics do seem to increase the likelihood of recurrence after a first seizure, including EEG abnormalities, previous neurologic injury, partial seizures, and a

family history of seizures. Also, it is not known whether anti-epileptic pharmacologic therapy following a single seizure alters the subsequent risk of epilepsy. Because of these uncertainties and because antiepileptic pharmacologic therapy is associated with a significant incidence of adverse effects, often exceeding the risk of recurrent seizures, many family physicians elect not to prescribe antiepileptic medications for most patients after a single seizure.

Although many agents are available for the treatment of seizures, carbamazepine (Tegretol), phenytoin (Dilantin), phenobarbital, and divalproex (Depakote) have been traditional first-line therapies for most patients with epilepsy. Increasing availability of newer agents to treat seizures has often resulted in more favorable side effect profiles. Phenobarbital is the oldest agent but has certain disadvantages. Its adverse effects include irritability, decreased cognition, and hyperactivity or lethargy. The degree of sedation and cognitive effects produced at therapeutic dosages are frequently significant enough that many family physicians do not prescribe phenobarbital as a first-line agent. The recommended dosage for common antiepileptics and adverse effects are summarized in Table 42-5. Most patients with epilepsy can achieve remission with the use of a single medication. Because the addition of another antiepileptic agent is usually associated with an increase in adverse drug effects, patients not controlled with one agent should be given a trial of a different agent rather than combining agents early in the course of treatment. Treatment with more than one agent is usually attempted only after a number of trials of monotherapy have failed.

Family physicians should exercise caution when measuring levels of antiepileptic drugs. Therapeutic ranges for most antiepileptics are only guidelines for treatment. Some patients achieve therapeutic remission without significant side effects with drug concentrations ordinarily toxic. Other patients develop intolerable side effects with subtherapeutic serum levels. Serum levels of most antiepileptic drugs should generally be determined when remission of seizures is achieved or the patient develops significant side effects. Drug concentrations can also provide evidence of compliance. More frequent serum testing is necessary for patients taking more than one agent, pregnant women, older adults, patients with hepatic or renal dysfunction, and patients taking medications for other medical problems. Box 42-8 lists drugs used to treat other medical conditions that can lower the seizure threshold. Nevertheless, serum levels should not be the primary basis for decisions regarding antiepileptic drug dosing. Seizure control and the development of adverse effects related to drug therapy are more important than serum levels alone.

Status Epilepticus

Status epilepticus is generally defined as more than 30 minutes of unconsciousness and continuous or intermittent, generalized seizure activity. However, because most seizures last 2 minutes or less, any seizure longer than 5 minutes may progress to status epilepticus. Patients with recurrent seizures without recovery to wakefulness should also be considered to be in status epilepticus. Status epilepticus can be alarming to observe, even for experienced clinicians. A systematic approach to patients in status epilepticus can facilitate

optimal patient care during such an episode. The first step in the management of patients with status epilepticus is to support vital functions. The airway should be protected. Although the patient should be intubated if necessary, this usually requires neuromuscular blockade, and bag and mask ventilation is often preferable. The patient's vital signs should be closely monitored, including continuous oximetry and ECG. Supplemental oxygen at a rate of about 4 L/min is recommended. Intravenous access should be secured for the administration of parenteral medications and blood drawn for a CBC, toxicology screen, and determination of electrolyte, glucose, calcium, magnesium, and anticonvulsant drug levels. The patient should receive thiamine, 100 mg IV, followed by 50 mL of D50W.

If the patient continues to seize, parenteral agents may be given, including lorazepam, 0.1 mg/kg IV at 2 mg/min, or diazepam, 0.2 mg/kg (max 10 mg) at a maximum rate of 5 mg/min. These agents have a relatively rapid onset and short duration of action. Simultaneous loading with phenytoin is therefore recommended. Phenytoin is loaded at 20 mg/kg IV at a rate of less than 50 mg/min through a line infusing glucose-free saline, to avoid precipitation of phenytoin in the line. Fosphenytoin (Cerebyx) is the prodrug of phenytoin and has a more favorable safety profile compared with phenytoin, can be given at a faster rate (150 mg/min), and converts to phenytoin after first-pass metabolism, but it is more costly than phenytoin. Blood pressure and cardiac rhythm must be closely observed because of the ability of phenytoin to precipitate hypotension and heart block. If these side effects appear, they often resolve when the rate of administration is decreased. If seizures continue despite these measures, phenobarbital may be administered parenterally. As a last resort, barbiturate coma or general anesthesia can be instituted. Propofol (Diprivan) and midazolam (Versed) administered as continuous IV drips are often used in neurocritical care settings to induce coma for status epilepticus.

Central Nervous System Infection and Inflammation

Key Points

- Bacterial meningitis is a neurologic emergency.
- Acute bacterial meningitis has a high morbidity and mortality.
- Antibiotic therapy should be started as soon as possible after meningitis is considered likely, usually by CSF analysis.
- Knowing the most prevalent organisms that cause bacterial meningitis in different age groups is important in guiding therapy.
- Gram stain of CSF is recommended for all patients with suspected bacterial meningitis.
- Adjunctive dexamethasone therapy for infants, children, and adults who have already received antibiotics is not recommended.

Bacterial Meningitis

Acute bacterial meningitis has a high morbidity and mortality rate, even under the best circumstances. For this reason, prompt recognition of the clinical syndrome, performance of appropriate testing to confirm the diagnosis, and initiation of appropriate therapy are essential.

Table 42-5 Common Antiepileptic Agents

| Agent | Usual Dosage | Adverse Effects |
|---------------------------|--|--|
| Carbamazepine (Tegretol) | Start: 3 mg/kg/day (adults), 5 mg/kg/day (children) Maintenance: 5-20 mg/kg/day (adults), 20-40 mg/kg/day (children) Usually divided qid | Drowsiness or agitation, diplopia and blurred vision, disequilibrium, benign leukopenia, hepatic failure, rare SIADH, rare aplastic anemia |
| Phenytoin (Dilantin) | Start: 4-6 mg/kg/day (adults), 3-10 mg/kg/day (children) Maintenance: same Usually divided tid | Dose related: nausea and vomiting, nystagmus, ataxia Not dose related: gingival hyperplasia, hirsutism, acne, coarsening of features, hepatic failure, osteomalacia |
| Divalproex (Depakote) | Start: 10-15 mg/kg/day Maintenance: 15-30 mg/kg/day Usually divided bid-qid | Transient GI side effects Toxic effects: tremor, thrombocytopenia Side effects: weight increase, alopecia, hepatotoxicity (controversial whether LFTs detect in time to avoid), pancreatitis |
| Phenobarbital | Starting and maintenance: 1-3 mg/kg/day (adults) and -5 mg/kg/day (children) Usually given in single or divided doses | Lethargy, sedation, decreased cognition, decreased attention, hyperactivity, depression |
| Levetiracetam (Keppra) | Start: 1000 mg/kg/day (adults), 20 mg/kg/day (children) Maintenance: max 3000 mg/day (adults), 60 mg/kg/day (children) Usually divided bid | Depression, hostility, aggressive behavior, psychosis, somnolence, headache, URI symptoms, infection, fatigue, irritability |
| Oxcarbazepine (Trileptal) | Start: 600 mg/day (adults), 16 mg/kg/day (children) Maintenance: max 2400 mg/day (adults), 60 mg/kg/day (children) Usually divided bid | Hyponatremia, hypersensitivity reaction, leukopenia, thrombocytopenia, angioedema, Stevens-Johnson syndrome, dizziness, somnolence, diplopia, headache, nausea, ataxia |
| Lamotrigine (Lamictal) | Start: dosing varies with concomitant anti-epileptics Maintenance: max 400 mg/day Usually divided bid | Rash, Stevens-Johnson syndrome, angioedema, neutropenia, pancreatitis, dizziness, headache, ataxia, nausea, somnolence |
| Tiagabine (Gabitril) | Start: 4 mg/day (adults/children >12 yr) Maintenance: max 56 mg/day Usually divided bid-qid | CNS depression, seizures, weakness, rash, dizziness, asthenia, somnolence, nausea, diarrhea, tremor, confusion, impaired concentration |
| Gabapentin (Neurontin) | Start: 300 mg/day (adults), 10 mg/kg/day (children) Maintenance: up to 3600 mg/day (adults), 50 mg/kg/day (children) Usually divided tid | Leukopenia, depression, dizziness, somnolence, ataxia, fatigue, peripheral edema, weight gain, tremor, diarrhea |
| Pregabalin (Lyrica) | Start: 150 mg/day (adults) Maintenance: up to 300 mg/day Usually divided bid-tid | Thrombocytopenia, hypersensitivity reaction, angioedema, dizziness, somnolence, ataxia, peripheral edema, weight gain |
| Lacosamide (Vimpat) | Start: 100 mg/day (adults) Maintenance: up to 400 mg/day Usually divided bid | Syncope, atrial fibrillation (rare), dizziness, headache, diplopia, vomiting, fatigue, ataxia |
| Rufinamide (Banzel) | Start: (Lennox-Gastaut) 10 mg/kg/day (children) Maintenance: 45 mg/kg/day Usually divided bid | Suicidality, seizures, QT shortening, hypersensitivity reaction, leukopenia, somnolence, vomiting, headache, dizziness, nausea |
| Vigabatrin (Sabril) | Start: (infantile spasms) 50 mg/kg/day (children) Maintenance: up to 150 mg/kg/day Usually divided bid | (Restricted in U.S.) permanent vision loss, anemia, neuropathy, headache, dizziness, fatigue, somnolence, weight gain |

LFTs, Liver function tests; SIADH, syndrome of inappropriate secretion of antidiuretic hormone; URI, upper respiratory infection; CNS, central nervous system; bid, twice daily; tid, three times daily; qid, four times daily.

Most adult patients (85%) present with the classic triad of fever, headache, and neck stiffness (Roos et al., 1997). Other symptoms include nausea and vomiting (35%), seizures (30%), cranial nerve palsies, and other focal neurologic signs (10%-20%). Meningismus (50%) may be subtle or marked, as with Kernig's sign (resistance to knee extension after flexion of hip and knees by examiner) or Brudzinski's sign

(involuntary flexion of knees in supine patient in response to rapid neck flexion by examiner) (Tunkel and Scheld, 1997). Other symptoms include nuchal rigidity, lethargy, photophobia, confusion, sweats, and rigors. Papilledema occurs in less than 1% of patients during the early phases of the disease. When papilledema is present early, an alternative diagnosis such as a brain abscess or mass lesion should be sought.

Box 42-8 Drugs that Can Lower Seizure Threshold

Theophylline
 Isoniazid
 Tricyclic antidepressants
 Penicillin
 Phenothiazines
 Diphenhydramine
 Pseudoephedrine
 Cocaine
 Amphetamines
 Alcohol (withdrawal)
 Benzodiazepines
 Barbiturates (including phenobarbital)

Not all patients present with the classic signs and symptoms. Neonates may present with poor feeding or weak sucking response, irritability, vomiting, temperature instability (hyperthermia or hypothermia), diarrhea, and apnea. Nuchal rigidity and meningismus are not reliable signs in children younger than 1 year (Prober, 1996). A bulging fontanelle may occur late in the disease, and seizures occur in 40% of neonates. A maculopapular rash that later becomes petechial and purpuric on the extremities should suggest meningococcal meningitis. Older-adult patients may have a more insidious presentation, with variable meningeal signs, change in mental status, lethargy, obtundation, and no fever.

The host is an important determinant of susceptibility to meningitis. Obvious risk factors include a history of recent open trauma, surgery (especially neurosurgery), and burns. Closed-head trauma can cause cerebrospinal fluid (CSF) leaks, which have been associated with pneumococcal meningitis. Common predisposing factors include otitis media (most common), sinusitis, mastoiditis, alcoholism, perinatal exposure, and nonimmunized, immunocompromised, or asplenic status (Swartz, 1997).

Knowing the most prevalent organisms that cause bacterial meningitis in the various age groups is important in guiding empiric therapeutic choices (Table 42-6). The three most common pathogens for community-acquired bacterial meningitis are *Haemophilus influenzae*, *Neisseria meningitidis*, and *Streptococcus pneumoniae*, accounting for about 80% of cases in the United States. Until the development of the *H. influenzae* type b (Hib) vaccine in the early 1990s, this was the most common bacterial meningitis, occurring in almost 50% of cases. As a result, *S. pneumoniae* and *N. meningitidis* have become relatively more common, especially in the pediatric population. *Escherichia coli* has been superseded by group B streptococci as the most common cause in infants during the first months of life. Other common pathogens include *Listeria monocytogenes*, *Klebsiella pneumoniae*, *Staphylococcus aureus* and *S. epidermidis*, other gram-negative bacilli, and other streptococci.

Initial Management

The Infectious Disease Society of America (IDSA) practice guidelines call for prompt blood cultures and lumbar puncture for most patients with suspected acute bacterial meningitis (Tunkel et al., 2004). Nevertheless, emergency LP may not be successful or prudent because of overriding

Table 42-6 Common Pathogens of Bacterial Meningitis Based on Age

| Age | Pathogens |
|------------|--|
| 0-1 mo | Group B streptococcus, <i>Listeria monocytogenes</i> , <i>Escherichia coli</i> , <i>Streptococcus pneumoniae</i> |
| 1-3 mo | Group B streptococcus, <i>E. coli</i> , <i>L. monocytogenes</i> , <i>S. pneumoniae</i> , <i>Neisseria meningitidis</i> , <i>Haemophilus influenzae</i> |
| 3 mo-18 yr | <i>H. influenzae</i> , <i>N. meningitidis</i> , <i>S. pneumoniae</i> |
| 18-50 yr | <i>H. influenzae</i> , <i>N. meningitidis</i> , <i>S. pneumoniae</i> |
| >50 yr | <i>S. pneumoniae</i> , <i>L. monocytogenes</i> , gram-negative bacilli |

Table 42-7 Criteria for Adult Patients with Suspected Bacterial Meningitis Recommended for CT before LP

| Criterion | Comment |
|---------------------------------|--|
| Immunocompromised state | HIV infection or AIDS, receiving immunosuppressive therapy, or after transplantation |
| History of CNS disease | Mass lesion, stroke, or focal infection |
| New-onset seizure | Within 1 week of presentation; some authorities would not perform LP on patients with prolonged seizures or would delay LP for 30 minutes in patients with short, convulsive seizures. |
| Papilledema | Presence of venous pulsations suggests absence of increased intracranial pressure. |
| Abnormal level of consciousness | — |
| Focal neurologic deficit | Includes dilated nonreactive pupil, abnormalities of ocular motility, abnormal visual fields, gaze palsy, arm or leg drift. |

From Tunkel AR, Barry J, Hartman SL, et al. Practice guidelines for the management of bacterial meningitis. *Clin Infect Dis* 2004;39:1267.

CT, Computed tomography; LP, lumbar puncture; HIV, human immunodeficiency virus; AIDS, acquired immunodeficiency syndrome; CNS, central nervous system.

concerns about a CNS mass lesion or other cause of increased ICP, necessitating CT before LP. In these patients, blood samples should be drawn and appropriate antibiotic and adjunctive therapy provided before LP or CT (Table 42-7).

The LP is the foundation of the diagnosis of bacterial meningitis. In adults, opening pressure is typically 200 to 500 mm H₂O, although lower values may be observed in infants and children. Table 42-8 illustrates typical CSF findings. Gram stain is recommended for all patients, because it permits rapid organism identification in 60% to 90% of patients with community-acquired bacterial meningitis, with a specificity of more than 97% (Tunkel et al., 2004). Other rapid diagnostic tests, such as latex agglutination, and limulus lysate assay have not shown clinical usefulness in diagnosis

Table 42-8 Typical Cerebrospinal Fluid Findings in Bacterial and Viral Meningitides

| Parameter | Bacterial Meningitis | Viral Meningitis |
|--|--|--|
| Opening pressure (mm H ₂ O) | >180 | Often normal or significantly elevated |
| Leukocyte count (cells/mm ³) | 1000-10,000 Median: 1195 Range: 100-20,000 | <300 Median: 100 Range: 100-1000 |
| Neutrophils (%) | >80 | <20 |
| Glucose (mg/dL) | <40 | >40 |
| Protein (mg/dL) | 100-500 | Often normal |
| Gram stain (% positive) | 60-90 | Negative |
| Culture (% positive) | 70-85 | 50 |

or management of bacterial meningitis. Polymerase chain reaction (PCR) assay to amplify DNA may be helpful, particularly for patients with negative Gram stains. The serum C-reactive protein (CRP) concentration may be particularly helpful for patients with findings consistent with meningitis, but for whom the Gram stain is negative and withholding antibiotics is being contemplated, because a normal CRP has a high negative predictive value (Tunkel et al., 2004).

Additional laboratory studies include CBC, platelet count, PT, PTT, ABGs, and determination of electrolyte, protein, glucose, BUN, and creatinine levels. Further laboratory workup and imaging studies (chest film, sinus series, skull films) may be indicated, depending on the clinical setting.

Bacterial meningitis is a neurologic emergency. Accordingly, antibiotic therapy should be started as soon as possible after the diagnosis is considered likely, usually once the diagnosis has been established by CSF analysis. Antibiotic therapy is generally targeted by the results of the Gram stain (Table 42-9), or may be chosen empirically based on age and predisposing conditions (Table 42-10). Table 42-11 outlines recommendations for specific antimicrobial therapy based on isolates and susceptibility, and Table 42-12 recommends doses.

Role of Corticosteroids

The theoretic goal of using corticosteroids in bacterial meningitis is to minimize meningeal inflammation, thereby decreasing the severity and incidence of brain injury. However, IDSA recommends adjunctive dexamethasone therapy in certain patients based on age.

Neonates

There are currently insufficient data to make recommendations involving newborns (Tunkel et al., 2004).

Infants and Children

Available evidence supports the use of adjunctive dexamethasone in infants and children with *H. influenzae* type b meningitis initiated 10 to 20 minutes before (or at least concomitant with) the first doses of antibiotic at a dose of 0.15 mg/kg every 6 hours for 2 to 4 days. However, adjunctive

Table 42-9 Antimicrobial Therapy in Adult Patients with Presumptive Pathogen Identification by Positive Gram Stain

| Microorganism | Recommended Therapy | Alternative Therapies |
|---------------------------------|--|---|
| <i>Streptococcus pneumoniae</i> | Vancomycin plus third-generation cephalosporin* † | Meropenem (C), fluoroquinolone‡ (B) |
| <i>Neisseria meningitidis</i> | Third-generation cephalosporin* | Penicillin G, ampicillin, chloramphenicol, fluoroquinolone, aztreonam |
| <i>Listeria monocytogenes</i> | Ampicillin [§] or penicillin G [§] | TMP-SMP, meropenem (B) |
| <i>Streptococcus agalactiae</i> | Ampicillin [§] or penicillin G [§] | Third-generation cephalosporin*(B) |
| <i>Haemophilus influenzae</i> | Third-generation cephalosporin* | Chloramphenicol, cefepime, meropenem, fluoroquinolone |
| <i>Escherichia coli</i> | Third-generation cephalosporin* | Cefepime, meropenem, aztreonam, fluoroquinolone, TMP-SMP |

Modified from Tunkel AR, Barry J, Hartman SL, et al: Practice guidelines for the management of bacterial meningitis. Clin Infect Dis 39,1267, 2004.

Note: All recommendations are (A) unless otherwise indicated. In children, ampicillin is added to the standard therapeutic regimen of cefotaxime or ceftriaxone plus vancomycin when *L. monocytogenes* is considered and to an aminoglycoside if a gram-negative enteric pathogen is of concern.

*Ceftriaxone or cefotaxime.

†Some experts would add rifampin if dexamethasone is also given (B).

‡Gatifloxacin or moxifloxacin.

§Addition of an aminoglycoside should be considered.

TMP-SMP, trimethoprim-sulfamethoxazole.

dexamethasone should not be given to infants and children who have already received antimicrobial therapy, because it is unlikely to improve patient outcome (Tunkel et al., 2004). Adjunctive dexamethasone in infants and children with pneumococcal meningitis is controversial. On the use of steroids for pneumococcal meningitis, the Committee on Infectious Diseases of the American Academy of Pediatrics stated, "For infants and children 6 weeks of age and older, adjunctive therapy with dexamethasone may be considered after weighing the potential benefits and possible risks. Experts vary in recommending the use of corticosteroids in pneumococcal meningitis; data are not sufficient to demonstrate clear benefit in children" (AAP, 2003). Also, data support adjunctive corticosteroids in children from high-income countries, but show no beneficial effect for children in low-income countries (Cochrane review; van de Beek et al., 2007).

Adults

Adjunctive dexamethasone, 0.15 mg/kg every 6 hours for 2 to 4 days, with the first dose administered 10 to 20 minutes before (or at least concomitant with) the first dose of antibiotic, should be initiated in all adult

Table 42-10 Empiric Antimicrobial Therapy for Purulent Meningitis Based on Patient Age and Specific Predisposing Condition (A)

| Predisposing Factor | Common Bacterial Pathogens | Antimicrobial Therapy |
|--|---|--|
| Age | | |
| <1 mo | <i>Streptococcus agalactiae</i> , <i>Escherichia coli</i> , <i>Listeria monocytogenes</i> , <i>Klebsiella</i> spp. | Ampicillin <i>plus</i> cefotaxime or ampicillin <i>plus</i> an aminoglycoside |
| 1-23 mo | <i>Streptococcus pneumoniae</i> , <i>Neisseria meningitidis</i> , <i>S. agalactiae</i> , <i>Haemophilus influenzae</i> , <i>E. coli</i> | Vancomycin <i>plus</i> third-generation cephalosporin* † |
| 2-50 yr | <i>N. meningitidis</i> , <i>S. pneumoniae</i> | Vancomycin <i>plus</i> third-generation cephalosporin* † |
| >50 yr | <i>S. pneumoniae</i> , <i>N. meningitidis</i> , <i>L. monocytogenes</i> , aerobic gram-negative bacilli | Vancomycin <i>plus</i> ampicillin <i>plus</i> third-generation cephalosporin* † |
| Head Trauma | | |
| Basilar skull fracture | <i>S. pneumoniae</i> , <i>H. influenzae</i> , group A β -hemolytic streptococci | Vancomycin <i>plus</i> third-generation cephalosporin* |
| Penetrating trauma | <i>Staphylococcus aureus</i> , coagulase-negative staphylococci (especially <i>Staphylococcus epidermidis</i>), aerobic gram-negative bacilli (including <i>Pseudomonas aeruginosa</i>) | Vancomycin <i>plus</i> cefepime, vancomycin <i>plus</i> ceftazidime, or vancomycin <i>plus</i> meropenem |
| Postneurosurgery | Aerobic gram-negative bacilli (including <i>P. aeruginosa</i>), <i>S. aureus</i> , coagulase-negative staphylococci (especially <i>S. epidermidis</i>) | Vancomycin <i>plus</i> cefepime, vancomycin <i>plus</i> ceftazidime, or vancomycin <i>plus</i> meropenem |
| Cerebrospinal fluid shunt | Coagulase-negative staphylococci (especially <i>S. epidermidis</i>), <i>S. aureus</i> , aerobic gram-negative bacilli (including <i>P. aeruginosa</i>), <i>Propionibacterium acnes</i> | Vancomycin <i>plus</i> cefepime, ‡ vancomycin <i>plus</i> ceftazidime, ‡ or vancomycin <i>plus</i> meropenem ‡ |
| Modified from Tunkel AR, Barry J, Hartman SL, et al: Practice guidelines for the management of bacterial meningitis. Clin Infect Dis 2004;39,1267. | | |
| *Ceftriaxone or cefotaxime. | | |
| †Some experts would add rifampin if dexamethasone is also given. | | |
| ‡In infants and children, vancomycin alone is reasonable unless Gram stain reveals gram-negative bacilli. | | |

Table 42-11 Specific Antimicrobial Therapy in Bacterial Meningitis Based on Isolated Pathogen and Susceptibility Testing

| Microorganism, Susceptibility | Standard Therapy | Alternative Therapies |
|---|--|--|
| <i>Streptococcus pneumoniae</i> | | |
| Penicillin MIC | | |
| <0.1 $\mu\text{g/mL}$ | Penicillin G or ampicillin | Third-generation cephalosporin,* chloramphenicol |
| 0.1-1.0 $\mu\text{g/mL}$ † | Third-generation cephalosporin* | Cefepime (B), meropenem (B) |

| <i>Staphylococcus epidermidis</i> | Vancomycin ^{¶¶} | Linezolid (B) |
| <i>Enterococcus</i> spp. | | |
| Ampicillin susceptible | Ampicillin plus gentamicin | — |
| Ampicillin resistant | Vancomycin plus gentamicin | — |
| Ampicillin and vancomycin resistant | Linezolid (B) | |

—Modified from Tunkel AR, Barry J, Hartman SL, et al. Practice guidelines for the management of bacterial meningitis. Clin Infect Dis 2004;39:1267.

Note: All recommendations are (A), unless otherwise indicated.

TMP-SMX, Trimethoprim-sulfamethoxazole; MIC, minimum inhibitory concentration.

*Ceftriaxone or cefotaxime.

†Ceftriaxone/cefotaxime-susceptible isolates.

‡Consider addition of rifampin if the MIC of ceftriaxone is >2 µg/mL.

§Gatifloxacin or moxifloxacin.

¶Addition of an aminoglycoside should be considered.

¶¶Consider addition of rifampin.

**Choice of a specific antimicrobial agent must be guided by in vitro susceptibility test results.

patients with suspected or proven pneumococcal meningitis. Although data are insufficient to make this recommendation for other bacterial pathogens, many experts would initiate dexamethasone in all adults because the cause of meningitis is not always ascertained at the initial evaluation. As in children, dexamethasone should not be given to adult patients who have already received antibiotics (Tunkel et al., 2004).

Dexamethasone should only be continued if the CSF stain reveals gram-positive diplococci, or if the blood or CSF cultures are positive for *S. pneumoniae*.

Antimicrobial Therapy

Prompt and accurate treatment of meningitis is essential to increase survival and reduce morbidity. Treatment recommendations for a known pathogen of community-acquired bacterial meningitis and for selected clinical settings are listed in Tables 42-13 and 42-14. Duration of therapy is based more on tradition than on clinical evidence and varies, depending on the pathogen. Repeat LP for CSF analysis of response to therapy is not necessary for most patients who demonstrate clinical improvement within 24 to 48 hours. Patients who do not demonstrate significant clinical improvement and show high resistance on culture and sensitivity, as well as neonates with meningitis caused by gram-negative bacilli, should undergo repeat LP (Tunkel et al., 2004).

Prophylaxis and Prevention

Prophylaxis is indicated for any close contacts of persons with documented meningococcal meningitis or *H. influenzae* type b meningitis. For meningococcal meningitis, adults should receive 600 mg of rifampin orally twice daily for 2 days; children older than 1 month should receive 10 mg/kg every 12 hours orally for 2 days (5 mg/kg every 12 hours if younger than 1 month). Rifampin is not recommended for pregnant women, and the reliability of oral contraceptives may be affected by rifampin therapy. An alternative for children is ceftriaxone intramuscularly as a single dose, 125 mg for those 15 years and younger and 250 mg for those older than 15 years. Ciprofloxacin, 500 mg orally as a single dose, is another alternative to rifampin in nonpregnant, nonlactating adults (ACIP, 1997; CDC, 2000; Pickering, 2003).

Prevention of nasopharyngeal carriage in patients treated for meningitis is achieved by starting prophylaxis doses (same as earlier) before discharge. Prevention is also achieved by immunoprophylaxis. The Hib vaccine is now part of the primary vaccination series for children and has been immensely successful at almost eliminating *H. influenzae* meningitis. A vaccine for meningococcal disease is now a part of the standard immunization regimen for all children between the ages of 11 and 12 years. It should also be administered to children between the ages of 13-18 years and all previously unvaccinated freshmen living in a dormitory setting (Advisory Committee of Immunization Practices, 2009).

Table 42-12 Recommended Dosages of Antimicrobial Therapy in Patients with Bacterial Meningitis (A)

| Antimicrobial Agent | Total Daily Dose (Dosing Interval in hr) | | | |
|---------------------|--|---------------------|----------------------|--------------------|
| | Neonates (Age in days) | | Infants and Children | Adults |
| | 0-7* | 8-28* | | |
| Amikacin | 15-20 mg/kg (12) | 30 mg/kg (8) | 20-30 mg/kg (8) | 15 mg/kg (8) |
| Ampicillin | 150 mg/kg (8) | 200 mg/kg (6-8) | 300 mg/kg (6) | 12 g (4) |
| Aztreonam | — | — | — | 6-8 g (6-8) |
| Cefepime | — | — | 150 mg/kg (8) | 6 g (8) |
| Cefotaxime | 100-150 mg/kg (8-12) | 150-200 mg/kg (6-8) | 225-300 mg/kg (6-8) | 8-12g (4-6) |
| Ceftazidime | 100-150 mg/kg (8-12) | 150 mg/kg (8) | 150 mg/kg (8) | 6 g (8) |
| Ceftriaxone | — | — | 80-100 mg/kg (12-24) | 4 g (12-24) |
| Chloramphenicol | 25 mg/kg (24) | 50 mg/kg (12-24) | 75-100 mg/kg (6) | 4-6 g (6)‡ |
| Ciprofloxacin | — | — | — | 800-1200 mg (8-12) |
| Gatifloxacin | — | — | — | 400 mg (24)§ |
| Gentamicin† | 5 mg/kg (12) | 7.5 mg/kg (8) | 7.5 mg/kg (8) | 5 mg/kg (8) |
| Meropenem | — | — | 120 mg/kg (8) | 6 g (8) |
| Moxifloxacin | — | — | — | 400 mg (24)§ |
| Nafcillin | 75 mg/kg (8-12) | 100-150 mg/kg (6-8) | 200 mg/kg (6) | 9-12 g (4) |
| Oxacillin | 75 mg/kg (8-12) | 150-200 mg/kg (6-8) | 200 mg/kg (6) | 9-12 g (4) |
| Penicillin G | 0.15 mU/kg (8-12) | 0.2 mU/kg (6-8) | 0.3 mU/kg (4-6) | 24 mU (4) |
| Rifampin | — | 10-20 mg/kg (12) | 10-20mg/kg (12-24)¶ | 600mg (24) |
| Tobramycin† | 5 mg/kg (12) | 7.5 mg/kg (8) | 7.5 mg/kg (8) | 5mg/kg (8) |
| TMP-SMX§ | — | — | 10-20mg/kg (6-12) | 10-20mg/kg (6-12) |
| Vancomycin** | 20-30 mg/kg (8-12) | 30-45 mg/kg (6-8) | 60 mg/kg (6) | 30-45 mg/kg (8-12) |

Modified from Tunkel AR, Barry J, Hartman SL, et al. Practice guidelines for the management of bacterial meningitis. Clin Infect Dis 2004;39:1267.

*Smaller doses and longer intervals of administration may be advisable for very-low-birth-weight neonates (<2000 g).

†Need to monitor peak and trough serum concentrations.

‡Higher dose recommended for patients with pneumococcal meningitis.

§No data on optimal dosage needed in patients with bacterial meningitis.

¶Maximum daily dose of 600 mg.

**Maintain serum trough concentrations of 15-20 µg/mL.

¶¶Dosage based on trimethoprim component.

TMP-SMX, Trimethoprim-sulfamethoxazole.

The heptavalent pneumococcal conjugate vaccine (PCV-7) is recommended for all children as part of the Advisory Committee of Immunization Practices immunization schedule (ACIP, 2009).

KEY TREATMENT

Evidence supports the use of adjunctive dexamethasone in infants and children with *Haemophilus influenzae* type b meningitis (IDSA; Tunkel et al., 2004) (SOR: A).

Adjunctive dexamethasone is recommended for adult patients with suspected or proven pneumococcal meningitis (IDSA; Tunkel et al., 2004) (SOR: A).

Recurrent Meningitis

Recurrent meningitis can have both infectious and noninfectious causes. A CSF leak accounts for approximately 75% of cases of recurrent meningitis. Clinically, it presents more like aseptic meningitis. A careful history may detect a drug exposure, structural lesion, or associated systemic disorder. To be truly recurrent, the CSF must confirm pleocytosis. Between episodes, the CSF must also be documented to return to normal. The interval between recurrences can be months to years. Unless the source is bacterial, the course of recurrent meningitis is usually self-limited, and spontaneous recovery is generally the rule. Optimal treatment is aimed at the underlying cause.

Table 42-13 Specific Antibiotic Treatments for Known Pathogens

| Pathogen | Primary Therapy | Alternative* |
|--|---|---|
| Group B streptococcus | Penicillin G or ampicillin | Vancomycin or third-generation cephalosporin [†] |
| <i>Streptococcus pneumoniae</i> (MIC <0.1) | Third-generation cephalosporin [†] | Meropenem penicillin |
| <i>S. pneumoniae</i> (MIC >0.1) | Vancomycin plus third-generation cephalosporin* | Substitute rifampin for vancomycin; or meropenem; or vancomycin as monotherapy if highly allergic to other alternatives |
| <i>Haemophilus influenzae</i> (β-lactamase negative) | Ampicillin | Third-generation cephalosporin [†] or chloramphenicol or aztreonam |
| <i>H. influenzae</i> (β-lactamase positive) | Third-generation cephalosporin [†] | Chloramphenicol or aztreonam or fluoroquinolones‡ |
| <i>Listeria monocytogenes</i> | Ampicillin plus gentamicin | TMP-SMX |
| <i>Neisseria meningitidis</i> | Penicillin G or ampicillin | Third-generation cephalosporin [†] |
| Enterobacteriaceae | Third-generation cephalosporin [†] plus aminoglycoside | TMP-SMX or aztreonam or fluoroquinolones or antipseudomonal penicillin [§] (or ampicillin) plus aminoglycoside |
| <i>Pseudomonas aeruginosa</i> | Ceftazidime plus aminoglycoside | Aminoglycoside plus aztreonam or aminoglycoside plus antipseudomonal penicillin [§] |
| <i>Staphylococcus aureus</i> (methicillin sensitive) | Antistaphylococcal penicillin** ± rifampin | Vancomycin plus rifampin or TMP-SMX plus rifampin |
| <i>S. aureus</i> (methicillin resistant) | Vancomycin plus rifampin | |
| <i>Staphylococcus epidermidis</i> | Vancomycin plus rifampin | |

*If patient is highly allergic or intolerant of primary therapy.
[†]Ceftriaxone or cefotaxime.

Table 42-14 Common Pathogens of Bacterial Meningitis and Empiric Treatment Based on Age

| Age | Common Pathogens | Treatment* | Duration (days) |
|------------|--|--|-------------------------------|
| 0-1 mo | Group B streptococcus <i>Listeria monocytogenes</i> <i>Escherichia coli</i> <i>Streptococcus pneumoniae</i> | Ampicillin plus third-generation cephalosporin [†] or ampicillin plus aminoglycoside | 14-21 14-21 21 10-14 |
| 1-3 mo | Group B streptococcus, <i>E. coli</i> , <i>L. monocytogenes</i> <i>S. pneumoniae</i> <i>Neisseria meningitidis</i> , <i>Haemophilus influenzae</i> | Ampicillin plus third-generation cephalosporin [†] | 14-21 10-14 7-10 |
| 3 mo-18 yr | <i>H. influenzae</i> , <i>N. meningitidis</i> <i>S. pneumoniae</i> | Third-generation cephalosporin [†] or meropenem or chloramphenicol | 7-10 10-14 |
| 18-50 yr | <i>H. influenzae</i> , <i>N. meningitidis</i> <i>S. pneumoniae</i> | Third-generation cephalosporin [†] or meropenem or ampicillin plus chloramphenicol | 7-10 10-14 |
| >50 yr | <i>S. pneumoniae</i> <i>L. monocytogenes</i> Gram-negative bacilli (other than <i>H. influenzae</i>) | Ampicillin plus third-generation cephalosporin [†] or ampicillin plus fluoroquinolone [‡] or meropenem | 10-14 14-21 21 |

*Add vancomycin in areas where there is greater than 2% incidence of highly drug-resistant *S. pneumoniae*.
[†]Ceftriaxone or cefotaxime.
[‡]Ciprofloxacin or levofloxacin.

Chronic Meningitis

There are no pathognomonic features of chronic meningitis. The classic symptoms, if present, may be extremely subtle and variable. There may be unusual symptoms such as psychoses, movement disorders, and parkinsonian syndrome. The average duration of symptoms is 17 to 43 months, during which symptoms may fluctuate or remain static. CSF that shows a mildly decreased glucose level in the setting of mononuclear pleocytosis should always raise the suspicion of chronic meningitis. The causes are numerous, and attention should be paid to a history of previous systemic diseases, specific infections that could involve the meninges, possible exposures, geographic risk factors, immunologic compromise, and concurrent extraneural involvement (Boxes 42-9 and 42-10).

Viral Meningitis

Viral meningitis is actually a subset of aseptic meningitis. *Aseptic meningitis* antedates the modern science of virology and signifies an infection of the subarachnoid space and meninges with no obvious bacterial cause. *Encephalitis* occurs when there is inflammation of brain tissue. *Viral meningitis* presents with similar signs and symptoms as bacterial meningitis, but with less severity. A history of a preceding viral respiratory infection is common. Obtaining LP for CSF evaluation is the only method for determining the difference. There are numerous causes of viral meningitis (Box 42-11). Outbreaks are often seasonal.

Treatment is mainly supportive, with the exception of herpesvirus (herpes simplex virus [HSV]) and HIV, for which specific antiviral therapy is available. Data regarding herpes meningitis treatment are limited, and both high-dose acyclovir (60 mg/kg/day) and lower-dose therapies have been advocated (Kohlhoff et al., 2004). For HIV and acquired immunodeficiency syndrome (AIDS)-dementia complex (ADC), many antiviral combinations have been suggested. The factors to be considered when choosing a combination therapy for ADC include toxicity, the many potential drug interactions, CNS penetration, and resistance. Because the treatments for HIV and its complications are often changing, consultation with an infectious disease specialist should be considered.

With the exception of HSV encephalitis and ADC, the prognosis is generally very good for other viral meningitides. Children seem to recover within 1 to 2 weeks, whereas adults may take several months.

Brain Abscess

Brain abscess, a rare disease in the United States, can occur in single or multiple sites. It usually arises from a secondary focus outside the CNS. Examples may include upper or lower respiratory infection, intracardiac infection, penetration skull trauma, local osteomyelitis, any source of bacteremia, or no source (20%). Risk factors include IV drug use, HIV infection, and any other immunocompromised state. Common pathogens include streptococci, staphylococci, enteric gram-negative organisms, and anaerobes.

Clinically, brain abscess usually has a more aggressive onset of symptoms than bacterial meningitis. Symptoms usually present as typical meningeal irritation, along with

Box 42-9 Causes of Chronic Meningitis

Bacterial

- Tuberculosis

IgG, immunoglobulin G; *TB*, tuberculosis.
 Modified from Coyle PK. Overview of acute and chronic meningitis. *Neurol Clin* 1999;17:691.

mental status changes that progress to stupor or coma, seizures, and focal neurologic findings. Laboratory studies are not impressive. Caution should be exercised before performing LP because brain edema is often present. Once past the initial cerebritis stage, CT or MRI of the brain often identifies the abscess. A search for a secondary cause is important. A radionuclide-labeled leukocyte scan may be needed to differentiate a brain tumor from infection. Aspiration or biopsy of the area in question usually confers a definitive diagnosis.

Treatment is directed toward the cause and lasts for 4 to 6 weeks. Drainage of the abscess is achieved by CT-guided needle aspiration or craniotomy. Recurrence can be expected

 Hepatitis B virus (HBV)
 Human immunodeficiency virus (HIV)

in 5% to 10% of patients. Morbidity is significant and includes the risk of epilepsy (10%-70%), focal neurologic sequelae (25%), and cognitive impairment (15%). Overall mortality is 5% to 10%.

Dizziness**Key Points**

- Dizziness is a risk factor for falls and functional decline in older adults.
- Characterizing the type of dizziness can narrow the differential diagnosis.
- Benign paroxysmal positional vertigo patients complain of episodic vertigo without aural symptoms.

Dizziness is a common problem encountered by the family physician. It is a typical complaint of elderly patients and has a broad differential diagnosis. Fortunately, dizziness is usually benign and self-limited. Nevertheless, it is a risk factor for falls and functional decline in the geriatric population and, in a small subset of patients, can signal a life-threatening condition.

Evaluation

The evaluation of dizziness is often frustrating for both patients and physicians. This frustration arises from the vast differential diagnosis, the potential for multiple etiologies, and the lack of a dependable method of diagnosing the more serious causes of dizziness. The initial step in the evaluation of a patient with dizziness is a thorough history. First, the physician should clarify the category of dizziness reported by the patient. Dizziness can be categorized as *vertigo*, which is the sensation of spinning or motion; *presyncopal lightheadedness*, which is a sensation of impending faint; *disequilibrium*, a sensation of unsteadiness; or dizziness that cannot be adequately quantified, reported by patients as a feeling of lightheadedness or floating sensation. Categorizing the type of dizziness can

Table 42-15 Types of Dizziness

| Category | Differential Diagnosis |
|---|--|
| Vertigo (sensation of spinning) | Inner ear, vestibular, brainstem and cerebellar abnormalities, sinusitis, drug toxicity, panic disorder, cervical spine disease |
| Presyncopal lightheadedness | Cerebral hypoperfusion, venous pooling in extremities, low blood volume, cardiac abnormalities (arrhythmia, cardiac insufficiency), vasovagal phenomenon |
| Disequilibrium (unsteadiness more prominent when standing) | Broad differential—any disturbance of the neurosensory system |
| Other (vague descriptions of lightheadedness without presyncope, or a floating sensation) | Broad differential, but many times associated with psychological disorders |

limit the differential diagnosis (Table 42-15). Many patients, however, will be unable to limit their dizziness symptoms to one specific category. Classically, the category of vertigo was further defined as peripheral or central vertigo based on symptoms and signs, including nystagmus. This is not clinically useful, especially in the older-adult population, because many of these findings are seen in normal patients as well.

After categorizing the type of dizziness experienced by the patient, the physician should next determine the temporal pattern of the symptoms. *Continuous* dizziness is typically produced by a stroke. *Episodic* dizziness lasting a few seconds to a minute and associated with head movement is usually a sign of benign positional vertigo. Meniere's disease tends to cause dizziness lasting hours to days. Finally, the history should focus on the onset of the symptoms, alleviating or aggravating factors, and a review of the patient's medications (Box 42-12).

The physical examination should include orthostatic blood pressure and pulse determinations; examination of ears, nose, and throat for signs of infection; cardiovascular examination for murmurs and arrhythmias, with auscultation for carotid bruits; and neurologic examination, including evaluation of cranial nerves, hearing and vision screening, observation of gait, cerebellar testing, and neuromuscular assessment of extremities. A Dix-Hallpike maneuver should be tested if the differential diagnosis includes benign positional vertigo, because a positive test confirms this diagnosis. Screening audiometry should be considered to rule out Meniere's disease and acoustic neuroma, if warranted by the type of dizziness described by the history.

Laboratory and imaging studies should be ordered based on history and physical examination findings. Laboratory tests frequently include CBC, electrolytes, BUN, creatinine, glucose, serum calcium, LFTs, and TSH. If neuroimaging is indicated, MRI is the preferred modality because of its superior ability to evaluate the posterior fossa and brainstem. In some patients, carotid Doppler evaluation, cardiac event monitoring, or echocardiography may be necessary. Subspecialty consultation should be considered before proceeding with further, extensive testing.

Box 42-12 Medications associated with dizziness

- Alcohol
- Alpha blockers
- Anticholinergic
 - Antihistamines
 - Tricyclic antidepressants
 - Meclizine
- Anticonvulsants
- Beta blockers
- Caffeine
- Calcium channel blockers
- Cough and cold medication
- Diuretics
- Muscle relaxants
- Nonsteroidal medications
- Psychotropic medicines
- Vasodilating agents

Conditions Associated with Dizziness

Benign Positional Vertigo

Benign positional vertigo is believed to be caused by a dislodged otolith from the semicircular canal. Symptoms include episodic vertigo without aural symptoms. Nausea and vomiting may also be present secondary to the vertigo. Common histories include vertigo precipitated by rolling over in bed or bending over to tie shoes. The diagnosis can usually be made by the history and eliciting a positive Dix-Hallpike maneuver. Patients can be expected to have gradual resolution of their symptoms over 4 to 6 weeks with supportive therapy. The canalith repositioning (Epley) maneuver provides short-term resolution of the vertiginous symptoms (Cochrane review; Pinder, 2004).

Postural Dizziness

Nonvertiginous postural dizziness suggests postural hypotension. *Orthostatic hypotension* is usually defined as a 20 mm Hg drop in systolic BP or 10 mm Hg drop in diastolic BP 2 minutes after moving from a recumbent to standing position. Older-adult patients, however, can develop postural dizziness without apparent postural hypotension. In some cases, no BP decline occurs, although enough blood pools in the older adult's lower extremities to impair cerebral perfusion. When postural dizziness without postural hypotension is suspected, an evaluation of the cardiovascular system should be considered. If significant cardiovascular pathology, such as congestive heart failure, is not identified, a therapeutic trial of support stockings and optimized hydration can be contemplated.

Labyrinthitis, Vestibular Abnormalities, and Meniere's Disease

A comprehensive review of these topics is beyond the scope of this chapter but should be considered when evaluating any patient with dizziness. Patients with the abrupt onset of a single episode of vertigo that gradually resolves over several days often have *labyrinthitis* or *vestibular neuritis*, usually distinguished clinically by the presence or

absence of hearing changes. Patients with labyrinthitis usually experience hearing changes, whereas those with vestibular neuronitis do not. A viral infection is the usual cause in younger patients while infarction becomes more likely in the older adult. Older-adult patients may recover more slowly and experience feelings of imbalance for several months. Treatment during the symptomatic period may include vestibular rehab exercises and pharmacologic agents such as meclizine, promethazine, or low-dose benzodiazepine (e.g., lorazepam). *Meniere's disease* should be suspected when an older adult reports recurrent episodes of vertigo, tinnitus, gradual development of low-frequency hearing loss, and in some cases ear fullness before onset of vertigo.

Dizziness of Cervical Origin

Cervical spine problems, especially osteoarthritic changes, can cause dizziness that may be vertiginous in nature and of vascular or proprioceptive origin. In cases of vascular origin, flow through one of the vertebral arteries is temporarily disrupted by an osteoarthritic spur that compresses the vessel when the patient turns the head or looks up. In cases of proprioceptive origin, overstimulation of the proprioceptive receptors in the facet joints produces the sensation of dizziness. Either of these conditions can cause a "drop attack." These patients should avoid the position that precipitates the symptoms and, in some cases, cervical collars or cervical traction may be helpful.

Vertebrobasilar Transient Ischemic Attacks and Stroke

The TIAs that produce vertigo of abrupt onset lasting minutes to hours are a manifestation of ischemia in the distribution of the vertebrobasilar arteries, not the carotid arteries. Unfortunately, the TIA diagnosis can be difficult to make because vertigo may be the only symptom reported, and more definitive neurologic symptoms suggestive of a vertebrobasilar event may be absent, such as blurred vision, visual field deficits, diplopia, dysarthria, and unilateral motor or sensory changes. When a patient presents with symptoms of a vertebrobasilar TIA, the physician should consider causes such as cardioembolic disease, polycythemia, and subclavian steal syndrome. A significant BP difference in the arms and symptoms with arm abduction may signal subclavian steal syndrome, which may be corrected surgically. If the cause of these symptoms is related to vertebrobasilar vascular disease, treatment is usually medical with aspirin or other antiplatelet agents.

Vertigo is also a component of several well-recognized *vertebrobasilar stroke syndromes* (Table 42-16). *Lacunar strokes*, particularly those affecting the cerebellum, are also an important cause of dizziness. The dizziness associated with lacunar strokes is often reported as a sense of disequilibrium that is difficult to explain clinically. Such patients often report a sense of imbalance when standing that started when they were not feeling well and persists even after they return to their otherwise usual state of health. Neuroimaging is rarely helpful. CT lacks the necessary resolution to identify many of these strokes, and MRI, which may demonstrate lacunar disease, rarely identifies the lesion responsible for the patient's symptoms. Aggressive efforts to control blood pressure are advised for patients believed to have experienced lacunar strokes.

Table 42-16 Vertebrobasilar Stroke Syndromes

| Anatomy | Symptoms |
|--|---|
| Occlusion of vertebral artery | Lateral medullary syndrome: vertigo, nausea, ipsilateral facial numbness, Horner's syndrome, contralateral body loss of pain and temperature sensation, tendency to fall to affected side |
| Occlusion of anterior inferior cerebellar artery: affects labyrinth, pontomedullary region, and inferolateral cerebellum | Lateral pontomedullary syndrome: severe vertigo, nausea, vomiting, unilateral hearing loss, tinnitus, facial paralysis, asymmetric cerebellar testing |
| Cerebellar infarction | Severe vomiting, vertigo, and ataxia; brainstem signs may be absent, making differentiation from labyrinthitis difficult or impossible. |

Peripheral Neuropathies

Key Points

- In developed countries, diabetes and alcoholism are the most common causes of peripheral neuropathy in adults.
- Polyneuropathies are often inflammatory and caused by HIV infection, Lyme disease, and leprosy; no cause can be found in up to 20% of cases.
- There is no specific laboratory study or serum marker for the diagnosis of peripheral neuropathy.
- Electromyography and nerve conduction studies are most useful for evaluation of peripheral neuropathy and should be considered early.
- Mononeuropathies are usually caused by entrapment, compression, or other physical injury to a specific nerve.
- Carpal tunnel syndrome is a common mononeuropathy caused by decreased tunnel size (Colles' fracture, rheumatoid arthritis), enlargement of median nerve (diabetes, amyloidosis), or increased volume of other structures (tenosynovitis, gout).
- Common symptoms of CTS include numbness and paresthesias in the median nerve sensory distribution, pain at rest (especially at night), weakness in the thumb, and thenar atrophy.

The incidence of peripheral neuropathy is not known, but it is a common feature of many systemic diseases. In developed countries, diabetes and alcoholism are the most common causes of peripheral neuropathy in adults (Poncelet, 1998). Worldwide, leprosy is the primary treatable cause of peripheral neuropathy, and HIV is one of the fastest-growing causes (Sabin et al., 1993).

Peripheral neuropathies are frequently overlooked. The evaluation can be time-consuming and costly without a systematic approach based on a careful history, clinical evaluation, and select studies. Despite a thoughtful approach, however, no cause can be found in up to 20% of cases (Dyck et al., 1981; McLeod et al., 1984). The goal in treating peripheral neuropathy should be to identify the treatable cause or underlying medical condition, such as diabetes, alcohol, drugs, or nutritional disorder. Hereditary neuropathies are uncommon but underdiagnosed; thus a careful family history (e.g., longstanding distal neuropathy) should not be neglected.

Anatomy

The peripheral nervous system (PNS) consists of cranial nerves III to XII, spinal roots (dorsal and ventral), spinal nerves, dorsal root ganglia, and most autonomic ganglia and roots. Because the motor neuron cell bodies are located in the spinal cord or CNS, diseases affecting these are considered separately. Peripheral nerves consist of different types of fiber bundles called *axons*. Large and medium-sized axons are normally myelinated and carry information about proprioception, vibration, and light touch. Small axons, consisting of myelinated and unmyelinated types, are responsible for light touch, pain, and temperature, as well as autonomic information. These small, unmyelinated fibers of the autonomic PNS travel within most peripheral nerves and convey poorly defined visceral sensations and monitor autonomic functions. Most peripheral nerves carry incoming sensory information (afferent fibers) and outgoing motor and autonomic messages (efferent fibers).

Clinical Pathophysiology

Sensory Changes

Large-fiber and small-fiber neuropathies can often be distinguished clinically by whether they affect proprioception and vibration or pain and temperature. Because processes that affect small fibers cause pain and sensory changes, symptoms may include reduced sensitivity to stimuli (hypoesthesia) or burning and tingling sensations (dysesthesias and paresthesias, respectively). There may also be impaired pain or temperature sensation and autonomic dysfunction. When large fibers are damaged, vibratory sense and proprioception are affected. This can lead to unsteady gait, complaints of coolness in the extremities, or *allodynia*, in which non-noxious stimuli such as light touch are perceived as pain. In polyneuropathies, pain and sensation are commonly affected in a stocking-glove distribution.

Motor Changes

Symptoms are usually most pronounced distally. This is especially true with polyneuropathies, in which symptoms of stumbling, clumsiness, and weakness are most common because of the effects on the intrinsic muscles. Motor symptoms can range from mild weakness to complete paralysis. Diminished DTRs may be one of the early signs of motor dysfunction. Denervation of muscles causes eventual atrophy. An example is the “sharp shin” sign, whereby atrophy of the tibialis anterior muscle gives a prominent appearance to the tibia. As the intrinsic muscles deteriorate, the wasting gives the hands and feet a skeletal appearance. In long-standing neuropathies, trophic changes such as high-arched feet (*pes cavus*), hammertoes, kyphoscoliosis, and hair loss with or without ulcerations can be seen. Cramps, fasciculations, and restless legs may also be present.

Autonomic Changes

Autonomic changes are especially common with diabetes. The skin may become smooth, cold, and shiny. It may be unusually dry and devoid of perspiration. Orthostatic hypotension is one of the most common autonomic symptoms associated with neuropathy from systemic disease. The genitourinary and gastrointestinal systems are also often affected.

Classification

Peripheral neuropathies are often categorized in terms of the anatomy affected, pathophysiologic process, temporal development, and functional outcome.

Anatomic Classification

The major anatomic patterns of peripheral nerve disease can be distinguished by the clinical presentation—mononeuropathy, multiple mononeuropathy, and polyneuropathy. *Mononeuropathies* occur when there is damage to a single peripheral nerve or root. This is seen with local entrapment from causes such as trauma (acute or chronic), tumor infiltration, or infarction. *Multiple mononeuropathies* (mononeuropathy multiplex) occur when several nerves are individually affected by a disease process. Involvement is usually asymmetric and noncontiguous. These mononeuropathies are much less common than other peripheral neuropathies and are more difficult to recognize and treat. Multiple mononeuropathies are usually seen with systemic diseases such as vasculitis, diabetes, and rheumatoid arthritis. *Polyneuropathies* occur in a symmetric, diffuse, bilateral pattern and produce a characteristic stocking-glove pattern of sensory changes. However, most polyneuropathies affect both sensory and motor nerves. Some can affect peripheral autonomic nerves. Many common peripheral neuropathies fall into this category.

Pathophysiologic Classification

Based on the primary site of involvement, peripheral neuropathies can be classified as neuronopathies, axonal neuropathies, and myelinopathies. Electrodiagnostic studies can help define this in a clinical setting. *Neuronopathies* result from damage to the sensory cell bodies in the dorsal root ganglia or motor neuron cell bodies in the spinal cord. Their location in the CNS usually results in a degenerative process that produces incomplete recovery. Diseases that specifically affect the motor neuron cell bodies in the CNS are usually not categorized as peripheral neuropathies. *Axonal neuropathies* occur when damage occurs at the level of the axon. When the axon is disrupted (e.g., by trauma), the axon and distal myelin sheath may degenerate distal to the site of injury (wallerian degeneration). In toxic or metabolic injuries, when the distal axon is injured and myelin degeneration spreads proximally, it is known as “dying back” neuropathy. With the dying back process, the longer nerves tend to be affected earlier and more severely. *Myelinopathies* (demyelinating neuropathies) result from a process affecting primarily the myelin sheath. They can result from acute conditions such as Guillain-Barré syndrome (GBS), chronic inflammatory demyelinating polyradiculoneuropathies (CIDPs), and certain hereditary neuropathies.

Temporal Classification

Acute peripheral neuropathies develop over a few days. When motor signs are predominant, GBS should be suspected first. Vasculitic or toxic processes can also present acutely. A subacute presentation may be seen in toxic, inflammatory, infiltrative, or carcinomatous processes that develop over weeks. A chronic-onset neuropathy may develop gradually and progress over months to years, as is the case in metabolic or hereditary neuropathies. Peripheral neuropathies may also have a relapsing course (Box 42-13).

Box 42-13 Neuropathies Classified by Temporal Presentation**Acute Onset (within days)**

GBS
 Vasculitis

| Hereditary | Alcoholism |

HIV/AIDS, Human immunodeficiency virus/acquired immunodeficiency syndrome. Modified from Poncelet AN. An algorithm for the evaluation of peripheral neuropathy. *Am Fam Physician* 1998;57:755.

Electromyography (EMG) and nerve conduction studies (NCS) are probably the most useful laboratory studies for the evaluation of peripheral neuropathy and should be considered early. They can confirm the presence of peripheral neuropathy and provide information about the type of fibers involved (sensory, motor, or both) and whether the problem is symmetric, asymmetric, or multifocal. EMG can define entrapment neuropathies and differentiate these from more proximal radicular compression. It can also help differentiate muscle wasting caused by neuropathic or myopathic disorders from simple disuse atrophy. NCS can help define pathophysiology (axonal loss vs. demyelination). EMG and NCS are useful but have limitations and should complement the history and examination. EMG is usually not as helpful in diseases that cause a diffuse small-fiber peripheral neuropathy, in which only pinprick and temperature sensation are affected (Box 42-14). In fact, the electromyogram may be normal. EMG needles also mildly inflame the muscles into which they are inserted. Thus, if a muscle biopsy is anticipated, that muscle should not be tested with EMG (Corse and Kuncl, 1999). NCS are most diagnostic with diseases affecting large, fast fibers and thus may be normal in patients with small-fiber neuropathies. Evaluation of small, proximal sensory nerves is not reliably done using EMG or NCS.

Nerve biopsy is helpful only in specific cases and is usually a last step in the workup. This includes patients with suspected amyloidosis, vasculitis, leprosy, leukodystrophies, sarcoidosis, or demyelinating disorders. Because the sural nerve, a sensory nerve, is generally used, disease affecting only motor nerves may be missed. Possible complications include permanent numbness or dysesthesia in the distribution of the excised nerve (typically lateral heel and ankle), infection, and poor wound healing.

In the evaluation of neuropathies, a carefully performed history that identifies key features of the presentation correlated with the findings of electrodiagnostic studies is the critical first step in developing a reasonable diagnosis. Questions include the following:

- Is the pattern of involvement focal or multifocal (Box 42-15)?
- Is the pattern symmetric (Boxes 42-16 and 42-17)?
- Did symptoms evolve acutely, subacutely, or chronically? Was there a predilection for the upper extremities (Box 42-18)?
- Were the extremities affected in a distal versus a proximal distribution (see Boxes 42-16 and 42-17)?
- Are the symptoms sensory, motor, or both (Box 42-19; see also Boxes 42-16 and 42-17)?
- Is there autonomic or cranial nerve involvement (Boxes 42-20 and 42-21)?

Laboratory Evaluation

There is no specific laboratory study or serum marker for the diagnosis of peripheral neuropathy. Information from the history and physical examination may direct specific laboratory tests (e.g., testing for specific toxins, infections, or inflammatory disorders). If the cause of neuropathy is not obvious, some screening laboratory studies should be considered: ESR, CBC, LFTs, and determination of fasting blood glucose, glycosylated hemoglobin, BUN, creatinine, serum vitamin B₁₂, and TSH levels. Additional studies may be warranted, depending on the initial workup, such as chest radiograph to rule out sarcoidosis, pulmonary function tests for GBS, or ECG for processes that affect cardiac conduction. An LP for CSF showing an elevated protein level with normal white blood cells (WBCs) may indicate an acquired inflammatory neuropathy (GBS or CIDP).

- What did the EMG and NCS show? Were other significant laboratory studies done?

Taking this approach to peripheral neuropathies will prove to be more efficient and fruitful than less ordered approaches, despite the often elusive nature of these diagnoses.

Mononeuropathies

Mononeuropathies are usually caused by entrapment, compression, or other physical injury to a specific nerve. Peripheral nerves most at risk are those that occupy spaces with confining borders. Electrodiagnostic studies are useful in confirming the diagnosis and quantifying the degree of injury. Treatment is generally conservative, involving protection of the affected nerve from further injury by the use of activity avoidance or modification, ergonomic workplace correction, and bracing. Local (by injection) or systemic anti-inflammatory treatment is often helpful. Surgical intervention is

usually reserved for patients who fail conservative therapy, have evidence of progressive weakness and atrophy, or have a significant focal conduction block on electrodiagnostic examination.

Brachial Plexus Neuropathy

Brachial plexus neuropathy (plexopathy) can result from blunt or penetrating trauma. The typical injury is directed into the axilla or violently increases the angle between the shoulder and head. In the latter case, *stingers* or *burners*, which frequently occur in football players, result in temporary

paresthesias and diffuse weakness in the upper extremity. Recurrent stretch injuries to the brachial plexus can result in permanent weakness and atrophy. Also, apical lung tumors with direct extension or compression can cause pain in the upper extremity and hand numbness. Radiation therapy also can result in brachial plexopathies. *Idiopathic brachial plexopathy* (Parsonage-Turner syndrome) often occurs abruptly without any clear precipitating factor, although it can develop after an infection, injection, surgery, or childbirth. It typically begins with an aching sensation in the neck or shoulder and progresses over days to produce weakness, sensory loss, and diminished reflexes. Patients with brachial plexopathy often have considerable pain. Recovery is usually spontaneous but can take weeks to months. Some residual weakness may be present in a few patients.

Median Neuropathy (Carpal Tunnel Syndrome)

Carpal tunnel syndrome (CTS) is one of the most common mononeuropathies. It typically occurs within the confines of the carpal tunnel in the wrist. The median nerve can also be entrapped in the forearm as a pronator or interosseous syndrome. The entrapment can be caused by anything that causes a decrease in the size of the carpal tunnel (e.g., Colles' fracture, rheumatoid arthritis, congenital carpal tunnel stenosis), enlargement of the median nerve (e.g., diabetes, amyloidosis, thyroid disease, neuroma), or an increase in the volume of other structures within the carpal tunnel (e.g., tenosynovitis, ganglion, gout, urate deposits, lipoma, hematoma, fluid retention in pregnancy).

Other risk factors include any tasks that require repeated or sustained stress over the base of the palm. Low-frequency vibration exposure is another well-recognized risk factor for CTS. Repetitive wrist and hand movements such as knitting, typing, painting, woodworking, and weightlifting are also implicated as high-risk factors.

Common symptoms include numbness and paresthesias in the sensory distribution of the median nerve (palmar surface of thumb, index finger, and middle finger; radial side of ring finger; radial two thirds of palm). The patient may also have pain at rest (especially at night), weakness in the thumb, and thenar atrophy. Signs include a positive Tinel's sign at the wrist (tingling in median nerve distribution on percussion over ventral wrist), positive Phalen's sign (similar findings within 45 seconds after placing patient's wrist in maximal flexion), pain or paresthesias in a median distribution with thumb pressure over the median nerve for up to 30 seconds, and thenar atrophy. CTS can present with many variations, including proximal pain in the arm and shoulder, and with normal EMG.

Ulnar Neuropathy

The most common place to have ulnar nerve injury is at the elbow, where the nerve is anatomically most exposed and vulnerable as it traverses superficially in the ulnar groove. Pressure at the elbow such as with prolonged elbow weight bearing, coma, intoxication, or anesthesia can account for this problem.

Cubital tunnel syndrome occurs when the nerve is compressed as it runs beneath the aponeurosis of the flexor carpi ulnaris just distal to the medial epicondyle (cubital tunnel). Activities that involve repetitive or sustained elbow flexion, such as baseball pitching, can injure and stretch

the nerve. This results in hypermobility of the ulnar nerve and allows recurrent subluxation over the medial epicondyle. Common symptoms include paresthesias or pain in the ring and small fingers and dorsoulnar aspect of the hand and forearm. There may be generalized loss of grip or fine motor control in the hand because of impairment of the intrinsic muscles. Symptoms may improve with elbow extension. Recurrent subluxation of the ulnar nerve at the elbow, especially in young throwing athletes, often requires surgical intervention.

Ulnar neuropathy distal to the elbow usually presents as *ulnar tunnel syndrome* when the nerve is compressed within Guyon's canal in the wrist. Prolonged pressure over the hypothenar eminence, as occurs with cycling, is a common cause, as are similar causes listed for CTS. Dysesthesias may or may not be present in the ulnar regions. Depending on where the specific entrapment occurs, all the intrinsic hand muscles may be weak, or hypothenar function may be selectively preserved.

Radial Neuropathy

Radial nerve injuries are much less common than other upper extremity neuropathies. Proximally, the radial nerve is most vulnerable in the axilla, where it can be injured by hyperabduction of the arm, which puts traction on the nerve. This is the case with "Saturday night palsy," when an intoxicated person sleeps with an arm draped over a chair. A similar circumstance occurs when the nerve is compressed against the humerus at the spiral groove. It is also seen with improper fit or use of crutches. Other sources of compression that can injure the radial nerve along its course include lipoma, fibroma, and new or previous (from callus) humerus fracture.

The radial nerve is predominantly a motor nerve, so symptoms depend on the level of injury. If the compression is proximal enough, there will be sensory loss over the dorsum of the hand, along with weakened triceps (elbow extension) and brachioradialis (elbow extension and supination) motor function. The most obvious finding in radial palsy is wristdrop and drop finger (digital extensor paralysis).

In *posterior interosseous syndrome* (radial tunnel syndrome) the compression is more distal; the purely motor branch of the radial nerve, the posterior interosseous nerve, is entrapped at the supinator muscle, causing only weakness in the finger extensors without affecting wrist extension.

Lumbosacral Neuropathy

Compared with the brachial plexus, the lumbosacral plexus is less susceptible to trauma. Injury caused by trauma or compression from surgery, pregnancy, childbirth, tumors, or aortic aneurysm can occur. Diabetes can also cause multiple mononeuropathy of the plexus (see later).

Meralgia Paresthetica

Compression of the lateral femoral cutaneous nerve as it passes over the anterior superior iliac spine at the lateral end of the inguinal canal is common. It is seen in those who have diabetes, are obese, or wear their pants too tight. Patients experience numbness, paresthesias, and pain over the anterolateral aspect of the thigh, without weakness.

Femoral Neuropathy

Any blunt or penetrating trauma, surgery or angiography in the groin, prolonged lithotomy position, or hyperextension during dance or gymnastics can injure the femoral nerve. A tumor or inguinal hernia involving the plexus can also compress the nerve. The femoral nerve supplies the quadriceps muscles for knee extension and provides sensory information from the anterior medial thigh and medial leg. Dysfunction in this nerve can result in pain in the groin that radiates to the thigh, buckling of the knee caused by quadriceps weakness, and sensory loss over its area of distribution. Weakness in the hip flexors indicates a more proximal lesion in the lumbar plexus or roots. Diabetic lumbosacral plexopathy should also be distinguished from femoral neuropathies. With the former, patients are older than 50 years, with diabetes, and develop acute severe pain in the thigh that progresses over days to weakness in the femoral nerve distribution. Sensory symptoms are mild. EMG helps distinguish these different conditions.

Sciatic Neuropathy

The sciatic nerve arises from the sacral portion of the plexus. It leaves the pelvis through the sciatic notch and divides into the tibial and peroneal nerves at the popliteal fossa. The sciatic nerve provides sensation to the perineum, posterior thigh, lateral calf, and foot. It innervates the thigh extensors, hamstrings, and all the muscles of the lower leg and foot. Pain, weakness, and sensory changes caused by injury of the sciatic nerve or one of its two branches can be caused by trauma from gunshots, hip fracture or dislocation, compression from surgery or prolonged sitting on a hard edge, tumor, endometriosis, lipoma, aneurysm of the gluteal artery, or improper intramuscular injection into the gluteus. Symptoms of sciatic nerve compression can mimic L5-S1 radiculopathy. Again, EMG is helpful in these clinical situations.

Peroneal Neuropathy

The common peroneal nerve is most often compressed as it passes close to the fibular head. Such compression occurs from prolonged leg crossing, squatting, or kneeling, improperly fitted cast or stockings, or prolonged pressure in an intoxicated or comatose patient. Symptoms of peroneal palsy consist of sensory loss over the lateral calf and dorsum of the foot and a weakness of ankle dorsiflexion (footdrop) and foot eversion without pain. If a clear history of trauma or compression cannot be elicited, imaging of the posterior fossa is necessary to rule out a mass lesion. Patients with a more permanent injury to the peroneal nerve may need an ankle-foot orthotic device to provide ankle stability and prevent plantar flexion contractures.

Tibial Neuropathy (Tarsal Tunnel Syndrome)

The tarsal tunnel is located at the inferoposterior margin of the medial malleolus. Its boundaries include the bones of the ankle and fibrous flexor retinaculum. The posterior tibial nerve and three flexor tendons of the foot and vessels lie within this tunnel. Compression can occur within the tunnel from tenosynovitis, enlarged veins, and fracture or dislocation of the ankle. Prolonged standing or walking may lead to vascular stasis and engorgement within the tunnel. A horse jockey is in one of the few occupations associated with this syndrome. The primary

symptom of tarsal tunnel syndrome is painful, burning paresthesias in the sole of the foot that are worse after a day of activity and may extend into the night. The symptoms can be reproduced or exacerbated by gentle percussion over the tarsal tunnel (Tinel's sign). The patient may also have weakness in the intrinsic muscles of the foot, making it difficult to push off during walking. Definitive treatment is surgical decompression involving release of the retinaculum.

Interdigital Neuropathy

A common cause of foot pain, entrapment of an interdigital nerve is often caused by a Morton's neuroma or benign swelling of the nerve. Tenderness is appreciated in the web space between the metatarsal heads. Any space can be affected, but the second and third web spaces are most often involved. Running, ballet dancing, and wearing tight shoes or high heels are all risk factors. Modifying risk factors, local corticosteroid injection, and surgical release are treatment options.

Polyneuropathies

Inflammatory Neuropathies

With inflammatory neuropathies, an inflammatory process is directed against the peripheral nerve; the most common causes follow. Treatment is usually directed toward the causative agent.

Human Immunodeficiency Virus

Several opportunistic infections of the PNS may result from HIV infection. The HIV itself, cytomegalovirus, and herpes zoster are most common. Painful sensorimotor polyneuropathies or demyelinating polyradiculoneuropathies occur during the early and late stages of HIV disease. Symptomatic relief of neuropathic pain may be achieved with antidepressants (e.g., amitriptyline) or anticonvulsants (e.g., carbamazepine).

Lyme Disease

The early stages of disseminated Lyme disease have resulted in Bell's palsy or an inflammation of CN VII (facial nerve) in approximately 11% of Lyme disease patients (Wilkinson, 1998). In the later stages of Lyme disease, a neuropathy mimicking CIDP can occur.

Leprosy

Although uncommon in the United States, leprosy is the most common worldwide treatable cause of neuropathy. Symptoms of neuropathy can occur before the systemic manifestations of disease are present. As leprosy progresses, with its characteristic skin lesions, the risk for peripheral nerve injury increases. Sensory loss of some degree is expected. Treatment is directed toward the disease itself.

Acute Inflammatory Demyelinating Polyradiculoneuropathy

Guillain-Barré syndrome, or acute inflammatory demyelinating polyradiculoneuropathy, is a rapidly progressive paralytic syndrome affecting persons of all ages. GBS seems to occur through an immune-mediated process. Many cases follow a mild gastrointestinal or upper respiratory viral illness by 1 to 3 weeks. Other risk factors include pregnancy, influenza immunization, the postoperative period, and HIV infection. A particularly strong link between *Campylobacter*

jejuni infection and GBS has been suggested in up to 20% of cases (Dyck et al., 1993).

The traditional description of a rapid progression of ascending symmetric weakness starting in the lower extremities and moving to the upper extremities is often useful, *but variations are quite common*. Indeed, early development of proximal weakness is frequently seen, and involvement of upper extremities before lower extremities is not rare. In general, the presentation is one of rapid progression of an ascending symmetric weakness, usually starting in the lower extremities and moving to the upper extremities. Patients may initially complain of pain and paresthesias in the back and proximal limbs. The progressive weakness that involves the legs as well as the upper extremities, trunk, intercostals, head, and neck muscles may take several days to 4 weeks and often results in paralysis. There may be mild sensory impairment in the extremities, early loss of DTRs, and bilateral facial nerve palsy in up to 40% of patients. Nerve conduction studies demonstrate demyelination, and the CSF may show an increased protein level, with normal cell counts.

The differential diagnosis of a rapid-onset polyradiculoneuropathy includes botulism, diphtheria, hypophosphatemia, acute intermittent porphyria, poliomyelitis, Lyme disease, poisoning from contaminated shellfish (e.g., tetrodotoxin), and toxic neuropathies (e.g., arsenic, mercury, thallium).

Because of the rapidly progressive nature of GBS, patients should be monitored in the hospital for signs of respiratory failure and autonomic instability (arrhythmias, hypotension, hypertension, and hyperpyrexia in two thirds of patients). Treatment usually consists of plasmapheresis or intravenous human immune globulin (IVIG). There is no role for steroids in the acute treatment of GBS. In most patients, recovery is complete or nearly complete, although it may take a few weeks to 18 months. About 10% of cases result in severe permanent disability. Even under the best circumstances, 3% to 5% of patients do not survive.

Chronic Inflammatory Demyelinating Polyradiculoneuropathy

CIDP is an acquired motor and sensory neuropathy of unknown cause. As with GBS, an immune-mediated pathogenesis is suspected. Unlike GBS, CIDP usually occurs in the absence of a preceding illness. Unusual exceptions include HIV infection, dysproteinemias, and lupus erythematosus. CIDP is predominantly a motor polyneuropathy affecting those of all ages, with a progressive or relapsing course. Weakness can be proximal or distal but usually develops in the legs over at least 2 months, distinguishing CIDP from GBS. Sensory changes include numbness or paresthesias but can be variable. DTRs are decreased or absent. Electrodiagnostic and CSF findings are similar to those found in GBS. Treatment includes prednisone, along with plasmapheresis or IVIG. CIDP should be distinguished from other acquired and hereditary neuropathies.

Metabolic Neuropathies

Diabetic Neuropathy

Diabetes is the cause of the most common polyneuropathy seen by family physicians, occurring in up to 50% of all diabetic patients. Its incidence usually rises with disease

progression. Diabetic peripheral neuropathy has a widely variable presentation but usually is seen as a symmetric polyneuropathy, with predominant sensory signs and mild motor signs. Patients experience burning dysesthesias and pain in the soles of the feet. Impaired position sense leading to ataxia and arthropathy (Charcot's joints) implies the involvement of large, myelinated, sensory fibers. Patients with diabetic neuropathy experience bilateral symptoms that include burning pain in the back and thigh with proximal muscle weakness, decreased patellar DTRs, and normal sensory function. This is thought to be caused by microvascular ischemia of the proximal motor trunks. Diabetes is also associated with autonomic neuropathies. Symptoms may include postural hypotension, gastroparesis, intestinal dysmotility, atonic bladder, impotence, and loss of pain fibers in the cardiac sympathetic system, permitting silent MI.

Uremic Neuropathy

Patients with chronic renal disease develop a symmetric sensorimotor neuropathy involving the upper and lower extremities. They complain mostly of burning paresthesias. Uremic neuropathy is thought to be secondary to a toxic effect on the peripheral nerves. Because many chronic renal patients also have diabetes, it is often difficult to isolate a single cause. However, patients with true uremic neuropathy who have undergone renal transplantation can have dramatic improvement of symptoms (Rees, 1995).

Nutritional Neuropathies

Most nutritional neuropathies involve one of the B-complex vitamins. Patients at risk for these neuropathies usually have chronic alcoholism, malabsorption syndrome, eating disorder, or unusual diet (food faddist). It presents as a symmetric polyneuropathy with burning in the feet. Weakness, atrophy, and hypoactive reflexes may also occur.

Alcoholic neuropathy is caused from inadequate intake and poor absorption. Treatment with multivitamin supplementation is usually adequate but may take time to be effective. Thiamine (vitamin B₁) deficiency, or beriberi, is seen most often with chronic alcoholism. It may present as a distal polyneuropathy or as a more serious Wernicke-Korsakoff encephalopathy, with mental status changes. In the latter case, intramuscular thiamine (100 mg/day) is preferred initially over oral administration. Pyridoxine (vitamin B₆) deficiency can be associated with the use of dapsone or isoniazid, which interfere with vitamin B₆ metabolism. Prevention requires supplementation with 50 mg of pyridoxine three times daily. Prolonged intake of pyridoxine of more than 2 g/day has also been associated with sensory neuropathy (Rostami, 1995). Vitamin B₁₂ deficiency may present only with vague paresthesias. Determining the serum vitamin B₁₂ level is the best way to assess a patient when this problem is suspected, because abnormal RBC indices may not be apparent until irreversible neurologic symptoms have already occurred.

Hereditary Neuropathies

The hereditary neuropathies are often missed by family physicians and even by those close to the affected patient. These indolent, slowly progressive polyneuropathies may present with motor, autonomic, and less often, sensory symptoms.

Box 42-22 Neuropathies Caused by Drugs and Toxins

| Drugs | | Toxins |
|-----------------|----------------------|-----------------------------|
| Axonal | Demyelinating | Industrial |
| Amitriptyline | Amiodarone | Organophosphates |
| Chloroquine | Colchicine | Lead, arsenic, mercury |

| Metronidazole | | |
| Nitrous oxide | | |
| Nitrofurantoin | | |
| Paclitaxel | | |
| Phenytoin | | |
| Pyridoxine | | |
| Procainamide | | |
| Vincristine | | |

These include pes cavus, absent tendon reflexes, a high-stepping or slapping gait, footdrop, slowly progressive wasting and weakness of peroneal muscles, foot ulcers, joint arthropathy, and absence of sweating. Without a specific treatment for these neuropathies, efforts are focused on management of physical disabilities, education, genetic counseling, and reassurance. Hereditary neuropathies and CIDP can both have a familial pattern, the important difference being that CIDP is treatable.

Toxic Neuropathies

Toxic neuropathies occur from repeated exposure to drugs, industrial toxins, or heavy metals (Box 42-22). Presentation depends on the exact exposure and what part of the nerve is affected. It may present as a progressive, symmetric, ascending polyneuropathy, as in many occupational exposures, or with vague sensory changes similar to those of nutritional neuropathies. Lead intoxication creates a motor neuropathy starting in the upper limbs, affecting the radial nerve and causing wristdrop. Many of these neuropathies slowly improve once the offending agent is removed; however, this is not always the case. A careful medical and occupation history is important. Treatment is directed accordingly.

Dysproteinemic Neuropathies

Dysproteinemias such as cryoglobulinemia, myeloma, amyloidosis, lymphoma, monoclonal gammopathies, and some leukemias are associated with peripheral neuropathy. In patients with idiopathic peripheral neuropathies, a *monoclonal gammopathy* can be identified in up to 10% (Kissel and Mendell, 1996). Plasma exchange is useful as a treatment option for some of the dysproteinemic neuropathies.

Carcinomatous Neuropathies

Carcinomatous neuropathies may result from direct compression by a solid tumor or local infiltration of nerves. The most common association is lung carcinoma. Some chemotherapeutic agents, such as vincristine and cisplatin, have neurotoxic side effects. The most common presentation is that of a distal sensorimotor polyneuropathy. In up to 16% of patients with lung carcinoma and 4% of those with breast carcinomas, peripheral neuropathy preceded the actual signs of the disease.

Cranial Neuropathies

Key Points

- Bell's palsy is an acute unilateral paralysis of the facial nerve and involves the forehead muscles.
- Trigeminal neuralgia is usually a unilateral severe lancinating pain lasting a few seconds, triggered by innocuous stimuli (light touch to face, toothbrushing).
- Trigeminal neuralgia is rarely seen in patients less than 40 years of age.

Many conditions or infections may affect the cranial nerves and cause a peripheral neuropathy. Two common problems encountered by family physicians are idiopathic acute peripheral facial paralysis (Bell's palsy) and trigeminal neuralgia (tic douloureux).

Idiopathic Acute Peripheral Facial Paralysis

Bell's palsy is an acute, unilateral paralysis of the facial nerve of unknown etiology but possibly linked to an antecedent herpes infection (Adour, 1975). Bell's palsy is likely the most common isolated cranial neuropathy (23 per 100,000) seen by family physicians (Hauser, 1971). Symptoms tend to develop over hours to days and may be associated with recent upper respiratory infection. Symptoms include partial or complete paralysis of the ipsilateral facial muscles, forehead involvement, otalgia, phonophobia, and cephalgia. If the forehead muscles are spared, one must consider a central etiology to the symptoms. Bilateral findings of Bell's palsy should prompt consideration of GBS, sarcoidosis, disseminated Lyme disease, or diabetes.

Most patients with Bell's palsy will recover with only supportive therapy within a few days to a few months. This makes aggressive treatment controversial. A recent meta-analysis showed that high-dose corticosteroids (>450 mg total dose) were associated with greater benefit and decreased risk of unsatisfactory recovery, whereas antiviral agents showed no benefit alone but may have additional benefit when used with corticosteroids (de Almeida et al., 2009). A typical corticosteroid regimen may include oral prednisone, 60 mg/day for 7 days, then tapering by 10 mg/day, with or without valacyclovir, 500 mg orally three times daily for 7 days.

KEY TREATMENT

High-dose corticosteroids (>450 mg total dose) help reduce the risk of unsatisfactory recovery from Bell's palsy (de Almeida et al., 2009) (SOR: A).

Trigeminal Neuralgia

Trigeminal neuralgia (tic douloureux) usually involves the second and third (maxillary and mandibular) divisions of the trigeminal nerve, causing pain of the innervated structures (lips, gums, teeth). It is almost always unilateral, with the pain sudden, sharp, and severe, lasting a few seconds at a time. This cycle of pain can occur hundreds of times a day. It may be described as lancinating, ice pick like, or an electric shock and characteristically is precipitated by innocuous stimuli such as light touch to the face or toothbrushing. It is rarely seen in patients younger than 40. Pain that is longer in duration, bilateral, or described as more aching or pressure like is usually not related to trigeminal neuralgia and should cause the physician to search for another cause. Other conditions that should be considered include multiple sclerosis, acoustic neurinoma, aneurysm, meningioma, trigeminal neuroma, and early herpes zoster or postherpetic neuralgia. Herpes zoster should be suspected in patients younger than 40 who present with pain following the upper division of the trigeminal nerve (forehead and eye). Neuroimaging with MRI scanning of the brain is recommended to exclude these causes from idiopathic disease.

A common initial pharmacologic treatment for idiopathic trigeminal neuralgia is carbamazepine (Tegretol), up to 800 mg/day, or oxcarbazepine (Trileptal), up to 1200 mg/day. Usually, these medications are started at relatively low doses (100-200 mg once or twice daily) and increased at 7- to 10-day intervals until adequate symptom control is achieved. Patients should be educated that these medicines will only work when taken on a consistent basis and not as an analgesic medication. Other medications that have been used but are not FDA approved include gabapentin (Neurontin), amitriptyline, and baclofen. Toxicities from these medications, including allergic reactions, bone marrow suppression, and liver toxicity, may develop and thus require close monitoring. Patients with refractory symptoms or who do not tolerate pharmacologic treatment should be considered for neurosurgical evaluation.

Parkinson's Disease

Key Points

- The hallmark clinical features of Parkinson's disease include resting tremor, rigidity and bradykinesia of asymmetric onset.
- Symptoms such as hallucinations, gait abnormalities, paralysis of upward gaze, early dementia, early postural instability, early autonomic dysfunction, involuntary movements other than a tremor and a failure to respond to levodopa suggest a parkinsonism-plus syndrome and require further evaluation.
- Drug therapy for Parkinson's disease should be initiated when the symptoms are significant enough to cause functional impairment.

Parkinson's disease is the second most common progressive neurodegenerative disorder in the United States after Alzheimer's disease. Parkinson's affects about 1% of the population over age 60 and 4% to 5% of those older than 85. The disease is uncommon before age 40, and incidence is higher in men than women. A genetic predisposition to Parkinson's disease may be present; up to 15% of patients will have a first- or second-degree relative with Parkinson's

disease. At present, no clear environmental links to Parkinson's disease have been identified. The disease is caused by a disruption of dopaminergic neurotransmission in the basal ganglia and the development of eosinophilic intracytoplasmic inclusions (Lewy bodies) in the residual dopaminergic neurons.

Symptoms and Signs

The hallmark clinical features of Parkinson's disease include tremor, rigidity, and bradykinesia, usually of asymmetric onset. Tremor is the presenting symptom in up to 70% of patients, and in fact, an asymmetric rest tremor is virtually pathognomonic of Parkinson's disease. Many patients present to the family physician complaining of a tremor and the concern they may have Parkinson's disease. Most will have *essential tremor*, which can be differentiated from the tremor of Parkinson's disease in that essential tremor is usually symmetric and exacerbated by action, whereas the tremor of Parkinson's disease is usually at rest and asymmetric.

Rigidity is often associated with *cogwheeling*, a ratchety quality during passive movement of the limb. *Bradykinesia* refers to the slowness of movements, which usually begins in an asymmetric fashion, described by the patient as "weakness" of an extremity, although no abnormalities are noted with strength testing. Other clinical features associated with Parkinson's disease include micrographia, paucity of facial expression (masked facies), narrow shuffling gait, and postural instability (late finding). Behavioral and cognitive symptoms are frequently seen in patients with Parkinson's disease as well.

Differential Diagnosis

Up to 20% of patients initially diagnosed with Parkinson's disease ultimately have an alternative diagnosis. The term *parkinsonism-plus syndrome* is used for patients who have similar symptoms but also have additional abnormalities or do not respond to the usual medications. Symptoms that suggest a parkinsonism-plus syndrome include hallucinations, gait abnormalities, paralysis of upward gaze, early dementia, early postural instability, early autonomic dysfunction, involuntary movements other than tremor, and a failure to respond to levodopa (Italian Neurological Society, 2003). Conditions that frequently may be confused with Parkinson's disease include progressive supranuclear palsy, dementia with Lewy bodies, multiple-system atrophy, vascular parkinsonism, and drug-induced parkinsonism.

Progressive supranuclear palsy (PSP) may initially be mistaken for Parkinson's disease. Patients have ophthalmoparesis of vertical gaze, primarily downward gaze. Early loss of postural reflexes, predominantly axial rigidity, pseudobulbar palsy, and frontal lobe signs are other characteristics of PSP. Response to dopaminergic medications is minimal.

Dementia with Lewy bodies has motor symptoms similar to those of Parkinson's disease, and there may be a response to levodopa. Rigidity is usually more prominent than bradykinesia or tremor. Additionally, there is early cognitive impairment and hallucinations early in the disease course.

Multisystem atrophy includes a number of diseases, and it is not clear if they represent distinct diseases or a single, pathologic continuum. This group includes olivopontocerebellar atrophy, striatonigral degeneration, and Shy-Drager syndrome.

Symptoms are related to autonomic nervous system dysfunction and include orthostatic hypotension, cerebellar dysfunction, bladder dysfunction, and a poor levodopa response.

Vascular parkinsonism may be associated with multiple vascular lesions in the basal ganglia. There is usually a stepwise progression to the disease. Tremor at rest is not a common finding, and the bradykinesia and rigidity tend to be more significant in the legs. The gait is often broad based. Associated symptoms include dementia, spasticity, and weakness. MRI studies show multi-infarct changes, and the response to levodopa is poor.

A final category of Parkinson-like conditions is *drug-induced parkinsonism*. It is important to identify this cause because it is usually reversible. Drug-induced parkinsonism accounted for 20% of cases of parkinsonism-plus conditions in a population-based study (Bower et al., 1999). Medications that can cause these symptoms include neuroleptics, atypical neuroleptics, antiemetic medications (e.g., metoclopramide, prochlorperazine), amiodarone, valproic acid, and lithium. Medicines that block the synthesis of dopamine, such as methyldopa (Aldomet), or deplete dopamine (e.g., reserpine), can also induce parkinsonism (Nutt and Wooten, 2005).

Diagnostic Evaluation

An extensive diagnostic evaluation is not necessary when the history and physical examination reveal classic findings of Parkinson's disease. Imaging of the brain with CT or MRI may be performed if the diagnosis is in question and to rule out other conditions such as NPH or vascular parkinsonism. Consultation with a neurologist may be helpful, especially if the diagnosis is in question or a parkinsonism-plus diagnosis is likely.

Treatment

Currently, diagnosis of Parkinson's disease does not relegate a patient to pharmacologic treatment. Drug therapy should be initiated when the symptoms are significant enough to cause functional impairment (Rao et al., 2006). Current therapies do not appear to slow the progression of the disease and no studies have clearly demonstrated a best initial treatment for this condition (Schreck et al., 2003). [Table 42-17](#) summarizes the pharmacologic agents available to treat Parkinson's disease.

Pharmacotherapy

Levodopa, a precursor of dopamine, is the most frequently prescribed agent for the treatment of symptomatic Parkinson's disease and is particularly effective at controlling bradykinesia and rigidity (Miyasaki et al., 2002). Alone, levodopa is absorbed but is peripherally metabolized to dopamine by dopa-decarboxylase enzymes. This peripheral conversion limits the overall effectiveness of levodopa and increases the side effects, including nausea, vomiting, and hypotension. To remedy this, levodopa is combined with carbidopa, which prevents this peripheral conversion. Dopa-decarboxylase is saturated with 70 to 100 mg of carbidopa. Thus the usual starting dose of carbidopa-levodopa is 25 mg/100 mg three times daily (Rao et al., 2006).

Dopamine agonists directly stimulate dopamine receptors, thus bypassing the presynaptic synthesis of dopamine. These medications cause less dyskinesia and fewer fluctuations

Table 42-17 Medications for Parkinson's Disease

| Generic Name | Recommended Dosage | Side Effects/Comments |
|--|--|---|
| Anticholinergics | | |
| Trihexyphenidyl (Artane) | 1 mg tid; increase to 2 mg tid | Effective for tremor. Side effects include impaired memory, blurred vision, and urinary retention. |
| Benzotropine (Cogentin) | 0.5 mg at bedtime; increase by 0.5 mg up to max 1 mg bid. | Same as for trihexyphenidyl. |
| Carbidopa-Levodopa Combinations | | |
| Immediate release (Sinemet) | 25 mg/100 mg initially ½ tablet tid; increase by ½ tablet every 4-7 days. | "Gold standard" of therapy. Long-term therapy may result in motor fluctuations, dyskinesias, confusion, and hallucinations. |
| Controlled release (Sinemet-CR) | 1 tablet bid | Same as for immediate release. |
| Carbidopa-levodopa plus entacapone (Stalevo) | 1 tablet tid | Same as for other carbidopa-levodopa preparations, plus diarrhea. |
| Catechol-O-Methyltransferase (COMT) Inhibitors | | |
| Tolcapone (Tasmar) | 100 mg or 200 mg tid | Adjunct to levodopa to prevent motor fluctuations. Monitor liver functions. |
| Entacapone (Comtan) | 200 mg with each dose of carbidopa-levodopa, up to 8 times daily | Same as for tolcapone. |
| Dopamine Agonists | | |
| Bromocriptine (Parlodel) | 1.25 mg with meals bid; increase by 2.5 mg every 2-4 weeks to max 15 mg/day. | Effective in monotherapy or as adjunct to levodopa. |
| Pramipexole (Mirapex) | 0.125 mg tid, max 1.5 mg tid | Side effects include excessive daytime somnolence, hypotension, confusion, and hallucinations. |
| Ropinirole (ReQuip) | 25 mg tid; increase weekly by 0.25 mg tid to 3 mg tid. Max dose 8 mg tid | Same as for pramipexole. |
| Monoamine Oxidase Type B (MAO-B) Inhibitors | | |
| Selegiline (Eldepryl) | 5 mg at breakfast and lunch | Avoid use with SSRIs, TCAs, and meperidine. Side effects include nausea, dizziness, hallucinations, abdominal pain, and vivid dreams. |
| Rasagiline (Azilect) | 0.5 mg/day to 1 mg/day | Side effects include extrapyramidal symptoms, dyskinesia, hallucinations, hypotension, and depression. |
| N-Methyl-D-Aspartate (NMDA) Antagonist (Receptor Inhibitor) | | |
| Amantadine (Symmetrel) | 100 mg twice daily | May be used as monotherapy. Side effects include dizziness, confusion, livedo reticularis, and hallucinations. |

bid, Twice daily; *tid*, three times daily; *SSRIs*, selective serotonin reuptake inhibitors; *TCAs*, tricyclic antidepressants.

than levodopa. They can be used alone or in conjunction with levodopa. Currently, bromocriptine (Parlodel), pramipexole (Mirapex), and ropinirole (ReQuip) are medications in this class available for the treatment of Parkinson's disease. Apomorphine (Apokyn) is also available as a subcutaneous injection for the treatment of sudden, resistant "off" periods (Goetz et al., 2005). It has significant adverse effects and should only be used by individuals experienced with its use. Dopamine agonists should not be used in patients with

dementia because of the high likelihood of producing hallucinations (Nutt and Wooten, 2005).

Monoamine oxidase type B (MAO-B) inhibitors were initially thought to provide a neuroprotective effect to patients with Parkinson's disease. This has not been supported in the literature. Agents available in the United States in this class include selegiline (Eldepryl), orally disintegrating selegiline (Zelapar), and rasagiline (Azilect). A meta-analysis of 17 trials comparing MAO-B inhibitors with placebo or levodopa

revealed MAOIs reduce disability, incidence of motor fluctuations, and need for levodopa (Ives et al., 2004).

Anticholinergic medications primarily work on the muscarinic acetylcholine receptors. These medications have low effectiveness and a high incidence of side effects which limit their overall usefulness to patients younger than 70 years and with preserved cognitive function.

Degradation of levodopa in the periphery is known to be associated with motor fluctuations and dyskinesia in Parkinson's disease. The enzyme catechol-*O*-methyltransferase (COMT) is responsible for part of this degradation. *COMT inhibitors* prolong the dopamine response. Two medications in this category are tolcapone (Tasmar) and entacapone (Comtan). These medications reduced "off" time, reduced total levodopa dose, and improved motor symptoms in patients with advanced Parkinson's disease and motor complications (Cochrane review; Deane et al., 2004). As such, COMT inhibitors are usually reserved for more advanced cases.

Among *NMDA antagonists* (NMDA receptor inhibitors), amantadine (Symmetrel), originally developed as an antiviral agent, is useful for tremor, rigidity, and bradykinesia associated with Parkinson's disease, although few studies demonstrate its clear efficacy. Amantadine may also have a dopamine agonist effect as well as an anticholinergic effect. Side effects include dizziness, insomnia, nausea, and vomiting.

Surgical Treatment

Surgical treatments are options to be considered when tremor, motor fluctuations, and dyskinesia are not adequately controlled with medications alone. Techniques that offer potential benefit include unilateral pallidotomy and deep brain stimulation of the globus pallidus interna or subthalamic nucleus (Goetz et al., 2005). Patients with symptoms not controlled medically should be referred to specialized centers with surgeons experienced in performing these procedures.

Treatment of Nonmotor Symptoms

Patients with Parkinson's disease frequently develop other comorbid conditions such as depression or dementia. In the case of depression, an SSRI can be used. Up to 40% of patients develop dementia (Aarsland et al., 2003). In these patients the cholinesterase inhibitors can be effective. Parkinson's disease is a progressive illness, so it is important for the family physician to discuss advanced directives, establishment of power of attorney for health care decisions, and the patient's wishes surrounding the use of artificial nutrition. Living wills and other legal documents should be prepared and appropriate discussions documented. Common symptoms such as constipation, sleep disturbance, and orthostatic hypotension should be aggressively treated.

KEY TREATMENT

Levodopa, dopamine agonists, and MAO-B inhibitors, alone or in combination, are effective in treating the symptoms of Parkinson's disease (Rao et al., 2006) (SOR: A).

Usual starting dose of carbidopa-levodopa is 25 mg/100 mg three times daily (Rao et al., 2006) (SOR: A).

Surgical therapies (unilateral pallidotomy, deep brain stimulation) are effective when medical therapy fails to control Parkinson symptoms (Goetz et al., 2005) (SOR: B).

Multiple Sclerosis

Key Points

- The diagnosis of multiple sclerosis requires evidence of demyelinating disseminated disease.
- Optic neuritis, nystagmus from internuclear ophthalmoplegia, and Lhermitte's sign are highly suggestive of MS.
- The currently most widely accepted diagnostic criteria for MS are the McDonald criteria, established by an international panel in 2001 and revised in 2005.

Multiple sclerosis (MS) is a recurrent, chronic, demyelinating, autoimmune disorder that affects the central nervous system. The mean age of onset for MS is 29 to 33 years, although the range is 15 to 50 years, which makes this the most common cause of neurologic disability in young adults.

Diagnosis

The diagnosis of MS is based on clinical signs and symptoms combined with diagnostic testing, which may include MRI, CSF analysis, and visual-evoked potentials (VEPs). Definitive diagnosis of MS requires evidence of demyelinating disease disseminated over time and space (McDonald et al., 2001). That is, clinical symptoms should last at least 24 hours and should be separated by at least 30 days, and should affect two different areas of the CNS: the brain, spinal cord, or optic nerves. The clinical symptoms vary, depending on which part of the CNS is involved. Three symptoms are highly suggestive of MS: optic neuritis, nystagmus resulting from internuclear ophthalmoplegia, and Lhermitte's sign, which is an electrical sensation extending down the back and legs with flexion of the neck. The International Panel of the Diagnosis of Multiple Sclerosis developed criteria for the diagnosis of MS (McDonald et al., 2001), revised in 2005 and summarized in [Table 42-18](#) (Polman et al., 2005). It is important to remember that alternative diagnoses should be considered and excluded. These would include CNS vasculitis, paraneoplastic syndromes, sarcoidosis, leukodystrophies, CNS tumors, infections, CNS lymphoma, and nutritional deficiencies, such as B₁₂ deficiency.

The precise relationship between clinical symptoms and MR findings are not well understood. Thus, MRI alone is not useful in predicting the clinical course of MS. T2-weighted MR images best define the size of white matter lesions, and gadolinium can reveal the disruption of the blood-brain barrier associated with an active MS lesion. In general, MR findings consistent with MS must include at least three of these findings: (1) one gadolinium-enhancing lesion or nine T2 hyperintense lesions if gadolinium-enhancing lesions are not present; (2) at least one infratentorial lesion; (3) at least one juxtacortical lesion; and (4) at least three periventricular lesions. These lesions should be at least 3 mm in cross section (Barkof et al., 1997; Tintore et al., 2000). Spinal cord lesions can be substituted for one of the brain lesions as long as it reveals little or no swelling of the spinal cord, is unequivocally hyperintense if detected with T2-weighted MR images, at least 3 mm in size but less than two vertebral segments in length, and occupies only part of the cross section of the spinal cord (Polman et al., 2005).

Table 42-18 Criteria for Multiple Sclerosis (MS)

| Clinical Presentation | Additional Data Needed |
|--|--|
| Two or more attacks (relapses); two or more objective clinical lesions | None; clinical evidence will suffice (additional evidence desirable but must be consistent with MS) |
| Two or more attacks; one objective clinical lesion | Dissemination in space, demonstrated by MRI or Positive CSF and two or more MRI lesions consistent with MS or further clinical attack involving different site |
| One attack; two or more objective clinical lesions | Dissemination in time, demonstrated by MRI or second clinical attack |
| One attack; one objective clinical lesion (monosymptomatic presentation) | Dissemination in space by demonstrated by MRI or Positive CSF and two or more MRI lesions consistent with MS and Dissemination in time demonstrated by MRI or Second clinical attack |
| Insidious neurologic progression suggestive of MS (primary progressive MS) | Positive CSF and Dissemination in space demonstrated by MRI evidence of nine or more T2 brain lesions or Two or more spinal cord lesions or Four to eight brain and one spinal cord lesion or Positive VEP with four to eight MRI lesions or Positive VEP with less than four brain lesions and one spinal cord lesion and Dissemination in time demonstrated by MRI or Continued progression for 1 year |

Modified from McDonald WI, Compston A, Edan G, et al. Recommended diagnostic criteria for multiple sclerosis: Guidelines from the International Panel on the diagnosis of multiple sclerosis. *Ann Neurol* 2001;150:121.
MRI, Magnetic resonance imaging; CSF, cerebrospinal fluid; VEP, visual-evoked potential.

The CSF analysis of patients with MS generally demonstrates a normal opening pressure, cell count, glucose level, protein level, and culture. The most clinically useful CSF abnormality is the presence of oligoclonal immunoglobulin G (IgG) bands resulting from intrathecal IgG synthesis, which can be found in up to 90% of patients with MS (Freedman et al., 2005). IgG bands are not specific to MS and are also seen in sarcoidosis, AIDS, and subacute sclerosing panencephalitis. The value of CSF analysis is mainly limited to MS patients with only a few lesions on MRI, or to make the diagnosis of primary progressive MS, as discussed later. Visual-evoked responses may also provide supporting evidence for MS, particularly in situations with few abnormalities on MRI. Other VEP analysis offers little in establishing a diagnosis of MS (Gronseth and Ashman, 2000).

Clinical Course

Four subtypes of MS are currently described—relapsing remitting, secondary-progressive, primary progressive, and progressive-relapsing. *Relapsing-remitting* MS accounts for about 85% of the initial diagnosis of MS patients and is characterized by acute attacks followed by full recovery. The interval between relapses can be variable and is characterized by a lack of disease progression. *Secondary-progressive* MS is characterized by a pattern that is initially relapsing-remitting but then evolves into a pattern of progressive neurologic decline. MRI demonstrates more extensive lesions, and approximately 50% of patients initially diagnosed with relapsing-remitting MS will develop secondary-progressive disease. *Primary-progressive* MS, characterized by a gradual disease progression from the initial onset, accounts for approximately 10% of MS diagnoses and has limited

treatment options. *Progressive-relapsing* MS demonstrates a pattern of steady progression from the time of onset that may be punctuated by clearly defined relapses. The patients may or may not fully recover from these acute relapses.

Treatment

The treatment of MS can be divided into disease-modifying therapies, medications for acute relapses, and symptomatic management. Although there is no definitive cure, disease-modifying therapies may reduce the frequency of relapses, slow the rate of progression, and reduce the acute inflammatory response. Symptomatic therapy can improve the control of many of the functional disabilities and thus improve quality of life.

Disease-Modifying Therapies

It is generally held that disease-modifying therapy should be initiated immediately on the diagnosis of MS (Coyle and Hartung, 2002). Disease-modifying therapy has been shown to be more effective in preventing new lesion formation than repairing old lesions. These therapies include interferon beta-1b (Betaseron), interferon beta-1a (Avonex, Rebif), and glatiramer acetate (Copaxone). The beta interferons are immunomodulating medications that also have antiviral activities. They have been shown to reduce relapses in patients with the relapsing-remitting form of MS. Betaseron is given as an alternating-day subcutaneous (SC) injection, Rebif is a three-times-weekly SC injection, and Avonex is administered as a weekly intramuscular injection. All have similar side effects, including injection site reactions, influenza-like symptoms, and worsening of preexisting depression. Bone marrow suppression and transient elevation of liver enzymes may also occur.

Glatiramer (Copaxone) is a synthetic polypeptide consisting of four amino acids. It is thought to lead to the induction of antigen-specific suppressor T cells. It is administered as a daily SC injection and has been shown to reduce relapses by approximately 30% (Comi et al., 2001). Side effects include postinjection reactions and occasionally a reaction involving flushing, chest pain, anxiety, and dyspnea. The reaction is self-limited and does not require discontinuation of the medication.

Two other disease-modifying drugs for MS are mitoxantrone and natalizumab. Mitoxantrone is a synthetic anthracenedione given by IV infusion once every 3 months. It has been shown to reduce MS relapses by 67% (Hartung et al., 2002). Mitoxantrone is blue and can lead to transient bluish discoloration of the sclera and urine. It also can cause cardiotoxicity, and as a chemotherapeutic agent, should only be prescribed for worsening cases of MS not responding to first-line agents. Also, only experienced health care professionals should prescribe mitoxantrone.

Natalizumab is a monoclonal antibody that blocks α_4 -integrin. This molecule is involved in moving circulating leukocytes into the brain in response to inflammation. It is administered as a 1-hour infusion every 4 weeks. Natalizumab has been shown to reduce clinical relapses, slow the progression of disability, and reduce the development of new brain lesions (Polman et al., 2006). Complications that limit its use include a hypersensitivity reaction up to an hour after infusion. Natalizumab has also been associated with progressive multifocal leukoencephalopathy, a destructive brain infection caused by JC virus. Therefore the distribution and use of natalizumab is closely monitored, and it can be administered only by registered physicians.

Medications for Acute Relapses

Glucocorticoids are still widely used for the treatment of acute exacerbations of MS. The principal effects of corticosteroids appear to be related to their anti-inflammatory and

antiedema effects. It is recommended as standard therapy for any patient with an acute attack of MS (Goodin et al., 2002). Treatment normally consists of 3 to 5 days of a 1-g/day IV infusion of methylprednisolone. Oral prednisone taper may or may not be used after infusion.

Symptomatic Management

Medications used for symptomatic management depend on the specific symptoms encountered by the patient. MS patients frequently develop spasticity, which can be treated with baclofen, tizanidine, or benzodiazepines. Physical therapy can also help with spasticity. Bladder dysfunction can also occur in patients with MS. New bladder symptoms should be evaluated with a urine culture to rule out infection. A postvoid residual should also be obtained, as well as urodynamic testing to determine whether the problem is overflow incontinence from urinary retention or urge incontinence from detrusor instability. In the presence of urge incontinence, the anticholinergics oxybutynin (Ditropan) and tolterodine (Detrol) may be useful. If the problem is urinary retention and overflow incontinence, patients will usually need to be treated with intermittent self-catheterization. Patient may also experience depression, constipation, and sexual dysfunction. The usual evaluation and treatment options should be considered for patients who experience these problems.

KEY TREATMENT

Beta interferons have been shown to reduce the number of relapse in patients with the relapsing remitting form of MS (Coyle and Hartung, 2002) (SOR: A).

Glucocorticoids are recommended as standard therapy for any patient with an acute attack of MS (Goodin et al., 2002) (SOR: A).

Disease-modifying therapy should begin at diagnosis of MS (Coyle and Hartung, 2002) (SOR: B).

Overview

Sexuality is a fundamental aspect of human self-concept and a complex biopsychosocial process. Physiologic aspects of sexuality are interpreted within the patient's cultural and social context. Family physicians and primary care providers are well situated to offer patients basic information regarding human sexual health issues and to evaluate and treat most common sexual problems; however, they seldom ask patients about sexual functioning. This chapter describes the basic principles of evaluation of female and male sexual dysfunction and clinical management of common disorders.

Sexual Self-Concept

Humans possess a gender identity and a sexual orientation. *Gender*, in many Western cultures, is synonymous with their chromosomal or genital phenotype (male or female sex). *Gender identity*, however, is a more comprehensive internal self-perception of being male or female, masculine or feminine. Many cultures, including Native American and African groups, do not regard gender as being determined by sex characteristics, and these cultures may provide an accepted role for persons in whom these aspects are not congruent. *Sexual orientation* may be defined as the attraction individuals feel toward sexual partners of their own or the other gender. Sexual orientation is self-defined, and individuals may describe themselves at different points in their lifetime as exclusively attracted to their own gender (homosexuality) or the opposite gender (heterosexuality), or somewhere between these two (bisexuality).

Models of Human Sexual Response

Masters and Johnson first described the physiology of "human sexual response cycle" in 1966. Based on the physical components of sexual functioning, they described four phases of the sexual response cycle: excitement, plateau, orgasm, and resolution (Fig. 43-1). Helen Singer Kaplan subsequently described a more subjective, psychologically oriented sexual responsiveness model with three phases: desire, excitement, and orgasm. Recently, however, nonlinear alternative models have been suggested, especially for women's sexual response (Basson and Schultz, 2007) (Fig. 43-2). In certain settings, men may have similar nonlinear sexual responses. Response phases establish a framework to discuss sexual dysfunction.

Initial Evaluation of Sexual Problems

Many patients would benefit from detection and treatment of sexual problems; however, many clinicians do not ask, and patients may not volunteer the information. In the Global Study of Sexual Attitudes and Behaviors, which surveyed more than 27,000 adults age 40 to 80 in 29 countries, 49% of women and 43% of men reported experiencing at least one sexual problem; fewer than 20% had sought medical assistance for sexual issues (Moreira et al., 2005). Health care providers should proactively and routinely address sexual health.

The sexual health interview may be approached with a screening or abbreviated method, followed by in-depth questioning, if necessary (Nusbaum and Hamilton, 2002) (Box 43-1). The answers on the detailed sexual history then

direct the physical examination and appropriate laboratory testing. A physician may open the sexual history questioning with an *inclusion* technique: "Sexual health is important to overall health, therefore, I ask all my patients about it. I'm going to ask you a few questions on sexual matters now."

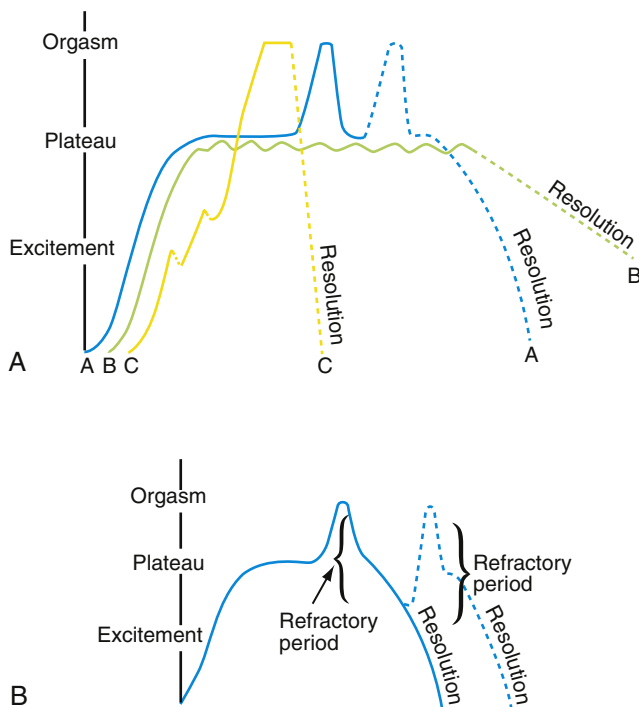

Figure 43-1 Female (A) and male (B) sexual response cycles. Desire precedes both cycles in this model. The phases illustrated are excitement, plateau, and orgasm. The length of the plateau phase is variable. Women may have a brief plateau followed by orgasm (cycle C) or a long plateau with no orgasm (cycle B). Women may have multiple orgasms before resolution, although many do not (cycle A). For men with premature ejaculation, the plateau phase is brief. After ejaculation, men enter a refractory period lasting minutes to hours during which they are unable to ejaculate.

The clinician can use normalization or universalization techniques. In *normalization* the clinician introduces emotionally laden or difficult subjects by implying these experiences are quite prevalent: "Many people have been sexually abused or molested as children. Did you have any experiences like that when you were young?" *Universalization* phrases questions as if everyone has done everything, making an affirmative answer easier for sensitive questions. For example, patients may be asked "How often do you masturbate?" instead of "Do you masturbate?" The clinician should also reassure the patient about physician-patient confidentiality.

Jack Annon in 1976 proposed the PLISSIT model to approach sexual concerns: Permission, Limited Information, Specific Suggestions, and Intensive Treatment (Box 43-2). The clinician can alternatively use the ALLOW acronym: Ask, Legitimize, Limitations, Open up, and Work together (Hatzichristou et al., 2004), as discussed next.

Ask. Questions regarding sexual functioning should be asked in a matter-of-fact yet sensitive manner. Physicians should avoid terms that make assumptions regarding patients' sexual behaviors. When inquiring about past or recent sexual encounters, the clinician may inquire "with men, women, or both?" Using the term "partner" instead of "husband" or "boyfriend" or "wife" or "girlfriend" may allow patients to discuss their sexual orientation openly. Slang words should be redefined in medical terminology so that the clinician and patient may communicate clearly.

Legitimize. By acknowledging the clinical relevance of sexual dysfunction, the clinician legitimizes the patient's sexual problem. Opening questions also can be linked to the patient's medical problems: "Many people with hypertension and heart disease notice a change in sexual functioning. Have you noticed any change?"

Limitations. The patient's knowledge may have limitations, and patient education may address the patient's perceived sexual dysfunction. For example, an older man with longer time between erections may not know the refractory period normally increases with age. Patient education and

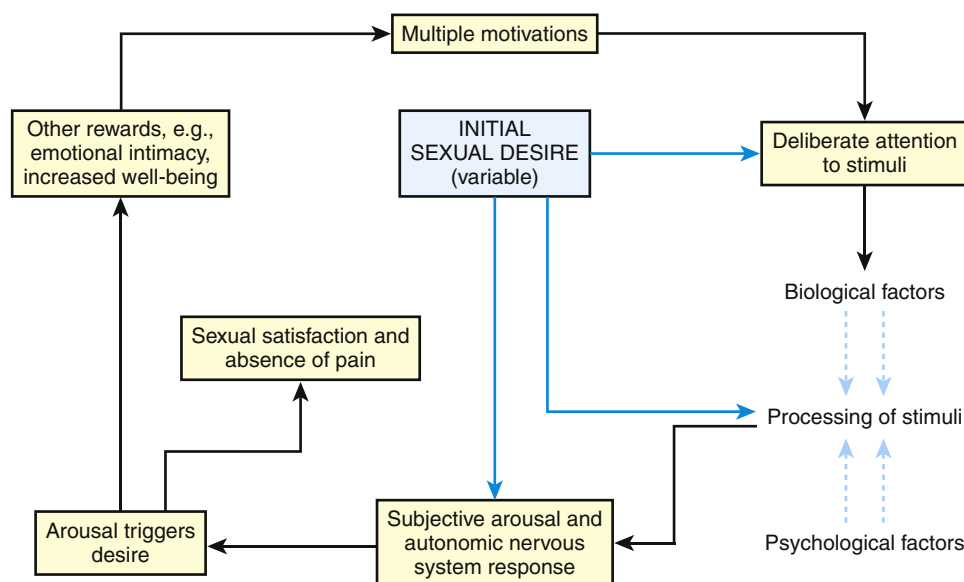

Figure 43-2 Circular model of female sexual response showing cycle of overlapping phases. (From Basson R, Schultz WW. *Sexual sequelae of general medical disorders*. Lancet 2007;369:409-424.

reassurance may eliminate his perceived “sexual dysfunction.” Physicians should recognize their own limitations and, if necessary, refer a patient to the appropriate specialist for further evaluation and treatment of a sexual dysfunction.

Open up, for further discussion and evaluation. A detailed sexual history may be needed to evaluate fully a patient’s

Box 43-1 Questions for a Detailed Sexual History

Are you currently sexually active? Have you ever been sexually active?

Are your sexual partners men, women, or both?

How many sexual partners have you had in the past month? Past 6 months? Lifetime?

How satisfied are you with your (and/or your partner’s) sexual functioning?

Has there been any change in your (or your partner’s) sexual desire or the frequency of sexual activity?

Do you have, or have you ever had, any risk factors for HIV (blood transfusion, needle stick injuries, IV drug use, STIs, partners who placed you at risk)?

Have you ever had any sexually related diseases?

Have you ever been tested for HIV? Would you like to be?

What do you do to protect yourself from contracting HIV?

What method do you use for contraception?

Are you trying to become pregnant (or father a child)?

Do you participate in oral sex? Anal sex?

Do you or your partner(s) use any particular devices or substances to enhance your sexual pleasure?

Do you ever have pain with intercourse?

Women: Do you have any difficulty achieving orgasm?

Men: Do you have any difficulty obtaining and maintaining an erection? Difficulty with ejaculation?

Do you have any questions or concerns about your sexual functioning?

Is there anything about your (or your partner’s) sexual activity (as individuals or as a couple) that you would like to change?

From Nusbaum MRH, Hamilton CD. The proactive sexual health history. *Am Fam Physician* 2002;66:1705-1712.

HIV, Human immunodeficiency virus; *STIs*, sexually transmitted infections; *IV*, intravenous.

Box 43-2 PLISSIT Model for Approaching Sexual Problems

Permission

- For physician to discuss sex with the patient.
- For the patient to discuss concerns now or in the future.
- To continue sexual behaviors not potentially harmful.

Limited Information

- Clarify misinformation.
- Dispel myths.
- Provide factual information in a limited manner.

Specific Suggestions

- Provide specific suggestion directly related to the particular problem.

Intensive Treatment

- Provide highly individualized therapy for more complex issues.

Modified from Annon JS. *The Behavioral Treatment of Sexual Problems*. Honolulu, Enabling System, 1974-1975.

sexual concern (see Box 43-1). If the time constraints limit the current visit, the physician should offer the patient a future follow-up visit.

Work together, to develop a treatment plan. In some cases, simply following the previous four steps may be therapeutic. Many clinical cases can be managed with brief education or limited advice, such as discussing normal physiologic sexual changes with aging or recommending books or products (e.g., water-based lubricant for vaginal dryness). When a referral has been made, scheduled follow-up supports the patient during the process and helps address administrative or adherence issues. Counseling may be extremely important, and the physician should research local resources. The American Association of Sex Educators, Counselors, and Therapists (AASECT) may be contacted for referral information (<http://www.aasect.org>).

Female Sexual Dysfunction

Key Points

- Low sex drive is the most common sexual problem reported by women. A woman distressed by her low sexual drive has hypoactive sexual drive disorder.
- The cyclic model of sexual functioning postulates that arousal may be the initial trigger for a woman’s sexual encounter, not desire.
- Ovarian androgens may play an important role in female sexual drive. Androgen levels in premenopausal women should be measured at the peak on days 8 to 10 of a 28-day menstrual cycle.
- Women may believe they have primary inhibited orgasm disorder because, unlike many men, they do not reach orgasm solely with vaginal intercourse.
- In most cases of orgasmic dysfunction, no specific physical examination or laboratory testing is necessary.
- Vaginismus is an involuntary, usually painful, spastic contraction of the pelvic musculature surrounding the outer third of the vagina and is complete, partial, or situational.

The linear model of sexual functioning classifies female sexual dysfunction as disorders of sexual interest/desire, arousal, orgasm, or pain. The cross-sectional, population-based PRESIDE study (Prevalence and Correlates of Female Sexual Disorders and Determinants of Treatment Seeking) estimated the prevalence of any female sexual problems was 44.2%, with “personal distress” reported by 22.8% of participants (Hatzichristou et al., 2004). Sexual dysfunction associated with personal distress became a disorder defined in the American Psychiatric Association’s *Diagnostic and Statistical Manual of Mental Disorders*, 4th edition, text revision (DSM-IV-TR).

Hypoactive Sexual Desire Disorder

For women, low sexual drive is the most frequently reported sexual problem. Four in 10 women state they have low sexual drive. The lack of sexual desire may not be distressing for all women, with “distress” prevalence ranging in studies from 23% to 61% (Lindau et al., 2007; Shifren et al., 2008). Hypoactive sexual desire disorder (HSDD) may be *general* (a general lack of sexual desire), *situational* (previously

present sexual desire is now absent), *acquired* (beginning after a period of normal sexual function), or *lifelong* (persistent no or low sexual desire). The cyclic model of sexual functioning postulates that arousal, not desire, may be the initial trigger for a woman's sexual encounter. Recently, therefore, experts suggest defining HSDD as a recurrent, consistent lack of ability to experience any desire or arousal (Basson et al., 2004). A brief questionnaire can be helpful to screen patients for HSDD (see eTable 43-1 online).

Female sexual desire is a complex interaction among biologic, psychological, social, interpersonal, and environmental components. Ovarian function, and especially ovarian androgens, may play an important role. In women age 20 to 49, HSDD is almost threefold more likely in surgical postmenopausal women than premenopausal women. However, no significant difference in HSDD exists between naturally or surgical postmenopausal women over age 50 (Leiblum et al., 2006). Medical illnesses, such as thyroid disease, chronic pain conditions, urinary incontinence, and depression/anxiety, may negatively impact sexual desire. Medications can affect sexual drive, especially selective serotonin reuptake inhibitor (SSRI) antidepressants, antihypertensives, antipsychotics, and narcotics. Fear of pregnancy or sexually transmitted infection and discord or communication difficulty in a couple's relationship may diminish sexual desire. The clinician must explore all aspects of the biopsychosocial model when evaluating a woman with hypoactive sexual desire.

Evaluation for HSDD includes a thorough history and physical examination to detect any gynecologic, neurologic, cardiovascular, or endocrine disorders. Laboratory testing should include thyroid function, fasting glucose, lipid profile, and liver function. If a hormonal problem is suspected, prolactin, total and free testosterone, sex hormone-binding globulin (SHBG), dihydroepiandrosterone (DHEA), and estrogen levels may be drawn. Androgen levels in premenopausal women should be measured at the peak on days 8 to 10 of a 28-day menstrual cycle.

Treatment

The U.S. Food and Drug Administration (FDA) has not approved any medication specifically for treatment of HSDD. Estrogen therapy improves vaginal dryness but does not affect sexual desire. The manufacturer of oral esterified estrogen and methyltestosterone discontinued distribution in the United States in March 2009. Although the transdermal testosterone patch is approved in Europe (Intrinsa), in 2004 the FDA did not approve it because of concerns regarding relatively low effectiveness, large placebo response, masculinizing side effects, and possible long-term consequences (cardiovascular and breast cancer when given with estrogen). Further Phase III clinical trials are ongoing. A randomized controlled trial (RCT) of sildenafil in postmenopausal women with SSRI-associated sexual dysfunction demonstrated a significant improvement in delayed orgasm and arousal (lubrication), but no improvement in desire (Nurnberg, 2008).

In small studies, bupropion improves HSDD in premenopausal women and women taking SSRIs, but large-study data are lacking (Segraves et al., 2004). Given the lack of allopathic treatment for HSDD, many women turn to complementary and alternative therapies (CAM). DHEA, an

adrenocorticosteroid the body converts to testosterone, was found to improve sexual interest, thoughts, and fantasies in women with adrenal insufficiency, but studies are conflicting for women without adrenal insufficiency (Arlt et al., 1999). Limited data exist for *Ginkgo biloba*, damiana leaf, ginseng, and other proprietary herbal blends that are marketed to improve HSDD (Simon, 2009). For psychological interventions for HSDD, cognitive-behavioral therapy appears most beneficial (Basson et al., 2004).

Female Sexual Arousal Disorder

The DSM-IV-TR defines female sexual arousal disorder as the inability to attain or maintain a genital lubrication-swelling response during sexual activity. The American Foundation for Urologic Disease recommended division of this diagnosis into subjective, genital, and combined subtypes. It also urged recognition of "persistent" sexual arousal disorder characterized by "spontaneous, intrusive, and unwanted genital arousal . . . unrelieved by one or more orgasms" (Basson et al., 2003).

With the exception of persistent sexual arousal disorder, evaluation should include assessment for hypoactive sexual desire disorder. Neurologic and vascular causes should be considered when adequate genital vasocongestion and swelling do not occur but subjective arousal and lubrication are intact.

Treatment is based on the suspected cause of the sexual arousal disorder. Supplemental water-soluble lubrication may be needed. Off-label use of PDE-5 inhibitors (e.g., sildenafil) may be helpful in restoring the vascular response (Kaplan et al., 1999). The FDA-approved Eros Clitoral Therapy Device uses a silicon cup to apply a vacuum to increase blood flow to the clitoris and surrounding tissue. The device appears effective in women without detectable disease and after radiation treatment for cervical cancer (Munarriz et al., 2003, Schroder et al., 2005), although sample sizes have been small. Herbal supplements and botanical genital massage oil showed some effect in small studies (Ito et al., 2001, Ferguson et al., 2003). Partner issues and situational factors may need to be addressed.

Female Orgasmic Disorder

Orgasmic dysfunction, the inability to reach orgasm when desired, may be *primary*, with the patient never having experienced orgasm, or *secondary*, with the dysfunction manifesting after previous satisfactory orgasmic functioning. Some women may believe they have primary inhibited-orgasm disorder because, unlike many men, they do not reach orgasm solely with vaginal intercourse. Portrayals of female orgasm in novels and films are often overstated or misleading. A basic description of physical orgasm (i.e., pleasurable sensation in genital area and contractions of vagina, followed by a feeling of physical and psychological relaxation) may facilitate discussion of orgasm. Many women prefer simultaneous vaginal and clitoral stimulation, oral-genital sex, or clitoral stimulation alone to have an orgasm and do not have an orgasmic disorder.

In both primary and secondary orgasmic dysfunction, it is important to ask about past or current experiences of violence, victimization, and abuse. Social factors also affect a woman's experience of orgasm. Women taught negative messages regarding sexuality or with strict religious or cultural

prohibitions on sexual attraction and thoughts may experience orgasmic difficulty, even if the specified conditions for sexual behavior (e.g., marriage) have been fulfilled. Women who were born later in the 20th century are more likely to experience orgasm than those born earlier, likely reflecting social changes. Secondary inhibited orgasm can be caused by other medical illnesses and contributing contextual factors.

The clinical history in secondary inhibited orgasm should focus on the patient's perception of this dysfunction: time and circumstances of onset, possible causes, effect on relationship(s), and treatment goals. Physiologic functioning during sexual stimulation, including adequacy of lubrication and ability to sustain states of high arousal, should be explored. Contributing factors such as fatigue, depression, postpartum physical and social changes, preoccupation with other life issues, substance abuse, and other medical illnesses should be considered. Contextual and relationship issues, including lack of tenderness or interest in non-intercourse stimulation by the partner, early ejaculation, problems regarding contraceptive responsibility, lack of privacy, relationship conflicts, and the possibility of abuse, should be discussed. In most cases of orgasmic dysfunction, no specific physical examination or laboratory testing is necessary. As with other sexual dysfunctions, neurologic, gynecologic, or other examination may be suggested by the clinical history.

Treatment of orgasmic dysfunction usually involves increasing knowledge and sexual options for the patient and partner. Masturbation (self-pleasuring) may provide information about sexual responsiveness and preferred stimulations, which can then be transferred to sexual situations with the partner. Partner education regarding clitoral stimulation and adequate pre-intercourse lovemaking (foreplay) can change the focus from intercourse to mutual pleasuring, spontaneity, and sexual satisfaction. Referral for more in-depth therapy is indicated if the evaluation reveals significant relationship dysfunction, past abuse, or other severe medical or psychosocial complications.

Sexual Pain Disorders

Vaginismus

Vaginismus is an involuntary, usually painful, spastic contraction of the pelvic musculature surrounding the outer third of the vagina. It is classified as *complete* (e.g., precluding intercourse, tampon insertion, or other vaginal penetration), *partial* (resulting in dyspareunia or difficulty with other forms of vaginal penetration, including speculum examination), or *situational* (e.g., occurring when intercourse is anticipated). Vaginismus is often idiopathic. Many cases, however, may follow pelvic trauma, such as painful intercourse, sexual assault, rough gynecologic examination, complicated episiotomy, vaginal infections, pelvic inflammatory disease, or pelvic surgery. Childhood or adolescent sexual abuse may also lead to vaginismus during adulthood. Regardless of the cause of vaginismus (traumatic, psychological, or idiopathic), once a pattern of pain and anticipation of pain has been established, it will likely recur unless treatment is provided.

Diagnosis is usually made by history. Patients report pain and difficulty with, or inability to engage in, vaginal intercourse or digital vaginal stimulation; using tampons or vaginal contraceptives; or having a pelvic examination.

Patients may demonstrate visible contraction of the pelvic floor musculature with anticipated speculum examination. Physical examination may detect pertinent anatomic abnormalities, such as vaginal septa.

Few studies exist on vaginismus. Uncontrolled reports suggest that sex therapy may be helpful (McGuire and Hawton, 2005). Vaginismus is not under the patient's conscious control. Therapy must be directed at restoring conscious control under conditions that respect the patient's autonomy and maintain the patient's safety from further trauma. If the patient expresses fear or anxiety, pelvic examination may be deferred, and in severe cases, sedation may be necessary. Any physical abnormalities detected on pelvic examination, such as infections, should first be treated. After this, the patient may begin self-treatment with size-graded plastic or silicone vaginal dilators, gradually teaching her vagina to remain relaxed and receive nonpainful, self-controlled penetration (see Web Resources). Specialized physical therapists teach patients to use biofeedback to relax the pelvic floor musculature; this can be more effective than treatment with dilators and is often preferred by patients. Treatment of posttraumatic stress disorder and other sequelae of past trauma may be crucial. Referral to a sex therapist is often helpful.

KEY TREATMENT

Cognitive-behavioral therapy appears beneficial for hypoactive sexual desire disorder (Basson et al., 2004) (SOR: B).

Treatment of orgasmic dysfunction usually involves increasing knowledge and sexual options for the patient and partner (SOR: C).

Sex therapy and vaginal dilators of increasing size may help treat vaginismus (SOR: C).

Dyspareunia

Dyspareunia refers to pain experienced immediately before, during, or after intercourse. Diagnosis of dyspareunia is made by history and physical examination. Useful questions include the onset, duration, and circumstances in which this problem occurred, the location of the pain (e.g., superficial, deep, unilateral, bilateral), and whether it is specific to a particular partner or practice. Physical exam may reveal perineal trauma or vaginal infection, vaginal mucosal atrophy, or other anatomic factors (e.g., vaginal septa, partial vaginismus). Emotional factors may contribute, such as ambivalence or distaste regarding the sexual relationship, as well as the sequelae of childhood abuse. Inadequate lubrication, relationship difficulties, poor sexual technique or a rough or abusive partner can cause dyspareunia.

Treatment of physiologic dyspareunia caused by atrophic vaginitis may require vaginal estrogen. Vaginal infections must be diagnosed and treated. For poor lubrication, supplemental water-based lubrication may be sufficient. Deep dyspareunia is often caused by overvigorous penetration or excess cervical pressure and may respond to brief educational interventions. Many people do not realize that penises and vaginas vary in length, and the vagina may not stretch to accommodate full penile engulfment. Changing position to allow the woman to control the amount of cervical pressure may ameliorate the dyspareunia. Referral for sex therapy for the couple may prove helpful. In some cases, the patient may be able to bring about change in the sexual relationship with

sufficient information and assertiveness. If dyspareunia is the result of deliberate carelessness or abuse by the partner, ending the relationship is usually the only reasonable option.

Male Sexual Dysfunction

Key Points

- The prevalence of erectile dysfunction increases with age.
- Vascular risk factors (e.g. diabetes, smoking, sedentary lifestyle, and being overweight) increase the risk for ED.
- Behavioral techniques for premature ejaculation are important for sustained success without pharmacologic treatment.

Erectile Dysfunction

Historically, male sexual dysfunction was described as “impotence”; however, the term *erectile dysfunction* (ED) is now preferred. The National Institutes of Health (NIH) Consensus Development Conference (1992) defined ED as “the inability for a male to achieve an erect penis as part of the overall multifaceted process of male sexual function.” ED becomes “male erectile disorder” defined by the DSM-IV-TR when “marked distress or interpersonal difficulty” accompanies it, and is not better accounted for by another mental health disorder (other than a sexual dysfunction), and not exclusively caused by the direct physiologic effects of a substance (e.g., drug of abuse, medication) or a general medical condition.

Both sympathetic and parasympathetic nerves regulate blood flow into the corpus cavernosum of the penis. Stimulation of the parasympathetic nerves causes release of nitric oxide (NO) from the noradrenergic, noncholinergic nerves and endothelial cells. NO increases the intracellular levels of cyclic guanosine monophosphate (cGMP) in the cavernosal smooth muscle, which relaxes the cavernosal tissues. With the resultant rapid blood flow into the corporal bodies of the penis, the small emissary veins that cross the tunica albuginea are occluded, and blood is trapped inside the corpus cavernosum, leading to an erection. The level of cGMP is also affected by prostaglandins. Phosphodiesterase-5 (PDE-5) is the main cGMP-catalyzing enzyme in human smooth muscle. PDE-5 inhibitors (sildenafil, tadalafil, vardenafil) increase cGMP levels and facilitate and maintain penile erection. The intact functioning of four body systems—vascular, neurologic, endocrine, and usually psychological—is necessary for a man to experience a penile erection.

Erectile dysfunction can occur at any age, but prevalence increases with age; 2% for ages 40 to 49, 6% for 50 to 59, 17% for 60 to 69, and 39% for 70 or older (Inman et al., 2009). Medical conditions associated with peripheral vascular disease, such as diabetes, coronary artery disease, stroke, and hypertension, increase the prevalence of ED. In men younger than 60, smoking, sedentary lifestyle, and being overweight increased the risk for ED (Bacon et al., 2003).

Evaluation

Clinicians should carefully evaluate the patient’s complaint of ED, because some men consider premature ejaculation as “erectile dysfunction.” After obtaining the pertinent

history, the clinician should carefully review the patient’s past medical history. Because penile erection depends on intact vasculature, the medical history is similar to one assessing cardiovascular risk factors: “What is bad for the heart is bad for the penis.” Several common classes of medicines can cause sexual dysfunctions (Box 43-3). The social history should include the patient’s smoking, alcohol, and marijuana use, and the patient’s important social and sexual relationships. The physician should also assess psychological factors such as depression and anxiety.

Physical examination focuses on signs related to the vascular, neurologic, and endocrine systems. Peripheral pulses should be palpated and carotids auscultated for bruits. The thyroid should be examined for enlargement or nodular disease. A thorough genitourinary examination should be performed. The clinician can assess perineal enervation with anal sphincter tone, perianal sensation, and the bulbocavernosus reflex. The penile shaft may show Peyronie’s disease (fibrous plaques of corpus cavernosa affecting erectile function or causing pain with erection). The prostate should be evaluated. Testicular atrophy may indicate low testosterone levels. If secondary sexual characteristics are lacking or the patient has other signs of hypogonadism, further endocrine evaluation should be undertaken.

Few laboratory tests are necessary. Vascular risk factors should be assessed with fasting glucose and lipid profile. Blood urea nitrogen (BUN) and creatinine, serum transaminases (AST, ALT), thyroid-stimulating hormone (TSH), and prostate-specific antigen (PSA) levels should be considered. If the patient is young, is deficient in secondary sexual characteristics, or has other signs of hypogonadism, testosterone level should be determined. A low testosterone level, however, cannot be considered a definitive cause of ED. Many

Box 43-3 Medications Affecting Sexual Function

Antihypertensives

- Beta blockers (atenolol, metoprolol, bisoprolol, propranolol)
- Thiazide diuretics (hydrochlorothiazide, chlorthalidone)
- Sympatholytics (clonidine, methyl dopa)
- Calcium channel blockers (nifedipine, amlodipine)
- ACE inhibitors (enalapril, lisinopril)

Antipsychotics

Antidepressants (TCAs, SSRIs)

Anxiolytics/tranquilizers

Antiandrogens

- 5 α -Reductase inhibitors
- Gonadotropin-releasing hormone agonists
- Ketoconazole
- Spironolactone
- H₂blockers (cimetidine)

HIV medications

Fibrates (gemfibrozil, fenofibrate)

Statins

Digoxin

Cytotoxic agents (methotrexate)

ACE, Angiotensin-converting enzyme; TCAs, tricyclic antidepressants; SSRIs, selective serotonin reuptake inhibitors; HIV, human immunodeficiency virus.

men with very low levels of circulating testosterone have normal libido and erectile function. Testosterone is highly protein-bound to SHGB, with only about 2% circulating as free testosterone; therefore, total testosterone levels may not reflect the bioavailable testosterone. The prevalence of abnormally low serum testosterone levels, even among men with ED, is only about 7%. Controversy surrounds testosterone supplementation for ED treatment.

Treatment

Phosphodiesterase-5 inhibitors are first-line therapy for ED and are effective in most cases, including antidepressant-induced ED and diabetes related (Rudkin et al., 2004; Vardi and Nini, 2007). In 1998, sildenafil (Viagra) was the first PDE-5 inhibitor to become FDA approved, followed by vardenafil (Levitra) and tadalafil (Cialis) in 2003. The medications differ in absorption, potential effective time interval, and some side effects (Table 43-1). Evidence is insufficient to support one inhibitor over another (McVay, 2007). These medications have similar side effects, caused by their vasodilatory action. All PDE-5 inhibitors can cause increased vasodilation with nitrates and should not be used concomitantly; fatalities have been reported. Use with alpha-adrenergic blocker

medications should also be avoided due to risk of significant hypotension. Human immunodeficiency virus (HIV) protease inhibitors significantly increase the half-life of PDE-5 inhibitors by interfering with hepatic metabolism. PDE-5 medications have several dosages available to facilitate titration upward to an effective dose or dose reduction for age and hepatic or renal impairment.

Prostaglandin E₁ (PGE₁; alprostadil) is second-line treatment for men who have a contraindication for or have failed PDE-5 inhibitors. Intraurethral alprostadil (MUSE—medicated urethral system for erection) is a pellet of synthetic PGE₁ that is absorbed across the urethral mucosa and increases corpus cavernosum blood flow. Treatment has been effective in 50% of men with ED from radical prostatectomy after sildenafil failed (Jaffe et al., 2004). Intracavernous self-injection of alprostadil (Caverject, Edex) is another alternative, especially for patients with mild to moderate vascular disease not responsive to PDE-5 inhibitors. Complications, although relatively uncommon, include ecchymosis, hematoma, and painful erection. Although priapism occurs in less than 1% of users, patients should be warned to seek prompt medical attention if an erection lasts longer than 4 hours. Injection can also cause minor bleeding, so condom use is advised if blood-borne infection risk is present. Long-term

Table 43-1 Phosphodiesterase-5 (PDE5) Inhibitors

| Parameter | Sildenafil (Viagra) | Vardenafil (Levitra) | Tadalafil (Cialis) |
|------------------------|---|---|---|
| Dosages | 25, 50, 100 mg | 2.5, 5, 10, 20 mg | 2.5 mg (taken daily), 5 mg, 10 mg (as needed dosing) |
| Absorption | Decreased if taken with high-fat foods | Decreased if taken with high-fat foods | Unchanged with food; decreased if taken with antacids |
| Onset of action | 30-60 minutes | 30-120 minutes | 16-30 minutes |
| Length of effect | 3-5 hours | 4-5 hours | 24-72 hours |
| Side effects | Headache, flushing, nasal congestion, dyspepsia, abnormal color vision | Headache, flushing, dyspepsia, nasal congestion, abnormal color vision | Headache, flushing, nasal congestion, dyspepsia; back pain, myalgia 12-24 hr after dose; color vision changes very rare |
| Metabolism | Hepatic | Hepatic | Hepatic |
| Drug interactions | Strong CYP3A4 inhibitors (e.g., ritonavir, indinavir, ketoconazole, itraconazole), moderate CYP3A4 (e.g., erythromycin), nonspecific | Strong CYP3A4 inhibitors (e.g., ritonavir, indinavir, ketoconazole, itraconazole) increase plasma levels; potential hypotension with nitrates and alpha-adrenergic blockers | Strong CYP3A4 inhibitors (e.g., ritonavir, indinavir, ketoconazole, itraconazole) increase plasma levels; potential hypotension with nitrates and alpha-adrenergic blockers |
| Dose reduction | CYP450 inhibitor (cimetidine) causes significant increase in plasma levels; potential hypotension with nitrates and alpha-adrenergic blockers | Patients older than 65 years; hepatic impairment; no adjustment for moderate to severe renal impairment (CrCl <30 mL/min) | No dosage adjustment for age; not recommended in patients with severe hepatic impairment Daily use: no adjustment for moderate to severe renal impairment (CrCl >30 mL/min); not recommended for CrCl <30 mL/min As-needed use; reduce dose for CrCl <50 mL/min |
| Additional information | Patients older than 65 years; hepatic impairment; severe renal impairment (CrCl < 30 mL/min) | May prolong QT interval | Nitrates given no sooner than 48 hr after dose; substantial consumption of alcohol (e.g., 6 oz of 80-proof vodka) increases orthostatic hypotension; no blood pressure drop with tamsulosin (selective alpha-adrenergic blocker) |

Data from Lexi-Comp, 2009.
CrCl, Creatinine clearance

use can result in fibrosis of the corpus cavernosum, and administration more frequently than three times weekly is not recommended.

Vacuum constriction devices (VCDs) can be used by men with ED from any cause. The penis is inserted into a tube in which a vacuum is applied, filling the corpus cavernosum with blood. A soft, constricting ring is placed at the base of the penis to prevent venous drainage from the corpus. Side effects include penile pain and numbness, bruising, and trapped ejaculation. Anticoagulant therapy is a relative contraindication (Lue et al., 2004).

Apomorphine is a centrally acting dopamine agonist with affinity for dopamine receptors in the brain that are believed to be involved in sexual functioning. Apomorphine effectively treats ED, although it appears less effective than PDE-5 inhibitors (Eardley et al., 2004; Perimenis et al., 2004). Significant dose-related side effects include nausea, dizziness, severe sweating, and drowsiness. At present, sublingual apomorphine has been approved for use in Europe. In the United States, a subcutaneous form is approved only for treatment of Parkinson's disease.

Yohimbine antagonizes α_2 -adrenergic receptors. In one systematic review, yohimbine improved self-reported sexual function and penile rigidity compared with placebo (Ernst and Pittler, 1998). It has not been clinically researched for ED in the last decade. Yohimbine has significant adverse effects, including elevation of blood pressure and heart rate, increased motor activity, nervousness, irritability, and tremor.

Testosterone supplementation may or may not improve erectile function in hypogonadal men. One study found that previously unresponsive hypogonadal men using testosterone supplementation responded to sildenafil or apomorphine (Foresta et al., 2004). Other research showed that hypogonadal men who received testosterone supplementation and normalized their testosterone level had only short-term improvement in erectile function (Mulhall et al., 2004). Topical testosterone gel (AndroGel, Testim) is the most common form of supplementation and provides relatively steady serum testosterone levels. Transdermal patches can be applied on the upper body (Androderm) or scrotum (Testoderm), but skin irritation may occur in up to 15% of men. Intramuscular injection of testosterone enanthate or testosterone cypionate every 10 to 21 days may provide adequate supplementation but often causes significant peaks and troughs in testosterone levels.

Patients with ED primarily (or exclusively) of psychological origin may benefit from individual psychotherapy or pharmacologic therapy. Focused group therapy demonstrates greater efficacy than no therapy for ED (Melnik et al., 2007). Men who are experiencing sexual dysfunction often develop the "spectator effect"; fear of recurrent failure or difficulty focuses attention on self-performance rather than pleasuring and enjoyment, further decreasing arousal. Similarly, "performance anxiety" increases sympathetic tone, which physiologically impedes erectile function. Relationship conflicts, contraception or fertility concerns, and religious or moral conflicts regarding sexual activity can affect erectile function. Depression, anxiety, adjustment disorders, substance abuse, and other psychiatric symptoms should be evaluated and treated or referred. Survivors of physical or sexual abuse may require long-term treatment and support with a therapist experienced in this area.

KEY TREATMENT

Phosphodiesterase-5 inhibitors (sildenafil, tadalafil, vardenafil) are first-line therapy for erectile dysfunction (ED) (Rudkin et al., 2004; Vardi and Nini, 2007) (SOR: A).

Prostaglandin E₁, intraurethral or injected into the corpus cavernosum, is second-line treatment of ED (Jaffe et al., 2004) (SOR: A). Vacuum constriction devices may help ED of any cause (Lue et al., 2004) (SOR: B).

Focused group therapy improves erectile function better than no therapy (Melnik et al., 2007) (SOR: A).

Off-label use of SSRI antidepressants improves premature ejaculation by prolonging the preorgasmic plateau (Arafa and Shamioul, 2007) (SOR: A).

Premature (Rapid) Ejaculation

Premature ejaculation refers to the occurrence of male ejaculation, usually with orgasm, before desired by the individual, his partner, or both. Premature ejaculation is also referred to as *rapid ejaculation* or *difficulty with ejaculatory control*.

Evaluation of premature ejaculation is by history. Onset, circumstances, and meaning (personal and relationship) of the dysfunction should be explored, as well as pertinent past sexual experiences. For example, young men whose first sexual experiences were rushed may later have difficulty establishing ejaculatory control in more relaxed contexts. Men having intercourse infrequently are more likely to ejaculate rapidly. The clinician should determine whether a patient can delay his ejaculation while masturbating. In addition, information regarding the patient's level of sexual knowledge and his partner's expectations may be significant.

Behavioral techniques, such as the squeeze technique, stop and start, masturbation training, and non-intercourse-based pleasuring may be used to treat premature ejaculation. In the "squeeze technique," firm (squeezing) pressure for 3 to 5 seconds on the ventral surface of the penis at the frenulum or base, followed by quick release, will temporarily relieve the need to ejaculate. "Stop and start" refers to the man learning to stop or reduce penile stimulation when ejaculation is approaching (but not imminent) and resume when arousal has partially dissipated. Masturbation training aimed at increasing ejaculatory control may also be useful. Changing the focus of the relationship from achieving partner orgasm with intercourse to mutual pleasuring often results in an improved sexual relationship, regardless of immediate success in delaying ejaculation.

The SSRI antidepressants can cause prolongation of the preorgasmic plateau and thus may delay ejaculation. Using SSRIs for premature ejaculation is currently an off-label use, although research is ongoing. In a single-blinded prospective study of paroxetine, fluoxetine, and escitalopram, 100% of men complaining of premature ejaculation experienced an improvement in their symptoms, with no difference detected between the three treatment groups (Arafa and Shamioul, 2007). Dapoxetine is a short-acting SSRI that can be taken as needed, instead of daily as with other SSRIs, but is not yet approved by the FDA for use in the United States. Phase III randomized, double-blind, placebo-controlled trials show dapoxetine, 30 and 60 mg as needed, achieved statistically significant improvements in perceived control over ejaculation (Hellstrom, 2009). PDE-5 inhibitors added to SSRIs may further improve premature ejaculation. Sildenafil with paroxetine or fluoxetine and tadalafil with fluoxetine have

been shown to improve premature ejaculation better than the SSRI alone (Husseini and Yarmohammadi, 2007; Mattos et al., 2008; Salonia et al., 2002). Several studies show various formulations of topical treatments that reduce the sensory stimuli to the penis (e.g., topical eutectic mixture of lidocaine-prilocaine spray) appear to increase ejaculatory latency time compared to baseline or placebo (Morales et al., 2007). However, unless behavioral means of delaying ejaculation are also used, success is often not sustained following discontinuation of medication. In patients without underlying relationship difficulties, prognosis for premature ejaculation is excellent.

Male Orgasmic Disorder

Men who can sustain a full erection for a reasonable duration of sexual activity will usually be able to reach orgasm. When this is not the case, a more complete evaluation should be undertaken, evaluating the central and peripheral nervous systems, use of medications and substances, and relationship issues. SSRI antidepressants are well known to interfere with orgasm. Alcohol use can cause difficulty with sustaining arousal or with orgasm. Many contextual and partner issues discussed with regard to female patients also apply to men.

Dyspareunia

Although dyspareunia is a gender-neutral term, men experience dyspareunia much less often with vaginal-penile intercourse than women. Dyspareunia in men is often caused by concurrent medical illness, such as Peyronie's disease or neuropathy, although relationship dynamics and poor sexual technique may also cause sexual discomfort. Anal dyspareunia can occur with the anally receptive or insertive partner and is usually caused by insufficient lubrication or spasm of the anal musculature. Evaluation consists of the history and physical examination. As with most sexual dysfunctions, onset, context, patient perceptions regarding possible causes, and impact on the relationship(s) are important. Physical examination may reveal evidence of neuropathy, urethritis, epididymitis, Peyronie's disease, prostatitis, anal fissures, hemorrhoids, or other pertinent findings. Treatment of dyspareunia involves correction of underlying physical pathology, counseling regarding sexual technique, and referral of complicated cases to a urologist or sex therapist, as indicated.

Sexual Orientation Spectrum

Key Points

- Sexual orientation may be a continuous spectrum from exclusive homosexuality to exclusive heterosexuality.
- Some people who have been sexually active with members of their own gender identify themselves as heterosexual.
- Lesbians are less likely to obtain health maintenance services, such as mammography or Pap smears.
- Any intact organ in a transgendered individual should be screened according to current guidelines.

Sexual orientation is a social construct. Customs regarding which sexual acts are acceptable, with whom, and under

what circumstances, have varied in different cultures and eras. In the *Sexual Behavior in the Human Male* in 1948, Kinsey and colleagues hypothesized sexual orientation might be a continuous spectrum, from exclusive heterosexuality through exclusive homosexuality, and might vary across the life span in different people. Researchers have attempted to measure the prevalence of homosexuality and bisexuality in populations, with varying success and controversy. Some people who have been sexually active with members of their own gender identify themselves as heterosexual. In one study, although only 2.8% of male respondents and 1.4% of female respondents self-identified as gay, lesbian, or bisexual, 10.9% of men and 4.3% of women ages 40 to 49 years reported having had at least one same-gender sexual experience since puberty (Laumann, 1994). Because many gay, lesbian, and bisexual patients do not share information regarding sexual orientation and past sexual behavior with their physicians, most physicians likely overestimate the number of exclusively heterosexual patients in their clinical practices.

Clinical Considerations in the Care of Lesbian, Gay, and Bisexual Patients

All patients have the same medical needs and expectations, regardless of sexual orientation, such as accurate diagnosis and treatment and respectful communication. However, several issues are especially important to remember for the medical care of gay, lesbian, and bisexual patients.

Lesbians are less likely to obtain health maintenance services, including clinical breast examination, mammography, and cervical cancer screening than heterosexual women, perhaps because of an underinsured or uninsured status. Patients in same-gender couples are often not eligible for spousal health insurance benefits and may be less likely than their heterosexual counterparts to be adequately insured. Many lesbians mistakenly believe they do not need Papanicolaou smears. However, women self-identified as lesbian may have been a victim of childhood sexual abuse, had a remote history of consensual male sexual contact, or they are bisexual. Nulliparous lesbians are at a high risk for cancers of the breast, endometrium, and ovary. Female-to-female transmission of sexually transmitted diseases (STDs, including HIV infection) is much less efficient than male-to-female transmission; however, genital-oral sex and fomites such as sex toys can transmit gonorrhea and *Trichomonas*, respectively.

Gay men sometimes report difficulty in obtaining adequate health care caused by providers' bias and fear of discrimination. Any male patient who presents for treatment of urethritis should be asked about participation in oral-genital sex or receptive anal intercourse, because some treatment regimens for urethral gonorrhea and chlamydia are not effective against pharyngeal and anal infections. A careful exposure history should be taken, even if the patient self-identifies as heterosexual, because some heterosexual-identified men may have same-gender sexual experiences.

Spectrum of Gender Identity and Expression

People may seek medical assistance in changing their physical sex to be congruent with their internal self-perception. *Transsexuals* usually desire full hormonal transition and sex reassignment surgery. *Cross-dressers* (previously referred to as

“transvestites”) are persons who at times may dress as the other gender to be publicly perceived as such or for sexual pleasure. A *transgendered* individual is one who seeks to take on the social role of the other gender, either full- or part-time, often with the assistance of hormone therapy, but does not desire genital surgery. *Intersex* (transsexual) is a different medical concept and refers to persons born with ambiguous genitalia or for whom phenotypic and chromosomal sex do not match (e.g., 5 α -reductase deficiency). Some persons do not perceive themselves as being fully male or fully female and seek to create new gender identities, similar to those found in many indigenous cultures. Reliable population prevalence estimates for transgendered and transsexual people are difficult to obtain and vary among cultures. In Belgium, overall prevalence was 1:12,900 for male-to-female (MTF) and 1:33,800 for female-to-male (FTM) transsexuals (DeCuyper et al., 2007). People who identify as transgendered or who cross-dress, however, are likely to be more numerous than individuals seeking sexual reassignment surgery.

Transgender Health Care

Cross-dressers and transgendered persons often encounter difficulty in obtaining adequate medical services. In one study, 26% of respondents reported being denied medical care because they were transgender (Kenagy, 2005). Transgendered persons also suffer “hate crime” victimization, with more than half the transgendered people in one study reporting some form of harassment or violence within their lifetime, and a quarter experiencing a violent incident (Lombardi et al., 2001).

Transgendered people receiving hormones can present an unusual blend of gender-associated physical characteristics and may be reluctant to reveal their treatments. MTF sex reassignment surgery is currently technically advanced, with postoperative MTF individuals often not identified as such, even on cursory gynecologic examination. FTM surgery is less sophisticated, and results are more variable. Patients may obtain medical services without revealing their preoperative history.

Transgender patients need routine health promotion and preventive services. Any intact organ should be screened according to current guidelines (e.g., a woman with a prostate gland needs prostate cancer screening counseling). Similarly, screening mammography guidelines do not distinguish between natal women and transsexual women, although specific guidelines have been proposed. FTM reconstructive chest surgery does not remove all the glandular tissue, as with a mastectomy; thus FTM men who retain the axillary tail should at minimum continue self-examination. A transsexual, transgendered, or cross-dressed patient should be asked how he or she would like to be addressed. If a legal name change has not been finalized, cross-referenced filing of the medical chart under both names may be needed.

The initiation of hormone therapy for modification of visible sex characteristics and sex reassignment surgery are life-changing medical interventions that should only be undertaken for patients who have completed an appropriate mental health evaluation and are in supportive mental health care. For clinical gender transition, a multidisciplinary team approach is ideal, such as in a comprehensive program

(e.g., University of Michigan’s Comprehensive Gender Services Program; www.med.umich.edu/transgender/) or concurrent care from a mental health professional with experience in this area, a primary care physician knowledgeable about hormone supplementation and general transgender medical care, and urology, gynecology, and plastic surgery specialists. The World Professional Association for Transgender Health (formerly the Harry Benjamin International Gender Dysphoria Association) has resource links for patients (www.wpath.org).

Sexuality Issues at Specific Times of Life

Adolescence

Key Points

- Almost half of high school students report having experienced sexual intercourse.
- Adolescents perceive less health, social, and emotional risks with oral sex than vaginal intercourse.
- Adolescents report increased condom use over the last decade.
- About 8% of adolescents report being forced to have sexual intercourse they did not want.
- Nonheterosexual adolescents are more likely to engage in high-risk behaviors and are at risk for harassment and violence.

Physical, social, and sexual maturation can be a source of both pride and confusion or anxiety for teenagers. Peers, television, and the Internet provide information about sex, although often inaccurate, misleading, and inappropriate. School-based education regarding health and development, including sexuality, is often limited. Although shyness, reticence, and embarrassment are common, most adolescents (77% in one survey) would like their health care provider to ask them directly about their sexual knowledge and experience (Rosenthal et al., 1999). Family physicians can use routine outpatient visits for school, camp, or preemployment physical examination to offer medical information as it relates to the teenager’s current concerns.

Masturbation

Masturbation is a normal and healthy sexual activity at all ages and may serve as an appropriate substitute for partnered sexual behavior during adolescence. Adolescent boys usually learn about masturbation from their peers and demonstrate an increase in masturbation activity at age 13 to 15 years. Although some begin masturbation at preschool ages, girls tend to learn to masturbate at a later age, usually through self-discovery. Both boys and girls learn early in life that a social stigma is associated with masturbation and that it is not a topic for public discussion. Family physicians can reassure adolescents regarding the normal nature of masturbation behavior.

Partnered Sexual Activity

Human sexual behavior is an instinctive drive. Sexual urges often awaken or intensify at puberty. In premodern society, puberty marked adulthood and subsequent reproduction.

In modern Western society, full adulthood is delayed through the adolescent years. As the teenager undergoes sexual physical development, biologic urges for physical intimacy and reproduction may affect sexual behavior. Although many adolescents delay their sexual debut for a variety of reasons, the modern assumption that *all* teenagers will be willing or able to delay participation in intercourse and other sexual behaviors until age 18, marriage, or some other milestone is at odds with the experience of human history.

The Centers for Disease Control and Prevention (CDC) conducts the Youth Risk Behavior Surveillance (YRBS) surveys every 2 years. In 2007, 14,041 questionnaires were completed in 157 high schools nationally, with an overall response rate of 68%. Nationwide, almost half (48%) of all students reported having experienced sexual intercourse, with the prevalence by state ranging from 36% to 60%. Although 14% of teenagers reported experience with four or more sexual partners, prevalence varied by gender and ethnic/racial background. Significantly more African American boys (38%) reported four or more sexual partners than Hispanic (23%) and white (12%) boys. Similarly, 18% of African American girls compared to 11% of both Hispanic and white girls reported four or more sexual partners (degree of reporting bias is unknown). Psychosocially, adolescents frequently practice *serial monogamy*; they begin an exclusive relationship that over time may involve sexual behavior, then end that relationship and initiate another. Serial monogamy is the lifestyle practiced by most American adults, although the length of the sequential relationships often increases; a 17-year-old may experience two steady relationships during a single year, whereas a 40-year-old is more likely to have been married twice during the preceding 20 years.

Family physicians should remain mindful that teenagers may practice sexual acts other than intercourse. Some teens maintain sexual relationships involving mutual genital touching and masturbation (also referred to as “outercourse”) for months or years before beginning intercourse. In one study, a significantly greater number of ninth-grade students had engaged in oral sex than in vaginal sex (19.6% vs. 13.5%), and more participants intended to have oral sex than vaginal sex during the next 6 months (31.5% vs. 26.3%). These adolescents also perceived less health, social, and emotional risks with oral sex than vaginal intercourse (Halpern-Felscher et al., 2005). The Kaiser Family Foundation Survey (2000) of sexually active teenagers 15 to 17 years old found that 26% believed that one cannot become infected with HIV by having unprotected oral sex, and 15% did not know whether or not one could become infected. Risks involved in oral-genital or anal sexual acts, such as oral transmission of gonorrhea or HIV infection with unprotected anal intercourse, should be discussed frankly with adolescents.

Encouragingly, over the last 10 years, more adolescents report condom use with their last vaginal intercourse. The 1997 YRBS survey reported 57% of teens used condoms with their last vaginal intercourse, versus 62% in 2007. The prevalence of condom use, however, appears to diminish over time; 69% of sexually active ninth-grade students reported condom use with sexual intercourse, decreasing to 62% and 54% of 11th graders and 12th graders, respectively. After 5 years, sexual activity among teenagers who had taken “virginity pledges did not differ from non-pledgers, but did decrease the likelihood of taking precautions during sexual

activity” (Rosenbaum, 2009). Family physicians should remind sexually active adolescents to use a condom with each oral, genital, or anal intercourse to minimize HIV and other sexually transmitted infection (STI) risk.

Contextual Issues

Family physicians should not assume that adolescent sexual experiences are consensual or desired, even when the teenager denies having been sexually assaulted or raped. Both young women and men should be asked about unwanted sexual contact. In the YRBS 2007, 7.8% of youth reported having been forced to have sexual intercourse they did not want (11.3% female, 4.5% male). Many teenagers who have had coercive sexual experiences do not identify these as rape or abuse. Asking a neutrally worded question (e.g., “Have you ever done anything sexual when you really didn’t want to?”) may open the door to further dialogue regarding exploitive or traumatic sex.

For adolescent patients, drug and alcohol use is a significant risk factor for unprotected sexual activity. In the 2007 YRBS, 23% of teenagers reported alcohol or drug use immediately before they last had sexual intercourse. Long-acting contraception is often the best option for young women who are at risk for pregnancy because of substance use. Referral for treatment of addiction should be considered for adolescents who combine drinking with driving or sex and who are unable to discontinue this risk behavior without assistance.

Sexual Orientation

While in the process of discovering their adult identity, many adolescents have questions regarding sexual orientation, gender identity, or gender role. Concurrent heterosexual and homosexual feelings and attractions are common; a single or small number of same-sex sexual encounters are not necessarily predictive of a gay, lesbian, or bisexual identity as an adult. Predominantly homosexual attractions during adolescence, however, are unlikely to change with time. By maintaining an opening questioning style, such as asking, “When you think of people to whom you are sexually or romantically attracted, are they men, women, both, neither, or are you not sure yet?”, the health care provider gives the adolescent permission to express their sexual orientation freely.

In an environment critical of their emerging sexual orientation, nonheterosexual adolescents may experience profound isolation and fear of discovery, which interfere with achieving the developmental tasks related to self-esteem, identity, and intimacy. Censure, alienation, and abandonment by the family of origin represent a particularly devastating consequence for many gay and lesbian teenagers. Nonheterosexual adolescents are more likely to have had sexual intercourse, to have had three or more sexual partners, and to have experienced sexual intercourse against their will, putting them at increased risk of STDs, including HIV infection. Nonheterosexual teenagers are more likely than heterosexual peers to start using tobacco, alcohol, and illegal drugs at an earlier age. They are also at higher risk of dropping out of school, becoming homeless, and turning to prostitution or drug trafficking for survival (Garafolo et al., 1998). They are often subjected to harassment and violence; 45% of gay men and 20% of lesbians surveyed were victims of verbal and physical

assaults in secondary school, specifically because of their sexual orientation (Kreiss and Patterson, 1997).

Teenagers seeking family-planning or obstetric services are not necessarily heterosexual; bisexual and lesbian respondents are two to seven times more likely to become pregnant than their heterosexual peers (Saewyc et al., 2008). Although for American adults, no differences in suicide rates are detectable between heterosexual and homosexual cohorts, gay, lesbian, bisexual, and “not sure” high school students were three times more likely to report a suicide attempt than their heterosexual peers (Garafolo et al., 1998). Primary care providers who care for adolescents, especially gay, lesbian, or bisexual youth, should be alert to the possibility of depression and suicide. For support, clinicians can suggest they contact the Gay, Lesbian, Bisexual, and Transgender National Youth Talkline at 800-246-PRIDE or the Trevor Helpline (866-488-7386; 866-4UTREVOR), a 24-hour suicide prevention hotline that focuses on the needs of gay youth.

Older Adults

Key Points

- Although the likelihood of being sexually active declines with age, many older adults remain sexually active.
- Approximately half of sexually active older adults report at least one sexual problem, and two-thirds have at least two.
- The likelihood of being sexually active correlates with good health.
- Although testosterone levels decline with age, androgen supplementation is recommended only in hypogonadal men.

Although the likelihood of being sexually active declines steadily with age, many older adults remain sexually active; 84% of men and 62% of women age 57 to 64 and 67% of men and 40% of women age 65 to 74 report being sexually active in the previous 12 months, with two thirds of both genders in each cohort sexually active more than two to three times a month. For those age 75 to -85, only 39% of men and 17% of women reported sexual activity within 12 months (those sexually active still had >2-3/mo) (Lindau et al., 2007). Several factors impact the decline in sexual activity. As men and women age, physiologic changes in sexual functioning occur. During arousal, older men experience less scrotal vasoconstriction and testicular elevation, erection may be delayed or insufficient, and orgasm may be of shorter duration with less ejaculatory fluid. Women may have decreased labial engorgement and less vaginal lubrication during arousal and fewer and weaker uterine contractions during orgasm. Regardless of these physical changes, many older adults continue to have active sexual lives.

In one large U.S. study, approximately half of sexually active older adults reported at least one sexual problem, with almost two-thirds having at least two bothersome sexual problems. Sexual problems most often reported by women were lack of interest (43%), difficulty with lubrication (39%), inability to climax (34%), finding sex not pleasurable (23%), and pain (17%). Among men, the most common sexual problems were difficulty in achieving or maintaining an erection (37%), lack of interest in sex (28%), climaxing too quickly (28%), anxiety about performance (27%), and inability to climax (20%). The likelihood of being sexually

active is associated with good health. Men and women who reported good to excellent health were 80% and 70%, respectively, more likely to be sexually active than men and women with “poor” or “fair” health status (Lindau et al., 2007). Many common health conditions, such as arthritis or back pain, can inhibit sexual activity. Vascular disease and its risk factors, including coronary artery disease, stroke, diabetes, hypertension, hyperlipidemia, and smoking, correlated with ED in the Global Study of Sexual Attitudes and Behaviors (GSSAB). Women with diabetes are also less likely to be sexually active than women without diabetes (Laumann et al., 2005). Pudendal nerve disruption following hysterectomy and bladder, rectal, or prostate surgery may cause sexual dysfunction. Since they take more medications, older adults may be particularly susceptible to iatrogenic sexual dysfunction, because many common medications affect sexual functioning, especially antihypertensives and antidepressants (see Table 43-1).

At all ages, women are less likely to be sexually active than men. For example, 50% of women age 60 to 69 reported that a healthy sexual life was at least “moderately important” to them; however, only 30% reported continued regular participation in sexual intercourse (Ponholzer et al., 2005). Women may be more likely not to have a spouse or intimate partner because of their greater longevity. In those age 75 to 85, men are almost twice as likely as women to have an intimate partner (78% vs. 40%). In addition, women are frequently younger than their male partners. Partner health may be an issue; 64% of women reported the male partner’s physical health as the reason for sexual inactivity longer than 3 months (Lindau et al., 2007). Data from the 2005 Vermont Civil Unions suggest a similar age discrepancy among same-sex partners; for women and men age 40 to 44, more than 25% and about 50%, respectively, had a partner more than 5 years older (see Web Resources). Lack of privacy may be problematic for elderly adults, who may live with family members or in long-term care settings.

Decline in sex steroid production is a factor in sexual dysfunction for both women and men. Postmenopausal estrogen deficiency is responsible for loss of vaginal lubrication and elasticity. The Women’s Health Initiative (WHI) raised concerns regarding deleterious effects of systemic estrogen replacement (Rossouw et al., 2002). Clinicians should counsel women desiring long-term oral estrogen supplementation to diminish vaginal atrophy symptoms regarding the increased risk of coronary artery disease, thrombotic disease, and breast cancer. Vaginal estrogen supplementation may be helpful to decrease vaginal mucosal atrophy with much less systemic absorption. Using creams, pessaries, or a vaginal ring to apply estrogen vaginally relieves the symptoms of vaginal atrophy, although some creams may cause adverse effects such as uterine bleeding, breast pain, and perineal pain (Suckling et al., 2006). Women who remain sexually active may avoid significant vaginal atrophy through continued stimulation of the epithelium and vascular supply.

Androgen deficiency in adult males (ADAM), often called “male menopause” or “andropause,” is controversial. Testosterone levels do decline with age, eventually by 50% from midlife to old age, and predictable physiologic changes occur. One large, double-blind RCT demonstrated that supplementing older men with low-normal circulating testosterone levels with 80 mg of oral testosterone undecanoate twice daily for 6 months increased lean body mass and decreased fat mass,

but it did not improve functional mobility or muscle strength. There also was no demonstrable beneficial effect on cognition or quality-of-life measures (Emmelot-Vonk et al., 2008). Androgen supplementation does have risks, such as altering cholesterol metabolism; thus it currently is not recommended unless the man has hypogonadism (Bhasin et al., 2006).

In one global study in men 40 to 80 years old who visited a primary care physician, almost half (49%) had ED (Mulhall et al., 2008). Despite the increasing prevalence of sexual difficulties in aging persons, the GSSAB reported only 9% of both men and women had been asked about sexual health by their physician during the preceding 3 years. Only 18% of the men and women in that study population sought medical assistance for their sexual problems (Moreira et al., 2005). The increased acceptance and availability of PDE-5 inhibitors may have improved physician-patient discussions over the last few years. In a recent study, 38% of men and 22% of women reported having discussed sex with a physician since age 50 (Lindau et al., 2007). Clinicians can improve their older-adult care by inquiring about sexual health and illness during the course of routine geriatric health care. Normal physical changes can be explained. ED and other sexual problems can often be treated effectively, thus assisting elderly patients in maintaining healthy sexual lives.

Conclusion

Sexuality is a core aspect of personal identity. Knowledge regarding human sexual behavior in health and illness across the life span will enable family physicians to provide

appropriate care to patients who are experiencing sexual difficulties. Many sexual problems can be treated by family physicians and other primary health care providers without assistance. Referral to a certified sex therapist should be pursued for more complicated cases. Family physicians should maintain awareness of the health care needs of persons with same-gender sexual experience or orientation. Transgendered persons may have the health care needs of their former and present gender. Sexual health issues are pertinent for adolescent and older-adult well-health care. Family physicians should routinely include questions regarding sexual behavior, relationships, and personal identity during the clinical interview of all patients, to help maintain their optimum health.

EVIDENCE-BASED SUMMARY

- Estrogen creams, pessaries, tablets, and estradiol vaginal ring appear equally effective for the symptoms of vaginal atrophy. Women seem to favor the estradiol-releasing vaginal ring for ease of use, comfort of product, and overall satisfaction (SOR: A).
- In men with antidepressant-induced erectile dysfunction, addition of sildenafil is an effective strategy (SOR: A).
- PDE-5 inhibitors are a valuable treatment option for ED in men with diabetes (SOR: A).
- Group psychotherapy may improve erectile function, both compared to no treatment or sildenafil alone (SOR: A).

Overview

Key Points

- Discoveries related to common conditions such as diabetes, heart disease, and cancer are rapidly changing the role of genetics in health care.
- Primary care providers should know the limits of their own knowledge in genetics and should become familiar with supportive resources and seek out expert consult when in doubt.

We stand at a remarkable time in history regarding our understanding of how variations in the human genome contribute to health and disease. At least some of this progress can be attributed to the technologies developed to complete the Human Genome Project. The tools of genomics and molecular biology have begun to unlock the fundamental underpinnings of previously enigmatic conditions, shedding light on the fundamental nature of the human species.

The most exciting developments since 2005 are related to the genetics of common disease, a mainstay of primary care medicine. For the first time, geneticists have been able to use a very powerful technique known as *genome-wide association study* (GWAS) to identify human genome variations associated with common disease risk. Hundreds of risk markers known as *single nucleotide polymorphisms* (SNPs) have been reliably associated with the presence of a long list of common conditions. Although each individual marker confers only a small risk of disease (which greatly limits their use in the clinic to predict risk in individual patients), each has helped to better define disease pathogenesis (Kraft and Hunter, 2009; Manolio et al., 2008). With the advent of low-cost whole-genome sequencing, discoveries related to disease risk, prognosis, and treatment relevant to primary care should accelerate (Feero et al., 2010). Most chapters in a family medicine textbook will eventually include the

relevant information to the specific topic derived from genetics and genomics.

We are at an early stage in the discovery process, and our embryonic understanding of the human genome is *not* easily yielding improvements in clinical care. This perspective is often lost in the media hype and attention given to the latest genetic discovery. The lack of a rapid translation from a new discovery to a proven clinical application (e.g., genetic test, targeted therapy) frustrates clinicians and patients alike and can lead to unrealistic and potentially harmful expectations. Clinicians should recognize where the application of knowledge from genetic discovery is of proven benefit, and where it is not. Perhaps most importantly, physicians should recognize that a substantial and rapidly expanding number of genomic applications fall into a gray area of unexplored benefit. It is incumbent on providers to seek additional information from a reputable source when in doubt.

Genetics vs. Genomics

The terms genetics and genomics are often used interchangeably in the literature, and this chapter is no exception. However, *genetics* is best viewed as the study of *single genes*, what they do, and how mutations in these genes cause disease. It is a snapshot of a specific situation, and environmental and behavioral factors often play a subordinate role. A prototypical genetic condition, cystic fibrosis, is usually caused by a deletion mutation $\Delta F508$ in the *CFTR* gene. *Genomics* is the broader study of “the functions and interactions of all the genes in the genome,” including how those genes interact with environmental and behavioral factors (Guttmacher and Collins, 2002). When considering genomics, it is important to recognize that environmental factors may be much more important in determining phenotype than genetic mutations. Common, so-called complex conditions, such as diabetes, cancer, and heart disease, are best considered from the perspective of genomics.

Genetics and Evidence-Based Medicine

As a discipline, *clinical genetics* developed in an environment that focused on the diagnosis and treatment of rare, or at least uncommon, disease. Often, large numbers of patients were not available for clinical trials, and in many cases the severity of the conditions made randomized placebo-controlled trials (RCTs) untenable. This contrasts with *evidence-based medicine* (EBM), which primarily deals with common conditions and values large, prospective RCTs, as well as the societal consequences of individual medical choices. As genomic discoveries increasingly impact health care for common conditions, new applications should be evaluated through a lens of *evidence of benefit*. Established groups that follow EBM precepts, such as the U.S. Preventive Services Task Force (USPSTF, 2009), have addressed screening and testing for hereditary breast and ovarian cancer syndrome and hemochromatosis. The U.S. Centers for Disease Control and Prevention (CDC) has established newer groups such as the Evaluation of Genetic Applications in Practice and Prevention (EGAPP, 2009) specifically to review the evidence supporting genetic and genomic applications intended for health care use. Modeled after USPSTF, EGAPP has begun to produce evidence reviews and recommendations (Table 44-1). Considerable growing pains will occur as EBM and genomic medicine intersect.

Family History: Best Guide to Genetic Components of Disease

Key Points

- Family history is the best general tool for assessing a patient's risk for heritable conditions.
- Numerous guidelines relevant to primary care providers incorporate family history information.
- Evidence-based reviews have found that family history obtained from patients is generally accurate.
- Patient-completed web-based tools offer a convenient way to gather family history information.

Family history is arguably the single best tool for recognizing genetic components of disease in the primary care setting. In the context of single-gene disorders, family history has proved valuable for generations of clinicians and plays a major role in making a diagnosis and identifying at-risk individuals. Family physicians should be familiar with common patterns of inheritance of single-gene disorders, including X-linked recessive, X-linked dominant, autosomal dominant, autosomal recessive, and multifactorial/complex (Table 44-2). Classically, the three-generation genetic history

Table 44-1 Select Evidence-Based Recommendations for Genetic/Genomic Applications

| Condition | Clinical Scenario | Recommendation | Organization |
|-------------------|--------------------------|---|--------------|
| Breast cancer | Screening | Recommend referral of women with family history consistent with increased risk for hereditary breast and ovarian cancer syndrome for genetic counseling. | USPSTF, 2005 |
| | Screening | Recommend against using <i>BRCA1</i> and <i>BRCA2</i> testing as screening tool in average-risk populations. | USPSTF, 2005 |
| | Treatment | Insufficient evidence to recommend for or against routine use of expression profiles to guide care in specific populations of women with breast cancer. | EGAPP, 2008 |
| Colorectal cancer | Screening | Insufficient evidence to determine if fecal DNA testing is effective means to screen for colorectal cancer. | USPSTF, 2006 |
| | Case finding | Recommend offering counseling and tumor sample testing for Lynch syndrome to all patients with newly diagnosed colorectal cancer, to reduce morbidity and mortality in relatives. | EGAPP, 2009 |
| | Pharmaco-genetic testing | Insufficient evidence to recommend for or against <i>UGT1A1</i> testing for patients with metastatic colorectal cancer. | EGAPP, 2009 |
| Hemo-chromatosis | Screening | Recommend against screening for hemochromatosis in asymptomatic individuals. | USPSTF, 2008 |
| Hyperlipidemia | Screening | Recommend earlier screening for hyperlipidemia in patients with family history of premature cardiovascular disease. | USPSTF, 2008 |
| Depression | Pharmaco-genetic testing | Insufficient evidence, and recommend against routine use of CYP450 testing before prescribing SSRIs in adults with depression. | EGAPP, 2007 |

From the U.S. Preventive Services Task Force (USPSTF) and CDC Evaluation of Genomic Applications in Practice and Prevention (EGAPP) Working Group relevant to primary care. known as a *pedigree* or *genogram* has been taught as the “gold standard” of family history collection. Certainly, once a potential genetic issue has been identified, a family physician should be comfortable in collecting and accurately representing a complete family history. However, taking a complete family history can be time-consuming, and on a practical level, it is not always possible to collect in the context of a brief office visit. It is perfectly reasonable to gather, review, and update family history longitudinally.

Common diseases such as type 2 diabetes, coronary artery disease, and cancer also cluster in families. Family history captures both hereditary and environmental risks and is an important component of many validated risk algorithms for these and other conditions. Recent attention has focused on the systematic collection of family history as a screening tool in primary care settings. Family history information supplied by patients is generally fairly accurate for a wide range of conditions. However, few well-designed trials have examined health outcomes associated with use of family history as a screening tool (NIH Consensus Development Program, 2009).

Given competing demands on family physicians’ time and resources, what genetic family history is the most important to capture? A national collaboration of primary care and genetics professionals has developed mnemonics to help clinicians think genetically as they provide patient care (Burke et al., 2001). FamilyGENES highlights “red flags” that signal a genetic concern, as follows (Whelan et al., 2004):

- *Family history*—multiple affected siblings or individuals in multiple generations
- Groups of congenital anomalies
- Extreme (or exceptional) presentation of common conditions
- Neurodevelopmental delay or degeneration
- Extreme or exceptional pathology
- Surprising laboratory values

SCREEN (for familial disease) uses the following set of family history questions to uncover genetic implications:

- **Some Concerns:** Do you have any (some) concerns about diseases or conditions that seem to run in the family?

- **Reproduction:** Have there been any problems with pregnancy, infertility, or birth defects in your family?
- **Early disease, death, or disability:** “Have any members of your family died or become sick at an early age?”
- **Ethnicity:** How would you describe your ethnicity? *or* Where were your grandparents born?
- **Nongenetic:** Are there any other risk factors or nonmedical conditions that run in your family?

Electronic health record (EHR) systems seldom offer efficient and complete ways to collect and represent family history information. National efforts are underway to address this deficiency. Patient-completed paper and electronic tools provide another way to obtain a detailed genetic history. The U.S. Surgeon General’s Family History Initiative (2005) includes a web-based tool that can be completed by patients, stored on their local computer, and shared with relatives and their health care providers in pedigree or table format (My Family Health Portrait; <https://familyhistory.hhs.gov/>). This free, easy-to-use tool is an excellent way for patients with Internet access to record family history and is time-saving for the clinician. The family history collected by the tool is now stored using emerging data standards that allow the data to be shared with EHR and personal health record systems. Alternatively, a number of organizations have created paper family history tools for patients and providers that are available on the Internet.

Genetic Testing

Key Points

- Knowledge of the indications for and limitations of genetic testing is relevant to common clinical situations in family medicine.
- The context of testing and its limitations are important for proper interpretation.
- Pretest and post-test counseling are currently recommended for genetic testing, although the need for such counseling in all testing situations is controversial.

Table 44-2 Patterns of Inheritance Often Encountered in Primary Care

| Pattern of Inheritance | Characteristics Of Family History | Example Conditions |
|------------------------|---|--|
| X-linked recessive | Males affected more than females, maternal inheritance, 50% risk of female carrier sons affected | X-linked color blindness X-linked muscular dystrophy |
| X-linked dominant | Males and females may be affected, males more severe, daughters of affected males affected, male and female transmission | Fragile-X syndrome |
| Autosomal dominant | Affected individuals usually in every generation, 50% probability of affected individuals having affected offspring, M = F | Huntington’s disease Hyperkalemic periodic paralysis Lynch syndrome Marfan’s syndrome |
| Autosomal recessive | Often multiple affected individuals in same generation, skipped generations, 25% risk of affected child for carriers, M = F | α_1 -Antitrypsin deficiency Cystic fibrosis Sickle cell disease Most inborn errors of metabolism |
| Multifactorial | Clustering of cases in families, risk to first-degree relatives high; consequences of shared environment might be evident. | Coronary artery disease Types 1 and 2 diabetes Many cancers |

- Genetic testing results can have implications for the family, and providers generally have a duty to warn potentially affected members.
- Family physicians should be involved in ordering, interpreting, and managing the consequences of genetic testing with health implications.

Identifying what constitutes a genetic or genomic test can be challenging. Traditionally, a genetic test measures changes in the sequence of deoxyribonucleic acid (DNA), but a “genetic test” can also be a measure of a protein or metabolite (Table 44-3). From this perspective, a fasting lipid panel could be considered a genetic test. Also, a genetic test does not always need to be relevant to other family members, as when an individual’s cancer cells are tested for mutations that affect prognosis and therapy. In some cases a family physician’s most important role is simply to reassure low-risk individuals that they do not need genetic testing.

The indications for genetic testing include confirming a diagnosis, identifying disease risk, and guiding therapeutic interventions. A genetic test can be done using many types of specimens, although testing for mutations in DNA is often done on DNA extracted from whole blood, saliva, or a cheek swab. Some tests look for only specific mutations, whereas others scan for all mutations in a specific DNA region. Testing costs can range from \$100 to thousands of dollars, depending on the complexity and patent status of the test. Often, testing an affected family member first is the preferred strategy. Without knowing the mutation present in a family, an asymptomatic patient’s negative test result may not be informative, because the particular test done may not include the mutation affecting that family.

Family physicians should be aware that genetic testing may have implications for the extended family as well as the patient. For example, studies with Huntington’s patients have shown that genetic test results, whether positive or negative, have significant implications for patients and their families. This includes depression, lifestyle behavior changes, and relationship changes among family members. Those testing negative may have survivor’s guilt or may be treated as being outside the family. Patients can benefit from counseling about implications before undergoing genetic testing that is both highly predictive and associated with profound health

consequences (Martin and Wilikofsky, 2004). For genetic tests that are less predictive or are associated with conditions with less profound health consequences, the benefits of formal genetic counseling are less clear-cut.

Obtaining and interpreting molecular tests for DNA mutations often has unique considerations. First, it is important to order the correct test for the patient’s condition; this is not always obvious, particularly when multiple tests are available. Second, the presence of a mutation in an asymptomatic individual only rarely predicts disease onset, course, or severity. This is particularly true for the multitude of recently discovered SNP markers associated with risk for common complex conditions. Third, absence of a known causal mutation in a gene may not mean that an individual is at no or low risk of disease. For example, in families meeting the clinical criteria for hereditary breast and ovarian cancer syndrome, testing for mutations in the *BRCA1* or *BRCA2* occasionally fails to detect a mutation in affected members. The absence of detectable mutations in affected individuals means that the test is essentially uninformative, and the risk to asymptomatic family members needs to be estimated from the clinical scenario and is not that of the average population (GeneTests, 2009). Because of the complex factors involved, genetic tests are frequently ordered by physicians with particular expertise regarding the condition for which testing is being considered. Currently, there are insufficient genetics professionals in all U.S. areas to handle the counseling associated with genetic tests. As a result, primary care physicians will most likely be providing more genetic counseling and testing in the future. The next section provides a more in-depth look at settings in which different types of genetic testing are relevant to primary care.

Examples of Genetic Testing

Preconception and Prenatal Screening

Genetic screening or testing can occur either before conception or during the pregnancy. When possible, screening or testing before a pregnancy is ideal, because this provides the broadest range of choices if increased risk of a genetic defect is detected. Preimplantation genetic testing is available for

Table 44-3 Types of Genetic/Genomic Testing

| Test | Example Methods | Clinical Scenarios | Example Conditions |
|----------------------|--|---|---|
| Chromosomal analysis | Fluorescent in situ hybridization, karyotype, array comparative genomic hybridization | Pediatrics, prenatal testing | Down syndrome, unexplained mental retardation |
| DNA analysis | Allele-specific oligonucleotide hybridization, sequencing, fluorescent PCR assays, DNA microarrays | Adult, pediatric, prenatal testing, pharmacogenetic testing | Hereditary breast and ovarian cancer syndrome, Huntington’s disease, cystic fibrosis, warfarin pharmacogenomics |
| Biochemical tests | Various | Adult, pediatric, prenatal | Hyperlipidemia, phenylketonuria, quadruple screen |
| Expression profiling | cDNA measurement on microarrays, quantitative PCR | Adult, pediatric | Breast cancer, melanoma, colorectal cancer |

PCR, Polymerase chain reaction; *cDNA*, complementary (copy) deoxyribonucleic acid.

an increasing number of conditions but is costly and not accessible to many individuals. Most genetic evaluations occur after the pregnancy is established. The ability to detect genetic defects has grown rapidly over the past decade. Many ethical issues exist in both the preconception and the prenatal screening or testing environment, including the course of action if the fetus is found to have an incurable, life-altering condition. Common indications for prenatal testing are advanced maternal age, previous child with a chromosomal abnormality, family history of abnormality or single-gene disorder, family history of neural tube defect or other structural abnormality, abnormalities identified in pregnancy (e.g., on ultrasound), parental consanguinity, recurrent miscarriages, previous unexplained stillbirth, parental ancestral origin, and use of certain medications. The American College of Obstetricians and Gynecologists (ACOG) and the American College of Medical Geneticists (ACMG) have developed guidelines for recommended tests (Solomon and Feero, 2008). However, these guidelines are often based on consensus or expert opinion and do not always agree.

High-resolution ultrasound and quadruple serum panel are screening tests for congenital anomalies associated with a variety of genetic conditions. More invasive testing, such as chorionic villus sampling (CVS) and amniocentesis, may provide more accurate diagnosis, but at the cost of higher risk of complications. Recent guidelines suggest that amniocentesis be offered to all pregnant women to aid in the detection of Down syndrome (ACOG, 2007). The family physician should evaluate the risks and benefits of all forms of prenatal genetic screening or testing, discuss them with the patient and her partner, and make referrals to health care providers with genetics expertise as appropriate.

Pharmacogenetics

Pharmacogenetics is the study of genetically determined variations in response to medication. This can include variations in how a drug is metabolized as well as how drugs interact with intended as well as unintended targets in the body. Pharmacogenetic testing can be useful in ensuring accurate drug dosing, avoiding adverse side effects, and selecting drugs. The U.S. Food and Drug Administration (FDA) mandates that many drugs reference pharmacogenetic testing in their labeling. Although family physicians should be aware that such labeling exists, the evidence of benefit of testing for these variations is not uniform across drugs. Currently, several pharmacogenetic tests are routinely used to guide treatment of oncology and infectious disease patients. Pharmacogenetic testing is likely relevant to some of the family physician's patients (Table 44-4). This number will grow as more pharmacogenetic tests become available.

Recent promising applications of pharmacogenomics measure variations relevant to drug responsiveness in cancer. Often, cancer drugs are toxic and expensive, so more individually targeted therapy (personalized medicine) based on the mutations present in a patient's tumor prove valuable over time. Examples include testing breast cancer tumors for overexpression of *HER2* receptor to guide use of targeted therapies. Such testing is becoming a part of routine oncologic care. More recently, the American Society of Clinical Oncology (ASCO) has developed guidelines for testing for *KRAS* oncogene mutations to guide colorectal cancer treatment

(Allegra et al., 2009). More clinical applications of pharmacogenetic testing relevant to cancer care are in the pipeline for clinical release.

Direct-to-Consumer Testing

Since the completion of the Human Genome Project in 2003, more companies now offer direct-to-consumer (DTC) genetic testing. The public profile of DTC testing increased dramatically over the last several years with the advent of inexpensive, genome-wide scans for SNPs. Tests that measure millions of genetic variations simultaneously can be obtained with a saliva sample and a few hundred dollars. The majority of these markers are probably of little significance to the tested individual's health, and patients may both overestimate and underestimate their personal risk of disease based on the results of such testing. The other types of tests offered can be grouped into "medical" and "nonmedical" categories. Medical tests include highly validated DNA testing for specific mutations in classic single-gene mendelian disorders, pharmacogenetic testing, and paternity testing. Nonmedical testing ranges from determining one's ethnic and geographic origins or athletic prowess to ear wax type. DTC testing can offer advantages of anonymity for testing as well as easy access to genetic tests that might be difficult to obtain through routine health care channels. The consumer pays for most DTC genetic testing.

Clinicians should recognize that "buyer beware" applies to DTC genetic testing. National regulatory oversight ensuring the analytic and clinical validity of these tests is inadequate, although some states (California, New York) have enacted laws to increase scrutiny of consumer-oriented tests. Even

Table 44-4 Pharmacogenetic Testing

| Drug | Gene | Notes |
|-------------------------|----------------------------------|---|
| Abacavir | HLA-B*5701 | HIV-1 patients |
| Aminoglycosides | A1555G | Not routinely |
| Antifolate chemotherapy | MTHFR | Not routinely |
| Azathioprine | TPMT | Not routinely |
| Beta blockers | CYP2D6 | Not routinely |
| Irinotecan | UGT1A1 | Not routinely |
| Opioids | CYP2D6 | Not routinely |
| Oral contraceptives | FVL, prothrombin G20210A, others | Family and personal history of VT can be used |
| SSRIs | CYP450 | EGAPP recommended against, 2007. |
| Carbamazepine | HLA-B*1502 | For Asian-Americans |
| Warfarin | CYP2C9 and VKORC1 | Algorithms may work as well/better. |

with accurate testing, there is no assurance that the result will be clinically useful to the individual. This is particularly problematic when a trained health professional is not available to help individuals appropriately select and interpret genetic testing. Companies now offer phone-based genetic counseling services independent of any testing services. Phone counseling has been shown to be effective for a variety of genetic conditions, and it remains to be seen how this type of counseling service might affect the movement to increasing DTC access to genetic tests. Ideally, a trained health professional should be involved in ordering and interpreting any genetic or genomic testing with health implications.

Ethical, Legal, and Social Issues

Key Points

- Clinicians should consider potential ELSIs when discussing genetic testing with patients.
- GINA provides national protections against health insurance and employment discrimination based on genetic information. HIPAA provides insurance portability and privacy protections. Some states have more comprehensive statutes to prevent genetic discrimination.
- Case law suggests that family members have a right to know whether genetic information affects their personal health, and that health care providers have a duty to warn family members of health risks.
- Minors incapable of providing informed consent should not be tested for conditions not immediately relevant to their health or not treatable in childhood.

Significant potential ethical, legal, and social issues (ELSIs) are associated with the use of genomic technologies in health care, and funding for research regarding ELSIs was part of the Human Genome Project from the outset. ELSIs include concerns regarding potential for discrimination or stigmatization based on one's genome, the right to know or not know one's genetic status in family settings, potential adverse effects of genetic testing on reproductive decision making, and discomfort with genetic testing of conditions for which treatment in childhood is not recommended or is not available.

Many patients are concerned that genetic information could be used as a tool for discrimination by health insurers and employers. In 2008 the Genetic Information Non-discrimination Act (GINA) became U.S. law and provides national protection against use of genetic and family history information as a basis for discrimination by health insurers or employers (Hudson, 2008). However, the law does not prevent use of genetic information by life, long term care, or disability insurers. Some states have laws providing for more stringent protections than those afforded by GINA, and physicians should be aware of the protections their states provide (National Conference of State Legislatures, 2008).

Family physicians must remember that a genetic diagnosis affecting a patient has implications for the entire family. Before genetic testing, they should discuss the need to inform family members of abnormal results that might affect

them. When a patient does not want family members to know that they have a genetic disease, the Health Insurance Portability and Accountability Act (HIPAA) has clarified and strengthened the patient's right to privacy of medical information. When knowledge of the patient's condition would not change health outcomes for the relative, the physician has no duty to warn. If the information can affect other family members' health, this presents a quandary. Some courts have ruled that physicians are liable for failure to inform other family members. Physician assistance in informing family members can also help the patient (Offit et al., 2004).

Several national groups of genetics professionals have developed consensus guidelines against genetic testing in *minors*, unless there is a potential immediate benefit to the child's health. Experience in adult-onset conditions has revealed that many people choose not to know if they are at risk for a genetically determined condition. Knowing about the risk of developing an adult illness in childhood, when no treatment or intervention is available, may present unnecessary intrusion into normal child and family development. Consequently, rather than test minors, it is often advisable to wait until adulthood so that a fully informed decision can be made about testing.

Reproductive decision making can be complex. It is important to remember that the quadruple screen or high-resolution ultrasound during pregnancy is genetic testing. Before patients undergo preconception or prenatal screening or testing, family physicians need to discuss the patient's expectations about results and subsequent pregnancy planning. Counseling before fetal testing should include detailed information about risks, benefits to parents and infants, probability of abnormal result, and implications of possible results, including inconclusive results or those indicating alternate paternity. Reproductive counseling has followed a nondirective model, in which the health professional avoids biasing the woman's or the couple's decision-making process.

Genetics in Primary Care Practice: Disease Illustrations

Key Points

- Health care providers should recognize when genetic factors contribute meaningfully to risk assessment, diagnosis, or disease management for rare conditions as well as common multifactorial conditions.
- Staying current with advances in diagnosis and treatment of genetic conditions challenges both genetic specialists and family physicians.
- Family physicians should identify and utilize credible and current information resources to support their care of patients with heritable conditions because proper diagnosis and management can be lifesaving.

Table 44-5 lists examples of multifactorial, single-gene, and chromosomal disorders seen in family medicine, including genetic information about each disease (Acheson and Wiesner, 2004; Christiansen et al., 2005; Gaston et al., 1986). In aggregate, single-gene and chromosomal disorders are relatively common. Physicians should remain alert for

Table 44-5 Multifactorial, Single-Gene, and Chromosomal Disorders Seen in Family Medicine

| Condition | Inheritance Pattern | Genes Involved* |
|------------------------------------|---|--|
| Single-gene diseases | | |
| Early-onset Alzheimer's disease | Autosomal dominant | APP, PSEN1, PSEN2 |
| Breast cancer | Autosomal dominant with incomplete penetrance | BRCA1, BRCA2 |
| Colon cancer (Lynch syndrome) | Autosomal dominant with incomplete penetrance | MLH1, MSH2, MSH6, and PMS2 |
| Cystic fibrosis | Autosomal recessive | CFTR |
| Hemochromatosis, adult | Autosomal recessive | HFE |
| Marfan's syndrome | Autosomal dominant | FBN1, TGFBR2 |
| Sickle cell disease | Autosomal recessive | HBB |
| Tay-Sachs disease | Autosomal recessive | HEXA |
| β-Thalassemia | Autosomal recessive | HBB |
| Familial hypercholesterolemia | Various | LDLR, ApoB, PCSK9, LDLRAP1 |
| Chromosomal diseases | | |
| Down syndrome | Sporadic | Trisomy 21 |
| Fragile X syndrome | X-linked dominant with incomplete penetrance | FMR1, with >200 CGG repeats |
| Turner' syndrome | Sporadic | XO karyotype |

 *Most common mode of inheritance for each condition listed; for many common multifactorial conditions, there are rare instances of mutations in single genes causing a similar disease.
 SNPs, Single nucleotide polymorphisms.

single-gene diseases when seeing patients, which can include causes of cancers, anemia, liver disease, developmental delay, and deep vein thrombosis. Making a correct genetic diagnosis can lead to lifesaving interventions for affected patients and their families.

Much research is needed regarding the genetics of multifactorial disorders, and predispositional genetic testing for such conditions using newer markers (e.g., disease-associated SNPs) is not currently recommended. A few examples illustrate what can currently be done with genetics and genomics in primary care.

Hereditary Breast and Ovarian Cancer

A family history of premenopausal breast cancer in a first-degree relative doubles personal breast cancer risk. These women may benefit from earlier screening and should be counseled about the benefits of early detection. An autosomal dominant pattern of inheritance is seen in a much smaller number of families, perhaps 5% of women with breast cancer, known as hereditary breast and ovarian cancer (HBOC) syndrome. Current USPSTF guidelines suggest that physicians should recognize individuals from such families

because they may benefit from counseling about HBOC and testing for mutations in the *BRCA1* and *BRCA2* genes. The USPSTF recommends against using *BRCA* and mutation testing as a screening tool in the absence of a suggestive personal or family history. Numerous *BRCA* mutations have been found, and their prevalence in the general population is about 1 in 800, but up to 1 in 40 in people of Ashkenazi Jewish descent. Pretest and post-test counseling is very important for HBOC. The presence of many rare mutations and mutations of unknown clinical significance in the population can make interpretation of testing complicated, and involvement of a clinician with specialized knowledge is advisable.

Women with *BRCA* mutations may have up to an 80% lifetime risk of breast cancer and a 40% risk of ovarian cancer depending on the mutation. The risk of other cancers is also greater, although less so. It is important to recognize that males with a *BRCA* mutation develop breast cancer at much higher rates than the general population. In fact, a diagnosis of male breast cancer should lead to a careful review of family history. Personal risk depends on the specific gene variant involved and other risk factors. Aggressive strategies aimed at early detection (e.g., breast MRI) are frequently recommended, but evidence of comparative effectiveness is lacking. Interventions such as bilateral mastectomy and oophorectomy have an enormous impact on women's lives, but evidence suggests these surgeries may confer up to a 90% reduction in cancer risk (NCCN, 2008).

Evidence regarding prophylaxis with tamoxifen or related agents is equivocal and may be related to the specific causal mutation. Although routinely offered to individuals with *BRCA* mutations, little evidence supports the use of annual CA-125 and transvaginal ultrasound to screen for ovarian cancer. Options for prevention and treatment are increasing over time, and more targeted and less invasive options may become available.

KEY TREATMENT

Women with a family history suggestive of hereditary breast and ovarian cancer (HBOC) syndrome should be offered genetic counseling (USPSTF, 2005) (SOR: A).
Enhanced breast cancer screening with annual mammograms and breast magnetic resonance imaging (MRI) starting at age 25, or 10 years earlier than the age of earliest diagnosis in the family, are recommended for individuals with *BRCA* mutations (NCCN, 2008; Saslow et al., 2007) (SOR: C).
Prophylactic mastectomy and oophorectomy dramatically reduce the risk of breast and ovarian cancer in HBOC patients (NCCN, 2008) (SOR: B).

Hereditary Colorectal Cancer

About 10% of the general population has a first-degree relative with colorectal cancer (CRC); this history increases personal lifetime risk for CRC to 9% to 16%. Many guidelines recommend early screening for these individuals—by age 40, or 10 years earlier than the age at diagnosis of a family member. Early detection and removal of adenomatous polyps have made determining family history more difficult. Patients should be asked about removal of polyps in relatives, and those who have adenomatous polyps should be encouraged to tell their families.

A family history that contains many relatives with CRC, adenomatous polyps, or endometrial cancer, especially in more than one generation or with early-onset (age <50) suggests an autosomal dominant pattern of inheritance. Two relatively common, autosomal dominant, hereditary colorectal cancer syndromes account for about 3% to 5% of all CRC cases. *Lynch syndrome*, or *hereditary nonpolyposis colon cancer syndrome* (HNPCC), occurs in about 1 in 200 to 800 families and is underdiagnosed in primary care settings. Lynch syndrome is caused by mutations in mismatched repair genes and confers an approximately 80% lifetime risk of CRC. Often these cancers are right-sided and occur at an earlier age than sporadic CRC. Women with HNPCC have an increased risk for endometrial cancer; the incidence of other gastrointestinal and central nervous system cancers is also increased, but to a lesser degree. Evidence-based guidelines suggest that CRC screening with colonoscopy should begin in the 20s for affected individuals. Screening for endometrial cancer is also recommended, but there is less evidence of benefit. Evidence indicates that the disease burden could be reduced by screening tissue samples from all new CRC cases for molecular findings suggestive of Lynch syndrome. Family members of individuals testing positive then could be offered testing and enhanced surveillance if positive (EGAPP Working Group, 2009).

Familial adenomatous polyposis (FAP) is seen in about 1 in 8000 families, and affected individuals have a 100% lifetime risk of CRC. Management usually involves early screening (age 10-12) with sigmoidoscopy and early colectomy. Chemoprophylaxis with nonsteroidal anti-inflammatory drugs (NSAIDs) may also be of benefit.

Family physicians should recognize both FAP and HNPCC and ensure that genetic evaluation is offered to these families. If a specific mutation is identified, early screening of family members can be stopped for those testing negative. In the absence of a known mutation, all family members should be screened at an early age and the screening repeated at shorter intervals.

KEY TREATMENT

Individuals with a single first-degree relative (parent, sibling, child) affected by colon cancer should be offered screening at 40 years of age, or 10 years before the age at diagnosis of the affected relative (NCCN, 2009) (SOR: B).
All colon cancer tumor samples should be tested for changes suggestive of Lynch syndrome (HNPCC), to reduce morbidity and mortality in family members (EGAPP Working Group, 2009) (SOR: A).
Accelerated screening for colon cancer is recommended for individuals with Lynch syndrome (NCCN, 2009) (SOR: A).
Colon cancer screening beginning in the second decade of life and early colectomy are recommended to reduce risk of colorectal cancer for individuals with familial adenomatous polyposis syndrome (NCCN, 2009) (SOR: A).

Cystic Fibrosis

Cystic fibrosis (CF) is a relatively common autosomal recessive condition that causes progressive lung disease and exocrine pancreatic insufficiency. CF affects approximately 1 in 3200 U.S. Caucasians but is less common in other population groups. CF results from inheriting two mutated

copies of the *CFTR* gene, which is known to play a role in regulating chloride transport across epithelial membranes. More than 1000 *CFTR* mutations have been described, but the $\Delta F508$ mutation accounts for the great majority of classic CF cases.

The diagnosis of CF in symptomatic individuals can be made by the chloride sweat test, transepithelial nasal potential difference measurement, or genetic testing for *CFTR* mutations. Once almost universally fatal in adolescence or early adulthood, improved management has resulted in more CF patients surviving well into adulthood. Patient management in specialized CF centers is common, although it is unclear to what extent management by a specialized center is associated with improved patient outcomes. Lung transplantation has been used as a “cure” for the pulmonary complications of CF.

All women should be offered CF carrier screening as part of prenatal or preconception care to determine risk, so that reproductive planning is an option (ACOG, 2005). It is important to recognize that the common panels offered for prenatal CF screening contain tests for a variety of CF mutations but perform less well in certain ethnic groups. This lowered sensitivity results in residual risk of having an infant with CF despite a negative screening test in certain population groups.

Several U.S. states include CF in their newborn screening programs, and some evidence suggests that screening

is associated with improved outcomes (Grosse et al., 2006; Southern et al., 2009). Newborn screening for CF illustrates some important dilemmas. As a result of this screening, we now know that many patients with nonclassic *CFTR* mutations have only mild disease, such as congenital absence of the vas deferens or chronic sinus infections. Does diagnosis before the onset of symptoms improve outcomes for these individuals? What about the risks of informing parents of a serious disease in their apparently normal newborn—will it change parenting and child development? The answers to these questions are under investigation, but they are important factors to consider when assessing risks and benefits of early CF detection.

KEY TREATMENT

Newborn screening for cystic fibrosis occurs in some U.S. states and is associated with improved outcomes (Grosse et al., 2006; Southern et al., 2009) (SOR: B).

It is reasonable to offer CF carrier screening to women in the preconception or prenatal setting, regardless of race or ethnicity (ACOG, 2005) (SOR: C).

Consensus guidelines suggest sweat chloride testing or genetic testing for *CFTR* mutations for CF diagnosis in symptomatic individuals (GeneReviews, 2008) (SOR: C).

Family medicine physicians are frequently asked to assist a patient who is in a crisis, whether a life-threatening illness, intimate partner violence, suicide attempt, job loss, loss of insurance, depression, panic attack, or bipolar episode. In this emotional state of crisis, the patient feels panicked, helpless, and overwhelmed and cannot perform basic activities involving work, family relations, and even daily living. Urgent safety concerns surround patients with acute medical conditions, as well as those with suicidal ideation and victims of violence. Many family physicians feel unprepared to offer patients practical help during a general office visit.

The *crisis intervention approach* provides both a theory and a treatment model that can be readily applied to patients in crisis or to victims of intimate partner violence. This chapter describes the general principles of crisis intervention theory and treatment, as well as crisis evaluation and treatment of *intimate partner violence*, which is a pervasive and often underrecognized public health problem.

Development of Crisis Intervention, Trauma, and Disaster Theory

Historical Considerations

Key Points

- Crises can be effectively treated. Three core principles of crisis treatment are (1) the expectation that the patient will recover, (2) the provision of immediate treatment, and (3) the

encouragement of the patient to return to normal daily functioning as soon as possible. A crisis typically last 6 weeks and can resolve spontaneously. Crisis resolution depends on the severity of the crisis, personal reaction, support system, and effects on the community.

- A crisis is a brief psychological upheaval, precipitated by a stressor, resulting in an inability to cope, adapt, or function in daily life.
- A crisis may resolve with improved functioning, a return to baseline, or may be stabilized at a lower level of functioning.

Thomas Salmon (1917), a British military physician during World War I, was asked to evaluate severe “shell shock” (traumatic neurosis), which was producing psychological paralysis in Allied soldiers. In this first medical description of the psychological effects of war, Salmon noted that French soldiers suffered fewer psychological casualties than British soldiers. Three factors seemed to account for the French advantage: (1) French soldiers were told that they could expect to recover from their psychological traumas; (2) soldiers received immediate psychological treatment, close to the battlefield; and (3) soldiers were returned to battle as quickly as possible. These principles became the cornerstone of modern crisis theory and disaster management strategies. Patients entering crisis treatment can expect to be treated immediately, in their natural environments, with an expectation that they will recover from the crisis or disaster. Efforts should be made to return patients to their normal life and community as soon as possible.

Eric Lindemann (1944) applied and expanded Salmon’s theories. He studied the acute grief reactions of persons who lost family members in the Coconut Grove fire in Boston, which claimed 500 lives. Lindemann discovered that normal

people surviving such a horrific experience would develop an emotional crisis of pain, confusion, anxiety, and temporary difficulty in daily functioning. Also, he discovered that the psychological trauma caused by the crisis had little relation to preexisting psychopathology, and that only a small group of the victims declined to a lower level of functioning. Generally, the outcome of the crisis was most closely related to the severity of the stressor, personal reaction to the trauma, effect of trauma on the person's family and friends, and degree of community disruption. Lindemann found that most crisis survivors recovered spontaneously within 6 weeks.

Erik Erikson (1959), a sociologist, introduced the idea of a life cycle composed of developmental stages and developmental crises. His eight stages were seen as normative processes during which age-specific psychological tasks, transitions, and crises were routinely encountered. A difficulty or inability to negotiate a stage successfully affects the ability to progress to the next stage. For example, an adolescent seeks an adult identity and redefines social roles that emphasize peer relationships and increasing autonomy from parents. Those who do not successfully traverse adolescence develop a childlike dependence on parental figures and often have difficulty developing a career, getting married, or developing autonomous social relations.

Other crisis practitioners have expanded Erikson's basic concept of eight developmental crises to include other crises such as leaving home for the first time, the midlife crisis, and parents' experience of the "empty nest syndrome." For many patients, a transition from one life phase to the next, such as marriage, divorce, retirement, or an illness, may bring the potential for a new developmental crisis.

Gerald Caplan (1961, 1964) synthesized many of these earlier ideas into modern crisis theory and treatment. He defined the crisis state as a brief, personal, psychological upheaval precipitated by a stressor, or "hazard." A precipitant produces emotional turmoil so that the person is temporarily unable to cope, adapt, or function in daily activities. Caplan demonstrated that a crisis implies the potential for danger and an opportunity for growth. Although subscribing to Lindemann's theories of acute precipitants, Caplan believed that a person's preexisting psychiatric condition could influence the development, evolution, and resolution of a crisis. A crisis may be based on the failure of a person's individual coping style and ability to adapt. Caplan confirmed that most acute crises resolve in about 6 weeks, with four possible outcomes: improved functioning, functioning restored to precrisis levels, incompletely restored functioning with a susceptibility to the development of future crises, or a severely impaired but stable level of lower functioning. He corroborated Lindemann's findings that some people cope with a crisis by spontaneously and flexibly developing new coping or problem-solving styles. Caplan developed a crisis treatment focus on development of better coping mechanisms and adaptations to life's traumas.

Current Understanding of Crisis

Key Points

- Approximately 13% of the U.S. population has reported a lifetime exposure to natural or human-generated disaster.
- Posttraumatic stress disorder in the United States has an estimated lifetime prevalence of 8%, with women twice as likely as men to be affected.

The current understanding of "crisis" has been used as one of several core strategies in the management and treatment of trauma. The frequency of traumatic experiences is defined by the type of events called "traumatic." For example, early studies limited traumatic events to wars, natural disasters, and plane crashes, whereas more recent epidemiologic studies include intimate partner violence, car accidents, crime, or foreclosures. Estimates of lifetime trauma exposure vary with the definition of a "traumatic event," so community studies of exposure to lifetime trauma also varies (25%-90%). According to the American Psychiatric Association's *Diagnostic and Statistical Manual of Mental Disorders*, 4th edition, text revision (DSM IV-TR), the lifetime rate of posttraumatic stress disorder (PTSD) ranges between 1% and 14%.

Natural disasters such as earthquakes, tsunamis, hurricanes, tornadoes, and volcanic eruptions can traumatize individuals, devastate whole communities, and disturb an entire population in a large geographic area. Man-made disasters, such as 9-11 (2001), Oklahoma City (1995), suicide bombings, plane crashes, and environmental accidents, are all byproducts of the 21st century and, unfortunately, have become a part of modern life.

The prevalence of exposure to mass trauma is difficult to estimate. In one study, 13% of the U.S. population reported a lifetime exposure to natural or human-generated disaster (Burkle, 1996). The U.S. National Comorbidity Survey estimated that 18.9% of men and 15.2% of women reported a lifetime experience of a natural disaster (Kessler et al., 1995). These are merely exposure rates to trauma. Fortunately, most victims recover from traumatic exposure over time, without long-term sequelae. However, some will go on to develop *posttraumatic stress disorder* (PTSD). According to the National Center for Posttraumatic Stress Disorder, the estimated lifetime prevalence of PTSD among adult Americans is approximately 8%, with women twice as likely as men to be affected at some time during their life (Stein et al., 2003). Women who are victims of intimate partner violence are almost four times more likely than nonabused women to develop PTSD (Campbell, 2002).

The most common traumatic events include witnessing an injury, murder, fire, flood, or natural disaster; life-threatening accident; and combat exposure. According to the World Health Organization (WHO), 1.2 million people are killed in motor vehicle crashes and 50 million injured annually (Mayou et al., 1993). Well-known man-made disasters include the U.S. atomic bombings of Hiroshima and Nagasaki (WWII, 1945), the Chernobyl nuclear power plant accident in Russia (1986), the domestic terrorist bombing of Murrah federal building in Oklahoma City (1995), and foreign terrorist destruction of the World Trade Center in New York (2001). In addition, violence and trauma in American society continues with shootings in schools, community centers, and businesses.

Intimate Partner Violence

Key Points

- The American Association of Family Physicians estimates that one third of patients cared for by family physicians are affected by family violence.

- Children are adversely affected by intimate partner violence and may need a referral to child-focused treatment.
- Family violence leads to 39,000 physician visits and 73,000 hospitalizations annually.

Intimate partner violence (IPV) is a specific type of crisis requiring some special consideration; we use this term throughout this chapter to account for diverse populations and types of abuse. The Family Violence Prevention Fund (FVPE, 2004) defines intimate partner violence as “a pattern of assaultive and coercive behaviors that may include inflicted physical injury, psychological abuse, sexual assault, progressive social isolation, stalking, deprivation, intimidation, and threats. These behaviors are perpetrated by someone who is, was, or wishes to be involved in an intimate or dating relationship with an adult or adolescent, and are aimed at establishing control by one partner over the other.”

Worldwide, at least 10% to 50% of women have been physically or sexually abused in their lifetime (WHO, 2001). Annually, 2 to 4 million women and 835,000 men are assaulted by intimate partners in the United States (National Institute of Justice). Lifetime prevalence of physical or sexual abuse by an intimate partner of U.S. women is 20% to 30%, and for men, 7.5% (FVPE, 2004). From 22% to 46% of gays and lesbians have been victims of physical IPV (AAFP, 2000). Between 2000 and 4000 U.S. women die from these injuries each year. Up to one in six pregnant women is abused during pregnancy (AAFP, 2000). One study showed that IPV increased health care costs in affected women by 92% (Ramsey et al., 2009). Family violence leads to 39,000 physician visits and 73,000 hospitalizations annually (Kass-Bartelmes and Rutherford, 2004).

A common and costly problem, IPV is receiving increased attention. Several professional organizations and other groups have made policy statements and recommendations; some mandate screening. The majority of IPV research is about violence committed by men against women, although recent epidemiologic studies show that IPV remains a significant problem in male homosexual relationships and occurs in all types of relationships (FVPE, 2004). The previous statistics on IPV are even more striking when considering that IPV is almost universally underreported (Watts and Zimmerman, 2002). Many studies assess only physical violence, not accounting for the psychological, economic, and emotional abuse that may exist alone or with other forms of violence.

Health Effects

Intimate partner violence leads to significant morbidity and mortality and contributes to high health care costs. Victims of IPV experience similar problems as patients with general crisis or trauma (Box 45-1). Abused U.S. women show increased rates of poor general health, digestive problems, abdominal pain, urinary and vaginal infections, pelvic pain, sexual dysfunction, headache, and chronic pain (Campbell, 2002). In particular, these women suffer from gynecologic, central nervous system (CNS), and stress-related problems at an increased rate of 50% to 70% (Wathen and MacMillan, 2003). The largest difference between sexually abused and non-sexually abused women is in gynecologic complaints. In addition to direct harm caused by trauma, perinatal complications include low birth weight, antepartum

Box 45-1 Common Symptoms Associated with a Crisis or Trauma

Physical

General

Insomnia
Tremors
Profuse sweating
Chills
Loss of or increased sexual drive
Increased substance use or abuse

Gastrointestinal

Nausea
Vomiting
Upset stomach
Loss of or increased appetite

Cardiac

Racing heart/ palpitations
Chest discomfort

Neurologic

Headaches
Dizziness
Numbness, tingling
Acute or chronic pain

Thoughts

Recurring traumatic dreams or nightmares
Difficulty with memory, attention, concentration
Difficulty in making decisions
Obsessions or compulsions related to the trauma
Reconstructing events of crisis to master the trauma
Questioning spiritual or religious beliefs
Psychosis (extreme)
Suicidal ideation
Homicidal ideation

Feelings

Numbness, irritability, restlessness
Anhedonia
Fear, anxiety when reminded of traumatic event
Feeling sad, blue, depressed
Emotional outbursts and angry feelings
Hopelessness, helplessness

Behaviors

Overprotection of self and family
Easily startled
Isolation from others
Avoidance of activities associated with the event
Avoidance of places and people that trigger memories
Keeping busy to avoid thinking
Increase in conflict with family members
Agitation
Drug seeking
Suicidal behaviors
Acting out, violent behaviors

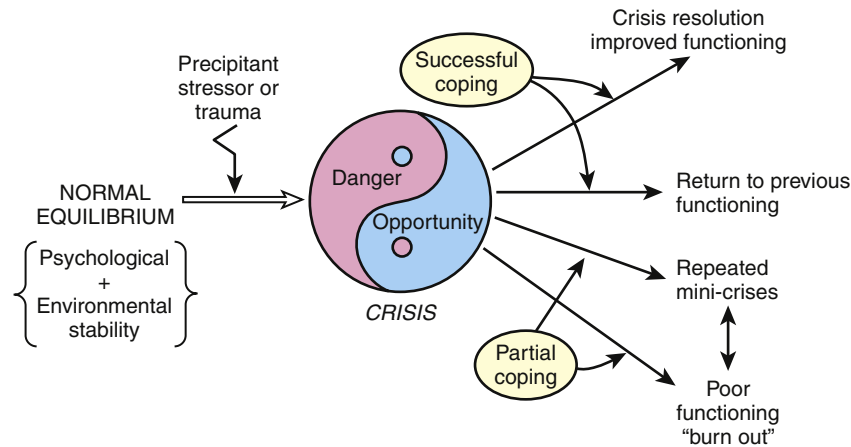

Figure 45-1 Crisis intervention theory.

hemorrhage, labor complications, preeclampsia, and mental health problems in the mother (Cherniak et al., 2005).

Children

Children are also adversely affected by exposure to IPV. Between 3.3 and 10 million children are exposed to IPV each year in the United States (Edelson, 1999). Exposure may be directly witnessing physical abuse, emotional abuse, or the sequelae of such abuse without viewing the violent acts. As a result of IPV, children may experience significant physical and behavioral symptoms acutely and throughout life, including somatic complaints, violence, substance abuse, and psychiatric illness (e.g., anxiety, depression, PTSD) (FVPE, 2009). When IPV is detected, the physician should decide if the children should be referred to child-focused mental health services. Furthermore, up to 60% of children exposed to IPV are themselves directly abused (Edelson, 1999). Physicians who detect IPV should be alert for child abuse and aware of mandatory reporting laws (see later Documentation and Reporting of IPV).

Evaluating the Crisis or Disaster

Key Points

A comprehensive evaluation of a crisis, trauma, or disaster includes assessment of the following:

- The normal equilibrium state
- The precipitant stressor or trauma
- The personal interpretation or meaning of the events
- The crisis state
- Preexisting personality or psychiatric conditions
- Selective past history
- System of social supports
- Effects on local society or community resources
- Special considerations for IPV (see later Key Points for IPV Approach).

Figure 45-1 presents an overview of a modern crisis intervention theory that is useful for the treatment of a crisis, IPV, or trauma.

Normal Equilibrium State and Stressors

Under normal circumstances, a person has a sense of internal psychological equilibrium and environmental support that generally permits activities of daily living (ADLs), working, and experiencing pleasure. A delicate balance among the person's internal wishes and fears, skills and capacities, and values and ideals determines psychological equilibrium. *Environmental equilibrium* refers to a stable balance among basic needs for food, water, shelter, physical comfort, and the integrity of community and social supports for job, family, religion, and society.

A patient in crisis enters an emotional storm after a stressor disturbs the normal equilibrium. Environmental precipitants typically seen in a family physician's office include IPV, sickness, and the stress of coping with death, divorce, marital separation, job loss, a financial crisis, and so forth. *Disasters* are acute environmental crises during which all concerned are focused on basic survival, acute medical care, and provisions of basic human needs. *Psychological stressors* may be related to events such as witnessing a trauma, surviving a disaster, loss of self-esteem, loss of love, a disturbing dream, sexual dysfunction, or sudden overwhelming fear, panic, or rage. *Developmental crises* such as latency, puberty, adolescence, marriage, birth of a child, midlife crisis, chronic medical illness, and retirement are common factors precipitating a crisis or may be comorbid factors.

Hobson and associates (1998) revised the Holmes and Rahe (1967) social readjustment scale. This newer scale lists 51 external life stressors that precipitate significant stress in most people. The top 20 items in this scale were in five separate domains: death and dying, health care issues, stress related to crime and criminal justice system, financial and economic issues, and family stresses. This scale includes events that range in severity from the most stressful being death of a spouse (rated as 1), divorce (7), experiencing domestic violence or sexual abuse (11), and surviving a disaster (16). It also includes events that many would consider positive yet stressful, such as getting married (32), experiencing a large monetary gain (42), and retirement (rated as 49). This list of stressors represents the most common precipitants causing a crisis. It is these types of stressors, and the internally disturbing feelings attached to the event, that produce emotional turmoil and a transient inability to adapt during the early stages of a crisis.

Most patients seeking treatment are surprised to discover that a major, unrecognized life stressor may have occurred on the same day or several days before the onset of the crisis. Less often, the stressor occurred sometime in the previous 6 weeks. Generally, events that occurred more than 6 weeks earlier are not acute stressors. Instead, these important past events may represent a previous crisis that was incompletely resolved and may be linked to the current crisis, as illustrated in Case Study 1.

Case Study 1

Melinda is a 42-year-old woman who presented to the office with insomnia, fear of public places, increased alcohol use, and irritability. Assisted by her physician's questions, Melinda realized that her symptoms had begun approximately 5 weeks ago, when she read about a violent local robbery in the newspaper. Since then, she felt anxious in public, coped by doing errands early in the morning, and began avoiding social interactions. Recently, she found it difficult to tolerate sex with her husband and unexpectedly felt emotionally distant from him. She began drinking alcohol so she could fall asleep and manage her anxiety. Her husband felt that she was "overreacting" to the robbery and expressed his concern about her escalating alcohol use. Nightmares returned of her experience in Hurricane Andrew 10 years earlier. She and a boyfriend stayed behind to protect their home, which was destroyed, and she witnessed a looter assaulting her friend. The couple broke up shortly thereafter, and she developed PTSD. A therapist helped Melinda move past the trauma and recover. She had been without symptoms for years.

Interpretation or Meaning of the Stressor

Whether a crisis is precipitated by an external life event or an internal psychological thought or feeling, each person interprets or adds meaning to the acute precipitant. For some people, like Melinda in Case Study 1, a local violent crime precipitated a major emotional crisis and a recurrence of her PTSD symptoms.

When listening for the precipitant of a crisis, it is important to understand the meaning of even minor stressors in the context of a patient's life. The robbery in Melinda's community had a personalized meaning to her that reawakened old wounds and PTSD symptoms, fueling a major emotional crisis. The following sequence of events, filtered through the lens of Melinda's select past personal experiences, created this current crisis. On learning of a local robbery, Melinda perceived a threat to her home and safety. This precipitant inundated her with traumatic memories of the hurricane and its aftereffects, which destroyed her home and her relationship. She felt anxious, insecure, and emotionally numb, and she was newly avoiding crowded places. The turmoil of her earlier relationship was being reenacted in her current marriage. Her nightmares interrupted her sleep, and she began using alcohol to fall asleep and quell her anxiety. Her alcohol abuse contributed to insomnia and feelings of numbness and intensified her anxiety. The violent robbery and her internal reactions and interpretation culminated in an acute crisis with recurrent PTSD symptoms, alcohol abuse, and marital discord.

Melinda presented to her physician unable to articulate her problem fully. As they discussed her symptoms and situation, Melinda realized that her current reaction was rooted in the seemingly unrelated events from her past. Her physician

helped her understand her interpretation of the local violent robbery in light of her past trauma. The patient realized that the reemergence of her PTSD symptoms was triggered by perceived threats to her current security. She could now better understand her reactions to her husband and acknowledge the pain and loss she suffered in the hurricane. Additionally, she recognized that her alcohol abuse was part of a maladaptive coping style. Based on her physician's input, Melinda was able to discontinue her alcohol use, felt more secure, and began efforts to reconnect with her husband.

Crisis State

The crisis state can be defined as a brief psychological upheaval, precipitated by a stressor, that produces an intense state of inner turmoil or disorganization that overwhelms a person's ability to cope and adapt. As with Melinda, the crisis state can be experienced as panic, disbelief, fear, confusion, sudden awareness of vulnerability, initial elation at having survived, or beginning of a grief reaction. For some, the crisis state may be denied or experienced as psychological numbing.

Often, patients in a crisis or suffering from a trauma present to their family physician with a confusing array of physical complaints. Patients like Melinda, who seek help while in an acute crisis, are typically impaired in some aspect of their daily interpersonal, work, social, or family life. Patients may have obvious psychological symptoms, unconscious psychological distress and pain associated with substance abuse, or physical symptoms. Four clusters of symptoms are typically experienced by patients during a crisis or secondary to a trauma (Box 45-1).

Case Study 2

Seth, an accountant and father of two, presented to his family physician at the urging of his wife. He complained of fatigue, difficulty concentrating, and anhedonia. His symptoms began the day of his son's 8th birthday party. He recalled inexplicably feeling a sense of dread and was near tears that day, despite having a good relationship with his son and looking forward to the party. His physician discovered that Seth's mother had died from a heart attack when Seth was 8 years old. Seth and his mother had been close; he remembered that she called him her "perfect little angel." After her death, Seth's family coped by telling him that he was too young to understand. His family avoided all conversations about his mother. He never fully mourned her. He maintained his attachment to his mother by his ambitious achievements and his perfectionism. His son's 8th birthday party reawakened Seth's unresolved maternal grief, sadness, and new symptoms of depression.

Typically, a patient in crisis such as Seth cannot explain what is upsetting him, although he is certainly aware that something is wrong. Seth's family physician asked, "Why now, at this point in time, are you depressed and feeling in crisis?" When asked, Seth felt distressed and confused. As he began to talk about his son and the birthday party, he realized that he was the same age as his son when his own mother died. He began to cry with the unresolved grief and the pride he imagined that she would have for him and her grandson.

Frequently, people in the crisis do not seek help by themselves and instead are brought in by concerned family members, lovers, friends, or perhaps the police or an ambulance. In these cases, it may take hours for the "Why now?" causes to be identified. Patients typically are not able to identify the

specific cause of their crisis. Physician questioning and asking patients to retell their experience is typically how the “Why now?” of the crisis emerges. “Why now?” questioning is the first step in treating a crisis.

Acute Crisis Resolution and Adaptation to the Crisis (Within 6 Weeks)

For many patients, the acute nature of the crisis is often resolved within 6 weeks as the patient learns to cope or adapt to the acute stress. The DSM-IV-TR (APA, 2000) has classified the initial 1-month period of a crisis marked by impaired functioning as an “acute stress disorder.” DSM IV-TR specifies that the acute symptom picture must last more than 2 days and no more than 4 weeks and must cause significant distress or impairment in social or occupational functioning. The result of the acute stages of the crisis is one of four possible outcomes specified in Figure 45-1. Successful coping and adaptation to a crisis can lead to crisis resolution that ultimately promotes growth and can even lead to improved functioning. For most patients, however, crisis resolution means a return to a previous level of baseline functioning. Still other patients only partially resolve the crisis and instead “seal over” and deny the significance of their feelings or recent events, setting the stage for a future crisis. Those with the worst prognosis typically have poor adaptation skills and, at best, stabilize at a lower level of daily functioning. For example, a patient who swallowed many pills after being left by her boyfriend may in retrospect deny any suicidal intent and instead say, “I just had a headache.” This patient has sealed over her crisis. Denial of her suicidal intent and anger with her boyfriend will probably lead to poor adaptation and latent weakness, called a *missed* or *unresolved crisis*. The patient may continue to use unsuccessful coping strategies, such as drinking or repeated suicide gestures, as a way to deal with her feelings. Unresolved crises predispose the patient to future episodes that may be caused by even less stressful precipitants. For example, this same patient may once again become suicidal after a minor argument with a male friend. Fortunately, future crises can afford new opportunities to rework past unresolved crisis, with better adaptation and coping.

Sequelae of Crisis, Trauma, or Disaster (6 Weeks to Lifetime)

Although many patients completely recover from a crisis within 4 to 6 weeks, others may suffer with the sequelae of trauma or a crisis. The prognosis generally depends on three groups of factors: pretraumatic, traumatic, and posttraumatic risk factors (Ursano et al., 1995). *Pretraumatic* factors may include prior psychiatric illness, genetics, typical coping styles, gender, and culture. *Traumatic* risk factors relate to the type of trauma, severity and duration of the trauma, and seriousness of a physical injury. *Posttraumatic* risk factors involve coping styles, resources available for repair, individual or community response, capacity for problem solving, and adaptation. In general, recovery is more likely if the crisis is not too severe and is short in duration. If the crisis is prolonged or totally devastating to the fabric of a community (as with a hurricane or earthquake), the resources available for repair and the coping strategies used are the best predictors of outcome.

When dealing with a patient who has been in a crisis or suffered a trauma, it is important for the family physician to assess for associated trauma-related conditions. This assessment begins with attention to physical illness or psychosomatic complaints, then focuses on basic health care needs (food, warmth, shelter, clean drinking water, good sanitation). From a psychiatric standpoint, the family physician must remember that it is normal to have symptoms of trauma after a crisis event. Most patients’ symptoms will wane gradually or resolve spontaneously and may not require psychological treatment. At 1 year, however, 30% to 40% of those exposed to a disaster will show lingering evidence of psychiatric morbidity (Raphael, 1986). For example, 1 year after being involved in a car crash, about 25% of patients will show signs of a psychiatric disorder, and 11% will go on to develop PTSD (Mayou et al., 1993). Table 45-1 summarizes the spectrum of psychiatric disorders that can occur in the wake of a crisis or trauma.

Previous Psychiatric Illness or Personality Disorder

For many people, there is little correlation between a previous psychiatric illness or personality disorder and their capacity to cope or adapt to an acute crisis or trauma. A person with schizophrenia may be just as capable of handling an acute crisis as others who do not have psychiatric disorders. How well a person handles an acute crisis or trauma depends primarily on the variables discussed earlier, including the precipitant, the meaning of the events, the crisis situation itself, the patient’s coping skills and styles, and the effectiveness of the patient’s support network.

However, there are many cases in which a preexisting psychiatric disorder or an unresolved trauma or crisis may influence the development of a new crisis. Consider the case of a mentally retarded boy who becomes severely violent because his mother ran out of his favorite breakfast cereal. This change would be a minor stressor for most people, but for this boy, disruption of his daily breakfast food and routine are perceived as catastrophic. His low IQ and lack of verbal skills, related to his mental retardation, predispose him to a crisis involving violence because he lacks the ability to consider other options. Patients with severe psychiatric illness or personality disorders, those with trauma-related disorders (see Table 45-1), and those who have rigid coping styles or poor adaptation skills all are at greater risk for future crisis.

Selective Past History

For an acute crisis, the patient’s past history is relevant only as it can help explain and resolve the current crisis. Many patients, wanting to avoid the pain of the current crisis, may unconsciously lead the family physician “down the garden path” to chronic problems, avoiding the pain of the current issues. To avoid the past history trap, the physician must try to understand the dynamics of the current crisis and then look for similar events in the patient’s past that can be used to understand more about the current situation. For example, a selective past history of suicide attempts and the circumstances surrounding those attempts may provide valuable clues to understanding a current suicidal crisis. This selective history can assist in developing an understanding of the “Why now?” of the current suicide attempt.

Table 45-1 Psychiatric Disorders Related to Trauma or Crisis

| Diagnosis | Diagnostic Criteria* and Symptom Picture | Onset/Duration |
|--|--|---|
| Adjustment disorder | Emotional, behavioral symptoms in response to identifiable stressor(s) Distress in excess of what would be expected from exposure to stressor Symptoms create marked distress or impairment in social or occupational functioning Does not represent bereavement | Begins within 3 mo of onset of stressor Symptoms usually resolve within 6 mo of termination of stressor. |
| Acute stress disorder | Exposure to traumatic event that involved actual or threatened death or threat of serious injury to self or others Response to threat—intense fear, helplessness, or horror Marked avoidance of stimuli associated with the trauma (including thoughts, places, conversations) Dissociative symptoms (e.g., numbing, detachment, feeling dazed, depersonalization, derealization, dissociative amnesia) Trauma reexperienced through flashbacks, distressing recollections, dreams, sense of reliving, or psychological-physiologic reactions when exposed to cues that represent the trauma Symptoms of increased arousal, exaggerated startle response, hypervigilance, motor restlessness, or anxiety Clinically significant impairment in social or occupational functioning Not merely an exaggeration of existing psychiatric condition | Lasts minimum of 2 days and maximum of 4 wk [†] |
| PTSD | Same as for acute stress disorder, with three possible time courses: acute, chronic, or delayed | Acute: 1-3 mo Chronic: >3 mo Delayed: >6 mo |
| Major depressive disorder | Must have depressed mood or loss of interest or pleasure In addition to above, 5 of following 9 symptoms present for at least 2 weeks: depressed mood most of day, anhedonia, weight loss or gain, insomnia or hypersomnia, agitation or motor retardation, fatigue, feelings of worthlessness or excessive guilt, poor or decreased concentration, and recurrent thoughts of suicide or death Symptoms represent change from previous functioning Causes distress or social or occupational impairment | Onset common 6-12 mo after crisis or disaster Symptoms present for most of day, nearly every day, for 2 wk |
| Substance use or abuse | Numbing substances (e.g., alcohol, heroin, marijuana) and sedative-hypnotic abuse usually preferred | Most common 6-12 mo after crisis |
| Dissociative disorders | Dissociative amnesia, dissociative fugue, dissociative identity disorder (formerly multiple personality disorder), depersonalization disorder Disturbance consists of one or more episodes of inability to recall important personal information, usually of traumatic nature | Sequelae of enduring chronic trauma, abuse, or neglect |
| Generalized anxiety disorder | Persistent symptoms of excessive anxiety or worry for at least 6 mo Also associated with restlessness, being easily fatigued, poor concentration, irritability, and sleep disturbances Free-floating anxiety unrelated to specific person(s) or situation | Any time after trauma |
| Panic disorder (with or without agoraphobia) | Recurrent, unexpected panic attacks, defined as episodic periods of intense anxiety, often with physical symptoms (e.g., palpitations, tremors, chest discomfort) Symptoms develop abruptly, increase in intensity over 10 min Persistent concerns about having additional attacks Anxiety, worry about implications or consequences of attack (e.g., heart attack, losing control) | Any time after trauma |
| Specific phobia, social phobia (social anxiety disorder) | Specific phobias: excessive or unreasonable fear of specific objects or situations (e.g., animals, heights, needles), which provokes immediate anxiety response Patient avoids feared situation or object. Social phobias: fear of social or performance situations in which patient fears possible excessive scrutiny by others Patient constantly worried about acting in humiliating or embarrassing way. | Any time after trauma |

Modified from American Psychiatric Association. Diagnostic and Statistical Manual of Mental Disorders, 4th ed, text revision. Washington, DC, APA, 2000.

Continued

Table 45-1 Psychiatric Disorders Related to Trauma or Crisis—cont'd

| Diagnosis | Diagnostic Criteria* and Symptom Picture | Onset/Duration |
|-----------------------|---|-------------------------|
| Brief psychosis | Presence of one or more: hallucinations, delusions, disorganized speech, and disorganized or catatonic behavior Eventual full return to premorbid level of functioning | At least 1 day to <1 mo |
| Somatization disorder | Unexplained physical symptoms (e.g., pain, gastrointestinal, sexual, neurologic) Symptoms begin before age 30 and occur over several years. Symptoms are not intentionally produced or feigned. | Any time after trauma |
| Conversion disorder | One or more symptoms affecting motor or sensory function suggest neurologic or general medical condition. Initiation or exacerbation of symptoms often is preceded by conflicts or stressors. Symptoms are not intentionally produced or feigned. | Any time after trauma |

Additional events from the past history that might be helpful in understanding a suicide attempt include deaths, separations, severe medical illnesses, and a history of depression, alcoholism, or family suicide. Selective past history that could be relevant for understanding an acute violent crisis might be the timing and circumstances of past episodes of violence, childhood experiences of abuse or neglect, previous hospitalizations for violence, prior incarcerations, past legal problems, and past neurologic or medical illness.

When dealing with trauma victims, it is important to ask about past trauma, previous successful coping styles or adaptations, and cultural and religious beliefs, because this information can help promote recovery. The less severe the current traumatic event, the more critical are predisaster variables, such as neuroticism or history of a psychiatric illness.

Social Systems

Everyone lives within a network of social interaction, social support, and community and national resources. Most of our daily social interactions are with family, friends, and work colleagues. These daily social interactions are made possible by the community supports that enable a person to obtain clean water, adequate sanitation, housing, food, clothing, work, education, finances, and medical care. Community structures are generally made possible because of the support of the country or nation. National resources support the entire infrastructure of the civilization, from roads to a monetary system to constitutional protections. In general, stable social systems at different levels tend to provide the greatest buffers against crises or disasters of all types. A patient's social system can be represented by an ecological map (see Case Study 3 and review [Figure 45-3](#)).

Often, a patient goes into a crisis because the immediate social environment is threatened or disrupted by such issues as divorce, a dysfunctional family, drug abuse, unemployment, or an eviction notice. Relative damage to a local support network can have profoundly varied effects on a patient. For example, the death of a spouse produces a more severe crisis if the deceased was also the sole financial provider. Even a minor disturbance in a small or dysfunctional support network can produce a major crisis. For example, an elderly woman who is housebound and without family,

friends, or a telephone can experience a major crisis when her home health aide misses a scheduled visit.

When assessing the local support network of a patient, a family physician should consider whether the patient's network is interested, available, and competent to help. Some networks are helpful and should be included, whereas other networks may be harmful to the patient. This determination may be especially complicated in IPV cases where a marital separation is necessary but results in the woman needing to face financial stresses, loss of her home, and the loss of her social network. When a patient is in a crisis, the family physician can help the patient choose and mobilize the most helpful people in the patient's immediate support network and exclude others. Such helpful mobilizations may include calling in a specific family member, speaking to a supportive boss, helping the patient retain an attorney, establishing health care, or obtaining Medicaid.

In general, social disruptions at the local level of support (e.g., job loss) are less damaging than community level disruptions (e.g., tsunami). National disruptions such as wars or earthquakes in poor countries cause a devastation from which many never recover. Disasters are long-lasting when the needed resources remain greater than the available resources. During a disaster, the social structure of a society can be damaged to such an extent that the existence and functioning of the entire community or nation are threatened (Eranen and Liebkind, 1993). This is the experience of Hurricane Katrina in 2005 and the earthquake in Haiti in 2010. Disasters of this magnitude require local, state, national, and even international support if there is to be a chance of restoring the social integrity of the community to the predisaster level of functioning.

Crisis Intervention Treatment in the Office Setting

Basic Approach

Key Points

- Develop a timeline of events starting with the "Why now?" and work from the initial presentation backward in time.
- Focus on acute risk assessment, including risk of suicide, violence, and acute medical conditions.

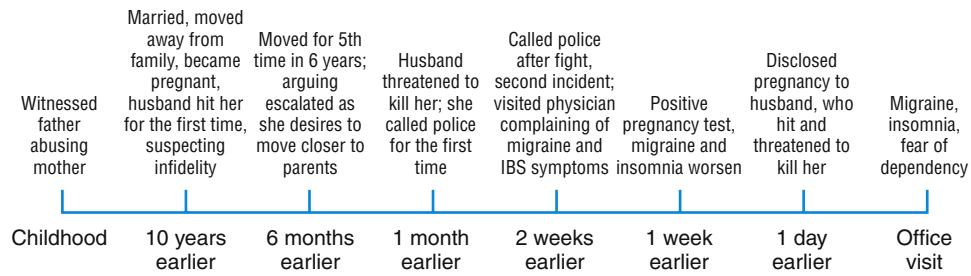

Figure 45-2 Crisis timeline: Case Study 3.

- Develop an eco-map or support network map, beginning with a three-generational genogram and other psychosocial supports.
- Select a single problem or symptom to begin crisis treatment.
- Build a wheel-and-spoke treatment plan with the single problem or symptom in the center and biopsychosociocultural factors as spokes.
- Treat the problem or symptoms by fostering the use of adaptive coping skills.
- Use a crisis resolution strategy.
- Use psychiatric medication, as needed, for symptom relief.

The focus of a crisis assessment involves the evaluation of the precipitants of the crisis or trauma, personal meaning of the events, crisis state itself, selective past history, support network, and current psychiatric illness, if relevant. These assessments are subsequently used to help formulate the causes of the crisis, so that if necessary, specific crisis intervention treatment and problem-solving approaches can be implemented.

A tailored crisis intervention treatment is typically one to five sessions, offered on a voluntary basis. The treatment is specifically geared toward helping the patient survive and cope with the acute biopsychosocial or cultural effects from the crisis. The time required for each session depends on the complexity of the case and the practitioner's skill. A family physician can begin the crisis assessment and treatment by exploring the "Why now?" or acute precipitant of the crisis. This inquiry can be followed by detective-style questioning designed to uncover the specific chronology and sequence of events, feelings, thoughts, and behaviors that led to the development of the acute crisis. Patients seeking help should be encouraged to tell the details of their traumatic experiences.

Helping the patient to describe the stressors and evolution of the acute problem may offer clues to problem-solving approaches to crisis resolution. Crises or disasters involving the lack of food, clothing, shelter, poor sanitation, or inadequate medical care should be given first priority. Crises involving violence, suicide, or a life-threatening medical illness have secondary priority and should become the focus of the crisis treatment. Crises in everyday life can be treated according to the patient's preferences.

Crisis treatment focuses on the dynamic interplay of events from the most recent precipitants and days, the previous 6 weeks, and selective elements from the patient's past history. Important tools and approaches that can guide a crisis formulation and treatment are the timeline, ecologic (eco) map/support network tool, wheel-and-spoke formulation, symptom-oriented treatment, and assessment and development of more adaptive coping styles. All these components can be used for the development of a general crisis resolution strategy.

Timeline

A timeline is a pictorial representation of the immediate, recent, and selective events from the past history contributing to the current crisis. A family physician can build a timeline while interviewing the patient. The physician asks the patient to discuss the immediate events and precipitants of the crisis on the day of the office visit or events from the past week. Together, the physician and the patient reconstruct the history by working backward over the previous 6 weeks. Finally, the physician tries to elicit the selective past history that may relate to the current crisis. Use of the timeline is illustrated in Case Study 3 (Fig. 45-2).

Developing a timeline with a patient helps both physician and patient focus on recent events and begins the process of formulating treatment. As illustrated in Figure 45-2, for

Case Study 3

Denise is a 30-year-old woman living with her husband and 10-year-old son. She presented to her family physician complaining of severe migraines and insomnia over the past week after having a positive home pregnancy test. She feared that having another child would make her permanently dependent on her husband. The couple met while she was a college student living with her parents. They married within weeks and moved frequently because of his jobs. She lost weight with each move and was eventually diagnosed with irritable bowel syndrome (IBS). He managed their finances and believed that women should not work outside the home. She was so afraid of him that she quickly abandoned her secret plans to become a teacher. When she was 7 months pregnant, her husband saw her talking with a male neighbor and accused her of infidelity. He then hit her for the first time.

Denise witnessed her alcoholic father physically abusing her mother throughout her childhood. Her father favored her brothers and spared them any abuse, while verbally and emotionally abusing her and her mother. When Denise left home, she and her mother remained close allies and maintained a lifelong bond. Denise's relationship with her father continued to be strained.

Since moving to the area 6 months ago, Denise and her husband argued daily about finances and her desire to move closer to her parents. One month ago, he threatened to kill her and their child. She had called the police twice in the past month, but she never pressed charges. In the past 6 months she had visited her physician 10 times, with various complaints (headaches, IBS, emotional symptoms). Ultimately, her physical injuries alerted the physician to abuse. He had asked about domestic violence during past visits, but she disclosed nothing. When she told her husband of the pregnancy, he became enraged, blamed her for getting pregnant, and hit her in the face and belly while threatening to kill her. During her appointment the next day, she was tearful and scared. Her physician asked her again if she was safe and when she said "no," they were able to discuss the beatings.

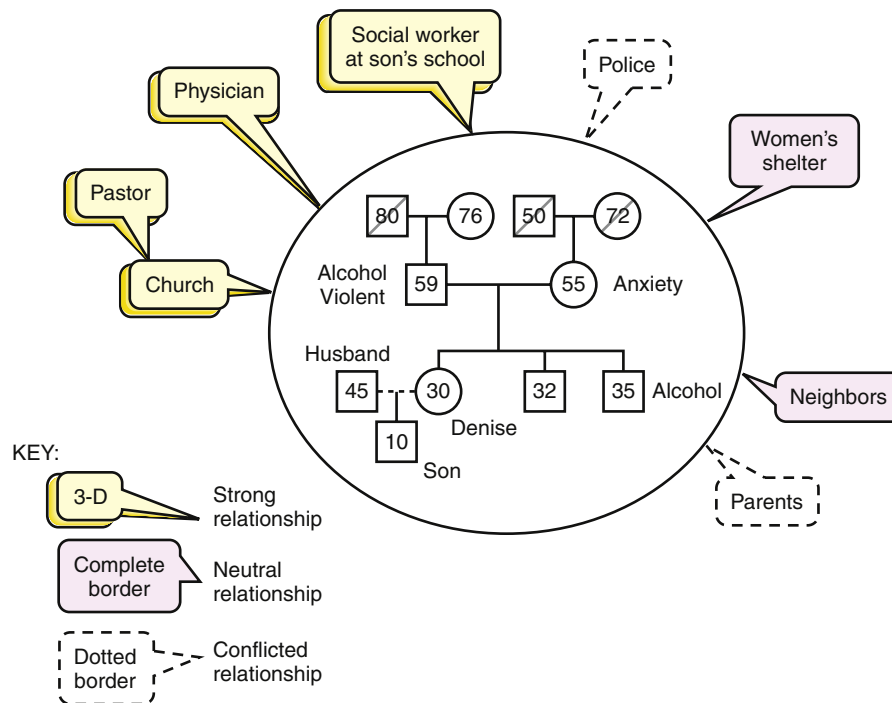

Figure 45-3 Eco-map (ecologic support network): Case Study 3.

Denise, her crisis was both becoming pregnant and being assaulted and threatened by her husband. During the office visit, her physician helped her build her timeline. Denise was able to recognize how her migraines and IBS were related to her growing anger at her husband for controlling and isolating her. The timeline highlighted the pattern of her husband's escalating abuse and how this endangered her and her pregnancy. This awareness enabled her to accept her physician's help. They developed a safety plan to move her and her child into a shelter for battered pregnant women.

Ecological Map

An ecological map (eco-map) is a pictorial representation of the patient's entire support network. Included in this eco-map are a genogram and the immediate support network. This map should include the patient's current family, the family of origin for three generations, and all the people and community resources in the patient's immediate living environment (e.g., family, neighbors, law enforcement, physician, church, social services agencies). An eco-map can be used by a family physician to help decide who can help the patient, who needs to be excluded, or what social, religious, legal, or economic resources need to be mobilized to assist the patient in crisis.

Using Case Study 3, Denise's eco-map is illustrated in Figure 45-3. Her physician, church, social worker from her son's school, a local shelter, and neighbors might be called on to assist her during this crisis. Her parents and the local police could also be important for her immediate safety. The decisions about which support elements to use should be negotiated with the patient. Denise and her physician decided that the safety plan would utilize church members to get her child to her at the local women's shelter. While there, she began talks with her parents about moving in with them.

Selecting the Problem or Symptom

Because most crises present with a number of problems and symptoms simultaneously, it is important to select the starting point of the treatment. Immediate survival and safety issues are almost always first priority. Preventing IPV, homicide, suicide risk, or acute medical emergency, or providing for food or shelter, must supersede all other concerns as was the case for Denise. Less severe problems or symptoms can be handled according to the patient's preferences.

Wheel-and-Spoke Formulation of the Crisis

The wheel-and-spoke format is a useful tool to help develop a formulation that specifies the causes of the crisis and can assist in the development of an effective, prioritized treatment plan. The acute crisis should be pictured as the center of a wheel. The spokes of the wheel are the problems or symptoms that are likely causing or contributing to the crisis. The physician can establish a numbered priority list for problem solving. For each problem listed, the family physician recommends a specific evaluation, test, or treatment approach designed to ameliorate the crisis. An application of the wheel-and-spoke diagram for Denise's case is illustrated in Figure 45-4.

Problem-Focused or Symptom-Oriented Treatment

Once the physician has formulated the case using the timeline and eco-map and developed a wheel-and-spoke treatment plan, the problem-focused or symptom-oriented crisis treatment can begin. A family practitioner may use educational, psychotherapeutic, or supportive approaches with or without medications. The cornerstone approaches to crisis treatment are fostering coping skills and adaptive problem

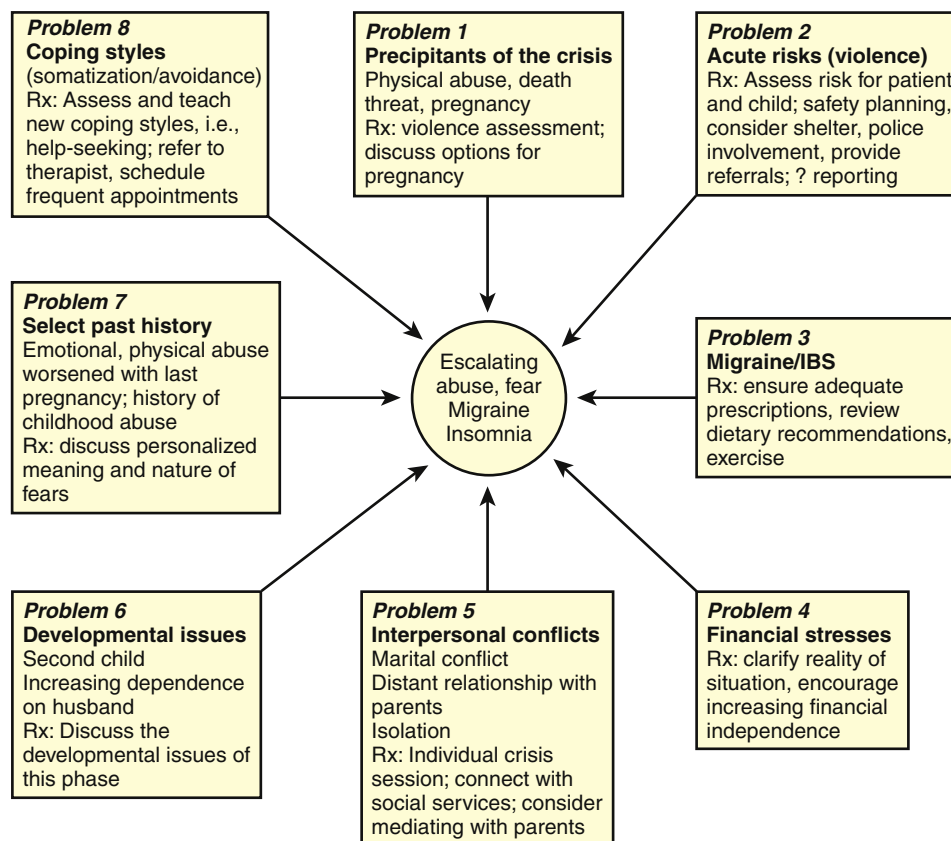

Figure 45-4 Wheel-and-spoke crisis formulation and treatment plan: Case Study 3.

solving, using a crisis resolution strategy. Medications may be necessary for symptom relief or as part of the treatment approach to a major psychiatric illness. In IPV cases, safety planning is of paramount importance (see Box 45-3).

Coping Skills and Adaptive Problem Solving

Fortunately, most people will find new ways to handle or cope with a crisis. Coping styles are the unique ways that patients deal with stress. For example, some cope with a stressful crisis by analyzing it, asking others for help, or gathering additional information. Some coping styles work better in certain situations than others. Box 45-2 lists some typical adaptive coping styles that can be suggested to patients, as well as pathologic coping styles that should be avoided whenever possible. Crisis resolution can be promoted by evaluating a patient's coping style and, when necessary, suggesting an alternative or more adaptive coping style. These new skills facilitate a patient's adaptation to the stressful life circumstances. In general, those who can flexibly use many coping styles are the most successful at crisis resolution and problem solving. Often, patients in crisis rely too heavily on one coping style, which may not be the most adaptive for a particular situation. Those patients who lack the capacity to develop new, more adaptive coping styles may become dysfunctional when confronted with a crisis.

To illustrate coping styles and new coping skills, review Case Study 3. Denise copes with threats of violence, isolation, and being controlled by her husband by keeping quiet and submitting to her husband's demands. This is patterned

after the relationship with her father. After her physician discussed her somatic and avoidant coping style, he suggested that she could use his help and talk openly and directly about her safety concerns and needs. Denise's use of a new help-seeking and informational style enabled her to develop a safety plan, prepare to leave her home, and utilize church members to help get her child to a local shelter for battered women. She also was able to tell her parents about her fears and ask for their support and help.

Crisis Resolution Strategy

In addition to teaching coping styles and coping skills, a family physician can also provide a patient with general strategies for crisis resolution and provide specific strategies that are necessary in the special case of IPV. A crisis resolution strategy, based on the crisis principles, is composed of 18 steps (Box 45-3). The family physician may need to walk through some or all of these steps with the patient first before encouraging the patient to attempt some steps as a self-help strategy for the future.

Intimate Partner Violence Approach

Key Points

- Universal screening for IPV is controversial but recommended by several professional organizations.
- Screening and referral of IPV patients are often the primary interventions in family medicine settings.

Box 45-2 Coping Styles**Adaptive coping styles**

Intuitive: Using imagination, feelings, and perceptions to solve a problem

Logical, rational: Carefully reasoned, logical, deductive style

Trial and error: Trying a random solution; if it fails, modifying it and trying again

Help seeking: Gathering information, then proceeding

Wait and see: Allowing time or circumstance to determine the outcome

Action oriented: Taking action to rectify the problem immediately

Contemplative: Quietly thinking over the problem before acting

Spiritual: Asking for God's direction

Emotional: Using emotions such as tears, anger, or fear to help solve problem

Controlling: Controlling people or oneself to gain power to solve problem

Manipulative: Using various manipulative styles to resolve crisis

Pathologic coping styles

Deceptive, antisocial: Use of dishonesty, lying, cheating, or stealing to resolve crisis

Suicidal: Using threat of suicide or suicide attempts to coerce someone or to solve problem

Violent: Using threat or actual violence to establish control and solve problem

Avoidance, denial: Failure to confront or acknowledge problems

Somatization: Displaying physical symptoms as a method of expressing emotions

Impulsive: Unpredictable or impulsive responses without anticipation of possible outcomes

Random, chaotic: Nonproductive and extreme form of trial and error and impulsive style; often seen in prolonged psychotic states

- Evidence shows the efficacy of legal interventions and batterer's treatment.
- Safety and safety planning are critical, regardless of stage of abuse.

General Recommendations

Intimate partner violence can be a sensitive issue, and it may be difficult for physicians to inquire about IPV and for patients to disclose it. Physicians should use direct and nonjudgmental language, conduct the interview in private, maintain confidentiality, and when needed, use professional interpreters who do not know the patient (FVPE, 2004). However, confidentiality may not be absolute, because threats of violence and suicide risk must be disclosed to reporting authorities or others. Effective interventions are often based on empowerment of the abused person, allowing her to define her own goals, explore her own solutions, and arrive at her own understanding of the situation (Ramsay et al., 2009). An analysis of provider-patient communications in emergency departments demonstrated that disclosure of IPV is facilitated by open-ended questions, responding to psychosocial cues, and asking at least one follow-up question (Rhodes et al., 2007). However, disclosure of IPV is not the only goal of inquiry. Well-conducted interviews may help a victim, even if she does not disclose the abuse (Rhodes and Levinson, 2003).

Screening

Universal screening for IPV in primary care settings is controversial. Multiple major medical organizations recommend universal screening, including the American Association of Family Physicians (AAFP), despite the US Preventive Services Task Force (USPSTF) finding that there is "insufficient evidence to recommend for or against routine screening of women for IPV." Proponents believe that screening is widely acceptable to patients, and that the availability of reliable screeners, the opportunity for intervention in identified victims, and the high prevalence and costs of IPV are good reasons for universal screening (MacMillan et al., 2009). Evidence overall is equivocal for the efficacy of advocacy interventions (Cochrane review; Ramsay, 2009).

Although evidence does not support universal screening, many physicians may still want to screen their patients. When using routine screening, begin with framing questions: "As violence is a major factor in people's lives, I have begun to inquire about this with every patient"; or, "I am concerned that some of your symptoms may be a result of someone hurting you." This should be followed with direct questions that focus on behavior: "Has someone physically harmed you: hit, slapped, kicked, or thrown something at you? Threatened you? Forced you to have sex when you did not want to? Do you feel controlled or isolated by your partner?" Several empirically validated screening tools focus on physical abuse by an intimate partner. The SAFE questions screen for nonphysical aspects of abuse provides a logical framework for interventions: The physician can inquire about stress and safety in patient's relationships (S), if the patient feels afraid or abused (A), awareness and support of friends and family (F), and emergency plans (E) (Neufeld, 1996).

Treatment of Intimate Batterers

An abusing partner may also present to the family physician's office and directly or indirectly disclose the violence. These perpetrators may portray themselves as the victim, may ask the physician for referrals to couples counseling or anger management, or present their situation as one of mutual conflict (Rhodes and Levinson, 2003). When domestic abuse is disclosed by the perpetrator, the physician should conduct a violence risk assessment. The physician may have a duty to warn or protect the threatened person, depending on state laws. As is clinically helpful, the physician may alternatively want to educate the patient regarding the effects of violence on the family or ask the patient to be responsible for his actions and seek treatment. Unfortunately, batterer's treatment only produces a marginal overall effect on recidivism rates (Babcock et al., 2004).

Optimal legal interventions for IPV are similarly unclear. Based on early studies, arrest has been shown to have variable outcomes on recidivism rates, despite widespread popularity. Orders of protection are another option for legal intervention, but also leading to mixed results. In one study, permanent protective orders lasting 12 months led to a significant decrease in reports of physical violence, whereas temporary orders actually led to an increase in psychological abuse (Wathen and MacMillan, 2003). Because of the lack of clearly efficacious interventions for intimate batterers, a prudent clinician will need to use his best judgment based on a thorough safety assessment and in accordance with local and state laws.

Box 45-3 Crisis Resolution Strategy

Assess safety. If a patient is in acute danger due to violence, suicide risk, or acute medical problems, more help may be required. Contact medical providers, law enforcement, or other resources as indicated.

In cases of intimate partner violence (IPV), use specific strategies for assessment, safety planning, and documentation (see Box 45-4).

1. Teach the patient to recognize the early warning signs of a crisis, which typically includes anxiety or depressive symptoms, occasional panic symptoms, feelings of being overwhelmed, sense of urgency, vigilance, confusion, disorganization, intrusive thoughts, flashbacks, nightmares, self-defeating actions, and suicidal or homicidal feelings.
2. Set the patient's expectations for recovery.
3. Inform the patient that after an acute event, most acute life crises take approximately 6 weeks to subside, stabilize, or resolve.
4. Normalize the patient's symptoms. Patients need to know that, after an acute crisis or trauma, somatic and psychiatric symptoms, and atypical daily routines (e.g., not going to work), are common and are part of normal, healthy coping.
5. It is important for patients to know that if problems and symptoms do not resolve after 6 weeks, they should obtain further evaluation and treatment, as necessary.
6. If desired, the patient can talk over the crisis with the family physician or a trusted friend. It is often best if these friends or family members are not directly involved in the crisis. For prevention or early intervention for the next crisis, the physician can assist the patient in developing a list of contacts of available friends, other physicians or specialists, and available community resources.
7. If a patient is overwhelmed with emotion, is coping poorly, or has a dysfunctional daily routine (beyond typical posttraumatic reaction), the patient may benefit by sharing painful feelings or discussing recurrent or intrusive thoughts, which may provide some immediate relief.
8. Identify the specific symptoms, problems, and area of the patient's functioning that is most affected by the crisis (e.g., work, home, interpersonal, economic).
9. Identify the specific precipitants, other stressors, and symptoms (e.g., insomnia) that are currently contributing to the crisis. This can be done by helping the patient develop a timeline (see Fig. 45-2).
10. Evaluate the support system by use of an ecological map (see Fig. 45-3). Using this support network tool, patients can be assisted in discovering who can help and who might exacerbate the situation.
11. Select the problem(s) or symptom(s) to treat first. This can be the most difficult part, because it requires an understanding or formulation of the causes of the crisis to prioritize what problem or symptom to treat first.
12. Use a wheel-and-spoke format to develop the treatment plan for a core crisis and prioritize the order of problems or symptoms that need to be treated (see Fig. 45-4).
13. Teach the patient to understand his or her current coping style and why and how it may not be working. Introduce other, more adaptive coping styles (see Box 45-2).
14. Obtain additional information from others who may be able to assist with crisis resolution. This should only be done once the crisis has been formulated and the focus of the treatment chosen.
15. Make a specific plan for crisis resolution based on additional information, newly discovered feelings, a crisis formulation, and treatment focus. This plan should involve the use of novel coping styles, a specific sequence of actions, and psychopharmacology, as clinically appropriate (see Box 45-4).
16. The patient should implement the plan. Initially, it may be less overwhelming to resolve one cause of the crisis at a time, instead of trying to handle many problems simultaneously.
17. Assess the results. Has the problem been resolved? If yes, go to step 1 and tackle a new symptom or problem. If not, go to step 18.
18. If the initial plan has not helped, try again, obtain additional help, or consult with a psychiatrist or other professional.

Couples

If the victim and the violent partner are both patients of the same family physician, this will present unique challenges. An American Medical Association consensus statement advises that this dual relationship is not a conflict of interest, but that each patient should be handled independently (Ferris et al., 1997). Confidentiality must be maintained unless the victim has given consent. Couples counseling is generally contraindicated, especially when violence is ongoing. Family physicians may have neither the time nor the training to address this complex situation; couples who are safe and desire counseling should generally be referred to appropriate mental health professionals.

Safety Planning

Safety planning is a key intervention for victims of IPV. Planning between the physician and patient helps to send the message that IPV is serious. The patient needs to hear that IPV will typically continue without an intervention, and that IPV can be life threatening and may require immediate action. This message can help reduce the patient's sense of isolation and despair, and is especially helpful for patients who are not yet ready to make or implement a safety plan on their own. Safety planning is important regardless of

whether a victim is in the midst of a violent incident, planning to leave, or living apart from her abuser. Safety planning should include gathering all essential documents, setting aside required finances, developing packing lists, developing child care plans, having a list of emergency numbers, and having shelter contact information (Box 45-4).

Documentation and Reporting

Documentation of cases of known or suspected IPV should include the patient's report, the physician's assessment and examination, interventions, and follow-up plans. Photographic evidence, body maps, and a clear discussion of the relationships between abuse and medical problems may also be prudent (FVPE, 2004). These practices may serve as both medicolegal necessity and advocacy measure for patients who may take legal action against the perpetrator.

A physician should have a basic understanding of local reporting laws. Mandatory reporting of intimate partner violence varies from state to state and may depend on type of injury, if a weapon was used and which type, if rape occurred, or other criminal conduct occurred. Cases that involve child abuse must also be reported. When children have not been directly abused, state laws vary as to what is a reportable IPV offense. Physicians have discretion in these cases and may be required to do a careful assessment of imminent risk and

Box 45-4 Intimate Partner Violence (IPV) Safety Planning**During a violent incident**

Know where to go.
 Know how to get there.
 Have keys and a packed bag ready.
 Move to a room with an exit.
 Avoid bathroom, kitchen, and other areas with access to dangerous items that could be used as weapons.
 Train children to call police/911.
 Use judgment and stay safe.
 Alert police and/or trusted friend or family once safe.

Planning to leave

Pack and keep hidden or with a friend:

1. Copies of important documents: legal documents, birth certificates, school and medical records, insurance information, financial records (deeds, mortgages)
2. Money and bank account numbers
3. Keys to house, car, safety deposit box
4. Personal items for self and children (e.g., medications, clothing)
5. List of important contact information. Cell phone use is risky because it may reveal details about your location and people with you.

Living apart from abuser

Neighbors, friends, and someone at work should know about the situation, including how and when to call the police.
 Inform school and child care providers if a partner is not allowed to pick up the children.
 Consider additional safeguards at the residence, including extra locks or alarm systems.
 Consider seeking a protection (restraining) order.

benefits of reporting. In IPV cases that do not require mandatory reporting and do not involve children, the physician should be prepared to help victims make decisions about their use of the legal system.

KEY TREATMENT

Patients in IPV situations should be treated individually, not as a couple, and children should be referred to child focus treatments as needed (SOR: C).
 Safety planning is recommended if IPV is detected (AMA; Ferris et al., 1997) (SOR: B).
 Referrals and resource information should be provided for every patient (AMA; Ferris et al., 1997) (SOR: B).

Other Trauma Treatments

Patients in an acute crisis or with disaster-related trauma may or may not require treatment. Crisis treatment is often necessary if the patient is suicidal or at risk for violence, has an acute medical emergency, or has a major psychiatric disorder (psychosis, PTSD, bipolar disorder, depression, overwhelming anxiety). All treatment is best when it is offered voluntarily or upon patient request.

Psychological treatment of trauma should be offered immediately, with the patient allowed to pursue treatment

voluntarily. Treatment should be vigorously pursued and possibly mandated if a major, life-threatening psychiatric illness appears acutely (APA, 2004; NICE, 2005).

No acute psychiatric treatment is often the best course of action if symptoms and non-life-threatening problems are resolving and if social and occupational functioning have remained intact over the first 6 weeks. Evidence indicates that mandatory crisis intervention in non-life-threatening circumstances, often called *critical incident stress management* (CISM), or “debriefing” (Mitchell et al., 1983), is not helpful (Rose et al., 2004). Patients who have experienced a mass trauma or disaster may benefit from “psychological first aid” (Bisson et al., 2007). This approach fosters safety, calmness, self and community efficacy, social connectedness, and optimism. The best personnel to deliver this treatment remains controversial (clinician responder or emergency responder with community leader?) (Watson, 2007).

Exposure-based cognitive-behavioral therapy (CBT) is recommended for patients with PTSD (Bradley et al., 2005). CBT includes reexposure to past trauma through imagined, in vivo, directed therapeutic, written, verbal, or taped narrative. In addition, psychoeducation, breathing and relaxation training, and homework are often included (APA, 2004; Benedek et al., 2009; NICE, 2005).

KEY TREATMENT

Crisis intervention and psychotherapeutic techniques are a first-line approach for a crisis or mass trauma (Bradley et al., 2005; NICE, 2005) (SOR: A).
 Exposure-based CBT is recommended for patients with PTSD (Bradley et al., 2005) (SOR: A).
 Psychoeducation, breathing and relaxation training, and homework can be helpful for PTSD (APA, 2004; Benedek et al., 2009; NICE, 2005) (SOR: B).
 Psychological intervention is helpful after mass trauma or disaster if offered on a voluntary basis (Bisson, 2007) (SOR: B).
 Mandatory critical incident stress management (CISM, debriefing) is not helpful (Rose et al., 2004) (SOR: C).

Medications for Symptoms of Psychiatric Disorders

Although psychotherapeutic techniques are a first-line approach for a crisis or mass trauma (Bradley et al., 2005; NICE, 2005), use of medications for treatment of specific symptoms or psychiatric disorders can also be helpful. In general, pharmacology targeting symptom reduction parallels the pharmacology of the treatment for the major psychiatric disorders. For example, if a patient has an isolated sleep disturbance, use of the newer hypnotics is warranted. Similarly, for depressive or psychotic symptoms, antidepressants or antipsychotics can be used. This symptom-oriented approach has not been well studied.

During the acute crisis or immediate posttraumatic state, insomnia or other sleep disturbances may greatly affect coping. Use of a nonbenzodiazepine such as zolpidem, zaleplon, or eszopiclone can be considered as first-line pharmacologic treatment for acute sleep disturbances. The use of benzodiazepines for sleep or anxiety in the acute postcrisis state is questionable, with little support for efficacy and

concerns that benzodiazepines may inhibit effective coping. Benzodiazepines also carry the risk of dependence and addiction. Although data are sparse regarding the effectiveness, trazodone is also often used clinically for chronic sleep difficulties because it carries no risk of dependence.

Thus far, no known interventions have prevented PTSD. For the primary treatment of PTSD, medications include selective serotonin reuptake inhibitors (SSRIs), prazosin, propranolol, and antiepileptics. PTSD symptoms, including reexperiencing the trauma, avoidance, numbing, and hyperarousal, are effectively treated with SSRIs, including sertraline, paroxetine, venlafaxine, and fluoxetine (APA, 2004; Benedek et al., 2009; Stein et al., 2006).

A distinction between non-combat-related and combat-related PTSD is warranted when considering pharmacologic therapy (Benedek et al., 2009). Non-combat-related PTSD includes civilian trauma, childhood or adult sexual assault, IPV, interpersonal trauma, or trauma caused by a motor vehicle crash. For non-combat-related PTSD, sertraline, paroxetine, fluoxetine, and venlafaxine are effective in short-term trials. These SSRIs either can be a primary form of treatment, if the patient does not want exposure-based CBT, or can be combined with CBT; no evidence yet shows that combined treatment is superior to SSRI or CBT alone. The efficacy of the antidepressant mirtazapine and the anticonvulsants topiramate and tiagabine is equivocal but reportedly somewhat beneficial (Benedek et al., 2009). No efficacy for beta blockers or bupropion has been established.

The results for pharmacologic treatment of combat-related trauma are less convincing. It seems that younger veterans with PTSD from more recent wars are responsive to the same SSRIs and SNRIs as non-combat-related patients. However, older veterans from previous wars do not appear to respond to sertraline or fluoxetine. Thus the common SSRIs may be only somewhat effective for this group (Benedek et al., 2009). For PTSD nightmares in both groups, prazosin (3-15 mg/night) has been used with some success.

Although SSRIs are the first-line choice for the pharmacotherapy of PTSD, not all patients will have a full treatment response. Adjunctive treatment with risperidone and olanzapine may be helpful. Augmentation with a mood stabilizer such as divalproex or lithium may be considered, but evidence for success is limited. Buspirone or benzodiazepines

may also be used, but only sparingly and adjunctively, to decrease anxiety or panic attacks. These medications are not recommended as monotherapy.

KEY TREATMENT

Acutely, nonbenzodiazepine sleeping medications may be used as first-line treatment for insomnia (Bradley et al., 2005; NICE, 2005) (SOR: B).

PTSD is often effectively treated with SSRIs, including sertraline, paroxetine, venlafaxine, and fluoxetine, though this effect may be less in older veterans (APA, 2004; Benedek et al., 2009; Stein et al., 2006) (SOR: A).

The antidepressant mirtazapine and the anticonvulsants topiramate and tiagabine may be beneficial in PTSD therapy (Benedek et al., 2009) (SOR: B).

For PTSD nightmares, prazosin may be effective (SOR: B).

Risperidone and olanzapine may be effective augmentation to SSRIs for persistent PTSD symptoms (Benedek et al., 2009) (SOR: B).

Conclusion

Family physicians are routinely faced with a variety of acute crises, patient-reported traumas, intimate partner violence, and disaster situations that require a specialized knowledge to understand patient complaints and to successfully develop management and intervention strategies. The goal of crisis intervention and disaster management is to evaluate the precipitants of the crisis, understand the personal meaning of the events, deal with the crisis state itself, and use the selective past history to comprehend the current situation better. It is also important to mobilize the support network and, if relevant, diagnose and treat any comorbid psychiatric illnesses. A crisis evaluation strategy using a timeline, eco-map, and wheel-and-spoke formulation can be used to help implement a specific problem-solving approach. Crisis treatment includes problem or symptom-oriented therapy, use of adaptive coping styles, 18-step crisis intervention approach, and medications when indicated. Cases involving intimate partner violence require particular attention to violence risk, safety planning, and documentation. All these interventions can be helpful when seeking a resolution of the crisis.

The chapters in Part Two of this book generally are devoted to topics in family medicine practice that can be understood and managed as discrete clinical problems. Although several problems might coexist in a patient, this is the usual way the family physician approaches health problems. In this chapter, however, we follow our conviction that the clinical encounter is the ground on which *all* problems in family medicine are addressed. An effective clinical encounter, at its best, develops as an extended, trusting partnership between patient and physician. However, disturbances or difficulties in the encounter can ruin even the best therapeutic plan. In this chapter we use the term *difficult patients* to refer to two patient groups: those with personality traits (styles) or personality disorders and those with unexplained physical symptoms or somatoform disorders.

Our treatment of "personality styles" follows a spectrum or dimensional approach. In the mildest form, *personality traits*

are present in normal, healthy patients, and under certain circumstances are assets. Although sometimes unpleasant, these are not necessarily pathologic. At the other end of the spectrum are features of personality that are so extreme as to constitute full-blown disorders: Axis II of the DSM-IV-TR contains a set of *personality disorders* that are real, difficult, and disabling and that often present in primary care settings.

Our treatment of patients with "unexplained physical symptoms," as with personality styles, also follows this spectrum or dimensional approach. In its mildest form, unexplained physical complaints will present in generally normal, healthy patients. These benign physical complaints are often accompanied by psychological issues just as often as psychological symptoms are accompanied by physical complaints. Features of psychological problems just as psychological symptoms always accompany physical problems (Kroenke et al., 1994). Moreover, symptoms of both a physical and a psychological nature frequently appear in patients—indeed,

in all people—without obvious explanation. Mild physical symptoms such as “butterflies” in the epigastrium just before a public speech may disappear as mysteriously as they appear and are of no consequence. At the other end of the spectrum are increasingly severe, persistent, or disabling, unexplained physical symptoms that eventually cross a threshold and become a disorder in their own right. The *somatoform disorders* are this family of full-blown diagnostic conditions, characterized by disabling physical symptoms with no physical explanation.

This chapter discusses difficult patients at all points on the personality and somatic continuum, from normal to disordered, to patients with comorbid conditions. Success in managing these difficult patients depends more often on the physician’s reaction to the patient’s personality traits or somatic complaints (and resulting interventions) than on assignment of a specific diagnosis. These problems do not exist in the patient, but rather in the transactions between patient and physician. Here the physician’s task is not simply to discover and describe patient problems, but also to create a relationship with the patient that is therapeutic rather than problematic. Our approach here is to address difficult clinical encounters in terms of patients’ personality style and somatic presentation and the responses elicited in physicians. Interventions based on the physician’s responses and an understanding of the patient’s issues offer a convenient and parsimonious framework for constructive management strategies.

Personality Style vs. Personality Disorder

A personality style is the lifelong habitual way that a person thinks, feels, and behaves. Styles are determined by genetics and are often called *temperament*. Temperamental aspects, such as the ability to filter external stimuli or shyness, are often observable at birth. Other personality traits are determined by upbringing from early parent-child interactions, such as *mentalization*, which is the ability to empathize with another’s emotions or perspective and utilize this to read the intentions of others. Each personality has unique, enduring, and slowly evolving characteristics, including the organization of perception, a set of core beliefs, thinking style, fantasy life, hierarchy of emotional needs, value system, ideals, characteristic ways of relating to self and others, and adaptation to external reality.

The distinction between personality style and a personality disorder is a matter of degree. Personality styles tend to be relatively stable over a lifetime but can be modified by psychotherapy or needs to adapt to the environment. Personality disorders are also stable, but are more difficult to modify, if at all, and then by long-term or special forms of psychotherapy or by life events. Personality styles that become rigid, extreme, maladaptive, or damaging to self or others, or that lead to social or occupational impairment, are called “personality disorders.” Although everyone is unique, there seems to be a set of personality styles and disorders that are commonly encountered. Some personality disorders can be recognized in the movies (schizotypal personality disorder, Robert DeNiro in *Taxi Driver*; narcissistic personality disorder, Tom Cruise in *Top Gun*; dependent-borderline personality disorder, Bill Murray in *What About Bob?*).

Classification

Personality Disorders

Inflexible and maladaptive personality disorders cause distress or social or occupational impairment. A patient with a personality disorder typically has problems in at least two of these areas: cognition, affectivity, interpersonal functioning, and impulse control. Pervasive manifestations occur across a range of situations. A *personality disorder* is stable and of long duration, typically begins in adolescence or early adulthood, and is diagnosed in adulthood.

The two primary classification approaches to personality disorders are categorical and dimensional. The *categorical* approach, currently represented in DSM-IV-TR, describes people as having clusters of associated traits, symptoms, or behaviors that form discrete “prototypes,” or categories of personality. The *dimensional* approach, likely the wave of the future, assesses multiple traits or dimensions of a personality that are present, absent, or have varying degrees of intensity; measurable dimensions of personality might include novelty seeking, harm avoidance, reward dependence, cooperativeness, and self-directedness. Categorical approaches have the advantage of colorfully describing and differentiating distinct groups of different personality types. This classification convention remains popular with family physicians because it follows the concept of disease categories within general medicine. The *Diagnostic and Statistical Manual of Mental Disorders*, fourth edition, text revision (DSM-IV-TR), uses a categorical personality disorder classification as part of a multiaxial system that encourages physicians to consider personality variables in every patient (American Psychiatric Association [APA], 2000).

The preliminary diagnosis of a personality disorder begins by identifying the appropriate cluster or dimension, because it is easiest to recognize the broad traits of a cluster diagnosis first. The three clusters of personality disorders are *cluster A*, odd and eccentric; *cluster B*, dramatic, emotional, or erratic; and *cluster C*, anxious or fearful. These clusters or dimensions are subdivided into specific personality subtypes with general characteristics (Box 46-1). Because personalities are complicated, it is not unusual for a patient to meet the criteria for two cluster diagnoses and more than one specific personality disorder diagnosis.

Unexplained Physical Symptoms vs. Somatoform Disorders

Physical symptoms appear and disappear on a regular basis in normal people. Less than 3% of these symptoms result in a visit to a physician (Banks et al., 1975), but more than half the visits to primary care physicians are for symptoms. Even symptoms severe enough to trigger a visit are usually self-limited; about three-quarters improve or disappear in 2 weeks, and over half of those remaining have improved or disappeared at 3 months (Kroenke and Jackson, 1998). Most patients do not remember having a symptom that they reported 1 year earlier (Simon and Guerje, 1999). From this cohort of symptomatic patients, a substantial number have symptoms sufficiently persistent, severe, or numerous to justify a diagnostic workup, which usually reveals a medical problem that the family physician manages in the usual

Box 46-1 Personality Disorder Clusters***Cluster A (Odd, Eccentric)**1. **Paranoid**

Expects exploitation, harm; questions loyalty, fidelity; bears grudges; easily slighted

2. **Schizoid**

Loner; aloof; indifferent to praise or criticism; social anxiety; constricted affect

3. **Schizotypal**

Odd, eccentric; social anxiety; magical thinking; suspicious, paranoid ideation

Cluster B (Dramatic, Emotional)1. **Antisocial**

Cruelty; problems with authority, unlawful behaviors, exploits others, dishonesty, irresponsibility

2. **Histrionic**

Overly emotional; seductive, sexual attention seeking; shallow, superficial

3. **Borderline**

Unstable intense relationships; self-destructive, suicidal; impulsive; affect instability; identity disturbances

4. **Narcissistic**

Grandiose; inflated self-importance; entitled; exploits others; lacks empathy; needs admiration; hypersensitive to criticism

Self-Defeating[†]

Suffers; self-sacrificing; defeats others; self-destructive; cannot enjoy; easily hurt

Cluster C (Anxious, Fearful)1. **Dependent**

Indecisive; lacks initiative; submissive; helpless; dependent; fears abandonment

2. **Obsessive-compulsive**

Perfectionism; inflexibility; preoccupation with details; wishes to control others; stingy; overconscientiousness; excessive morality or ethics

3. **Avoidant**

Easily hurt; timid, fearful; social discomfort; avoids interpersonal interactions

way, as described throughout this text. In about one third of patients, however, the symptoms are causing impairment and no physical explanation can be found; alternatively the symptom is out of proportion to the supposed explanatory finding; these patients are *somatic*. At the more severe end of the continuum, somatic symptoms cluster into discrete diagnostic categories: the somatoform disorders, including somatization disorder, conversion disorder, somatoform pain disorder, hypochondriasis, factitious disorder, malingering, and body dysmorphic disorder. Primary care physicians tend not to pursue diagnoses to the level of these categories, because it is a time-consuming process not yet shown to improve patient outcomes. However, these categories have promising implications for managing the difficult

clinical relationship, particularly in the context of personality types and disorders.

About 15% of primary care encounters are experienced by physicians as “difficult,” as determined by the self-administered DDPHQ (Hahn et al., 1996). Patients classified as difficult are not distinguished by the usual demographic categories (age, gender, race, social status) but rather by the presence of somatoform complaints; other DSM Axis I conditions, particularly depression and anxiety disorders; and unique personality styles, up to and including DSM Axis II personality disorders. There is extensive overlap among these symptom clusters, particularly at the less severe end of the spectrum.

Unexplained physical symptoms are often benign and transitory, and only 3% of patients with these symptoms see a physician. Somatic complaints are described by patients within all domains of the traditional review of symptoms. Somatoform disorders are a group of severe psychiatric conditions that present with physical symptoms that suggest a medical condition but that cannot be adequately explained by a medical condition. Patients can have both a medical condition and unexplained physical symptoms that meet criteria for a somatoform condition. Box 46-2 describes somatoform disorders (DSM-IV-TR classification). Social or occupational impairment in these patients exceeds what would be expected based on physical complaints.

Comorbidity of Personality and Somatoform Disorders

Personality and somatoform disorders have significant comorbidity, and clinical management of these disorders frequently overlaps. According to the DSM IV-TR, 1% to 5% of primary care patients meet the criteria for somatization disorder (APA, 2000). Prevalence rates for personality disorders are reported to be 4% to 13% in the general population and up to 24% of patients in primary care settings (Gross et al., 2002; Moran et al., 2000).

A meta-analysis of 18 studies demonstrated that significant comorbidity exists between somatization disorder and five personality disorders (Bornstein and Gold, 2008). The most robust comorbidity is between somatization disorders and antisocial, borderline, and histrionic personality disorders, with less robust but significant comorbidity with avoidant and dependent personality disorders. Exploring the connections between these two groups of disorders offers some insight into the intrapsychic and interpersonal dynamics of both groups. One clinically relevant factor common to both groups is that the early family relationships of these difficult patients were both rejecting and tenuous. This may have led both groups to an anxious or insecure attachment style. This translates into the persistent care-seeking style so recognizable by physicians, in both somatic patients and in patients with a personality disorder. Both groups may display clinging, dependent, manipulative, and ambivalent attachment styles, often seen in those with borderline, histrionic, antisocial, and dependent personality disorders.

Significant comorbidity also exists between other somatoform disorders and other personality disorders. For example, patients with hypochondriasis and body dysmorphic disorders are obsessed with fear of illness and fear of a body defect, respectively. Patients with both of these also display

Management of the physician-patient relationship requires special skills when dealing with a difficult patient. The following five-step process is useful for family physicians:

1. Understand the patient's core beliefs, fears, and irrational thoughts.
2. Identify the patient's defense mechanisms and coping style, and use confrontation, clarification, and interpretation to modify these.
3. Recognize recurrent patient behaviors and how these will likely affect patient adherence and use of medical services.
4. Learn to use the physician's own reactions to the patient to help identify the diagnosis and management strategy.
5. Recognize that specific interventions are helpful for different types of patients.

To create therapeutic relationships with patients who might otherwise be experienced as difficult, the clinician must first understand patient's core beliefs, thoughts, and fears; then understand their defenses and coping styles; and finally, understand the health-related behaviors that follow from these beliefs and styles. This understanding helps physicians utilize the reactions such behaviors evoke in them, thereby leading to alternative responses and potential interventions. Tables 46-1 and 46-2 outline this process using DSM-IV-TR classification.

Patient Core Beliefs, Irrational Thoughts, and Fears

Understanding core beliefs has therapeutic implications. The family physician can use simple principles of *cognitive-behavioral therapy* (CBT) to facilitate the management of these patients. The theory of CBT is that patients have core beliefs, a worldview, and personality/somatic-specific fears that can be identified and modified by bringing them to conscious awareness (Beck and Freeman, 1990; Greenberger and Padesky, 1995). Core beliefs and fears are deeply held, intense, and idiosyncratic in quality. When stress occurs against the background of a core belief, a reinforcing feedback sequence ensues. The core belief is acted on by the stressor, which leads to irrational fears, negative moods or emotions that lead to maladaptive physical symptoms or behaviors, which in turn confirm or amplify the core belief or fear. Core beliefs and fears are readily activated during a visit to the physician, when a patient has symptoms, feels sick, or is vulnerable. For example, a patient with hypochondriasis may fear she has a serious illness. She may have a core belief and fear that she is dying. She may believe that the physician knows she is severely ill but will not tell her. The physician, however, by understanding the patient's core beliefs and associated fears, can prevent unnecessary worry. The physician can empathize with the patient; discuss the patient's core beliefs and fears of an illness; help the patient recognize the distorted, irrational, or illogical thoughts; and ultimately, interpret the patient's defenses and suggest alternative ways for coping. The CBT sequence of stress, acting on core beliefs and irrational fears, and subsequent development of symptoms or maladaptive behaviors is described for difficult patients in Table 46-1. Adherence to medical recommendations and use

Hypochondriasis

Fears or ideas that one has a serious disease, which persist despite a negative medical workup and causes social or occupational dysfunction that lasts at least 6 months. Hypochondriasis is clinically similar to *obsessive-compulsive disorder*. Hypochondriac rumination are common in patients with *obsessive-compulsive personality disorder*.

Somatization Disorder

Consists of four pain symptoms, two gastrointestinal symptoms, one sexual symptom, and one pseudoneurologic symptom; symptoms are not fully explained by known medical conditions. Somatization disorder develops over years and causes significant social and occupational dysfunction. Patients with somatization disorder or a subthreshold disorder show a significant comorbidity with

antisocial, borderline, histrionic, dependent, and avoidant personality disorders.

Conversion Disorder

One or more symptoms or deficits affecting voluntary motor or sensory function; symptoms may include paralysis, somnambulism, pseudoseizure, psychogenic blindness, and mutism. Symptoms can

also mimic other neurologic or medical disorders. No clear physical cause is found. Psychological conflict is important in symptom development and is unconscious. Social and occupational dysfunction is typical. Patients with *histrionic personality disorder* often present with conversion symptoms.

Pain Disorder

Symptom is pain, and no medical cause is obvious. Psychological factors are important and unconscious. The pain causes social or occupational dysfunction and may be acute (<6 months) or chronic (>6 months).

Body Dysmorphic Disorder

Preoccupation and excessive concern with an imagined body defect, presenting with social or occupational dysfunction.

Factitious Disorder

Intentional production or feigning of physical signs or psychological symptoms, motivated by a desire to assume the sick role, with no other secondary gain in evidence. Factitious disorder is often comorbid with *antisocial personality disorder*.

Malingering

Intentional production or feigning of physical or psychological illness, motivated by secondary gain (e.g., monetary [disability], avoid the military, procure drugs). Malingering is often comorbid with *antisocial personality disorder*.

Table 46-1 Schema for Managing Difficult Patients

| DSM-IV-TR | Patient Core Beliefs | Patient Fears | Defenses | Coping Styles | Patient Health Behaviors |
|--------------------|---|---|---|---|---|
| Paranoid | Others are adversaries and are to blame; I am being examined; They are out to get me; I can't trust anyone. | Exploitation; slights; betrayal; humiliation; physical intrusions from medical procedures. | <i>Projection</i> : ascribe one's impulses to others <i>Projective identification</i> : project one's impulse plus control of others as way to control one's own impulses. <i>Denial</i> : refusal to admit painful realities <i>Splitting</i> : self and others seen as all good or all bad. | Guarded and protective of their autonomy, often with arrogant belief in their own superiority. | Wariness, suspicion, mistrust, jealousy, self-sufficiency, counterattacking, anger, and violence. |
| Schizoid | I need space; I need to be alone; people are replaceable or unimportant. | Emotional contact; warmth; intimacy; caring; intrusions or violation of privacy. | <i>Isolation of affect</i> : thoughts stored without emotion <i>Intellectualization</i> : replace feelings with facts. Denial, splitting (see above). <i>Regression</i> : revert to childlike thoughts, feelings, or behaviors. | Inner world is defended and/or insulated from others. | Withdrawal; seeking isolation and privacy. |
| Schizotypal | Idiosyncratic, magical, or eccentric beliefs (I know what they're thinking/feeling); premonitions. | Emotional contact; intimacy; warmth; caring; violation of privacy. | <i>Schizoid fantasy</i> : retreat to idiosyncratic fantasy when faced with painful experience. <i>Undoing</i> : symbolic magical action designed to reverse or cancel unacceptable thoughts, feelings, or actions. Regression, denial, splitting (see above). | Chaotic, idiosyncratic, disorganized. | Withdrawal; odd, autistic, or magical behaviors and movements; seeks isolation and privacy. |
| Antisocial | People are there to be used and exploited; I come before all others. | Boredom; loss of prestige, power, or esteem. | <i>Acting out</i> : expression in action or behavior rather than in words or emotions. Splitting (see above). | Seeks autonomy, freedom; seeks advantage or secondary gain. | Lies, deceit, and manipulation; violence; seeks secondary gain. |
| Histrionic | I need to impress, be admired/loved; I need to be taken care of, or helped; emotions rule. | Loss of love, admiration, attention, or dependent care. | <i>Sexualization</i> : functions or objects changed into sexual symbols to avoid anxieties. Regression, acting out, splitting (see above). <i>Dissociation</i> : disruption of perceptions or sensations, consciousness, memory, or personal identity. <i>Somatization</i> : physical symptoms caused by mental processes. <i>Regression</i> : involuntary forgetting of painful memories, feelings, experiences. | Self-centered, emotion driven, flirtatious, flighty. | Dramatics, exhibitionism, expressiveness, impressionistic. |
| Borderline | I am very bad or very good. Who am I? I can't be alone. | Separations, loss; emotional abandonment; not being loved and cared for; fluctuating self-esteem. | Splitting, projection, projective identification, dissociation, regression, acting out (see above). <i>Omnipotence</i> : seeing self or others as all-powerful <i>Idealization/devaluation</i> : vacillates between seeing self or others as ideal, then deprecating self or others. Minipsychotic experiences. | Hostile dependency; chaotic lifestyle; threatening, intimidating, or seeking intimacy, dependency, or pseudoautonomy. | Impulsive behaviors, suicidal actions, cutting, anger/violence, panic, anxiety, poor reality, stormy relationships. |

Continued

Table 46-1 Schema for Managing Difficult Patients—cont'd

| DSM-IV-TR | Patient Core Beliefs | Patient Fears | Defenses | Coping Styles | Patient Health Behaviors |
|---|---|--|---|---|---|
| Narcissistic | I am special; I am important; I come first. The world should revolve around me. | Loss of prestige, image, beauty, power, or esteem. | Splitting, projection, projective identification, acting out, denial, regression (see above). | Superiority and arrogance, self-aggrandizing, self-centered, self-protecting, demeaning, demanding, critical. | Self-aggrandizement; inflated/deflated self-view; entitled; devalue/idealize; viciousness; envy; competitive. |
| Avoidant | I must avoid harm or be cautious, as I may get rejected, exposed, or be humiliated. | Rejection; embarrassment in social situations; humiliation; exposure of inadequacies. | <i>Inhibition</i> : restriction of thoughts, feelings, behaviors to avoid shame; exposure of inadequacies, rejection, humiliation. <i>Phobias</i> : fears of objects, people, situations; avoided to prevent anxiety. Avoidance, withdrawal, regression, somatization (see above). | Withdraw or escape, avoiding criticism. | Avoidance, withdrawal, social timidity, caution, fear/anxiety. |
| Dependent | I am helpless without others; I can't make a decision; I need constant reassurance and care. | Fears separation, independence; making decisions; and anger. | <i>Dependent</i> : yearning for care, clinging; needing direction. <i>Passive-aggressive</i> : superficial compliance and passivity disguising stubbornness and anger. <i>Reaction formation</i> : unacceptable impulses expressed as the opposite. Regression, splitting (see above). | Passive, dependent, helpless. | Unusually submissive; clinging, indecisive, childlike; needing to be taken care of. |
| Obsessive-compulsive disorder (OCD) | People should do better; try harder; I must be perfect; make no errors or mistakes; details, not feelings, rule. | Disorder, mistakes, imperfection; fears no errors or mistakes; especially rage/anger, anxiety, self-doubt, dependency. | Isolation of affect, intellectualization, reaction formation, undoing, dependent, phobias, repression (see above). <i>Controlling</i> : efforts to regulate objects or others to avoid anxiety. <i>Displacement</i> : transfer of one's feelings from one person on to another. <i>Inhibition</i> : restricting thoughts, feelings, or behaviors for fear that unacceptable impulses will create anxiety or damage. | Inflexible, constricted, governed by details and rules; safety, or security concerns. | Perfectionism, driven orderliness; logical, obsessions and/or compulsions; controlling, critical; stubbornness; stinginess; workaholic; rational. |
| Self-defeating | I must suffer and sacrifice; I am a martyr; I should be punished. | Loss of love; fears pleasure; fears recovery. | <i>Ambivalence</i> : coexistence of opposite feelings. Displacement, denial, projective identification, reaction formation, passive-aggressive, splitting (see above). | Self-defeating, self-destructive. | Feels worse with good news; self-defeating; self-destructive. |
| Hypochondriasis (shares many features with both OCD and OCPD) | I am afraid that I have a horrible disease [based on symptom misinterpretation]. The doctor could be wrong or may have missed something. I must be absolutely certain that I am well. I must worry. I need to obsess and use compulsions. | Fears of a catastrophic illness; fears uncertainty; unconscious emotional fears. | Denial; avoiding awareness of painful experience; anger elicited when denial of emotions is suggested. <i>Externalization</i> : attributing internal state to external explanations. Hypochondriasis dominant; exaggerating or overemphasizing illness; somatization (less common); psychic or emotional experience converted to somatic symptoms; regression (returning to earlier developmental levels of functioning). | Highly anxious coping style. | Dependent; clinging is attached to their fears; demanding excessive health testing; doubting test results and physician assertions; seeks authoritarian, paternalistic doctors who give them answers. |

| | | | | | |
|---|--|--|---|---|--|
| Somatoform disorders (may be comorbid with antisocial, borderline, histrionic, avoidant, or dependent personality traits, sometimes disorders) | I will always have pain (or neurologic symptoms, or sexual symptoms). | Fears labeling their emotions; unable to see psychosocial stress as part of the explanation for physical symptoms; unconscious emotional fears. | Somatization dominates; psychic experience converted to somatic or physical symptoms; sexualization (expression of trauma as sexual); denial; externalization; attributing internal state to external explanations; regression. | Low anxious coping style. Anxiety converted to physical symptoms; do not recognize their own anxiety (but others do). | Entitled demander; attached to physical symptoms; expecting or demanding medical treatment for symptoms; dissatisfied with care or rejecting of help. |
| Conversion disorder/pain disorder (often associated with histrionic personality traits disorder) | I have a neurological disorder. I am powerless (and/or impaired). | Frightened by pain, which appears as varied neurologic symptoms; unconscious fears of anger or sexual wishes. | Repression, dissociation, sexualization (pseudoseizures), externalization. | Repressive coping style. Failure to recognize being upset or have difficulty recognizing their own emotional responses. | Requesting or demanding relief, analgesics, or surgery; assuming role of invalid. |
| Body dysmorphic disorder (shares many features with both OCD and OCPD) | Fear that a body part is deformed, defective, or ugly (nose, thinning hair, acne, scars, swelling, facial asymmetry); other defective body parts. | Tormenting distress, worry, shame, or embarrassment and fear about a specific body defect. | <i>Distortion</i> : reshaping external reality to internal needs Hypochondrias; denial, dissociation, sexualization (see above). | Highly anxious coping style. | Demanding or pressuring physician to “fix the defect” (often surgically). |
| Factitious disorder (may be comorbid or part of antisocial personality disorder) | I will fake or feign physical or psychological symptoms to be taken care of as if I am sick child. | Fears reexperiencing painful, frightening, or traumatic early life experiences Fears being discovered as fraudulent, abandoned, accused (See Dependent and Antisocial personality disorders). | <i>Acting out</i> : consciously feigning physical or psychological symptoms. Denial, splitting (see above). | Manipulative coping style. Seeks the patient sick role. | Outward concern while consciously misleading physician in pursuit of close medical relationship as substitute for desired, caring parent–child bond; defensive hostility when confronted that symptoms or history has been manufactured to obtain treatment or assume the sick role. |
| Malingering (may be comorbid or part of antisocial personality traits or disorder) | I will fake or feign physical or psychological symptoms to gain specific nonmedical benefits (e.g., money, disability payments, drugs, free food, shelter, avoiding police). | Fears true manipulative intention will be discovered (See Antisocial and Narcissistic personality disorders). | <i>Acting out</i> : consciously feigning physical or psychological symptoms. Denial, splitting (see above). | Manipulative coping style. Deceitful; seeks secondary gain. | Lies; uses conscious deceit and manipulation to mislead for secondary gain. Symptoms or history manufactured for a specific gain. |

OCPD, Obsessive-compulsive personality disorder.

Table 46-2 Difficult Patients: Adherence, Utilization, Physician Reactions, and Interventions (DSM-IV-TR)

| Adherence | Utilization | Physician Reactions | Interventions |
|---|--|---|--|
| Paranoid Personality Disorder | | | |
| <p>Difficult when requested by physician since patient is suspicious of need for compliance. Problematic, but may be easier when patient is seeking relief from symptoms.</p> | <p>Limited utilization; or as a condition for medical service utilization, the patient may seek detailed explanations or reasons for diagnostic testing or needs for other services.</p> | <p>Fearful; sense of danger; mistrust; feeling accused, blamed, or threatened.</p> | <ol style="list-style-type: none"> 1. Empathize with patient's fear of being hurt; acknowledge complaints without arguing or ignoring. 2. Openly and honestly explain medical illness. 3. Correct reality distortions and unreasonable patient expectations. 4. Gently question irrational thoughts, and suggest more rational thoughts. 5. Do not confront delusions. 6. If patient refuses care out of mistrust, rather than insisting, ask if you can disagree about need for the test or the specific medical care. 7. Interpret projection (blame) and other defenses. 8. Foster more adaptive coping styles. |
| Schizoid Personality Disorder | | | |
| <p>May be difficult. Will need reinforcement and monitoring. May need outreach services.</p> | <p>Underutilization Outreach, if not too frequent, may help foster appropriate use of medical services.</p> | <p>Detached or removed; wish to involve patient with others; to break through the isolation.</p> | <ol style="list-style-type: none"> 1. Empathize with patient's need for privacy and contact. 2. Accept patient's unsociability. 3. Reduce patient's isolation as tolerated. 4. Neutrally impart medical information. 5. Do not demand involvement or permit total withdrawal. 6. Correct reality distortions and unreasonable patient expectations. 7. Question irrational thoughts; suggest more rational ones. 8. Interpret isolation and other defenses. 9. Foster more adaptive coping styles. |
| Schizotypal Personality Disorder | | | |
| <p>May be difficult. May need outreach, visiting nurse, community resources, or case management.</p> | <p>Underutilization May need outreach to gain reasonable and appropriate utilization of medical services.</p> | <p>Detached; removed; "weird and alone"; wish to involve patient in additional medical care; or to break through the isolation.</p> | <ol style="list-style-type: none"> 1. Empathize with patient's idiosyncratic style, magical thinking, and perceptions without directly confronting. 2. Recognize the need for privacy and contact. 3. Accept patient's unsociability; reduce patient's isolation, as tolerated. 4. Neutrally impart information. 5. Do not demand involvement or permit total withdrawal. 6. Correct reality distortions and unreasonable patient expectations. 7. Question irrational thoughts; suggest more rational ones. 8. Interpret regression and other defenses. 9. Foster more adaptive coping styles. |
| Antisocial Personality Disorder | | | |
| <p>May be resistant, problematic, and intolerant of the need for ongoing compliance.</p> | <p>May misuse medical resources for secondary gain.</p> | <p>Used, exploited or deceived; anger, and wish to uncover lies, punish, or imprison.</p> | <ol style="list-style-type: none"> 1. Empathize with patient's fear of exploitation and low self-esteem. 2. Determine if you are being used for secondary gain. Should you suspect dishonesty, verify symptoms and illness progression with others. 3. Do not moralize. Explain that deception results in the physician giving the patient poor care. 4. Correct reality distortions and unreasonable patient expectations. 5. Question irrational thoughts; suggest more rational ones. 6. Interpret defenses. 7. Foster more adaptive coping styles. |

Table 46-2 Difficult Patients: Adherence, Utilization, Physician Reactions, and Interventions (DSM-IV-TR)—cont'd

| Adherence | Utilization | Physician Reactions | Interventions |
|--|--|---|--|
| Histrionic Personality Disorder | | | |
| Often dependent on others or inconsistent. | May misuse or overuse medical resources to gain attention from the physician or staff. | Flattered, captivated, seduced or aroused; flooded by emotions; depleted; wish to rescue. | <ol style="list-style-type: none"> 1. Empathize with patient's fear of losing love or care. 2. Interact in a friendly way, not too reserved or too warm. 3. Discuss patient's fears; reassure when possible. 4. Use logic to counteract an emotional style of thinking. 5. Set limits if the patient regresses. 6. Correct reality distortions and unreasonable patient expectations. 7. Question irrational thoughts; suggest more rational ones. 8. Interpret sexualization, regression, and other specific defenses. 9. Foster more adaptive coping styles. |
| Borderline Personality Disorder | | | |
| Inconsistent, because adherence is easily influenced by emotional storms, interpersonal conflicts, and chaotic lifestyles. | Misuse or high use for maladaptive behaviors, such as suicidal or disruptive behaviors. | Feeling manipulated, angry, impotent, depleted, self-doubting; wish to rescue or get rid of the patient; guilty. | <ol style="list-style-type: none"> 1. Empathize with patient's fear of abandonment and separation, and plan for absences by arranging coverage. 2. Express a wish to help and satisfy reasonable needs. 3. Ask the patient to monitor impulsive behaviors with a diary or log. 4. Set firm limits and do not punish. 5. Correct reality distortions and unreasonable patient expectations. 6. Question irrational thoughts; suggest more rational ones. 7. Interpret splitting and other defenses. 8. Negotiate emergency procedures in advance. If suicidal, patient must go to emergency room, if not safe. If patient refuses emergency help when you offer, tell patient in advance that this therapeutic breach may end the relationship. 9. Foster more adaptive coping styles. |
| Narcissistic Personality Disorder | | | |
| Can be problematic. Intolerant of need for ongoing compliance requirements. | Entitled to use, or may abuse medical services when needed. | Devalue/overvalue; inferior/superior; fearful of patient's criticism or anger; wish to retaliate, devalue, or get rid of the patient. | <ol style="list-style-type: none"> 1. Empathize with patient's vulnerability and low self-esteem. 2. Do not mistake patient's superior attitude for <i>real</i> confidence, and do not confront entitlement. 3. When devalued or attacked, acknowledge patient's hurt, your mistakes, and express your continued wish to help. 4. If devaluing continues, offer referral as option, not as punishment. 5. Correct reality distortions and unreasonable patient expectations. 6. Question irrational thoughts; suggest more rational ones. 7. Interpret splitting and other defenses. 8. Foster more adaptive coping styles. |
| Avoidant Personality Disorder | | | |
| Diverted or delayed by avoidant behavior. Guided by a wish to avoid disapproval of medical staff. | Seeks medical services to secure approval or avoid criticism, not necessarily seeking health benefits. | Frustrated because patient often cannot articulate fears; annoyed at patient's weakness. | <ol style="list-style-type: none"> 1. Empathize with patient's social fears, shame, shyness, and fears of revealing inadequacies, rejection, embarrassment, humiliation, and anger. 2. Help patient describe in detail the feared situation(s). 3. Encourage and support the need for the patient to gradually face their fears and tendency to avoid; if this seems overwhelming, choose smaller fears to confront or refer. 4. If frustrated or unclear about nature of the fears, ask for detailed descriptions of the problem. 5. Gently elicit irrational thoughts, and suggest more rational thoughts. 6. Correct reality distortions. 7. Interpret avoidance, phobias, and other defenses. 8. Foster more adaptive coping styles. |

Table 46-2 Difficult Patients: Adherence, Utilization, Physician Reactions, and Interventions (DSM-IV-TR)—cont'd

| Adherence | Utilization | Physician Reactions | Interventions |
|--|---|--|--|
| Dependent Personality Disorder | | | |
| Dependent on others for medical supervision and easily overwhelmed by demands of self-monitoring compliance. | Underuse when left to self, but may overuse service when physician or medical staff becomes the source of needed gratification. | Depleted; annoyed at patient's dependence/neediness; may deny patient's reasonable needs. | <ol style="list-style-type: none"> 1. Empathize with patient's need for care. 2. Frustrate total dependence. 3. Be careful to avoid telling patient what to do. 4. Encourage independent thinking and action. 5. Realize that what patient says he wants (caretaking) is not necessarily what he needs. 6. Ask patient what is so frightening about independence. 7. Do not abandon or threaten termination, because some dependent patients need regular physician contact for life. 8. Correct reality distortions and unreasonable patient expectations. 9. Gently elicit irrational thoughts, and suggest more rational thoughts. 10. Interpret regression and other specific defenses. 11. Foster more adaptive coping styles. |
| Obsessive-Compulsive Personality Disorder | | | |
| Rigid and inflexibly follows the rules; disrupted or anxious if unexpected changes are required. | Conflicted about utilization. Fears of uncertainty may drive increased use, whereas fears of loss of control may decrease use. | In a battle of control with negative reactions to patient stinginess, need for details, order, and stubbornness; distanced from feelings; bored with details. | <ol style="list-style-type: none"> 1. Empathize with patient's logical, detailed, unemotional style of thinking. 2. If obsessive thoughts are interfering with medical care, ask about patient's feelings. 3. Do not struggle with patient about control or critical judgments. 4. Avoid abandoning patient. 5. Correct reality distortions and unreasonable patient expectations. 6. Elicit irrational thoughts; suggest more rational thoughts. 7. Interpret specific defenses. 8. Foster more adaptive coping styles. |
| Self-Defeating Personality Disorder* | | | |
| Dependent on others; may be "help seeking," then "help rejecting." | Underutilization; because patient feels undeserving of services, or believes they will not help. Overutilization, when patient perceives being treated badly. | Wish to rescue; fantasies that patient will suffer/die; defeated; self-blame; self-doubt, or hopelessness, helplessness. | <ol style="list-style-type: none"> 1. Empathize with patient's suffering. Acknowledge and appreciate the difficulty associated with illness and treatment. 2. Emphasize that recovery may be a slow, steady process. 3. Patient's need for recovery can be presented as necessary to benefit others. 4. Inquire about obviously self-destructive or self-defeating behaviors. 5. Do not abandon patient. 6. Correct reality distortions and unreasonable patient expectations. 7. Elicit irrational thoughts, and suggest more rational ones. 8. Interpret specific defenses. 9. Foster more adaptive coping styles. |
| Hypochondriasis | | | |
| "Doctor shopping" Adhere to medical testing, but have difficulty adhering to recommendations for psychosocial evaluation or treatment. | High utilization. Repetitive physician visits, or avoidance of doctors because the situation is hopeless. | Frustrated, angry, and annoyed with patient's needs, demands, and help-rejecting behaviors. Wants patient to stop complaining. Wants to end the doctor-patient relationship. | <ol style="list-style-type: none"> 1. Empathize/understand involuntary nature of symptoms. 2. Use parallel diagnostic inquiry. (Suggest from start that symptoms have biopsychosocial components.) Workup proceeds simultaneously in all domains. 3. Use emotion-focused interviewing <p>Kroenke's algorithm*</p> <p>Is the symptom medically explained? Acutely serious? Seriously persistent or bothersome?</p> <p>What are patient's specific concerns or expectations?</p> <p>What else is the patient worried about? Anything else helpful?</p> <p>Does patient have depression, anxiety disorder, or abuse history?</p> <p>Has the patient been tried on antidepressants?</p> <p>Does patient have history of chronic somatization?</p> <ol style="list-style-type: none"> 4. Reassure the patient that the disorder is not lethal. 5. Do not abandon the patient. 6. Correct reality distortions and unreasonable patient expectations. 7. Elicit irrational thoughts, and suggest more rational ones. 8. Interpret specific defenses. |

Table 46-2 Difficult Patients: Adherence, Utilization, Physician Reactions, and Interventions (DSM-IV-TR)—cont'd

| Adherence | Utilization | Physician Reactions | Interventions |
|--|--|--|--|
| Hypochondriasis—cont'd | | | |
| | | | 9. Foster more adaptive coping styles. 10. Provide additional treatment. Encourage regular office visits. With physical complaint, do a focused physical exam. Refer for consultation rather than hospitalization. Goal is preservation and restoration of function, not elimination of symptoms. |
| Somatization Disorder | | | |
| “Doctor shopping” Adhere to requests for medical testing, but highly resistant to psychosocial exploration, evaluation, or treatment. | Up to 9x the health care expenditures of typical primary care patients. Utilization increases depending on number of symptoms. Doctor seeking until patients can find a physician who believes them or will do what they seek. | With more somatic complaints, perceives patient as more difficult. Frustrated, puzzled with inability to explain or diagnose problem. Wants patient to stop complaining. | 1. Empathize/understand involuntary nature of symptoms. 2. Screen for reasonable medical condition that could explain symptoms. 3. Use parallel diagnostic inquiry. (Suggest from start that symptoms have biopsyo-sociocultural components.) Workup proceeds simultaneously in all domains. 4. Use emotion-focused interviewing (see above). 5. Do not abandon the patient. 6. Correct reality distortions and unreasonable patient expectations. 7. Elicit irrational thoughts and suggest more rational ones. 8. Interpret specific defenses. 9. Foster more adaptive coping styles. |
| Conversion Disorder | | | |
| Adhere to medical recommendation. May accept psychosocial explanations. | Doctor seeking until patients can find one who believes them or will do what they seek. | Puzzled initially. Often feel helpless to address psychosocial or emotion conflict. | 1. Empathize/understand involuntary nature of “symptoms.” 2. Perform thorough neurologic and medical evaluation. 2. Make a timely diagnosis. 3. Give therapeutic reassurance that symptoms are not caused by a medical or neurologic condition but are secondary to underlying psychological conflict. 4. Combined medical model approach and psychological modalities best address physical needs and invite patient to engage in treatment without feeling humiliated (combined, if appropriate, with progressive physical therapy to promote sense of mastery and control). 5. Treat any comorbid psychiatric disorder. 6. Work through patient’s defenses and help to develop more mature and adaptive defense mechanisms to prevent future conversion episodes. 7. Foster more adaptive coping styles. |
| Body Dysmorphic Disorder | | | |
| Initially avoid medical care. Once disorder is acknowledged by patient, can be intensely medical seeking to correct the defect. | Avoid doctors initially, but then may overuse medical care, seeking variety of surgical and medical treatments. | Puzzled by patient’s complaints of body defect that is not readily visible or apparent. Frustrated that reassurance does not work. | 1. Empathize; understand involuntary nature of symptoms. 2. <i>Stepped care</i> attempts to provide most effective but least intrusive treatments appropriate to a person’s needs. Step 1: awareness and recognition Step 2: recognition and assessment <i>Treatment options:</i> exposure response; CBT or SSRI; or combined treatment. 3. NICE guidelines: SSRI or clomipramine, CBT (including exposure response prevention [ERP]), or combination of SSRI or clomipramine and CBT (including ERP); consider care coordination, augmentation strategies, admission, social care. 4. Do not abandon or threaten termination. 5. Correct unreasonable patients expectations. 6. Gently elicit irrational thoughts and suggest more rational thoughts. 7. Interprets specific defenses. 8. Foster more adaptive coping styles. |

Continued

Table 46-2 Difficult Patients: Adherence, Utilization, Physician Reactions, and Interventions (DSM-IV-TR)—cont'd

| Adherence | Utilization | Physician Reactions | Interventions |
|---|--|---|---|
| Factitious Disorder | | | |
| Patients will only adhere to medical recommendations when these support the patient's goal of assuming the sick role. | Extremely high use of inpatient medical hospitalization and occasionally psychiatric hospitalizations. Willing to undergo mutilating procedures. | Initial wish to help, then anger/rejection of patient's complaints. Wish to expose, retaliate, punish, or terminate care. | <ol style="list-style-type: none"> 1. Empathize/explore with patient's history of trauma and painful early life experiences. 2. Clarify that you are being used to help patient seek dependent care. 3. Do not moralize. Explain that seeking care in a medical setting is fraught with iatrogenic injury. 4. Explain that there are other, more adaptive ways of receiving care, such as seeking psychiatric help. 5. Set limits on medical care; correct reality distortions. 6. Question irrational thoughts; suggest more rational ones. 7. Interpret defenses and maladaptive coping style. 8. Foster more adaptive coping styles. |
| Malingering | | | |
| Only adhere to medical recommendations when these support patient's secondary goal. | Exploit both inpatient but more often outpatient settings when needed. Symptoms abate or disappear as goals are obtained. | Initial wish to help, then anger/rejection of patient's complaints. Wish to expose, retaliate, punish, or terminate care. | <ol style="list-style-type: none"> 1. Empathize with fear of being discovered in lying and exploiting other. 2. Determine the secondary gain that patient seeks. If dishonesty suspected, verify symptoms and illness progression with others. 3. Do not moralize. Direct patient to use of other, appropriate resources. 4. Correct reality distortions and unreasonable patient expectations. 5. Question irrational thoughts; suggest more rational ones. 6. Interpret defenses and maladaptive coping style. 7. Foster more adaptive coping styles. |

CBT, Cognitive-behavioral therapy; SSRI, selective serotonin reuptake inhibitor.

of medical services are somewhat predictable based on the particular personality or somatoform disorder.

Defenses and Coping Styles

Patients with severe unexplained somatic symptoms tend to use denial, externalization, and somatization, converting psychosocial distress and problematic interpersonal relationships into unexplained physical complaints. Patients with severe unexplained somatic symptoms tend to use high/low anxious coping or manipulative coping styles (see Table 46-1).

A family physician can attempt to relieve a core problem or a symptom interfering with medical care by fostering the patient's awareness of his or her problems. It is important to appreciate the unconscious psychological processes known as *defense mechanisms*. These psychological processes (e.g., denial, projection) are used to resolve internal conflicts, manage moods, mediate external dangers, and facilitate adaptations to reality. *Coping styles*, on the other hand, are typically behavioral patterns and methods of coping with the external environment.

By understanding the constellation of defenses and coping styles used by difficult patients, the physician may be able to modify the pathologic defense or coping style that is interfering with the patient-physician alliance and the delivery of medical care. A physician can use clarification, confrontation, and interpretation (see Table 46-1). For example, a borderline patient may feel hurt and abandoned by the physician's vacation and accuse the physician of not caring. This patient may use a defense mechanism called *devaluation* (physician

is deprecated as uncaring) and a coping style of manipulation (threatens suicide). With this understanding, the physician can begin to help the patient by not taking the patient's efforts to devalue or manipulate personally. The physician can respond to the patient by empathizing with the patient's fears of abandonment. The physician may clarify that the patient has a distorted belief, and that the vacation is being incorrectly experienced as a personal abandonment of the patient. The physician may further clarify that the vacation does not communicate anything about the physician's future ability or wish to care for the patient. The patient can be reassured of the physician's return, future realistic medical availability, specific limits of availability, and medical coverage by another physician. In a preventive effort to allay a crisis and help a borderline patient manage separation fears, the physician (before the vacation) could suggest a new coping style of having the patient schedule a meeting with a medical colleague who will provide coverage while the physician is away. Often, it is helpful to anticipate issues that may arise for the patient and suggest specific problem solving and coping.

Patient Behaviors, Adherence, and Use of Medical Services

Difficult patients often display characteristic behaviors that affect their adherence to medical recommendations and use of medical services. Understanding these behaviors can also help physicians manage their expectations of these difficult patients and improve the chances for effective interventions

that might improve medical adherence and health outcomes. In general, patients with cluster A personality disorders (paranoid, schizoid, and schizotypal) tend not to adhere to medical recommendations and underuse medical services. They may require outreach to involve them in their own medical care. Cluster B patients (antisocial, histrionic, borderline, narcissistic, and self-defeating) tend to have variable adherence to medical recommendations and may misuse, overuse, or underuse medical care. Cluster C patients (dependent, obsessive-compulsive, avoidant) tend to adhere to medical recommendations because of fear of the consequences of nonadherence. They are ambivalent users of the medical system and tend to use medical services appropriately when others are involved in their care.

Patients with somatic symptoms tend to overuse medical services and are reluctant to adhere to medical recommendations, even while seeking care from several providers. Somatic patients usually seek relief of physical symptoms through medical, not psychological, interventions. Patients with hypochondriasis or body dysmorphic disorder often initially avoid physicians out of fear or shame that they will be viewed as “crazy.” Once they become patients, however, somatic patients also tend to pressure physicians to order many diagnostic tests and perform multiple procedures. They also tend not to adhere to medical recommendations.

Physician Reactions to Difficult Patients

Although DSM-IV-TR is a useful aid for making a diagnosis, family physicians often recognize a patient with a personality trait or unexplained physical complaint by their own reaction to the patient. Physicians working with difficult patients seem to have specific and characteristic reactions to these patients that need to be recognized, understood, and used for the patient’s benefit. Patient-generated feelings provoked in the physician are created through the interpersonal interaction between patient and physician. These reactions to a patient should alert the physician to a possible diagnosis of a difficult patient. Typical physician reactions to patients that are provoked by the patient are also called *patient-generated countertransferences*. These include intense feelings, uncharacteristic fantasies, or atypical behaviors by the physician.

Intense Affects

Intense physician feelings elicited through patient interactions may include hate, fury, or frustration toward a patient (Groves, 1978; Strous et al., 2006). Alternatively, the physician may have strong feelings of love, sexual arousal, or wanting to rescue the patient or provide exceptionally good medical care. These may alternate with other wishes to avoid the patient, terminate the relationship, or transfer the patient to a colleague. In extreme cases, intense feelings aroused in a physician can become a focal point for leading the physician into boundary violations with a patient. These are extremely damaging to both parties and violate the tenets of professional behavior.

Fantasies

Physicians may recognize that they are interacting with a difficult patient by their own fantasies. These might include excessive worrying about a patient after normal work hours, dreams

of discovering or being unable to discover a medical cause for complex somatic complaints, dreaming about a patient, or experiencing exaggerated or intrusive, angry, sexual, or curious fantasies about the patient during personal time.

Atypical Behaviors

A physician may notice behaviors with certain patients that are atypical for their usual customary medical practice. These unusual physician behaviors should trigger self-examination by the physician and consideration that the patient may have a personality or somatoform disorder. Frequently, difficult patients are capable of arousing unconscious reactions that lead to new and unusual physician behaviors.

Common atypical physician behaviors may include ordering tests to placate a patient, asking for more than the usual number of consults on a patient whose case does not seem medically complicated, suggesting increasingly aggressive diagnostic testing or procedures when the yield of these tests is likely to be low, repeatedly extending the time spent with a particular patient or family, lowering the customary fee, offering free treatment, or developing a personal (not professional) relationship with a patient. Common physician reactions associated with difficult patients are reviewed in [Table 46-2](#).

Physicians can use the scope of patient-generated countertransferences (their feelings, fantasies, and atypical medical behaviors) as a valuable diagnostic aid, because difficult patients tend to provoke the same feelings in most physicians who deal with them. For example, a patient with a borderline personality disorder often leaves many physicians exhausted and worried about the patient’s suicidal threats. A patient with multiple somatic complaints may leave physicians feeling frustrated that they cannot alleviate the patient’s pain symptoms or suffering. Physicians who learn to recognize feelings provoked by patients will find it easier to identify the subtype of difficult patients according to the feelings elicited. More importantly, physicians who can recognize their unusual reactions will be better able to tolerate them and avoid acting out their feelings with a patient. This will improve the physician-patient relationship, medical decision making, and ultimately patient care (Feinstein et al., 1999).

General Management Principles for Difficult Patients

- Attend to the physician-patient relationship.
- Focus the interview on manageable goals within the time frame available.
- Use psychotherapeutic techniques when interviewing the patient.
- Attend to the patient’s emotional needs.
- Modify the patient’s surroundings.
- Improve the patient’s capacity to test reality.
- Empathize with the patient’s worldview.
- Accept the patient’s limitations and strengths.
- Manage unreasonable patient expectations, and set limits.
- Question illogical feelings, thoughts, or behaviors.
- Discuss and interpret defenses and coping style.
- Prescribe medications as needed.
- Use specific interventions and suggest better coping styles for each type of difficult patient.

Attending to a Problematic Alliance

To establish a good working alliance based on trust, acceptance, and confidence, the family physician should begin each patient encounter by listening, asking open-ended questions, and continually striving for empathy. The alliance is also fostered by the physician's own self-awareness, ability to acknowledge mistakes, and efforts to adapt to the patient's wishes or needs that will foster improved health. Problems often occur in developing an alliance with a patient who has a personality or somatoform disorder. If tension develops in the alliance, the physician should first ask what the patient thinks of the current problem. If the patient expresses the problem clearly, the physician should join with the patient in solving the problem to deliver effective medical care. If the problem is the physician-patient relationship, nondefensive reflective listening, clarifications, admitting mistakes, and expressing new efforts to improve the situation are often helpful. If the physician believes that there is a different problem affecting the alliance, the physician may say, "I believe that there is a different problem [identify the problem, e.g., psychosocial distress, problem drinking] that is affecting my ability to help you get well and offer you the best medical care available. We need to think about this problem and come up with some solutions."

Choosing a Focus for the Interview

When delivering medical care with a difficult patient, it is important to be consistent, reliable, and predictable to avoid future problems. Difficult patients typically experience an inability to verbalize or prioritize their most important medical or psychosocial concerns. For these patients, it is particularly important to strive for a mutually agreed focus for short-term and long-term treatment goals. It is often helpful to use a process called *informed shared decision making*, in which the physician takes time with the patient to discuss and negotiate the acute focus of medical care, long-term medical goals, strategies to achieve these goals, and specific timelines for accomplishing the prioritized medical plan (Feinstein et al., 1999).

Using Basic Psychotherapy Techniques

As is often the case, a general medical approach may not be sufficient to help a difficult patient. After a brief period of immersion in the patient's complaints, the family physician can respond with empathic responses, initially acknowledging the patient's fears and symptoms (see Table 46-1). If this is not helpful, the physician can use general psychotherapeutic techniques, such as confrontations, clarifications, or interpretations, directed toward the current problem interfering with medical care.

A *confrontation* is an observation by the physician offered to a patient for examination. It is usually a comment that draws attention to contradictions in the patient's beliefs, thoughts, feelings, or behaviors. For example, one might say to an anxious-somatic patient who denies that psychosocial factors might be contributing to her symptomatology, that her physical complaints may be caused by medical, psychological, or social stresses, and that her high levels of anxiety could be making her physical symptoms worse.

A *clarification* adds new information or perspective or elucidates misunderstandings, miscommunications, or other information that seems vague or confusing. The need for repeated clarifications occurs regularly with difficult patients. It is important to use clarifications before suggesting a new plan to correct the problem.

Interpretations are integrating comments that link confrontations and clarifications with the patient's current problem that is interfering with medical care. Interpretations can be made about the immediate medical situation and may address the patient's core beliefs, irrational thoughts, fears, maladaptive symptoms or behaviors, defense mechanisms, or coping style. Interpretations can also be directed at a difficulty in the physician-patient interaction, problems with the patient coping with the disease, problems in the patient's life circumstances, or patient refusal of a necessary medical workup or treatment. For example, an interpretation to a somatic patient who is refusing to acknowledge any psychosocial contribution to her symptoms might be the following:

I think you want relief from your physical symptoms. However, your refusal to consider that any of your psychosocial stress is contributing to your pain makes relief from your physical symptoms less likely [confrontation]. You then get annoyed with me and more depressed, which leads you to have new physical symptoms, and then you feel hopeless [clarification]. Instead of accepting my help to look broadly at all factors causing your pain, you blame me for not making you better. Your physical symptoms become an excuse for why you have difficulty managing your life [interpretation].

Such interpretations take practice but can powerfully restore a realistic and helpful physician-patient relationship.

Attending to Patient's Emotional Needs

Difficult patients are often exquisitely sensitive and distressed by internal emotional states, desires, and physical complaints. At a basic level, this often means listening empathically and carefully before attempting an intervention. It may be important initially to attend to physical or psychological pain. The most helpful initial intervention for some patients may be pain medication, to address physical complaints, or psychiatric medication, to address the patient's anxious, depressed, or agitated moods.

Modifying Patient's Surroundings

Difficult patients will often show fewer symptoms and a dramatic improvement in their acute emotional, physical, and behavioral functioning when the physician recruits additional support from the environment. This may mean bringing in a helpful spouse, friend, or other personal support into the patient's medical care. Other approaches to improving the patient's external environment may include allowing the nurse or office staff to spend more time with the patient and adding social services, self-help support groups, or psychiatric care. In extreme situations, using the psychiatric or medical emergency services can be helpful interventions. Some patients with personality disorders need to be managed with the help of the police.

Improving the Capacity to Test Reality

Difficult patients often have distorted views of reality. Stressed patients with cluster A and B personality disorders may transiently hear voices, hallucinate, have brief episodes of delusional thinking, or have other severe distortions in perception of reality (e.g., paranoia). This can occur with paranoid, schizotypal, and borderline personality disorders. If psychotic disturbances in reality are present, assess and treat these first before providing the requested medical care. Mobilizing external supports, using medications, or placing the patient in a safe and calm environment is often sufficient.

A stressed or somatic patient can also present with a tenuous or disturbed relationship to reality. Some hypochondriac patients appear delusional in their belief that they have a serious medical condition, even when medical testing contradicts this. Patients with body dysmorphic disorder are certain that a part of their body is defective, even when no visual evidence confirms this. Difficult patients may have a disturbance in the sense of reality, such as *derealization* (watching own life as if it were a movie), *depersonalization* (not feeling a part of one's own life), dramatic distortions of what has been said, transient misperceptions of real events (interpreted according to core beliefs or irrational thoughts), or misunderstanding the physician or patient role. Such reality distortions are not usually dangerous but can lead to severe problems in the physician-patient relationship if they are not recognized and addressed. Verbal techniques include uncovering and clarifying the patient's irrational thoughts or core beliefs and using confrontation, clarification, and interpretation to improve the patient's reality testing.

Empathizing with Patient's Worldview

All psychological interventions depend on the patient feeling understood by the physician. Listening and reflecting back the problems identified by the patient while empathizing with the patient's worldview can be extremely helpful in management. For example, an avoidant patient may refuse a prostate examination while having complaints of urinary hesitation and dribbling. The physician could say:

I understand your wish to avoid dealing with this problem. The testing—a blood test, the prostate-specific antigen (PSA) test, and a rectal examination—take only a few minutes and are not terribly uncomfortable. I am not trying to criticize you. I just think it is in your interest to get these examinations. Could we do this today? Then we can plan a way to relieve your symptoms.

A patient may be certain there is a medical cause of pain. Empathy can be shown by performing a detailed physical exam; often the physical touch allows the patient to feel that the physician is taking him seriously.

Accepting Patient's Limitations and Strengths

Difficult patients are often rigid in their approach to the world and limited in their capacity for social and occupational functioning. They do not seek or make changes quickly. However, because they often seem reasonable at first impression, there can be a temptation to try to change the patient's belief. This typically leads to frustration for all con-

cerned. It is more effective to accept the patient's beliefs and limited functioning, focus on the patient's strengths, and address how other issues or circumstances can be modified to help the patient cope.

Managing Unreasonable Expectations and Setting Reasonable Limits

Difficult patients often have unreasonable expectations. They may expect an unrealistic cure, never-ending diagnostic testing, constant availability of the medical team, special treatment, an unwarranted disability diagnosis, excessive pain medication, or many consultations. The physician must set limits on a patient's unreasonable expectations. Effective limit setting involves exploring why the patient believes that her particular expectation can or should be met. This involves a reasonable physician response about what can or cannot be done. Ultimately, limit setting is about agreeing to a reasonable approximation of the patient's request and tactfully saying "no" to requests that are not appropriate.

Questioning Illogical Feelings, Thoughts, and Behaviors

Patients often have irrational thoughts about their illness and the care that they will receive. They may also misunderstand the physician's efforts to communicate. For example, a patient may think that nothing can be done to ameliorate his physical complaints, or that a prescribed medication may make him sick; another may think that magnetic resonance imaging (MRI) will cure her, or that MRI may give her cancer. These types of irrational thoughts should be explored and the reality clarified. If done tactfully, this usually reduces anxiety in most patients. If a patient is frankly delusional, it is not useful to confront a patient's fixed belief. It is better to accept the patient's viewpoint while asking the patient's permission to have a different viewpoint.

Discussing Defense Mechanisms and Coping Styles

Patients may benefit from discussing their maladaptive defenses and coping styles and exploring ways of effectively dealing with their situation. For example, an obsessive-compulsive patient has a high cholesterol level and is calling the physician's office for more details about other laboratory tests. The results of the lipid profile are given to the patient, who now wants to know whether a lifestyle change or a statin medication would work better. With the recommendation for an initial lifestyle plan of more exercise and nutritional counseling, the patient becomes concerned about how to pay for this. Repeated efforts to help the patient with additional information are not making the patient feel any better. In fact, more information just raises more requests for additional information. The patient is asked to come for another visit. At this visit, the physician might say, "I can continue to give you more information, but it seems that anxiety is driving your questions. What are you worried about?" In essence, this says, "Your coping style of seeking information and details is not helping you. If you can recognize your anxiety about this subject, you may feel calmer." Review [Table 46-1](#) for specific defenses and coping styles. Interpreting defenses or modifying a coping style requires the ability to recognize

these and then to implement the preparatory confrontations and clarifications before making an interpretation and subsequently suggesting new ways to cope with the situation.

Prescribing Medication

Prescribing medication for patients with personality disorders is similar to prescribing for the major psychiatric disorders. Low-dose, typical or newer antipsychotics can be tried if the patient has psychotic symptoms, such as ideas of reference or severe paranoid ideation. A full dose of the newer antidepressants—selective serotonin reuptake inhibitors (SSRIs) or selective noradrenergic reuptake inhibitors (SNRIs)—is often recommended if the patient has depressive symptoms. Patients with an unstable mood who may be irritable or impulsive may be treated with full doses of a newer antidepressant, a monoamine oxidase inhibitor (MAOI), lithium, an anticonvulsant, or other mood stabilizer. An anxious patient can be treated with benzodiazepines, as needed. If the anxiety is persistent or chronic, the patient can be treated with low-dose and full-dose antidepressants (SSRI, SNRI) or MAOIs. The use of medication for patients with personality disorder can be very important for acute and long-term management.

The psychopharmacology of personality disorders can also be steered in the categorical direction toward specific personality disorders. There is evidence for the effectiveness of pharmacotherapy for patients with borderline personality disorder (Soloff, 2000, 2009; Nose et al., 2006). Affective instability and anger are treated with SSRIs and mood stabilizers, not antipsychotics, and impulsivity and aggressions are best treated with antipsychotics. Some studies of schizotypal personality disorder also indicate the effectiveness of antipsychotics (Markovitz, 2004; Soloff, 2009). The pharmacotherapy used for other personality disorders is variable.

Another approach to the pharmacology of personality disorders is to treat target symptoms. Using this approach with patients with borderline personality disorder has also been studied (Nose et al., 2006; Ypriitham, 2004). Borderline patients have three main symptom clusters: *cognitive-perceptual symptoms* (e.g., suspiciousness, referential thinking, paranoid ideation, hallucinations), *affective dysregulation* (e.g., irritability, unstable moods, anger or temper outbursts, hypomania, depression), and *impulse control symptoms* (e.g., suicide attempts, cutting, binge eating, substance abuse, reckless spending, gambling, promiscuity). Table 46-3 lists medications that have been used with some efficacy in treating symptoms associated with borderline personality disorder.

KEY TREATMENT

Mood symptoms can be treated with an SSRI, mood stabilizer, or antipsychotic medication (Nose et al., 2006; Soloff, 2009) (SOR: B). Somatic symptoms can be treated with pain medications or SSRIs (SOR: B). Psychotic symptoms can be treated with low doses of typical or atypical antipsychotic medications (SOR: B). Irritability or impulsive behaviors can be treated with an SSRI, low-dose antipsychotic, or mood stabilizer (Markovitz, 2004; Soloff, 2009) (SOR: B). Drugs used for other personality disorders have trended toward SOR B and C and have variable effectiveness.

Table 46-3 Medication Dosages for Symptom Clusters in Personality Disorders*

| Mood Symptoms, Anger | Psychotic Symptoms | Irritability, Impulsivity, Aggression |
|--|--|---|
| SSRIs Fluoxetine, 20-80 Sertraline, 100-200 Venlafaxine, 75-225 Other Antidepressants Amitriptyline, 100-300 Amoxapine, 200-250 Antipsychotic for Anger See Psychotic Symptoms. Mood Stabilizers Divalproex, 1000-2000 Omega-3 fatty acid, 1000 | Atypical Antipsychotic Olanzapine, 2.5-10 Risperidone, 1-4 Aripiprazole 2.5-15 Clozapine, 75-460 Typical Antipsychotics Haloperidol, 1-4 Perphenazine, 12-16 Trifluoperazine, 2-6 Thiothixene, 2-40 Loxapine, 13.5-14.5 Chlorpromazine, 105-120 | SSRIs Fluoxetine, 20-80 Sertraline, 100-200 Venlafaxine, 75-400 Low-Dose Antipsychotic See Psychotic Symptoms. Mood Stabilizers Divalproex, 1000-2000 Carbamazepine, 800-1200 Lamotrigine, 25-200 Lithium, 1000-2000 Anxiety† Alprazolam, 1-7 Clonazepam, 0.25-4 |

*All doses are daily doses in milligrams.
 †Use with caution if anger, impulsivity, or substance abuse is present.
 SSRIs, Selective serotonin reuptake inhibitors.

Strategic Principles for Working with Somatic Patients

Key Points

- Trying to explain somatic symptoms through a medical workup is the usual approach, although this is not always effective.
- Parallel diagnostic inquiry can help the physician maintain a therapeutic relationship with somatizing patients, even when physical explanations for symptoms cannot be found.
- Positive diagnostic features of somatization (chronicity, number of symptoms, patient defensiveness, provider suspicion, psychosocial evidence, medication history) help the clinician judge the likelihood that symptoms are somatoform.
- Emotion-focused interviewing may prove to be a useful technique for diagnosing specific subsets of somatizing behavior.
- The somatoform module of the PRIME-MD, or its self-administered counterpart, the PHQ-15, is the best diagnostic instruments for the clinician to use for formal diagnosis of somatization in primary care.

Parallel Diagnostic Inquiry

Although most clinicians regard patients with somatization as difficult, effective and rewarding approaches exist for recognizing and managing these patients. We first present a general approach to the diagnostic strategy with somatic patients, then describe a more specific diagnostic algorithm that has proved useful in managing patients with somatization.

In the course of a normal clinical encounter, a clinician (1) hears a complaint, (2) asks questions to elicit related symptoms and to understand the context of the symptoms more fully, and (3) performs the appropriate physical and lab-

oratory examination. In other words, the clinician attempts to *explain* the symptoms. This universal clinical process is appropriate for many presenting complaints but has at least three important limitations. First, some symptoms are not easily explained; at some point, explanatory efforts can be seen as increasingly futile and irrelevant. Second, poor interrater reliability exists between explainers; on close inspection, symptom explanations do not meet scientific standards. Third, in some patients the sheer number of symptoms overwhelms the capacities of a symptom-by-symptom diagnostic approach. In other words, at some point it does not make sense to try to continue explaining symptoms or to pursue diagnostic workups. Even the most compulsive, biologically oriented physician knows when a diagnostic pursuit is pointless.

Before reaching this point, the physician needs a different mode of diagnostic pursuit. For example, a patient presents with several days of intermittent, heavy chest pain. The physician might test for angina pectoris, then for other cardiac causes, then for gastroesophageal reflux disease (GERD), while looking for pleuritic explanations and perhaps ruling out costochondritis. If all these tests are negative, the physician might initiate an exploration of psychological or psychosocial factors that could be responsible. After an exhaustive focus on various physical explanations for this pain, the patient might question the physician's competency. With no explanation for the chest pain, the patient also may think the physician is saying, in effect, "It must all be in your head."

It is not good practice to complete a physical workup for a symptom with no explanation. By that time, the physician could have elaborated a set of psychosocial connections to the symptoms. By pursuing a strategy of *parallel diagnostic inquiry*, the physician can avoid this trap. This process begins by explaining that all symptoms, illnesses, and diseases are produced, sustained, and amplified by interacting physical and psychosocial factors. Symptoms can be explained as having a physical cause with psychosocial factors that are secondarily important, and vice versa. Many symptoms, diseases, and illnesses with biomedical or psychosocial etiology produce symptoms and problems in both domains. Therefore the physician should inquire into both domains concurrently, in parallel. Thus, while eliciting the characteristics of the chest pain and arranging for an electrocardiogram, the physician should also ask about stressors, depression, and panic. The physician can incorporate both physical and psychosocial inquiry into a comprehensive understanding of the presenting problem and of the patient. If the workup for angina pectoris, valvular disease, pericarditis, pleuritis, GERD, and costochondritis is negative, the physician is already far down the road with the psychosocial inquiry. The point is never to communicate directly or give the impression that the "real" workup has failed, leaving a psychosocial explanation. Rather than viewing psychosocial explanations simply as the only ones left after a failed biomedical workup, the physician should remember that positive diagnostic features are also associated with somatization spectrum disorders. The physician should consider the following issues as suggestive of, but not definitive for, somatization:

Chronicity. Most symptoms are quick to improve or disappear. The longer a symptom persists, particularly after diagnostic efforts, the greater the likelihood that it is a somatic complaint.

Number of symptoms. Somatization disorder, abridged somatization disorder, and multisomatoform disorder are all

defined by the presence of numerous unexplained symptoms; the more explained symptoms, the more unexplained symptoms. Therefore, patients with many symptoms should be provisionally regarded as having a somatoform component to the illness.

Provider suspicion. An experienced physician's initial judgment about an explanation eventually being found has about 90% accuracy.

Patient defensiveness. Fierce denials or anger by the patient when exploring psychosocial dimensions suggests somatization.

Psychosocial evidence. Major current stressors, a family history of illness behavior, violence or abuse, or comorbid depression or anxiety are all associated with somatization. Moreover, these factors have management implications.

Medication history. Look for polypharmacy, multiple drug reactions or "allergies," multiple drug failures, and prior use of psychotropic drugs and controlled substances.

For the family practitioner, the finer points of diagnostic classification of somatic manifestations do not generally contain corresponding management differences. Thus, the physician would manage a patient with somatization disorder similar to one with multisomatoform disorder, or even somatoform pain disorder. There may be exceptions. However, using videotaped case studies and clinical trials, Davanloo (1990, 2001) proposed four main patterns of somatization: striated muscle tension, smooth muscle tension, cognitive-perceptual disruption, and conversion. These patterns can be elicited with a simple interviewing technique known as *emotion-focused interviewing* (Abbass, 2005). This technique involves examining the emotional system by actively exploring emotionally charged situations and observing the response. This allows classification into a somatization category for specific short-term psychotherapy. Psychiatrists have developed credible research efforts aimed at classifying somatic patients into more refined, therapeutically meaningful categories, which are beyond the scope of this chapter.

Although there is no formal evidence that active case finding (testing for disease in patients whose presenting complaint does not suggest it) for somatization is beneficial, there is a place for confirmatory testing in suspected cases, and perhaps for diagnostic testing in high-risk situations. A number of diagnostic instruments are available, but the emerging "gold standard" in primary care, both for research and clinical purposes, is the somatoform module of the PRIME-MD (Spitzer et al., 1994) or its self-administered derivative, the PHQ-15 (Kroenke et al., 2002). This instrument can make the diagnosis of multisomatoform disorder in a few minutes and can track the severity of the symptoms.

Management Algorithm for Somatization

Kroenke's algorithm can lead to a medical explanation, an antidepressant-responsive condition, or presumptive evidence of chronic somatization. Primary care clinicians can use the following guidelines when dealing with patients who present with symptoms (Kroenke, 2002):

- In the patient with chronic somatization, the physician should follow the guidelines offered in Smith's consultation letter (see next section).
- Many somatic patients have sustained serious abuse. The physician should inquire about abuse, and in most cases offer a referral to a skilled mental health professional.

- Antidepressants may be effective against some forms of somatization. Further study is needed.
- Cognitive-behavioral therapy, group psychotherapy, and short-term dynamic psychotherapy are effective for somatic patients. If available, such therapy should be offered.
- St. John's wort has been shown to be effective against somatoform disorders.
- Massage therapy may be effective for somatic pain syndromes.

When dealing with potential somatization, the clinician can never become complacent and assume without further inquiry that any given symptom is somatoform. If the symptom is not medically explained, a focused history and physical examination are warranted, and if there are physical abnormalities, additional laboratory work may be indicated. Some symptoms suggest conditions that require immediate attention, such as dyspnea, crushing chest pain, syncope, severe abdominal pain, and sudden severe headache. Because many symptoms resolve spontaneously, however, the physician is often justified in deferring an extensive workup until nonthreatening symptoms have time to resolve. Follow-up is preferable to workup; if symptoms persist at follow-up, the physician is justified in beginning a focused diagnostic workup.

What are the patient's specific concerns or expectations? For the one third of patients whose symptoms are neither acutely serious nor readily explainable, two patient questions are in order:

1. "Is there anything else you are worried about?" This question elicits unexpressed concerns. Patients can be concerned that their symptoms might mean something serious, or they can be concerned about a particular disease such as cancer. They might be concerned about the prognosis of the symptom, wondering whether it is advisable to take a planned vacation, or whether they are likely to miss work. They might be concerned about whether further testing is ahead.
2. "Is there anything else you have thought might be helpful?" This question is designed to elicit additional expectations. Some patients present for symptom relief, others for an explanation. Some patients want further diagnostic tests, and others expect a referral to a specialist or a mental health professional. This question helps the clinician address expectations that might not have been voiced during the discussion of specific symptoms. The physician should ask himself or herself three additional questions:

1. Does the patient have a depressive or anxiety disorder? Most patients with somatic symptoms meet criteria for a mental diagnosis. If such a diagnosis is present, prescribing an antidepressant or other treatment known to be effective is appropriate. In addition to the benefit to the patient's overall health, it can specifically improve the symptom severity.
2. Does the patient have a syndrome known to respond to antidepressants? There is some evidence that syndromes such as fibromyalgia, irritable bowel syndrome, premenstrual syndrome, chronic pain disorders, and chronic headaches, or even recurrent migraine headaches respond to antidepressants (O'Malley et al., 1999). Thus, a trial of antidepressants is warranted in these patients.

3. Does the patient have a history of chronic somatization? The physician can answer this question affirmatively only after working through the previous questions and determining that the patient has had a number of unexplained complaints over time, or at least had a single unexplained symptom that has persisted for a long time. At this point, a number of management recommendations apply.

Consultation Letter

It has been shown that writing a consultation letter to assist other physicians or health care providers improves the health of patients with somatization disorder (Smith et al., 1986), abridged somatization disorder (Smith et al., 1995), and multisomatoform disorder (Dickinson et al., 2003) and also reduces costs. The recommendations in the consultation letter improve outcomes for somatic patients, as well as making these patients seem less burdensome and difficult for clinicians. The consultation letter should include the following:

- Notification of physician or other health care provider that the patient meets criteria for somatization.
- Reassuring information about the nonlethal prognosis of somatization.
- Encouragement to schedule the patient for regular, brief visits, rather than waiting for the patient to develop a new symptom or schedule an urgent visit.
- Recommendation to follow all complaints with a focused physical examination and generally to pursue workups only if physical findings are present.
- To avoid hospitalization, surgery, and subspecialty referral, if possible.
- To view the symptoms as part of an unconscious process, and to avoid telling the patient, "It's all in your head."

Pharmacotherapy and Psychotherapy for Somatoform Disorders

In a review of 34 randomized clinical trials of treatments for somatoform disorders, two thirds involved somatization disorder or one of its less severe variants (Kroenke, 2007). CBT was effective in 11 of these 13 studies. Antidepressants were effective in four of five pharmacotherapy trials. The consultation letter was effective in 8 of 16 studies. Effective treatments for conversion disorder and pain disorder have not yet been demonstrated.

Short-term group therapy has been shown in at least two trials to have modest effectiveness for somatizing patients (Kashner et al., 1995; Lidbeck, 1997). These interventions may be difficult to offer in the primary care setting, unless the physician has access to mental health professionals trained in these techniques.

Other treatments have also proved effective. Short-term dynamic psychotherapy has been studied extensively for a variety of somatizing syndromes and appears to be effective in reducing symptom severity and reducing costs. Access to this therapy depends on the availability of a skilled psychotherapist. St. John's wort has been shown to be unambiguously effective for somatizing patients in two randomized, double-blind, placebo-controlled trials (Muller et al., 2004; Volz et al., 2002). Massage therapy should be mentioned as a potential therapy for the somatic patient

KEY TREATMENT

Cognitive-behavioral therapy is effective in the treatment of somatoform disorder (Kroenke, 2007) (SOR: A).
 Antidepressants are effective in treatment of somatoform disorders (Kroenke, 2007) (SOR: A).
 Short-term group therapy has modest effectiveness for somatizing patients (Kashner et al., 1995; Lidbeck, 1997) (SOR: A).
 Short-term dynamic psychotherapy may be effective in reducing symptom severity in somatizing syndromes (Abbass et al., 2004) (SOR: B).
 St. John's wort is effective in somatizing patients (Muller et al., 2004; Volz et al., 2002) (SOR: B).
 Massage therapy is effective against somatoform back pain and other pain syndromes (Cherkin et al., 2001; Owens and Ehrenreich, 1991) (SOR: B).

with musculoskeletal symptoms; it has been shown effective against somatoform back pain and other pain syndromes.

Interventions for Specific Personality Disorders

To utilize specific interventions for each subtype of personality disorders is the art of medicine. A basic specific approach is outlined for each disorder in [Tables 46-1 and 46-2](#). This schema includes choosing the correct DSM-IV-TR cluster; identifying the specific personality diagnosis; understanding the patient's core beliefs, irrational thoughts, specific fears, main defense mechanisms, and coping style; and recognizing common physician reactions to each personality disorder. Using this knowledge, interventions are then tailored for each disorder (see [Table 46-2](#)). This conceptual framework allows the formulation of helpful interventions for the primary care management of specific personality disorders.

Paranoid Personality Disorder

When interacting with a paranoid patient, the physician typically reacts with fear, mistrust, and a sense of danger. The physician may also feel blamed or accused. The patients may have a similar fear of being hurt, exploited, or invaded. Patients often react to suggestions for medical care with mistrust, excessive fault finding, sensitivity to criticism, or hypervigilance. They may collect small insults as proof of the world's injustices. When invasive medical procedures are performed, the paranoid patient may react with full-blown panic and anxiety; many paranoid patients unconsciously experience a body invasion as a homosexual assault. Patients with paranoid personality disorder rely most heavily on projection as their main defense. Using projection, they accuse the physician of hurts that reflect their own aggressive style of hurting others.

A physician working with the paranoid patient needs to empathize with the patient's mistrust and hypersensitivity. The physician should avoid arguing or attempting to reason the patient out of the paranoid worldview. It is extremely important to use confrontations and clarifications to help correct the patient's distorted perceptions about his medical care. Unfortunately, direct confrontation of a delusion or hallucinations (the most troubling deficits in reality testing) often has the paradoxical effect of making these patients more suspicious of the physician.

Acknowledging that the patient's suspicion has an emotional reality can be helpful. Rather than confronting mistrust or suspicions directly, the physician can acknowledge responsibility for any actions that the patient might have perceived as mistakes. For example, the physician could say, "I did not appreciate how it might hurt you when I ordered that lab test." It may also help to express understanding and concern for the patient's rights. If there is a medical need for special testing of which the patient is suspicious, acknowledge the patient's fears, and describe openly and honestly the details of the procedures, potential for pain, and likely risks and benefits. If the patient still refuses to comply, do not use direct persuasion. Ask the patient, "Is it all right with you if we have different opinions?" With the patient's consent to hearing a different opinion, openly discuss the medical necessity of the testing without trying to resolve the problem. At future office visits, attempt new and ongoing discussions of the patient's fears of complying with the request for specialized testing. It may take months for the paranoid patient to trust enough to consent to the appropriate treatment. Counterprojective statements by the physician can diffuse the projections and distortions directed at the physician. The physician can use counterprojective remarks to help the patient access her feelings while focusing angry or suspicious feelings away from the physician toward others who are not present. For example, a physician harassed by an angry, suspicious, or blaming patient could use a counterprojective statement such as, "You felt angry and hurt when the lab technician drew your blood. You must be fearful of the results of these tests."

Schizoid and Schizotypal Personality

Physicians typically feel uninvolved or detached or have a desire to break through the aloofness of schizoid and schizotypal patients. *Schizoid* patients may give the physician the impression that the patient is a loner. A common physician reaction to *schizotypal* patients is a feeling that the patient is alone and "weird or strange." Superficially, patients with either diagnosis fear personal contact, emotional involvement, and invasion of their privacy. At the deepest level, they long for emotional contact that is not overwhelming. They may react to suggestions for medical care with avoidance, withdrawal, apparent emotional detachment, or denial of the medical problem. Schizotypal patients function at a psychotic level, with impaired reality testing manifested by magical, odd, or psychotic modes of thinking. Schizotypal patients use regression to schizoid fantasy and, to a lesser extent, denial as their main defenses. They appear increasingly idiosyncratic and withdrawn when stressed. Schizotypal personality disorder appears to be a significant risk factor for the future development of schizophrenia, although most patients do not go on to develop overt schizophrenia.

Schizoid patients do not appear psychotic or idiosyncratic in their behavior. They are disinterested in intimate contacts with others, appear detached and unemotional, and wish to be left alone. Infrequently, the schizoid personality will also be associated with the future development of schizophrenia. When stressed by a medical problem, schizoid patients will use isolation and intellectualization to hide their emotions. If necessary, they will regress to childlike functioning or use psychotic denial of their illness as their main defenses.

Patients with schizotypal and schizoid personalities tend to experience their physician as intruding into their privacy,

which may drive them away from the physician. They are relieved when the physician is not present and prefer fewer medical appointments and contacts. It is generally helpful to accept their lack of sociability at a level that does not demand involvement or permit total withdrawal. Neutral or unemotional expressions of medical information are most likely to be heard and used.

Antisocial Personality Disorder, Malingering, and Factitious Disorders

Common physician reactions to a patient with antisocial personality disorder are feelings of being used, exploited, or deceived. This can lead to physician anger and wishes to be free of the patient, uncover lies, and punish or imprison the patient. These patients fear that they will become vulnerable, lose respect or admiration from others, and become easy prey to manipulation when they become ill. They expect to be exploited, demeaned, or humiliated. Like the narcissistic patient, they often have low self-esteem, excessive self-love, compensatory feelings of superiority, grandiosity, recklessness, emotional shallowness, and show a lack of concern for others. They often react to medical care with entitled demands for special treatment. When caught in dishonesty, they may angrily attack or devalue the physician. They may resort to other psychopathic manipulations of deception, lying, cheating, or stealing. In fact, their friendly, facile, slick, superficial charm, and intelligent appearance is often beguiling for the physician. They can lose reality testing when stressed by the potential of getting caught in their deceptive practices. This is typically manifested by impulsive actions that reveal severely impaired or sometimes psychotic judgments. When receiving medical care for a legitimate illness, they typically function at the same level and often appear to have the same characteristic issues as the narcissistic personality disorder (Kernberg, 1992). They can often be managed similarly (see Narcissistic Personality Disorder).

To intervene with an antisocial patient, the family physician needs to be alert and anticipate that the patient may be requesting unnecessary medical care or even malingering or presenting a factitious disorder. This patient may be seeking the secondary gain of illegal benefits or money, excuses for work absenteeism, or avoidance of legal problems, or just seeking caretaking. It is important not to collude with the patient's plans for secondary gain inadvertently. For example, if the physician thinks that a patient's request for disability is fraudulent or unwarranted, the patient should not be referred for additional evaluations. If deception is suspected, the physician can ask for verification of symptoms from other reliable sources. There is often dishonesty in a patient's communication in the form of withholding important information, partial truths, or outright lying, cheating, or stealing. If this occurs, avoid the common reaction of moralizing. Instead, grant the patient the reality that he has the ability to fool all the physicians if he wants. The patient can be told that the result of deception is that the physician may make poorly informed medical decisions. This will ultimately result in the patient receiving inadequate or poor medical care. The physician can explore with the patient why he needs to act self-destructively. Patients may need to be reminded that the physician's role is to help with medical problems and not to pass judgment or help the patient obtain unfair medical benefits.

Histrionic Personality Disorder; Conversion or Somatic Symptoms

Patients with histrionic personality disorder have an emotionally expressive style, seek excessive attention, are often dramatic, and may present with a conversion disorder. Physicians may feel flattered, captivated, seduced, or sexually aroused by these patients. Alternatively, the physician may feel overwhelmed by the patient's exaggerated or excessive emotions, embarrassed by the sexual overtures, depleted, or confounded by unexplained physical symptoms, such as pseudoseizures, paralysis, and mutism. These patients may unconsciously use their symptoms to elicit attention or support from the physician (Bornstein and Gold, 2008). They may also use their sexuality to recruit others to satisfy their needs to be taken care of or romantically pursued. They fear that they are not desired and will lose the care or admiration of others.

There are two different levels of functioning with the histrionic personality disorder. Kernberg (1984, 1992) describes a neurotically functioning "hysteric" who shows intact reality testing, defenses centered on repression, and stable and mature relations with others. The female hysteric has a flirtatious, clinging, childlike dependence in intimate relationships but can function at mature levels in social and work situations. Male hysterics have similar psychological conflicts, but may appear as "macho" or "effeminate" (Kernberg, 1992). The hysteric of either sex often reacts to medical care with regression to a childlike, sexualized, dependent, and clinging position. They seek to gratify their wishes for dependent care by seducing or flattering others. Outside the office, they usually function well.

By contrast, the "histrionic patient" (Kernberg, 1984, 1992) can display transient losses of reality testing, defenses centered on splitting, and chaotic sexualized relations with others and a range of unexplained physical or somatic complaints. The histrionic patient is self-centered and self-indulgent, with a pervasive childlike dependence that extends from intimate relationships into all aspects of social and occupational functioning. Female histrionics typically act flirtatiously but may become indignant when a man shows sexual interest. Male histrionics also show the self-centered and dependent pattern, but may also have hypochondriacal and antisocial features. Histrionics of both genders may seek medical care because of unexplained medical symptoms. They may react to medical care with regression but, unlike the hysteric, use defenses centered on "splitting"; they may see the physician as "all good or all bad" and can be extremely devaluing. They may appear severely self-centered, attention seeking, diffusely sexual, hypochondriacal, somatic, and exploitative. All this may be coupled with an exhausting dependency on the physician.

In working with hysterics and histrionic patients, a physician needs to be friendly, not overly warm or reserved. Hysterics and histrionics often are helped when the physician uses parallel inquiry when they present with somatic complaints. Hysterics also may benefit from some gratification of their dependent wishes and a free discussion of their fears and emotions. They can often be reassured by an educational and informational approach to their medical illness and are capable of expressing gratitude to the physician. In contrast, the intense dependency of histrionics is often made worse by

gratifying the patient's needs. Offering excessive emotional care may make them greedy or demanding for satisfaction of their needs. Histrionics benefit from firm, kind limit setting (especially to their sexual overtures), with neutral acknowledgment and gratification of their reasonable needs. They may be further helped by focusing on their distortions in reality perception and through interpretation of their splitting mechanisms.

Borderline Personality Disorder; Somatization Symptoms or Disorder

Borderline patients, many of whom also have somatization disorders, frequently become dependent on their physicians in an extremely demanding, clinging, helpless, or self-destructive manner. Physicians may feel manipulated, angry, depleted, exhausted, or self-doubting. They may want to end the patient relationship or rescue the patient from herself, or they can be drawn into a cycle of extensive medical testing to try and explain many somatic complaints. These patients fear separation or abandonment and may react to potential losses with panic, emotional instability, anger, or impulsive (suicidal or self-destructive) actions. They may seek care and utilize defenses, which appears as a somatization disorder. These somatic symptoms and borderline personality structure often represent the sequelae of childhood abuse, sexual abuse, or other trauma (Kernberg, 1975; Sansone et al., 2001).

Use of parallel inquiry to uncover a history of trauma is often most helpful for the patient complaining of multiple somatic complaints. Borderline patients often react to medical care with an aggressive or dependent clinging to their physician and other caretakers. They may angrily devalue the physician who does not adequately explain their symptoms and may make entitled demands for special treatment when they become worried or frustrated. They tend to relate to others as "all good or all bad," which significantly contributes to their poor life functioning.

Typically, reality testing is intact. However, under stress, borderline patients may temporarily lose reality testing and manifest severe distortions in perceptions or sense of reality. They may misunderstand the physician's intentions or instructions. They may also experience episodes of derealization, depersonalization, or brief psychotic episodes. Borderline patients have *identity diffusion*, extreme fluctuations in self-perception from the grandiose to an excessively harsh underestimation of their abilities. They also have stormy and chaotic relationships with others. They rely heavily on splitting, projective identification, projection, and devaluing.

Office management of borderline patients involves an empathic understanding of their fears. These fears revolve around the threat to their security or fears of separation or abandonment and, secondarily, sensitivity to rejection, or fears of humiliation. They require firm limit setting (e.g., what physician can realistically offer). Attempts to satisfy these patients' intense needs often result in an exhausted or angry physician. This can be avoided by setting realistic limits while offering the patient different ideas or options for medical care, and suggestions of more adaptive behaviors. Initial interventions should attempt to establish reality testing or correct reality distortions. If reality testing is intact, the most helpful interventions can be aimed at attending to medical

care while decreasing the pathologic splitting defenses by using confrontation, clarification, and interpretations of the problematic situation.

The primary treatment for borderline personality disorder is psychotherapy complemented by symptom-targeted pharmacotherapy. Certain types of psychotherapy and medications are effective in the treatment of borderline patients. Most will need extended psychotherapy to attain and maintain lasting improvement in their personality, interpersonal problems, and overall functioning. Pharmacotherapy often has an important adjunctive role, especially for diminution of symptoms such as affective instability, impulsivity, psychotic-like symptoms, and self-destructive behavior (APA, 2001; Soloff, 2008).

Narcissistic Personality Disorder

The family physician's reactions to the narcissistic patient are often difficult to manage. The superior, entitled, self-loving, arrogant attitude of these patients can be intimidating. They may elicit feelings of being devalued and inferior. The physician may have concerns about the patient's anger and criticism. Alternatively, the lack of empathy and interpersonal exploitation of these patients can readily provoke the physician to anger, a wish to retaliate with harsh criticism, or a desire to end the patient-physician relationship.

The core fears of narcissistic patients are the result of a fragile self-esteem and their need for constant approval and praise from others. They fear loss of admiration, potency, and power, and fear being exploited when vulnerable. Any perceived insult to their "grandiose self" (Kernberg, 1984, 1992) makes them feel rejected, deflated, and criticized and frequently results in feelings of rage, shame, or humiliation.

The narcissistic patient has generally intact reality testing, yet can undergo severe reality distortions when he perceives slights, rejection, or competition from others with talent. Those narcissistic patients who have paranoid and antisocial features (Kernberg, 1992) have a worse prognosis. They often have a fragile identity that can swing from the grandiose to the worthless. They rely heavily on splitting mechanisms to regulate their self-esteem. They portray themselves as grandiose and superior. This helps defend against feelings of extreme inadequacy and vulnerability. They can devalue, viciously attack, or degrade those around them when they act in a self-important way. Alternatively, as splitting operates, they may idealize or be envious of others who are, for the moment, seen as more powerful or successful. In this position, their self-esteem plummets, as evidenced by their sense of worthlessness and their reports of deprecating and degrading self-attacks.

Office management of the narcissistic patient, as well as many antisocial patients, requires that the physician not mistake the patient's superior and entitled manner for genuine confidence. When being verbally devaluing, it may help the physician to view the demeaning or verbally attacking patient as a wounded child having a "temper tantrum." This may prevent the physician from retaliating, by demeaning the patient, which only escalates a maladaptive interaction. Intervening in the face of a devaluing attack involves acknowledging that the patient feels hurt and that the patient also has a right to her opinions. If this patient can discuss these hurt feelings with a nonjudgmental and

empathic physician, the problems generally resolve and a good physician-patient alliance can be restored. If this is not possible, offer the patient the right to seek another expert for consultation. This offer needs to be made without malice, defensiveness, or apology. This may help the patient calm down and reconsider his position.

In a long-term relationship with a narcissistic patient, the current splitting can be interpreted. This can be done by reminding patients that they previously praised the skill and abilities of the physician. Patients can be asked why they are now so critical and angry. When this is effective, it will allow patients to discuss their perception of insults to their self-esteem.

Avoidant Personality Disorder and Somatization Disorder

Patients with avoidant personality disorder suffer with feelings of inadequacy and fear of criticism. They have low self-esteem and believe that they are inept and inadequate. They believe that others are critical and disapproving until proved otherwise. Although avoidant patients crave human relationships and affection, their fear of being criticized, rejected, embarrassed, or hurt causes them to initially avoid social situations or meeting new people. Their shyness and avoidance protect them from their fears of being rejected or humiliated. In medical encounters, they often can seek psychosocial help through somatic complaints. This somatic approach of physical complaints can conceal psychological issues and makes them feel safer than revealing unconscious or unexpressed emotions. They prefer not to divulge personal aspects of themselves because this may leave them vulnerable. Their timidity, hypersensitivity, and cautiousness can generate feelings of frustration or annoyance in the physician. Patients with avoidant personality disorder typically use defense mechanisms based on repression, including inhibition, phobia, and isolation.

Managing avoidant patients is more effective when the physician utilizes both parallel inquiry and emotion-focused interviewing. It is most helpful when the physician can recognize and empathize with the patient's social fears, including the fear of the physician. Patients may minimize symptoms or delay seeking help because of fear of the physician or the feeling that they are unworthy or unimportant. Some avoidant patients do the reverse; they can only ask for emotional help through somatic symptoms. The physician should help the patient understand her symptoms and any specific fears revolving around the diagnostic or therapeutic plan. Irrational fears and thoughts can be gently corrected and alternative interpretations offered. Patients should be encouraged, with appropriate support, to face their somatic and other fears as the best way of mastering them. If the physician feels frustration or annoyance, it is often helpful to encourage the patient to describe what he is finding most difficult in the medical care or proposed medical plan.

Dependent Personality Disorder and Somatization Disorder

Patients with dependent personality disorder may be characterized by an exaggerated need for care or a need for direction from another person, or both. Dependent patients may present initially with a physical illness. These initial medical complaints, which often elicit and exaggerated caretaking response from physicians and may introduce into the medical relationship a tendency to return to the physician with increasing

somatic complaints (Bornstein and Gold, 2008). Dependent patients often feel helpless and inadequate in making even minor decisions, such as what to do next medically, what to wear, or whom to befriend. They have a core belief that they cannot function alone, are completely incapable of taking care of themselves, and must have someone else provide care and make decisions. Their major fear is of independence.

Although both borderline patients and dependent patients are extremely dependent on others, they react very differently to the threat of losing a significant other. The borderline patient becomes angry or enraged, whereas the dependent patient becomes submissive and obsequious. Dependent personality disorder patients use defenses that include regression, passive-aggression, and reaction formation.

Patients with dependent personality disorder are submissive and clinging with their caretakers because of fear of losing them. The dependence of these patients can make physicians feel annoyed, drained, or depleted. Physicians may tend to deny reasonable needs of the excessively dependent patient. The secondary gains that dependent personality patients receive from an illness also create extra challenges for the physician. Use of parallel diagnostic inquiry and emotion-focused interviewing is helpful. The physician must understand and empathize with the patient's need for being taken care of while encouraging and fostering independent thinking and action by the patient. Because these patients often use medication, alcohol, food, and other means to satisfy their dependency needs, the physician must exercise caution in how these are used in the therapeutic plan. Unreasonable expectations for being taken care of should be gently discouraged by the physician.

Obsessive-Compulsive Personality Disorder, Hypochondriasis, and Body Dysmorphic Disorders

Patients with obsessive-compulsive personality disorder (OCPD) are preoccupied with details, order, and control. Although their labels are similar, these patients differ in substantial ways from patients with obsessive-compulsive disorder (OCD). OCD patients have recurrent disturbing thoughts or obsessions that create marked subjective distress. Patients with hypochondriasis are obsessed about fear of an illness triggered by somatic sensations. Patients with body dysmorphic syndrome obsess about a bodily defect, such as a malformed nose, which is not readily apparent to an observer. OCD patients may be driven to ritualistic or compulsive behaviors, such as handwashing or checking rituals. Patients with hypochondriasis and body dysmorphic syndromes are often compulsively "doctor shopping." These behaviors help them manage, control, and distract them from intense anxiety.

The core adaptive traits of patients with OCPD are orderliness, attention to detail, and an emphasis on rational thinking and logic. These traits are lifelong patterns that many patients use adaptively in their professional life. Patients with OCPD often view these traits as a personal strength. However, often their attention to detail leads them to perfectionist beliefs, worry, or ruminations that they must not make mistakes or be imperfect. They can interpret rules, regulations, and values rigidly and stubbornly. Patients with OCPD often ruminate and are prone to interpret minor physical changes as worrisome somatic complaints (McGuire and Shore, 2001).

Because they are uncomfortable with feelings and emotions, patients with somatic presentations may be unconsciously

motivated to seek reassurance from their physician. They may fear disorderliness and dirt. The compulsive, critical, controlling, self-righteous side of their personalities often creates difficulty in relationships with co-workers, friends, and family. They can be stingy, orderly, and obstinate. Physicians, who often have obsessive-compulsive traits themselves, may feel irritated and competitive with these patients about who controls the diagnostic workup or treatment plan.

Patients with OCPD use defense mechanisms such as intellectualization, isolation, displacement, doing/undoing, and reaction formation. Using reaction formation, they may behave in a superficially deferential or obsequious manner to repress from themselves and hide from others their critical and self-righteous feelings. These defenses are used against their anger and dependency needs, which are often consciously denied. Illness often represents a dangerous threat to the sense of self-control in OCPD patients. A past illness can lead to a future somatic presentation. The physician should understand and empathize with this loss of self-control while helping the patient regain some control in the management of the problem. Struggle or conflict with the patient over control of medical care should be avoided. Reality distortions, including excessive perfectionism, idealization of logic, and avoidance of feeling, can be gently elicited, explored, and worked through with the patient.

Self-Defeating Personality Disorder

Self-defeating patients are often depressed, suffering, and self-sacrificing. They repeatedly make bad choices that lead to failure or pain. This diagnostic category was eliminated from DSM-IV-TR because of a gender bias (female) and an inability to reach a general agreement for the diagnostic features. However, it is included in this chapter because patients who are self-defeating are frequently seen and present difficult clinical problems for many physicians that still need to be addressed. A common physician reaction to self-defeating patients is an urge to rescue them from their own self-destructiveness. Trying too vigorously to help these patients often results in a worsening of their hypochondriasis or somatic complaints. This often leaves the physician frustrated, angry, defeated, self-doubting, self-blaming, or hopeless; alternatively, the physician may fantasize about the patient suffering or dying. Self-defeating patients are excessively dependent on love,

support, and acceptance from others. They cannot directly express their anger and may be harshly self-judgmental. They fear recovery, which to them means losing love and care. Improvement of their medical condition often leads to the development of new complaints that have no somatic basis.

Mildly self-defeating patients can make the physician feel mildly guilty that the physician is causing pain or suffering or not helping enough. The patient and the physician both suffer. However, these patients ultimately can be helped and can express genuine gratitude toward the physician. The patients with a severe self-defeating personality disorder may passive-aggressively reject the help of their physicians and make the physician feel helpless and responsible for the patients' severe suffering or self-destructiveness.

Physicians can manage self-defeating patients by empathizing with the patient's realistic medical suffering, symptoms, or complaints from the illness. It should not be suggested that the patient's symptoms are psychological or that they will improve or be cured quickly. These optimistic predictions by the physician may paradoxically increase the patient's symptoms, complaints, telephone calls, and office visits. Potential recovery can be presented as a likely but distant reality. If patients cannot permit or admit relief of the symptoms, they can be asked to speak less about their symptoms for the benefit of other family members.

Conclusion

Difficult patients contribute significantly to physician dissatisfaction with medical practice. The result is often poor quality of medical care for this difficult but all too common patient population. Special diagnostic, management, and intervention strategies exist for working with patients who have personality disorders or somatic complaints in the family medicine setting. The schema combines DSM-IV-TR diagnosis and cognitive-behavioral and psychodynamic viewpoints involving the patient's core beliefs and irrational thoughts, fears, defenses and coping style, behaviors, adherence to medical treatment, and use of medical services. Common physician reactions, general strategies, and specific physician interventions are also addressed, to maintain a working physician-patient relationship that permits the delivery of needed medical care.

Overview

Key Points

- Depression and anxiety increase medical morbidity and mortality.
- Mood disorders comprise unipolar and bipolar disorder.
- Anxiety disorders comprise eight disorders, of which generalized anxiety disorder and panic disorder are frequently encountered in primary care settings.
- Treatment of depression and anxiety improves overall health outcomes.
- The majority of mood and anxiety disorders are treated in primary care settings.

Major depression and anxiety disorders are the two most common psychiatric illnesses in the United States and are particularly prevalent in primary care settings. Despite the relative availability of specialty psychiatric care in the United States, most patients with depression or anxiety disorder continue to receive their treatment from primary care physicians. Moreover, patients with both medical illness and comorbid mood or anxiety disorder frequently have poorer outcomes, experience more prolonged and difficult treatment, and have greater morbidity and mortality than patients without psychiatric illness (Katon, 2003). Conversely, treating underlying depressive and anxiety disorders not only improves the emotional well-being of patients, but also improves overall health outcomes and lowers health care costs. Given their frequency, severity, prevalence, morbidity, and

mortality, depression and anxiety disorders remain important illnesses for primary care physicians to identify and treat.

The broader categories of mood and anxiety disorders comprise a large number of specific illnesses. *Mood disorders* include major depression (also called unipolar depression), bipolar disorder (which includes bipolar I and bipolar II disorder), cyclothymia, and dysthymia. The category of *anxiety disorders* includes generalized anxiety disorder (GAD), panic disorder with and without agoraphobia, agoraphobia without a history of panic disorder, specific phobia (e.g., fear of heights), social phobia (social anxiety disorder), obsessive-compulsive disorder (OCD), posttraumatic stress disorder (PTSD), and acute stress disorder. Describing the specific symptoms, epidemiology, assessment, and treatment of each illness is beyond the scope of this chapter; rather, we examine the illnesses that primary care physicians are most likely to encounter in clinical settings, and provide the most common strategies used in assessment, diagnosis, and treatment.

Epidemiology

Key Points

- Major depression and anxiety disorders are the two most common psychiatric illnesses in the United States.
- The economic burden of anxiety and depressive disorders is substantial in terms of workdays lost, disability, health care expenditures, and mortality.

- Anxiety and depression are chronic illnesses that typically run a waxing/waning course.
- Prevalence rates for anxiety disorders appear to decline with advancing age, except for GAD, which may increase in geriatric populations.
- Depression is often a highly recurrent illness; each episode of depression increases the likelihood of future episodes.

Prevalence estimates of mental disorders in the United States continue to find that anxiety and mood disorders are the two most common mental disorders in the general population. Lifetime prevalence for anxiety disorders is estimated at 16.6% to 28.8% (Conway et al., 2006; Kessler et al., 2005a) and for major depression is 14.9% to 16.2% (Kessler et al., 2003). Recent 12-month prevalence rates show a similar stratification, with anxiety disorders most common (18.1%), followed by mood disorders (9.5%). Lifetime prevalence rates of panic disorder and GAD are 4.7% and 5.7%, respectively (Kessler et al., 2005a). Anxiety disorders make up approximately 2% of all office visits to physicians in the United States, but almost 50% occur in primary care settings. In comparison, approximately 40% of patients presenting with anxiety disorders are seen by psychiatrists (Harman et al., 2002).

Major depression remains a common disorder and is associated with substantial symptom severity and role impairment (Kessler et al., 2003). One-year prevalence rates for major depression are approximately 6% in the general population, followed by dysthymia (1.8%) and bipolar disorders (1%-2%). Rates in primary care settings remain substantially higher, with prevalence of 10% or greater (Spitzer et al., 1994), although many of these patients suffer from depressions that are unrecognized by their primary care physician (Schultheis et al., 1999).

Costs

Both anxiety and depressive disorders account for substantial health care costs and thus constitute a major public health and economic concern. Despite an increasing treatment rate of depression in the United States between 1990 and 2000, estimated costs from depression failed to decline and were calculated to be \$83.1 billion in 2000, of which \$26.1 billion were for direct medical costs, \$5.4 billion for suicide mortality costs, and \$51.5 billion for work-related costs (Greenberg et al., 2003). Similarly, estimates from the 1990s placed the annual economic burden of anxiety disorders at \$63.1 billion (in 1998 dollars), of which nonpsychiatric direct medical costs accounted for 54% of the total, and direct psychiatric care accounted for 31% (Greenberg et al., 1999). Not surprisingly, patients with anxiety disorders are much more likely to see their primary care physicians or utilize emergency services. Patients with pure GAD (i.e., no comorbid medical illnesses), for example, were 1.6 times more likely to have seen a primary care physician four or more times in the past year than those without GAD or depression (Wittchen et al., 2002). Patients with panic disorder were almost twice as likely as controls to have visited an emergency room in the previous 6 months (Roy-Byrne et al., 1999).

Disease Course

Both anxiety and depressive disorders tend to run a chronic course, with waxing and waning symptomatology. Illness severity typically worsens the longer the illness remains

untreated. The age of onset for anxiety disorders varies greatly, depending on the specific condition. Specific phobias and separation anxiety, for example, often begin in childhood (median age of onset, 7 years), while panic disorder (median age, 21) and GAD (median age, 31) are typically seen in early to mid-adulthood (Kessler et al., 2005b). In elderly persons (>65 years) the prevalence of all anxiety disorders appears to decline, except for GAD, which is maintained at 4% prevalence and may increase over time (Krasucki et al., 1998). GAD is often a recurring illness in which patients may experience periods of residual symptoms and occasional interepisode remissions (Angst et al., 2009). More than one third of patients with panic disorder have full remission with treatment, but about 20% have an unremitting and chronic course despite treatment (Katschnig and Amering, 1998).

The onset of major depression can occur at any age, although the median age of onset is 30 (Kessler et al., 2005b). Depression is a highly recurrent illness, and each episode increases the likelihood of future episodes. Patients with a single episode have a 50% lifetime chance of recurrence, whereas those with three or more episodes have an almost 100% chance of recurrence without treatment (Eaton et al., 2008). Untreated depressive episodes can last 6 months or longer (Kessler et al., 2003). The Sequenced Treatment Alternatives to Relieve Depression (STAR*D) study found that a substantial number of patients receiving first-line treatment may require 8 weeks or more of treatment to achieve response or remission (Trivedi et al., 2006). Although most patients will recover from their depressive episode and return to normal functioning with treatment, approximately 15% of patients will continue to have an unremitting course, with worsening psychosocial functioning and higher risk for suicide (Eaton et al., 2008).

Neurobiology and Genetics

The neurobiology of both depressive and anxiety disorders is complex and incompletely understood. In contrast to illnesses such as Parkinson's or Huntington's disease, no single area of brain pathology or anatomic lesion has been implicated in the development of anxiety or depression; rather, these illnesses appear to be mediated by dysregulation of complex interactions between neural circuits (Nestler et al., 2002). In depression, most lines of investigation have involved dysregulation of the hypothalamic-pituitary axis (HPA) and hippocampus, along with investigations of neural circuitry mediating mood, reward, sleep, appetite, motivation, and cognition. In particular, hyperactivity of the HPA axis in some depressed patients has been found to lead to hippocampal volume reduction, likely by reduction of brain-derived neurotrophic factor (BDNF) and changes in the mechanisms that mediate BDNF expression. However, whether reduced hippocampal volume is a partial cause or merely a result of depression is currently unclear, and it is not seen in all patients diagnosed with depression. Although epidemiologic studies show that depression appears highly heritable, with some studies showing that 40 to 50% of the risk may be genetic, no one gene appears implicated, and depression likely is the phenotypic expression of multiple genetic vulnerabilities, coupled with environmental stresses (physical/emotional trauma, viral illness), physical factors (e.g., preexisting or comorbid medical illnesses such as

hypothyroidism or stroke), and random processes during brain development (Nestler et al., 2002).

Neurobiologic research in anxiety disorders has focused on elucidating the neural networks involved in the *fear response*, but despite advances in neuroimaging, the exact mechanism of each anxiety disorder has yet to be completely understood. Strategies to understand the neuroanatomic underpinnings of panic disorder have focused on translational research, using conditioned fear in animals as a model for panic attacks in humans. Panic disorder patients may have an especially sensitive fear mechanism involving the central nucleus of the amygdala, the hippocampus, thalamus, hypothalamus, periaqueductal gray region, locus ceruleus, and other brainstem sites (Gorman et al., 2000). Other areas of focus in anxiety disorders have involved investigations into alterations of interoceptive processing of the anterior insula (Mathew et al., 2008). Both the insula and the anterior cingulate cortex (ACC) are thought to be the regions of the brain that form a representation of the visceral state of the body. A heightened sensitivity of this region may underlie the misinterpretation of bodily signals in panic disorder.

Genetic epidemiologic studies have clearly documented that anxiety disorders aggregate in families and that this familial link primarily results from genetic factors (Smoller and Faraone, 2008). First-degree relatives of probands with the major anxiety disorders (panic disorder, social anxiety disorder, specific phobias, OCD) have a fourfold to sixfold increased risk of the index disorders compared to relatives of unaffected probands (Hettema et al., 2001). Genetic studies of GAD suggest that a common genetic susceptibility may apply to “clusters” of anxiety disorders and other comorbid disorders (Norrholm and Ressler, 2009). An overlap of genes may play a role in the development of multiple psychiatric conditions, including anxiety and depression.

Anxiety, Major Depression, and Medical Illnesses

Key Points

- Anxiety disorders and major depression often coexist.
- The more severe the anxiety disorder, the greater is the likelihood of major depression.
- Medical illnesses are associated with higher prevalence of anxiety and depression, and vice versa.
- Medically ill patients with comorbid anxiety or depressive disorders adapt more poorly to physical symptoms, complicating disease management.

Interaction of Depression and Anxiety

Major depression and anxiety are often found together, and each illness complicates the course and outcome of the other. Studies have consistently shown that anxiety disorders are the most frequently occurring comorbid disorder with major depression, with 50% to 60% of major depressed patients with both illnesses (Zimmerman et al., 2002). Anxiety can lead to depression in almost 60% of patients, whereas depression leads to anxiety in only 15% of patients (Mineka et al., 1998). Not surprisingly, the more severe anxiety

disorders are more likely to lead to subsequent depression; that is, panic disorder, agoraphobia, OCD, PTSD and GAD more frequently lead to depression compared to either social phobia or simple phobia. In addition, patients with both illnesses often have increased severity of symptoms, increased frequency of episodes (either mood or anxiety episodes), poorer response to treatment, higher suicide rates, a more chronic course, and overall poorer prognosis.

Treatment is complicated by the fewer studies on coexisting depression and anxiety, providing clinicians with a smaller evidence-base for treatment decisions. Patients with comorbid major depressive disorders are half as likely subsequently to recover from panic disorder with agoraphobia or GAD, and comorbid major depression almost doubles the likelihood of recurrence of panic disorder with agoraphobia (Bruce et al., 2005). In addition, children and adolescents with anxiety disorders are at eight times the risk of additional depression (Angold et al., 1999). Practitioners must therefore be aggressive in screening for anxiety disorders in patients reporting depressive symptoms, as well as screening for depression in patients reporting anxiety symptoms.

Interaction of Depression, Anxiety, and Medical Illness

A complex and reciprocal relationship exists between medical illnesses and comorbid anxiety and depressive disorders. Medical illnesses are associated with higher prevalence rates of anxiety and depression, and anxiety and depression are associated with higher rates of comorbid medical illnesses. Studies of patients with diabetes, cancer, stroke, myocardial infarction, HIV-related illness, and Parkinson’s disease have higher rates of depression compared to patients without such illnesses (Katon, 2003a). Common medical disorders seen in primary care settings have high comorbidity with anxiety disorders as well. Cardiovascular disease is associated with a 1.5 times greater risk of both GAD and panic disorder (Goodwin et al., 2008). Patients with back pain or arthritis are almost twice as likely to have panic attacks or GAD (McWilliams et al., 2004), whereas patients with asthma (pediatric or adult) may have a 30% increased likelihood of anxiety disorders (Katon et al., 2004). The prevalence of anxiety and depression in patients with diabetes is more than double that in the general population (Collins et al., 2009). Almost 100% of patients with irritable bowel syndrome will have major depression, GAD, or panic disorder (Lydiard et al., 1993).

Medical illnesses are associated with a higher risk for mood and anxiety disorders, so the presence of these disorders places patients at higher risk for multiple medical conditions. Patients with GAD or panic disorder are almost six times more likely to have a cardiac disorder, three times more likely to have a gastrointestinal (GI) disorder, twice as likely to have respiratory difficulties, and twice as likely to have migraine headaches compared to patients without anxiety disorders (Harter et al., 2003). Depression may be a predictor for the subsequent development of medical illness. Several studies found an association between history of major depression and subsequent development of type II diabetes (Eaton et al., 1996; Kawakami et al., 1999) and coronary artery disease (Rugulies, 2002).

Management of patients with comorbid medical illness and anxiety or depression is complex. Such patients have

higher rates of unexplained symptoms than patients without these disorders, even after adjusting for the severity of medical illness (Katon and Walker, 1998). An increasing body of literature suggests that patients with medical illness and comorbid depression/anxiety adapt more poorly to chronic symptoms, such as fatigue or pain, and tend to focus on both symptoms of their physical illnesses and physical symptoms associated with other organ symptoms. Not surprisingly, patients with medical illness and comorbid depression have 50% higher medical costs than patients with medical illness alone (Katon, 2003). Comorbid patients are more functionally impaired and have more lost workdays, poorer quality of life, and higher rates of medical utilization (Simon, 2003). Disease management is also complicated by higher rates of nonadherence to treatment and self-care regimens, as well as higher rates of risk behaviors (e.g., smoking, overeating, sedentary lifestyle). Response to antidepressant treatment may be less robust, as evidenced by patients with cardiovascular disease, stroke, and diabetes (Katon, 2003).

Diagnosis and Screening of Mood and Anxiety Disorders

Key Points

- Distinguishing unipolar from bipolar depression is critical for the proper management of depressed patients. The MDQ may aid practitioners in detecting bipolar disorder in primary care settings.
- The PHQ-9 is a common and easy-to-use screening tool for depression.
- No standard screening instrument for anxiety disorders has currently been accepted in general practice.

Diagnosis of Mood Disorders

Mood disorders are divided into depressive disorders, bipolar disorders, and disorders based on etiology (i.e., mood disorders caused by general medical conditions and substance-induced mood disorders). For primary care physicians, identification, treatment, and management of depressive disorders are essential. Bipolar disorders, which are typically more complex to identify and treat, are best referred to mental health professionals for ongoing treatment. Therefore, this chapter concentrates on identifying bipolar disorder and distinguishing between unipolar and bipolar depression, but does not delve into the specifics of treating bipolar patients.

The essential feature of a *major depressive episode* is a period lasting at least 2 weeks during which the patient experiences depressed mood or loss of interest or pleasure in almost all activities, a distinct change in usual self, and clinically significant distress or changes in functioning. It is accompanied by a constellation of other symptoms, such as changes in sleep, eating, energy, motivation, and concentration; difficulty making decisions; and often feelings of hopelessness, worthlessness and guilt (Box 47-1). Patients may ruminate about death, feel that life is not worth living, have thoughts about suicide, may make plans to kill themselves, or make attempts. Many patients complain of memory difficulties, become easily distracted, and describe an inability to

Box 47-1 Diagnostic Criteria for Major Depressive Episode

A. Five (or more) of the following symptoms have been present during the same 2-week period and represent a change from previous functioning; at least one of the symptoms is either (1) depressed mood or (2) loss of interest or pleasure.

Note: Do not include symptoms that are clearly due to a general medical condition, or mood-incongruent delusions or hallucinations.

1. Depressed mood most of the day, nearly every day, as indicated by either subjective report (e.g., feels sad or empty) or observation made by others (e.g., appears tearful). *Note:* In children and adolescents, can be irritable mood.
 2. Markedly diminished interest or pleasure in all, or almost all, activities most of the day, nearly every day (as indicated by either subjective account or observation made by others).
 3. Significant weight loss when not dieting or weight gain (e.g., a change of more than 5% of body weight in a month), or decrease or increase in appetite nearly every day. *Note:* In children, consider failure to make expected weight gains.
 4. Insomnia or hypersomnia nearly every day.
 5. Psychomotor agitation or retardation nearly every day (observable by others, not merely subjective feelings of restlessness or being slowed down).
 6. Fatigue or loss of energy nearly every day.
 7. Feelings of worthlessness or excessive or inappropriate guilt (which may be delusional) nearly every day (not merely self-reproach or guilt about being sick).
 8. Diminished ability to think or concentrate, or indecisiveness, nearly every day (either by subjective account or as observed by others).
 9. Recurrent thoughts of death (not just fear of dying), recurrent suicidal ideation without a specific plan, or a suicide attempt or a specific plan for committing suicide.
- B. The symptoms do not meet criteria for a Mixed Episode.
- C. The symptoms cause clinically significant distress or impairment in social, occupational, or other important areas of functioning.
- D. The symptoms are not due to the direct physiological effects of a substance (e.g., a drug of abuse, a medication) or a general medical condition (e.g., hypothyroidism).
- E. The symptoms are not better accounted for by Bereavement, i.e., after the loss of a loved one, the symptoms persist for longer than 2 months or are characterized by marked functional impairment, morbid preoccupation with worthlessness, suicidal ideation, psychotic symptoms, or psychomotor retardation.

From American Psychiatric Association. Diagnostic and Statistical Manual of Mental Disorders, 4th ed, text revision. Washington, DC, APA, 2000.

think clearly. Patients often pace, wring their hands or have an inability to sit still; conversely, they may become greatly slowed or immobilized. In some patients, irritable mood may predominate more than sadness, or they may have explosive, angry outbursts (Fava and Rosenbaum, 1999). Irritability is especially noted in depressed children and adolescents. In its most severe forms—major depression with psychotic features—patients may hear voices telling them to kill themselves or may develop delusional beliefs, such as having a serious illness despite numerous tests providing no evidence (APA, 2000).

The essential feature of *dysthymia* is a chronically depressed mood that occurs most days for at least 2 years. Patients may have a variety of other symptoms, such as feelings of inadequacy, generalized loss of interest or pleasure, social

withdrawal, feelings of guilt or brooding about the past, and decreased activity, productivity, or effectiveness (Box 47-2). Neurovegetative symptoms such as insomnia or hypersomnia, poor appetite or overeating, low energy, and poor concentration may be present but are less common than in major depressive episodes. These patients may state that they have been depressed for as long as they can remember and cannot recall episodes of recovery or remission of symptoms. In addition, dysthymic patients may periodically have superimposed major depressive episodes, often called “double depression” (APA, 2000).

Bipolar disorder is a chronic mood disorder characterized by the presence of mania (bipolar I disorder) or hypomania and depression (bipolar II disorder). Manic episodes are distinct periods of abnormally and persistent moods that can be euphoric, expansive, or irritable. Although manic patients are often thought to be always euphoric, only about 20% of patients experience pure euphoria; most describe a mix of severe irritability, severe emotional lability, and volatility (Goodwin and Jamison, 2007). Manic patients often have greatly inflated self-esteem, confidence, decreased need for sleep, pressured speech, racing or crowded thoughts, distractibility, increased involvement in goal-directed activities (e.g., starting many projects but being unable to finish any), hypersexuality, and excessive involvement in pleasurable activities with a high potential for painful consequences (APA, 2000). Patients can exert great levels of physical activity, appear tireless, and may become extremely physically agitated. Approximately 60% of bipolar I patients will experience psychosis, which may involve delusions of grandeur (feeling omnipotent, having special powers or “gifts”), persecution, or hallucinations (more often auditory as opposed to visual) (Goodwin and Jamison, 2007). Despite mania being the defining characteristic of the disease, depressed moods tend to predominate, with bipolar I patients experiencing a 3:1 ratio of depression to mania over the course of the illness (Judd et al., 2003).

Primary care physicians are more likely to encounter patients with *bipolar II disorder* than bipolar I disorder. Bipolar II disorder is characterized by hypomanic and major depressive episodes, although over the course of the illness it is primarily a disease of depression, with depressive episodes predominating over hypomanic episodes by a 37:1 ratio (Judd et al., 2003). Symptoms of hypomanic episodes are similar to full manic episodes, but the severity of manic behaviors is attenuated, and the extreme functional, occupational, and social impairment evident in manic episodes is absent in hypomania. Current DSM-IV-TR criteria require that distinct elevations in mood must be present for at least 4 days, must be clearly different from the patient’s usual non-depressed mood, and must be accompanied by a change in the patient’s usual functioning. Because patients primarily seek help during their depressive episodes and typically do not report hypomanic episodes as abnormal, undiagnosed bipolar disorder remains a major difficulty in primary care settings (Manning et al., 1999). Moreover, bipolar disorder may be more common in primary care settings than in general populations. Of 649 patients being treated for depression in a primary care clinic, 21% screened positive for bipolar disorder (Hirschfeld et al., 2005), whereas 10% of patients screened positive for bipolar disorder in a general medical clinic, although 80% of these patients had been diagnosed with unipolar depression (Das et al., 2005).

Box 47-2 Diagnostic Criteria for Dysthymic Disorder

Depressed mood for most of the day, for more days than not, as indicated either by subjective account or observation by others, for at least 2 years.

Note: In children and adolescents, mood can be irritable and duration must be at least 1 year.

- A. Presence, while depressed, of two (or more) of the following:
 1. Poor appetite or overeating
 2. Insomnia or hypersomnia
 3. Low energy or fatigue
 4. Low self-esteem
 5. Poor concentration or difficulty making decisions
 6. Feelings of hopelessness
- B. During the 2-year period (1 year for children or adolescents) of the disturbance, the person has never been without the symptoms in Criteria A and B for more than 2 months at a time.
- C. No Major Depressive Episode (see Criteria for Major Depressive Episode [Box 47-1]) has been present during the first 2 years of the disturbance (1 year for children and adolescents); i.e., the disturbance is not better accounted for by chronic Major Depressive Disorder, or Major Depressive Disorder, In Partial Remission.

Note: There may have been a previous Major Depressive Episode provided there was a full remission (no significant signs or symptoms for 2 months) before development of the Dysthymic Disorder. In addition, after the initial 2 years (1 year in children or adolescents) of Dysthymic Disorder, there may be superimposed episodes of Major Depressive Disorder, in which case both diagnoses may be given when the criteria are met for a Major Depressive Episode.
- D. There has never been a Manic Episode, a Mixed Episode, or a Hypomanic Episode, and criteria have never been met for Cyclothymic Disorder.
- E. The disturbance does not occur exclusively during the course of a chronic Psychotic Disorder, such as Schizophrenia or Delusional Disorder.
- F. The symptoms are not due to the direct physiological effects of a substance (e.g., a drug of abuse, a medication) or a general medical condition (e.g., hypothyroidism).
- G. The symptoms cause clinically significant distress or impairment in social, occupational, or other important areas of functioning.

From American Psychiatric Association. Diagnostic and Statistical Manual of Mental Disorders, 4th ed, text revision. Washington, DC, APA, 2000.

Unipolar Depression vs. Bipolar Depression

Distinguishing unipolar from bipolar depression remains a critical distinction and poses one of the greatest clinical challenges for professionals who treat mood disorders. Misdiagnosis of bipolar disorder can lead to mistreatment (typically with antidepressants alone), worsening of mood, switches into mania or mixed states (i.e., presence of both manic and depressive symptoms), rapid mood swings, worsening psychosocial impairment, greater suicide attempts, and higher mortality (Goldberg and Ernst, 2002; Goldberg and Truman, 2003; Schneck et al., 2008). Treatment of bipolar depression is rarely straightforward and often requires multiple medications and medication trials. Antidepressants do not appear to be especially helpful in the treatment of bipolar disorder, and antidepressants have not yet been shown to improve outcome compared to mood stabilizers alone (Sachs et al., 2007). Although no symptom is pathognomonic for bipolar depression, certain features of depression may suggest that

a patient's depression is a manifestation of bipolar illness. Bipolar depression can present similar to unipolar depression, but some depression features may help distinguish the two (Ghaemi et al., 2004; Perlis et al., 2006) (Table 47-1). If a primary care physician makes a diagnosis of bipolar disorder, the patient is best served by referral to a mental health provider, preferably with expertise in treating mood disorders.

Screening Tools for Depression

Numerous screening measures have been specifically designed to detect depression, and many are sensitive to change over time when used repeatedly at follow-up visits. The integration of such tools into clinical practice, referred to as *measurement-based care*, may enhance care and improve clinical outcome. Measurement tools in the public domain and sensitive to change over time are most practical for primary care physicians because they are a cost-effective way to

manage depressed patients over time (Trivedi et al., 2006). Self-report measures obviate the need for trained office personnel to administer tests. Depression screening measures do not diagnose depression but do provide critical information regarding symptom severity within a given period. Almost all measures have a statistically predetermined cutoff score at which depression symptoms are considered significant. When a depression screen is positive, an interview is necessary because screening will not include many confounding diagnostic variables (e.g., substance abuse, hypothyroidism, bereavement), and physician judgment is required. Screening measures do not address important clinical features of psychiatric illnesses (e.g., total duration of symptoms, degree of impairment) from other comorbid psychiatric conditions.

Patient Health Questionnaire 9

The Patient Health Questionnaire 9 (PHQ-9) is often used in primary care settings because of its ease of use, sensitivity to change over time, reliability, and validity (Kroenke et al., 2001). It uses only the nine depression items from the original self-report version of the PRIME-MD PHQ (Spitzer et al., 1999). Major depression is diagnosed if five or more of the depressive symptoms have been present at least "more than half the days" in the past 2 weeks, and if one of the symptoms is depressed mood or anhedonia. Other depressive syndromes (e.g., minor depression) are diagnosed if two, three, or four depressive symptoms have been present at least "more than half the days" in the past 2 weeks, and if one symptom is depressed mood or anhedonia. One of the nine test items ("thought that you would be better off dead or by hurting yourself in some way") counts if present at all, regardless of duration. Using cutoff scores from 9 to 15, sensitivity ranges from 68% to 95%, with specificity from 84% to 95%. Using the cutoff score of 9, sensitivity is 95% and specificity 84%.

Quick Inventory of Depressive Symptomatology—Self Report (QIDS-SR)

The 16-item Quick Inventory of Depressive Symptomatology Self Report (QIDS-SR₁₆) is an instrument designed to screen for depression and to follow the changes in severity of depression over time (Rush et al., 2006). The QIDS-SR₁₆ is a shortened version of the original 30-item Inventory of Depressive Symptomatology (IDS). The IDS includes criterion symptoms and symptoms typically associated with depression, such as anxiety and irritability, whereas QIDS assesses only the nine symptom domains used to characterize depressive episodes (sad mood, concentration, self-criticism, suicidal ideation, interest, energy/fatigue, sleep disturbance, changes in appetite/weight, presence of psychomotor retardation or retardation). The total score on QIDS ranges from 0 to 27 (0-5, no severity; 6-10, mild; 11-15, moderate; 16-20, severe; 21-27, very severe). The QIDS was effective in assisting management of depression in the STAR*D study, the largest depression trial conducted thus far in the United States (Trivedi et al., 2006).

Screening for Bipolar Disorder

Although no laboratory or imaging tests currently exist to distinguish unipolar depression from bipolar depression, screening questionnaires, as well as certain features of a

Table 47-1 Features Suggesting Bipolar Depression

| Feature | Bipolar | Unipolar |
|---|-------------------|--------------------------------------|
| Substance abuse | Very high | Moderate |
| Family history | Almost uniform | Sometimes |
| Seasonality | Common | Occasional |
| First episode before age 25 years | Very common | Sometimes |
| Postpartum illness | Very common | Sometimes |
| Psychotic features before age 35 | Highly predictive | Uncommon |
| Atypical features | Common | Occasional |
| Rapid on/off pattern | Typical | Unusual |
| Recurrent major depressive episodes (>3) | Common | Unusual |
| Antidepressant-induced mania/hypomania | Predictive | Uncommon |
| Brief episodes (<3 months) | Suggestive | Unusual (duration usually >3 months) |
| Antidepressant tolerance | Suggestive | Uncommon |
| Mixed depression (presence of hypomanic features within depressive episode) | Predictive | Rare |
| Tension, edginess, fearfulness | More common | Less common |
| Somatic symptoms (muscular, respiratory, genitourinary) | Less common | More common |

Modified from Kaye NS. Is your depressed patient bipolar? *J Am Board Fam Pract* 2005;18:271-281; and Perlis RH, Brown E, Baker RW, Nierenberg AA. Clinical features of bipolar depression versus major depressive disorder in large multicenter trials. *Am J Psychiatry* 2006;163:225-231.

patient's history and symptomatology, may prove helpful. The Mood Disorder Questionnaire (MDQ) is a tool that combines DSM-IV criteria and clinical experience to screen for bipolar disorder in primary care settings (Hirschfeld et al., 2000). It is a brief, 1-page self-report questionnaire with 13 yes/no items and two additional questions regarding functioning and timing of mood symptoms, and typically can be completed in 5 minutes or less. Seven or more positive responses to questions about manic symptoms, plus positive responses to the severity of impairment (moderate or severe) and coincident timing of symptoms yields a positive screen. Specificity and sensitivity of the MDQ vary widely by clinical setting, having the best combination of the two when given to patients with suspected mood symptoms (93% specificity; 58% sensitivity) but performs more poorly in general community samples (97% specificity; 28% sensitivity) (Hirschfeld et al., 2003; Hirschfeld et al., 2005). Other screening tools for bipolar disorder do not offer the ease of use and higher reliability and validity of the MDQ.

Diagnosis of Anxiety Disorders

The essential feature of *generalized anxiety disorder* is excessive anxiety and worry about a number of events or activities, occurring most days over 6 months. Patients have difficulty controlling the worry, report subjective distress, and may experience difficulties in social or occupational functioning. The intensity, duration, or frequency of the worry is out of proportion to the actual likelihood or impact of the feared event. Patients must have at least three associated physical symptoms, including restlessness, irritability, muscle tension, disturbed sleep, fatigability, and difficulty concentrating. The list of associated symptoms can be thought of as symptoms of inner tension (restlessness or edginess, irritability, muscle tension) and symptoms associated with the fatiguing effects of chronic anxiety (fatigue, concentration difficulties, sleep disturbance) (Box 47-3).

Panic attacks, a collection of distressing physical, cognitive, and emotional symptoms, may occur in a variety of anxiety disorders, such as specific phobias, social phobias, PTSD, and acute stress disorder. Panic attacks are discrete periods of intense fear in the absence of real danger, accompanied by at least 4 of 13 cognitive and physical symptoms (Box 47-4). The attacks have a sudden onset, build to a peak quickly, and are often accompanied by feelings of doom, imminent danger, and a need to escape. Symptoms of panic attacks can include somatic complaints (e.g., sweating, chills), cardiovascular symptoms (pounding heart, accelerated heart rate, chest pain), neurologic symptoms (trembling, unsteadiness, lightheadedness, paresthesias), GI symptoms (choking sensations, nausea), and pulmonary symptoms (shortness of breath). In addition, patients with panic attacks may worry they are dying, "going crazy," or have the sensation of being detached from reality.

Patients with panic disorder experience recurrent, unexpected panic attacks, followed by at least 1 month of persistent worry that they will suffer another panic attack. Panic disorder patients may begin to avoid places where a prior attack occurred or where help may not be available; such avoidance can lead to the development of agoraphobia and typically worsens their psychosocial functioning (Box 47-5).

Screening Tools for Anxiety Disorders

At present, screening tools for anxiety disorders have been developed to recognize anxiety as a broad syndrome, examining somatic symptoms (racing heart, lightheadedness) or cognitive symptoms (tendency to worry, intensity of worry). Other tools have been used to screen for single, distinct disorders, such as phobias or panic disorder. To date, no clear screening tool or symptom-severity measure has emerged for use in primary care settings, although newer instruments may be useful for primary care physicians. The Generalized Anxiety Disorder 7 (GAD-7) scale was developed and validated

Box 47-3 Diagnostic Criteria for Generalized Anxiety Disorder

Excessive anxiety and worry (apprehensive expectation), occurring more days than not for at least 6 months, about a number of events or activities.

- A. The person finds it difficult to control the worry.
- B. The anxiety and worry are associated with three (or more) of the following six symptoms:
 1. Restlessness and feeling keyed up or on edge
 2. Being easily fatigued
 3. Difficulty concentrating or mind going blank
 4. Irritability
 5. Muscle tension
 6. Sleep disturbance
- C. The focus of the anxiety and worry is not confined to features of an Axis I disorder, e.g., the anxiety or worry is not about having a Panic Attack.
- D. The anxiety, worry, or physical symptoms cause clinically significant distress or impairment in social, occupational, or other important areas of functioning.
- E. The disturbance is not due to the direct physiological effects of a substance or a general medical condition.

From American Psychiatric Association. Diagnostic and Statistical Manual of Mental Disorders, 4th ed, text revision. Washington, DC, APA, 2000.

Box 47-4 Diagnostic Criteria for Panic Attack

A discrete period of intense fear or discomfort, in which four (or more) of the following symptoms developed abruptly and reached a peak within 10 minutes:

1. Palpitations, pounding heart, or accelerated heart rate
2. Sweating
3. Trembling or shaking
4. Sensations of shortness of breath or smothering
5. Feeling of choking
6. Chest pain or discomfort
7. Nausea or abdominal distress
8. Feeling dizzy, unsteady, lightheaded, or faint
9. Derealization (feelings of unreality) or depersonalization (being detached from oneself)
10. Fear of losing control or going crazy
11. Fear of dying
12. Paresthesias (numbness or tingling sensations)
13. Chills or hot flushes

From the American Psychiatric Association. Diagnostic and Statistical Manual of Mental Disorders, 4th ed, text revision. Washington, DC, APA, 2000.

Box 47-5 Diagnostic Criteria for Panic Disorder without Agoraphobia

- A. Both (1) and (2):
 1. Recurrent and unexpected panic attacks
 2. At least one of the attacks has been followed by 1 month (or more) of one (or more) of the following:
 - (a) Persistent concern having additional attacks
 - (b) Worry about the implications of the attack or its consequences (e.g., losing control, having a heart attack, “going crazy”)
 - (c) A significant change in behavior related to the attacks
- B. Absence of Agoraphobia.
- C. The Panic Attacks are not due to the direct physiological effects of a substance or a general medical condition.
- D. The Panic Attacks are not better accounted for by another mental disorder.

From the American Psychiatric Association: Diagnostic and Statistical Manual of Mental Disorders, 4th ed, text revision. Washington, DC, APA, 2000.

in primary care clinics and is a brief, seven-item self-report screening tool for GAD (Spitzer et al., 2006). The GAD-7 helps identify probable cases of GAD and measure symptom severity. A score of 10 or greater represents a reasonable cut-off point for identifying patients with GAD, and cutoffs of 5, 10, and 15 correlate to mild, moderate, and severe levels of anxiety. An extended version of the PHQ includes five questions for panic disorder (Spitzer et al., 1999), but its utility as a stand-alone tool is currently unclear. The Overall Anxiety Severity and Impairment Scale (OASIS) is a five-item continuous measure that can be used across anxiety disorders, with multiple anxiety disorders, and with subthreshold anxiety symptoms. OASIS can be used to measure the severity of anxiety symptoms, but it was not developed as a diagnostic tool for any specific disorder (Norman et al., 2006).

Assessment of the Depressed or Anxious Patient in Medical Settings

Key Points

- Patients with anxiety and depressive disorders often present with somatic complaints.
- Risk assessment includes identifying modifiable risk factors and developing a corresponding treatment plan.
- “Contracts for safety” have no empiric data to support their effectiveness in risk management.
- Worsening symptoms or suicidal ideation may require psychiatric hospitalization.

Diagnosing anxiety and depressive disorders may prove especially challenging in medical settings. The majority of patients suffering from such illnesses will more frequently present with somatic complaints, while only a minority will present with purely psychological symptoms and concerns (Bridges and Goldberg, 1985). Difficulties in diagnosis may be secondary to a patient’s inability to articulate psychological problems, reticence to speak of emotional difficulties, the

short time allowed for patient visits, or a primary care physician’s relative lack of training in assessing and treating mental health disorders. Many presenting complaints may be consistent with symptoms of coexisting medical illnesses, further complicating assessment and likely requiring additional etiologic investigation. Of new patients presenting to an urban clinic, for example, only 17% presented with purely psychological symptoms. Of the remaining patients, 32% presented with pure somatization, 27% presented with symptoms for a coexisting medical illness, and 24% presented with an initial physical complaint that they were later able to relate to a psychological problem (Bridges and Goldberg, 1985). However, clinical clues in patients with physical complaints may identify a subgroup of patients who warrant further evaluation for an anxiety or depressive disorder. This includes patients who present with multiple physical symptoms (six or more), have higher ratings of symptom severity and lower ratings of overall health, and have an encounter that the physician perceives as “difficult” (Kroenke et al., 1997).

Assessment of anxious or depressed patients requires establishing specific psychiatric diagnosis(es), providing a thorough risk assessment (i.e., suicidality, homicidality, ability or inability to care for self), assessing the severity of the illness, identifying specific target symptoms to track over time, assessing factors that are likely complicating or exacerbating the illness (e.g. medical disorders, substance abuse), and gathering collateral information whenever possible from family, friends, or other providers (Box 47-6). Distinguishing bipolar from unipolar depression, as discussed previously, is one of the most important distinctions when establishing diagnosis. In addition, clinicians should look for the presence of comorbid anxiety disorders, because patients with such disorders often require lower initial antidepressant dosing and may have their anxiety symptoms paradoxically worsen as treatment is initiated unless lower doses are used (Table 47-2). Education on the medical nature of depression and anxiety may prove extremely helpful, because both patients and families often believe that psychiatric illness is evidence of “weakness” or indicative of some other personal failing. Information on prognosis and the expected treatment course may lessen pressure and expectations for rapid improvement and let the patient know when to expect medication benefit.

Physicians should assess the severity of illness and develop a list of target symptoms to track and measure over time, to better evaluate treatment response. Tracking specific symptoms particular to an individual patient’s depression improves objective assessment of change. Often, patients’ neurovegetative symptoms will improve before the subjective experience of their mood improving. Assessing sleep, appetite, energy level, anxiety, and concentration allows the physician to select a more appropriate antidepressant or anxiolytic by targeting specific symptoms. This may include using a sedating antidepressant such as mirtazapine for patients with insomnia or a more activating antidepressant such as bupropion for patients with lethargy or somnolence. Measurement tools that are symptom specific and sensitive to change over time (e.g., PHQ-9, QIDS-SR) may help the physician track such changes. In addition, assessing overall functionality (ability to shower, pay bills, shop, prepare meals) is equally important in establishing the degree of impairment caused by the patient’s mood disorder.

Box 47-6 Initial Assessment of Anxious or Depressed Patients

1. Establish diagnosis.
2. Perform risk assessment.
 - Suicide risk
 - Risks to others
3. Establish severity of illness.
 - Ability to care for self
 - Functioning/functional impairment
4. Identify specific target symptoms.
 - Neurovegetative symptoms (e.g., sleep, appetite, concentration)
 - Use of measurement scales (e.g., QIDS)
5. Assess factors complicating illness.
 - Alcohol or /drug use
 - Comorbid or contributing medical conditions
6. Gather input from family and friends if possible.

Table 47-2 Dosing for Common Antidepressant and Antianxiety Agents

| Medication | Usual Daily Starting Dose (mg) | | Daily Dose Range |
|---|--------------------------------|------------|------------------|
| | Anxiety | Depression | |
| Selective Serotonin Reuptake Inhibitors (SSRIs) | | | |
| Citalopram | 10 | 20 | 10-60 |
| Escitalopram | 5 | 10 | 5-30 |
| Fluoxetine | 10 | 20 | 20-80 |
| Fluvoxamine | 25 | 50 | 100-300 |
| Paroxetine | 10 | 20 | 20-60 |
| Sertraline | 25 | 50 | 50-200 |
| Serotonin-Norepinephrine Reuptake Inhibitors (SNRIs) | | | |
| Desvenlafaxine | 50 | 50 | 50-100 |
| Duloxetine | 30 | 30 | 30-120 |
| Venlafaxine | 37.5 | 75 | 150-300 |
| Tricyclic Antidepressants (TCAs) | | | |
| Amitriptyline | 25 | 50 | 100-300 |
| Imipramine | 25 | 50 | 100-300 |
| Nortriptyline | 10 | 25 | 50-200 |
| Desipramine | 25 | 50 | 100-300 |
| Norepinephrine-Dopamine Reuptake Inhibitors | | | |
| Bupropion | — | 150 | 300-450 |
| Norepinephrine-Serotonin Modulators | | | |
| Mirtazapine | 15 | 30 | 30-60 |

Differential Diagnosis

Many medical conditions may cause or mimic depression. Physical disorders that have been associated with depression include Addison's disease, acquired immunodeficiency syndrome (AIDS), coronary artery disease (especially in those with myocardial infarction), cancer, multiple sclerosis, Parkinson's disease, anemia, diabetes, acute infection, temporal arteritis, hypothyroidism, and especially dementias. It is imperative that the physician complete a neurologic evaluation to rule out an underlying disorder as the cause of the patient's depression. In addition, many medications may worsen depression, especially cardiovascular drugs, hormones, typical antipsychotic agents, anti-inflammatory agents, and anticonvulsants.

Anxiety disorders may be caused or exacerbated by medical conditions, medications taken for other psychiatric or medical disorders, and other substances with stimulant properties. For example, hyperthyroidism can mimic or exacerbate anxiety disorders, and therefore thyroid function should be carefully evaluated when patients present with anxiety symptoms. In addition, lifetime risk of thyroid dysfunction appears higher in patients with panic disorder or GAD (Simon et al., 2002). Physicians should also assess the patient's use of other medications, especially stimulants (whether prescribed or obtained from other sources), nicotine, illicit drugs, and caffeine.

Suicide Screening and Assessment

Identifying patients at risk for suicide is a complex and difficult task, particularly in the setting of a busy medical practice. Suicide is currently the 11th leading cause of death for all ages and accounts for approximately 32,000 deaths annually in the United States (CDC, 2009). It is the second leading cause of death in those 25 to 34 years old and the third leading cause in those 15 to 24. Older males 75 and older have the highest suicide rate, at 37.4 per 100,000. Males continue to take their lives at approximately four times the rate of females and account for almost 80% of all U.S. suicides. Women in their 40s and 50s have the highest rates of suicide among females (8 per 100,000), and women continue to make suicide attempts two to three times more often than men (Krug et al., 2002). Approximately 60% of all suicides are associated with patients with mood disorders, and approximately 50% of patients who completed suicide had contact with professional help in the month before their death (Isometsa et al., 1995).

Despite no definitive suicide assessment tool being available, risk factors have been defined that can help identify patients at risk for suicide. Suicide screening should include assessing current level of depression, severity of symptoms, feelings of hopelessness; current suicidal thoughts and behaviors (as well as past attempts), use of drugs or alcohol (which can increase levels of impulsivity and worsen dysphoria), current levels of anxiety and agitation, access to lethal means (especially firearms), presence of psychosis (command hallucinations, poor reality testing), recent acute stressors, and presence (or absence) of a psychosocial support system (APA, 2003). When possible, additional information from family or friends can be helpful in assessing statements or behaviors that may indicate a patient's intentions of committing suicide.

Physicians should be alert to those suicide risk factors that can be modified. Although numerous historical and biologic risk factors cannot be modified (history of suicide attempts, family history of suicide, male gender, history of childhood trauma), other risk factors are amenable to intervention. Mood, anxiety, and psychotic symptoms can be successfully treated with medications. Substance abuse referral may help the patient actively struggling with substance abuse or dependence, or for relapse prevention. Encouraging the patient to mobilize psychosocial resources, such as contacting family members for support, can provide a measure of safety while the patient is recovering from depression. Removing access to firearms can be especially helpful in preventing rapid access to lethal means during episodes of acute distress and high levels of impulsivity. Physicians should be aware that “contracts for safety” have not been shown to be effective in preventing suicide and may provide a false sense of patient safety (Rudd et al., 2006). Continued assessment of mood, hopelessness, and suicidal ideation is required throughout the course of treatment. Worsening symptoms, along with plans or active preparations for suicide, may require increased observation or hospitalization.

Management and Treatment of Major Depression and Anxiety Disorders

The key objective in treating depressive and anxiety disorders is remission of all symptoms. Studies in the treatment of major depression have consistently shown that lack of remission is associated with higher relapse rates, more severe subsequent depressions, shorter duration between episodes, continued impairment in work settings and social relationships, increased all-cause mortality, and increased risk of suicide (Judd et al., 2000). Initiation of treatment should include education about the expected temporal course of improvement; importance of regular eating, activity, social interaction, and sleep; medication selection; follow-up schedule; and safety management if symptoms worsen or suicidal ideation is evident (Box 47-7).

Box 47-7 Initiation of Treatment for Major Depression and Anxiety Disorders

1. Educate the patient.
 - Details of illness
 - Treatment course, prognosis, goal of treatment (remission of symptoms)
 - Importance of general health: exercise, sleep hygiene, nutrition
 - Inclusion of family when possible
 - Coordination with other providers
 - Resource lists for support groups, therapy referrals
2. Select medication from reasonable choices.
 - Patient history of antidepressant use/response
 - Family history of antidepressant response
 - Typical time course to antidepressant response
3. Administer starting dose, and initiate dose titration.
 - Common side effects of medications
4. Establish monitoring with measurement-based care (e.g., QIDS).
5. Schedule follow-up in 2 to 4 weeks.

Depression

Pharmacotherapy remains the mainstay treatment of depression. Treatment should be considered for the majority of depressed patients, especially those who are suicidal, functionally impaired from their depression, or experiencing a recurrent episode, or who have comorbid medical or psychiatric conditions likely to worsen unless their depression is treated (e.g., panic, GAD, chronic pain). Treatment of depression has clearly been shown to prevent relapse, shorten current episodes, decrease psychosocial impairment, decrease risk of suicide, and improve quality of life. Mild depression may be treated with symptomatic intervention alone (e.g., mild sedative for insomnia), although continuing depressive symptoms or inadequate response to purely symptomatic interventions warrants more aggressive treatment of the underlying depression. Patients with psychotic depression typically require treatment with both antidepressant and antipsychotic agents, or they may require electroconvulsive therapy (ECT). Often, psychotically depressed patients require hospitalization. Patients with psychotic depression should be referred to a psychiatrist, given the severity of illness and complexity of treatment.

Again, the aim of treatment is remission of all depressive symptoms and a return to the patient's previous baseline functioning. Pharmacotherapy combined with psychotherapy has been shown to be superior to either modality alone (de Maat et al., 2008; Thase, 1997); thus referral to a psychotherapist may be helpful, especially for patients with moderate to severe depression. Some patients may choose psychotherapy alone to treat depression; cognitive-behavioral therapy, interpersonal therapy, behavioral activation, and psychodynamic therapy may prove as effective as medication alone.

Selection of Medication

The effectiveness of antidepressants is generally comparable across classes, and therefore selection of an antidepressant depends mainly on patient preference, side effect profile, drug interactions, previous response to a specific medication, treatment overlap with other psychiatric conditions, and cost (Tables 47-3 and 47-4). Minimal data support the increased efficacy or speed of onset for any particular agent, with response rates across clinical trials generally 50% to 75% for patients receiving active treatment. Onset of improvement typically takes 3 to 6 weeks, although the STAR*D study indicates that patients may require up to 12 to 14 weeks to achieve remission of symptoms. In fact, 40% of patients in the multiyear, multisite STAR*D study who eventually achieved remission in the first level of treatment with citalopram did not show a response (i.e., 50% improvement in symptoms) until week 8 of treatment (Trivedi et al., 2006).

For most patients, initial treatment with a selective serotonin reuptake inhibitor (SSRI), serotonin-norepinephrine reuptake inhibitor (SNRI), bupropion, or mirtazapine is reasonable. Tricyclic antidepressants (TCAs) are more often used as second-line agents in the treatment of depression because of their potential toxicity in overdose, greater side effect burden (largely from anticholinergic, antihistaminic, and antiadrenergic properties), and potential cardiac complications (conduction delays). Monoamine oxidase

inhibitors (MAOIs) are complex drugs to use given their potentially fatal drug and dietary interactions and probably should not be prescribed in family practice settings. Most antidepressant studies have been conducted in specialty settings, but a number of studies in primary care settings have also shown the superiority of antidepressants over placebo (Arroll et al., 2009). Thus, given the comparable speed and efficacy of antidepressants across classes and within classes, selection of an antidepressant agent may be primarily guided by side effect profile, possible secondary uses of antidepressants (e.g., treating pain or insomnia), and contraindications to particular agents (e.g., bupropion in seizure disorder patients). Table 47-2 gives the usual starting doses for treatment of major depression.

Serotonin reuptake inhibitors are safe, effective medications that can treat a variety of psychiatric conditions. All SSRIs operate by the same mechanism of action and are considered equally effective in the treatment of depression. However, failure of one SSRI does not necessarily imply failure of all SSRIs; patients may respond preferentially to one SSRI over another (Rush et al., 2006). SSRIs differ substantially by their potential to inhibit particular hepatic cytochrome P-450 metabolic pathways, by half-life, potency, and presence or absence of active metabolites. Clinicians should

check for drug interactions in patients receiving complex polypharmacy regimens, because drug-drug interactions are constantly being updated and changing. For example, fluoxetine is a potent 2D6 inhibitor that can triple TCA and phenytoin levels or increase the anticoagulation associated with warfarin. Fluoxetine also has the longest half-life of any SSRI; its active metabolite norfluoxetine has a half-life of 10 days. SSRIs have sexual side effects (decreased libido, delayed orgasm or anorgasmia) and GI side effects (nausea, diarrhea) (see Table 47-4). GI side effects likely will remit over time, but sexual effects typically do not attenuate and may require treatment with other agents, such as a phosphodiesterase inhibitor (e.g., sildenafil), or choosing an antidepressant less likely to cause sexual side effects.

Serotonin-norepinephrine reuptake inhibitors (venlafaxine, duloxetine, desvenlafaxine) are similar in efficacy to SSRIs, although a few studies have suggested a mild advantage of SNRIs over SSRIs (Thase et al., 2001). Although SNRIs by definition inhibit the reuptake of both serotonin and norepinephrine, dual-neurotransmitter reuptake inhibition does not occur with venlafaxine until doses reach approximately 150 mg daily; below this dose, it acts primarily as an SSRI. Venlafaxine is available in immediate-release and extended-release (XR) formulations, although most patients

Table 47-4 Common Side Effects of Antidepressant Medications

| Class/Drug | Side Effects | Comments |
|--|---|---|
| Selective serotonin reuptake inhibitor (SSRI) | Gastrointestinal side effects (nausea, diarrhea, heartburn); sexual dysfunction (decreased libido, delayed orgasm); headache; insomnia/somnolence | Likely little difference between SSRIs in rates of sexual side effects. SSRIs have been used to treat premature ejaculation. |
| Serotonin-norepinephrine reuptake inhibitor (SNRI) | Hypertension, sweating, nausea, constipation, dizziness, sexual dysfunction | Risk of increased blood pressure escalates as dose is increased; abrupt withdrawal of venlafaxine may cause discontinuation syndrome. |
| Tricyclic antidepressant (TCA) | Dry mouth, constipation, blurry vision, orthostatic hypotension, weight gain, somnolence, headache, sweating, sexual dysfunction | Use with caution in patients with cardiac conduction delays. |
| Bupropion | Insomnia, dry mouth, tremor, headache, nausea, constipation, dizziness | Contraindicated in patients with seizure disorders or eating disorders; patients generally free of sexual side effects. |
| Mirtazapine | Somnolence, increased appetite, and weight gain, dry mouth | Sedation may be more pronounced at lower doses. |
| Trazodone | Sedation, orthostatic hypotension, priapism | Usually used as a sedative-hypnotic. |
| Benzodiazepines | Sedation, fatigue, ataxia, slurred speech, memory impairment, weakness | Risk of dependence or abuse, especially with shorter-acting benzodiazepines. |

and clinicians favor use of the XR preparation, given its once-daily dosing and lower likelihood of provoking a withdrawal syndrome on discontinuation of the drug, more frequently observed with the immediate-release formulation. Desvenlafaxine, the active metabolite of venlafaxine, is more potent than its parent compound, but any advantages over venlafaxine are currently unclear. Unlike venlafaxine, duloxetine provides dual-neurotransmitter reuptake inhibition at any dose, although this does not appear to confer any advantage over other SNRIs in terms of efficacy or side effect profile. Duloxetine currently is indicated for treatment of chronic pain as well as depression, but this is likely a class effect of SNRIs and not unique to duloxetine. Side effects are similar to SSRIs (see Table 47-4), with the additional side effects with SNRIs likely caused by increased noradrenergic activity,

including dose-related hypertension, excessive sweating, and dry mouth (Thase, 2008a; Thase et al., 2005).

Mirtazapine is a serotonin-norepinephrine modulator that also blocks postsynaptic hydroxytryptamine (HT) receptors, including those in the 5-HT-3 (serotonin) class. Mirtazapine is sedating and can increase appetite and therefore may be favored when patients have insomnia or decreased appetite and weight loss. Because of a dose-dependent ratio of neurotransmitter blockade involving histamine receptors, mirtazapine is generally more sedating at lower doses than higher. Although currently indicated only for depression, mirtazapine is reported to have general anxiolytic effects and may be beneficial for patients with mild to moderate anxiety. With its 5-HT-3 blockade, mirtazapine may be helpful when patients complain of nausea or other GI symptoms or side effects from SSRIs. Mirtazapine also has fewer sexual side effects than SSRIs or SNRIs, and has been tried as an antidote to SSRI-induced sexual side effects. Common side effects from mirtazapine include weight gain and daytime somnolence (see Table 47-4).

Bupropion is pharmacologically unique among antidepressants and is manufactured in immediate-release, slow-release (SR), and XR formulations. Although its primary mechanism of action is unclear, the drug has weak norepinephrine and dopamine reuptake inhibition. Bupropion is an activating drug, making it better suited for patients with poor energy or who feel they cannot tolerate a sedating medication. It is also virtually free from sexual side effects and has been used with limited success as an antidote for patients with SSRI-induced sexual side effects (Clayton et al., 2004). Bupropion rarely causes weight gain and is therefore a good choice for patients who are obese or who feel they cannot tolerate weight gain. Unlike SSRIs, SNRIs and TCAs, bupropion does not treat anxiety disorders and may even worsen anxiety in patients because of its activating properties. Bupropion carries a black-box warning against its use in patients with a history of seizures or eating disorders; the latter group was shown to have a higher incidence of seizures in clinical trials. Given its greater propensity for seizures, bupropion dosing should not be pushed above the FDA-recommended dosing limits. Bupropion has also been approved for treatment of smoking cessation and therefore may have particular utility for depressed patients who also want to quit smoking.

Tricyclic antidepressants are effective medications for treating depression and anxiety, with evidence of being more effective than SSRIs for severe depression, but TCAs confer a greater side effect burden than newer antidepressants and can be fatal in overdose. TCAs are divided into tertiary and secondary amines. Tertiary amines, such as amitriptyline and imipramine, have greater anticholinergic, antihistaminic and α -adrenergic blockade side effects than secondary amines, such as their respective metabolites nortriptyline and desipramine. TCAs offer an advantage over other antidepressants in that blood levels can readily be checked and dosing individualized. Reasonable evidence suggests TCAs may be more effective in severely depressed patients (Agency for Health Care Policy Research, 1999). In addition, nortriptyline has a therapeutic window, with superior antidepressant efficacy if levels are maintained at 50 to 150 ng/mL. Because of cardiac conduction side effects, however, TCAs must be used with caution in patients with conduction delays or who are taking class I antiarrhythmic agents, and electrocardiograms

(ECGs) should be checked and monitored in patients older than 50 or those with suspected cardiac disease. TCAs also may cause tachycardia and orthostatic hypotension and thus should be used with caution in patients at risk for tachyarrhythmias or falls. The greatest single disadvantage to TCAs is their potential lethality in overdose; a typical 10-day supply can be lethal, and therefore TCAs should be prescribed cautiously in patients at high risk for suicide. TCAs are also used in a variety of headache and pain syndromes and thus may be useful in patients with such comorbidities.

Trazodone is structurally distinct from SSRIs, TCAs, tetracyclics or MAOIs, but it still inhibits neuronal uptake of serotonin. Although the U.S. Food and Drug Administration (FDA) has approved it as an antidepressant, trazodone is most often used as a sedative-hypnotic. Dosing as an antidepressant is usually 300 to 450 mg, whereas sedative-hypnotic dosing is usually 50 to 150 mg. Risks and side effects of trazodone include sedation, priapism, and myocardial irritability; the latter effect includes the potential of inducing torsades de pointes.

KEY TREATMENT

All antidepressants are generally equally effective; selection is most often based on side effect profile, previous response, comorbid conditions, drug interactions, and cost (Arroll et al., 2009; Trivedi et al., 2006) (SOR: A).
SSRIs, SNRIs, mirtazapine, and bupropion are first-line treatments for depression (Rush et al., 2006) (SOR: A).
Antidepressant doses should be increased every 2 to 4 weeks until remission of depressive symptoms is achieved or side effects become intolerable (SOR: A).
Treatment of depressive episodes ranges from 6 to 9 months to years, depending on the number of prior episodes, severity of episodes, and risk of relapse (AHCPR, 1999; Geddes et al., 2003) (SOR: A).
Psychotherapy has proved effective in treating depression, either as monotherapy or combined with pharmacotherapy (de Maat et al., 2008; Thase, 1997) (SOR: A).

Initiation of Treatment

Once a patient has been initiated on an antidepressant, dosing should be optimized to treat depressive symptoms to remission while minimizing side effects (Box 47-8). Patients should be monitored for improvement in their mood and their specific array of depressive symptoms. Continued use of measurement-based care tools, such as the PHQ-9 or QIDS, can aid in the objective assessment of improvement. Patients should be followed more frequently on initiation of treatment, increasing time between appointments as the patient improves. Monitoring for side effects, particularly those that patients may be reluctant to bring up spontaneously, such as sexual side effects, can improve adherence and the therapeutic alliance. Patients should also be monitored for any worsening of mood, increased irritability, impulsivity, insomnia, sudden switches into euphoria, or suicidal ideation. Such symptoms may suggest *bipolar diathesis*, in which case discontinuing the antidepressant and changing to mood stabilizing agents may be indicated. Antidepressant doses should be increased every 2 to 4 weeks until the patient shows a response, maximum dose is reached, or side effects limit further dose changes. Antidepressant doses should

Box 47-8 Assessing Antidepressant Treatment

1. Monitor effectiveness of treatment.
2. Continue assessment of specific symptoms.
3. Assess need for further titration of medication.
4. Continue to use measurement-based care.
5. Assess any worsening of mood, increased irritability, or worsening suicidal ideation.
6. Assess adherence to medication regimen.
7. Assess for medication side effects.
8. Continue to emphasize nutrition, physical activity, and caring for self.
9. Minimize complexity of medication dosing (e.g., once daily or nightly, when possible).

Box 47-9 Discontinuation of Antidepressant Treatment

Remission of symptoms for 6-12 months.
Tapering of medications rather than abrupt cessation.
Discussion of relapse risks and early warning signs of recurrence.

continue to be pushed until remission is achieved, or the patient has undergone an adequate antidepressant trial, i.e., continuation of a therapeutic dose for at least 4 to 8 weeks (Nierenberg et al., 2000).

Continuation of Treatment

As noted, physicians are encouraged to push treatment until symptoms remit, maximum doses are achieved, or side effects become intolerable. Once symptoms remit, medications should continue for 6 to 9 months because risk of relapse is greater if patients discontinue medications prematurely (AHCPR, 1999; Geddes et al., 2003). Patients who have had multiple episodes of depression should continue pharmacotherapy because lifetime relapse rates for such patients are 50% to 85% (Eaton et al., 2008), and risk of recurrence increases by 16% with each successive episode (Solomon et al., 2000). Ongoing treatment should also be considered for patients who experienced severe functional impairment, severe suicidal ideation, or serious suicide attempts.

Discontinuation of Treatment

For patients who have achieved ongoing remission and want to discontinue their medications, withdrawal of treatment should be gradual and carefully monitored (Box 47-9). Timing of discontinuation often depends on a patient's current life stressors and the potential consequences of depressive relapse (e.g., loss of new job, stress on recently repaired relationship). Antidepressants should be gradually withdrawn to minimize potential withdrawal syndromes and allow for rapid upward titration should depressive symptoms recur. Physicians should discuss early warning signs of relapse (insomnia, early-morning awakening, loss of interest in activities) and instruct patients to contact the physician should such symptoms recur. Risk of relapse is greatest in the first few months of discontinuing antidepressants, and thus a scheduled appointment in this period is often needed to

monitor for relapse. Patients who relapse after cessation of antidepressants should be restarted on their previous medication and again titrated to remission of symptoms.

Antidepressant Failure

Patients who fail antidepressants should be carefully reevaluated, with reconsideration of medication adherence, adequacy of dosing and treatment duration, diagnosis, comorbid psychiatric illnesses, increased stressors, and unaddressed medical or substance comorbidities. Initial antidepressant failure may be relatively common; only one third of patients achieved remission after 12 to 14 weeks of treatment with citalopram in the STAR*D study (Trivedi et al., 2006). If a patient fails an adequate antidepressant trial, the next strategy is (1) switching to a different antidepressant, within the same class or across classes; (2) augmenting the existing antidepressant with a secondary agent; or (3) adding a second antidepressant to the first. Choice of strategy depends on patient preference, assessment of benefit from current antidepressant, current side effects, and psychiatric and medical comorbidities.

Switching antidepressants is generally considered when the patient has had little to no response to the first agent or is having intolerable side effects. Across-class switches are most often considered as an initial strategy (e.g., SSRI to SNRI), although within-class switches may also prove useful (e.g., fluoxetine to sertraline). Across-class or intraclass switching may yield response rates of 20% to 50% (Thase, 2008b). In the STAR*D study, switching from citalopram to either bupropion SR, venlafaxine, or sertraline yielded remission rates of 18% to 25% (Rush et al., 2006). No clear guidelines exist as how best to cross-taper medications, although it is generally unwise to stop antidepressants abruptly because withdrawal syndromes may ensue. Medications with a short half-life, such as venlafaxine (immediate release) or paroxetine, have most often been associated with withdrawal syndromes. Typically, patients complain of flulike symptoms, electric-like shocks in the back of their heads, or dizziness (Taylor et al., 2006). Consideration of half-life and slow cross-tapers often yields the most tolerable switch.

Augmentation strategies involve adding a second agent with no intrinsic antidepressant properties to the existing antidepressant. These are often considered when a patient has had a partial response to an antidepressant but has not reached remission, and switching to an alternate antidepressant may risk loss of existing response. The two best studied augmentation strategies to date are adding lithium and triiodothyronine (T_3). Although many lithium augmentation studies are limited by methodologic considerations, response has been seen as quickly as 48 hours or as long as 2 to 4 weeks. Standard lithium levels of 0.5 to 1.0 mmol/L have most often been used. T_3 augmentation has yielded similar results, if often better tolerated than lithium, usually with doses of 25 to 50 μ g/day. Overall remission rates in patients unable to achieve antidepressant-alone remission range from 15% to 50% (Nierenberg et al., 2006). Atypical antipsychotic drugs have also been used as augmenting agents in nonpsychotic major depression, with beneficial results. Aripiprazole currently has an indication as an augmenting agent, at 2 to 15 mg daily. To date, no other atypical antipsychotic has an FDA indication as an augmenting agent, though a meta-analysis

of atypical antipsychotics as augmenting agents found their efficacy superior to placebo, with a number needed to treat (NNT) of nine for both response and remission (Nelson and Papakostas, 2009). Buspirone has also been used as an augmenting agent, as its 5-HT-1A receptor agonism may enhance SSRI response. In the STAR*D study, 30% of patients who failed to achieve remission taking citalopram went on to remit with the addition of buspirone, up to 60 mg daily (Trivedi et al., 2006).

Combining two antidepressants to treat refractory depression is based on the theory that targeting a greater number of neurotransmitters will lead to improved antidepressant response. Common strategies include combining mirtazapine and venlafaxine, bupropion and SSRIs, or bupropion and SNRIs. Combining drugs of similar class (e.g., SSRI + SSRI or SNRI + SNRI) currently has few data to support its use. Venlafaxine combined with mirtazapine and citalopram plus bupropion SR were effective in the STAR*D study when patients failed to achieve remission on their current regimen. Adding bupropion to citalopram achieved a remission rate of approximately 30% in patients whose symptoms failed to remit after 12 weeks of citalopram therapy. The combination of venlafaxine plus mirtazapine was used in a highly treatment-refractory group (failed three previous medication trials) and achieved remission of symptoms in approximately 14% of patients (McGrath et al., 2006).

KEY TREATMENT

Patients who fail antidepressants should be carefully reevaluated for medication adherence, adequacy of dosing and therapy duration, diagnosis, comorbid psychiatric illnesses, increased stressors, and unaddressed comorbidities (Trivedi et al., 2006) (SOR: A). Common strategies used when patients fail an initial antidepressant treatment are switching antidepressants (either within class or across classes) (Rush et al., 2006; Thase, 2008b), augmenting with other agents (lithium, T_3 , atypical antipsychotics) (Nierenberg et al., 2006; Trivedi et al., 2006), or combining different antidepressants (McGrath et al., 2006) (SOR: A).

Anxiety

There is significant pharmacologic overlap between the treatment of depression and anxiety disorders. Most antidepressants are also effective anti-anxiety agents, or anxiolytics (see Table 47-3), thus simplifying treatment strategies when patients have both disorders. In addition, significant overlap also exists between medications that effectively treat GAD and panic disorder. Treatment recommendations for both GAD and panic will be explored separately in order to highlight some of the treatment differences between the two disorders.

Generalized Anxiety Disorder

Antidepressants are generally considered first-line agents for treatment of GAD because of efficacy and safety, effectiveness in treating comorbid major depression, and absence of addictive or abuse potential, as seen with benzodiazepines. As a general rule, starting antidepressant doses for patients with GAD should be approximately half the lowest starting dose for treatment of depression; many experience a paradoxical worsening of their symptoms on antidepressant

initiation if doses are high (see Table 47-2). Patients with anxiety disorders are typically more sensitive to antidepressant side effects (see Table 47-4), and thus starting at lower doses and titrating slowly will likely yield better results.

The SSRIs and SNRIs are considered first-line treatments, with numerous studies demonstrating both efficacy and effectiveness (Hoffman and Mathew, 2008). A Cochrane review of antidepressant treatment of GAD that included paroxetine, sertraline, venlafaxine, and imipramine found a very large effect size, with NNT of only five patients for one patient to receive benefit, with no clear evidence of one antidepressant superior to another (Kapczinski et al., 2003). At present, the SSRIs escitalopram and paroxetine and the SNRIs venlafaxine and duloxetine are the only antidepressants with an FDA indication for GAD (see Table 47-3). No randomized controlled trials (RCTs) have yet supported the efficacy of fluoxetine or citalopram in the treatment of GAD, although their clinical use is based on the assumption that SSRIs exert a class effect and are likely equally effective. The SNRI desvenlafaxine may be effective but currently is indicated only for major depression.

The TCAs, also effective agents for treating GAD, have been relegated to second-line treatment because of side effects (e.g., anticholinergic, sedative, orthostatic) and potential lethality in overdose. Imipramine has the strongest data to support its use in GAD (Kapczinski et al., 2003). Although used effectively in the treatment of anxiety disorders, monoamine oxidase inhibitors (MAOIs) have significant side effects (risk for hypertensive crisis, potential lethal interactions with other medications) and likely do not have a role in primary care and should be reserved for psychiatric practice. Mirtazapine has shown some efficacy in open-label trials (Gambi et al., 2005) but needs further study in RCTs to be considered a first-line agent in GAD. Bupropion has a less clear role in the treatment of anxiety disorders and may worsen rather than alleviate anxiety symptoms. However, a recent pilot study showed that bupropion XL had comparable anxiolytic efficacy with escitalopram in a 12-week, double-blind RCT and was well tolerated (Bystritsky et al., 2008). Bupropion may have a role in GAD treatment in the future but currently may be considered a second-line or third-line agent.

Benzodiazepines are also extremely effective for treatment of GAD and offer the advantage of rapid effect. Onset of action is typically within hours, versus weeks with antidepressants. All benzodiazepines are theoretically equally effective in GAD, and thus selection of individual agents often involves comparing half-lives, metabolic pathways, and the presence or absence of active metabolites (particularly in patients with liver disease), and speed of onset of action. Benzodiazepines with shorter half-life result in the inconvenience of multiple daily dosing, the risk of rebound anxiety, and the common need to use as-needed doses as a "rescue" medication when symptoms are inadequately controlled. Medications such as clonazepam, with a long half life, or alprazolam XR, with a slower and more prolonged onset of action, may be more effective than drugs with shorter half-life, such as immediate-release alprazolam or lorazepam. Scheduled dosing of a benzodiazepine provides for a more consistent medication blood level and may also be a more effective approach than as-needed dosing. The duration of therapeutic effect for benzodiazepines is determined by the rate and extent of drug distribution (lipophilicity) and not necessarily by the rate of

elimination. Benzodiazepines such as diazepam have a longer half-life than lorazepam, but because diazepam is more lipophilic, it has a faster onset of action and shorter duration of effect after a single dose (Schatzberg and Nemeroff, 2009). Drug elimination occurs in the liver through microsomal oxidation or glucuronide conjugation. Oxidation is sensitive to liver disease and certain medical conditions and medications (e.g., cimetidine), and therefore benzodiazepines metabolized through hepatic oxidation are more likely to show unpredictability than those metabolized via conjugation. Benzodiazepines such as temazepam, lorazepam, and oxazepam are cleared through hepatic conjugation and are safer and better tolerated when oxidative elimination has been altered.

Even though benzodiazepines offer the advantage of rapid onset and effectiveness, other disadvantages have relegated them to second-line agents. Benzodiazepines pose a significant risk of dependency and withdrawal, are potentially lethal in overdose if mixed with other sedating agents (especially alcohol), and are ineffective in treating comorbid depression. Benzodiazepines also can impair attention and vigilance and cause dose-dependent anterograde amnesia, with limited effect on psychic symptoms, including worry (Hoehn-Saric et al., 1988). Benzodiazepines should generally be considered second- to third-line agents as monotherapy in GAD, although they are often used as adjunctive agents when initiating antidepressant treatment, to provide immediate relief of anxiety symptoms until antidepressant effects begin. Symptom severity and patient preference should be considered when deciding whether to use an antidepressant as monotherapy or to start a benzodiazepine with an antidepressant. A subset of patients may benefit from long-term treatment with both an antidepressant and a benzodiazepine.

Nonbenzodiazepine and nonantidepressant treatment may also be effective in the treatment of GAD, especially for patients with mild to moderate symptom severity. *Buspirone*, an azapirone that exerts 5-HT_{1A} receptor agonism, carries an FDA indication for GAD. Buspirone appears useful in the treatment of GAD, particularly for patients who have not yet received a benzodiazepine (Chessick et al., 2006). In clinical practice, buspirone can be used as monotherapy in patients with mild to moderate symptoms, and it is often considered an alternative to benzodiazepines as an augmenting agent to antidepressants. *Hydroxyzine*, an antihistaminic agent, also carries an FDA indication for GAD and has shown efficacy in RCTs (Llorca et al., 2002). Its sedative properties and lack of efficacy in comorbid disorders have relegated hydroxyzine to a second-line agent. Interestingly, a meta-analysis of effect sizes in pharmacotherapy of GAD recently showed that hydroxyzine had a larger effect size (0.45) than SSRIs (0.36) (Hidalgo et al., 2007). At present, hydroxyzine may be considered an alternative to benzodiazepines when no comorbid illnesses are present as monotherapy. Recent studies of *pregabalin* have also shown efficacy in the treatment of GAD. In the meta-analysis cited, pregabalin was found to have the largest effect size (0.5) of all agents (SSRIs, SNRIs, benzodiazepines, azapirones, antihistamines, complementary/alternative agents). The effect size of pregabalin was determined from two large RCTs. In addition, pregabalin was found to be effective in relapse prevention compared to placebo over a 6-month trial (Feltner et al., 2008). *Beta blockers* such as propranolol and pindolol have also been used in the treatment of GAD. Although these can block the physiologic effects

of anxiety, such as sweating and increased heart rate, beta blockers appear ineffective in treating the underlying emotional component of anxiety, and little empiric evidence supports their use in GAD at present.

KEY TREATMENT

SSRIs and SNRIs are considered first-line treatments for generalized anxiety disorder, with starting dose typically half that used in depression (Hoffman and Mathew, 2008) (SOR: A). TCAs are effective in treatment of GAD (SOR: A), but their side effect profile and potential lethality have relegated them to second-line agents (Kapczinski, et al., 2003). Benzodiazepines offer the advantage of rapid effect and proven efficacy (Chessick et al., 2006; Schatzberg and Nemeroff, 2009) (SOR: A), but carry risk of abuse and dependence. Other agents for treatment of GAD include hydroxyzine (Llorca et al., 2002) (SOR: A), buspirone (Chessick et al., 2006) (SOR: B), and pregabalin (Feltner et al., 2008) (SOR: B). Maintenance treatment of GAD reduces the likelihood of relapse (Thuile et al., 2009) (SOR: B).

Panic Disorder

Similar to treatment of GAD, SSRIs, SNRIs, TCAs and benzodiazepines have all been found to be effective for the treatment of panic disorder. Effectiveness of these agents appears relatively equal, and thus selection of a particular agent is most often based on tolerability, cost, ability to treat comorbid disorders, potential for abuse and tolerance, and patient preference. First-line agents to treat panic are most often SSRIs and SNRIs. Fluoxetine, paroxetine, sertraline, and venlafaxine all have FDA indications for panic disorder (see Table 47-3), although all the SSRIs have data to support their use (Otto et al., 2001). The SNRIs duloxetine and desvenlafaxine do not currently have large-RCT evidence to support their use in panic disorder but may have efficacy based on class effect. TCAs are also as effective in treating panic as SSRIs, but are less well tolerated due to their anticholinergic and antihistaminic side effects (Bakker et al., 2002). Both imipramine and clomipramine have the most data to support their use in panic disorder (APA, 2009). Because of tolerability and toxicity in overdose, TCAs are second-line agents for panic.

Benzodiazepines offer several advantages over antidepressants in the treatment of panic, including rapid onset, as-needed dosing schedules, and relief of insomnia and somatic symptoms (Bruce et al., 2003). Similar to use in GAD, selection of a particular benzodiazepine is based on half-life, speed of onset of action, presence or absence of active metabolites, and metabolic pathways (particularly in patients with liver disease). All benzodiazepines are likely equally effective in treating panic, although in clinical practice, higher-potency benzodiazepines (e.g., alprazolam, clonazepam, lorazepam) are used more often than lower-potency drugs (e.g., oxazepam). Clonazepam and alprazolam both are FDA approved for panic disorder, and some clinicians prefer clonazepam to alprazolam because of clonazepam's longer half-life, less frequent dosing, and slower onset of action. Lorazepam and diazepam do not have an FDA indication for panic, but seem to be effective agents in RCTs and clinical practice (Mitte et al., 2005). Benzodiazepines may be considered as first-line monotherapy when no comorbid conditions exist with panic

disorder. Agents with rapid onset (alprazolam, lorazepam) may be preferred if taken on an as-needed basis or used as a rescue medication. However, shorter-acting agents can introduce problems with interdose rebound anxiety or more difficulty with adherence to multidose regimens. Agents with longer half-life, such as clonazepam and alprazolam XR, may be scheduled once or twice daily to provide more even coverage throughout the day, but do not provide immediate relief if taken on an as-needed basis.

Although benzodiazepines can bring quick relief from panic symptoms, their side effect profile and risk of dependency, abuse, and withdrawal must be considered when deciding on their use. Common side effects include sedation, fatigue, ataxia, slurred speech, memory impairment, and weakness. Geriatric patients taking benzodiazepines may be at higher risk for falls and fractures (Stone et al., 2008). Patients with a substance abuse history may need to be monitored closely for signs and symptoms of abuse; patients actively abusing substances should probably not be prescribed benzodiazepines. For many of these patients, discussing clear expectations that prescriptions will not be rewritten or refilled before a set date can limit later conflicts and improve treatment adherence.

Evidence for the use of beta blockers in panic disorder is sparse. Beta blockers have been used to reduce the somatic symptoms of panic attacks, such as palpitations, but do not seem to be effective in overall treatment of panic disorder.

KEY TREATMENT

SSRIs, SNRIs, TCAs, and benzodiazepines have all been found to be effective in the treatment of panic disorder (Otto et al., 2001) (SOR: A). First-line agents for panic disorder are SSRIs and SNRIs, with starting doses typically half that for depression (APA, 2009) (SOR: A). Benzodiazepines can be used as first-line agents when no comorbid psychiatric issues are present, including issues of substance abuse and dependence (Mitte et al., 2005) (SOR: A). Maintenance treatment of panic disorder has been shown to reduce the likelihood of relapse (Thuile et al., 2009) (SOR: B).

Continuation of Treatment in Anxiety Disorders

Treatment for anxiety disorders should be continued for 6 months to a year; a more definitive time frame is not yet clear. Results from long-term RCTs of antidepressants in anxiety disorders indicate that maintenance treatment significantly reduces the risk of relapse, whatever the disorder (Thuile et al., 2009). Decisions on length of treatment are generally made on a case-by-case basis, taking into account the risk/benefit ratio of treatment versus no treatment. If the decision is to discontinue treatment, the medication should be tapered at a rate that takes into account its pharmacokinetics and whether the patient experiences withdrawal symptoms (see Box 47-9).

Other Considerations

Antidepressants and Suicidal Ideation

In 2004 the FDA added a black-box warning to all antidepressants indicating that the use of antidepressants in children, adolescents, and young adults under 25 years of age

increased the risk of suicidal thinking and behavior. The warning on antidepressants was based on an analysis of 372 clinical trials involving 11 antidepressant medications, noting an increase in the number of patients who experienced an increase in suicidal ideation and behavior, although no increase in actual suicides was observed. Further analysis of the FDA data revealed a strong age-dependent relationship, such that the greatest risk was in patients younger than 25. In clinical terms, four additional patients in 1000, age 18 to 24 years, would be expected to experience suicidal ideation or behavior as a result of taking antidepressants, and an additional 14 patients in 1000, under age 18, would be expected to experience worsening. Patients older than 30 showed a reduction in suicidal ideation as a result of taking antidepressants, with a reduction of 6 patients of 1000 in adults over 65. The net effect of antidepressant use in patients age 25 to 64 seems moderately protective against suicidal ideation and more strongly protective for adults age 65 and older (Levenson and Holland, 2006). Antidepressants should be used cautiously in patients under age 25, with close monitoring for worsening of mood or thoughts of suicide, particularly in the days and weeks after the drug is initiated. For the majority of depressed patients, the beneficial effects of antidepressants greatly outweigh the risks (Libby et al., 2007).

Nontraditional Therapy

Interest in complementary and alternative medicine (CAM) for health disorders has been growing steadily in the last several decades. As a result, a greater number of alternative or complementary agents are being tested in more methodologically rigorous ways, allowing greater scientific assessment of such treatments. Survey evidence suggests that as many as 40% to 60% of patients may be taking CAM therapies, although patients often do not disclose such use to their physicians (Elkins et al., 2005). In addition, because production of alternative agents is unregulated, variability in product strength, dosing, and purity is common, which in turn likely affects the predictability of their outcomes. Given the widespread use of CAM agents and patients' apparent reluctance to spontaneously disclose such use to their providers, it is incumbent on physicians to inquire about such use.

The majority of CAM treatments have been used to treat depression, including St John's wort (*Hypericum perforatum*), S-adenosyl-methionine, and omega-3 fatty acids. In a Cochrane review of St John's wort for treatment of major depression, great heterogeneity was found among the 29 analyzed trials (Linde et al., 2005). St John's wort was found to be superior to placebo and similarly effective as standard antidepressants, but findings were more favorable to St John's wort studies from German-speaking countries, where use of the extract has a long tradition. The more positive results may be caused by physician expertise with the medication, patient selection, or flawed methodologies in some research. The larger, placebo-controlled studies have yielded mixed results, although compared to antidepressants, St John's wort has generally been better tolerated (Shelton, 2009).

S-Adenosyl-L-methionine (SAM-e), a dietary supplement, has been used to treat a variety of illnesses, ranging from major depression to osteoarthritis to liver disease. Clinical trials have shown SAM-e to be superior to placebo and

equivalent to TCAs in treating patients with depression, although the most robust findings have been shown with parenteral administration of the drug. Studies using the oral form have yielded more variable results. In adjunctive use with antidepressants, only one open-label study has been published to date. SAM-e has been shown to be safe and well tolerated thus far (Papakostas, 2009).

Omega-3 fatty acids have a variety of health benefits and may be helpful as augmenting agents in the treatment of major depression. The best-studied agents are eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA). Findings in depression are limited by variability in study design and small sample sizes, although the majority of evidence favors a positive effect in the treatment of mood disorders (Freeman, 2009).

At present, little robust evidence supports the efficacy of CAM agents in the treatment of anxiety disorders. Kava (*Piper methysticum*) has preliminary evidence of efficacy in GAD, but further testing is needed to determine its side effects and potential for hepatotoxicity (Sarris and Kavanagh, 2009). A meta-analysis found no statistically significant difference between kava and placebo (Hidalgo et al., 2007). Given the paucity of current evidence, caution should be used when considering kava as a therapeutic agent.

Other Treatments

Electroconvulsive Therapy

Electroconvulsive therapy (ECT) involves a brief electrical stimulation of the brain while the patient is anesthetized, inducing a seizure. ECT remains the most effective treatment for depression (UK ECT Group, 2003), although the stigma surrounding the treatment, misinformation about its practice, side effects, and cost have often made it a treatment of last resort. Although occasionally used as first-line therapy for severe depression, ECT is often used for multitransient-refractory patients, those with psychotic depression, suicidal patients (imminent), and depressed patients with compromised oral intake. A typical course is six to 20 treatments, with patients receiving ECT three times a week during the acute phase, gradually increasing the time between treatments as improvement becomes apparent. After acute treatment, patients are often returned to antidepressant therapy, although medication efficacy after ECT does not appear to be enhanced (Kellner et al., 2006). Physicians should be aware that ECT is safe, well tolerated, humane, and effective.

Vagus Nerve Stimulation and Transcranial Magnetic Stimulation

Vagal nerve stimulation (VNS) involves the surgical implantation of a nerve stimulator for the left vagus nerve at the cervical level and has been approved for treatment of refractory depression. VNS is not an acute treatment, but has shown some long-term benefit for depressed patients (George et al., 2005). Transcranial magnetic stimulation (TMS) involves the introduction of repetitive magnetic impulses to the right prefrontal cortex in a series of treatments over several weeks. TMS is approved for the treatment of unipolar depression for patients who have failed one trial of antidepressants or for those patients who have exhibited marked intolerance to antidepressants (O'Reardon et al., 2007).

Psychotherapy

In addition to pharmacologic interventions for depression, panic disorder, and GAD, psychotherapy continues to be an effective tool used by psychiatrists and psychotherapists for treating mood and anxiety disorders. Although primary care physicians will not administer such treatments, it is important to be aware of general psychotherapeutic concepts and strategies. Several types of therapy have strong evidence supporting their efficacy in treating both depression and anxiety disorders, including cognitive-behavioral therapy, interpersonal therapy, psychodynamic psychotherapy, problem-solving therapy, and supportive therapy (Cuijpers et al., 2008). Some patients may prefer to begin treatment with medications alone, whereas others may prefer only psychotherapy or a combination. Combined pharmacologic and psychotherapeutic interventions have generally been shown to be superior to either approach alone in trials for both anxiety disorders and depression (Furukawa et al., 2007) (Pampallona et al., 2004).

Referral to Mental Health Providers

Which patients should be referred to mental health providers? Referrals may be made because of patient preference, severity of illness, or because of the complexity of comorbid

illnesses. Patients who experience refractory depression or psychotic depression are best treated by specialty providers. Patients with bipolar disorder should be referred as well, especially those suffering from bipolar depressions, as they are often especially difficult to treat, usually require complex polypharmacy, and worsen with inappropriate treatment. Patients requesting or needing psychotherapy or behavioral therapy may be referred to a mental health provider.

Summary

For the majority of depressed patients, the beneficial effects of antidepressants greatly outweigh the risks. CAM treatments for depression may be beneficial for some patients, but study methodology limits their generalizability. ECT is still considered the most effective treatment for severe depression. VNS and TMS are emerging therapies for the treatment of depression.

KEY TREATMENT

Psychotherapy is an important and effective treatment strategy for both depression and anxiety. Psychotherapy combined with pharmacotherapy often yields superior results to either treatment alone (Furukawa et al., 2007; Pampallona et al., 2004) (SOR: A).

Dementia and delirium are organic brain syndromes characterized by global cognitive dysfunction. *Delirium* is the recognized terminology for what has also been called acute confusional state, acute brain syndrome, acute cerebral insufficiency, and toxic-metabolic encephalopathy. *Dementia* has commonly been called “senility” or the insufficiently specific “organic brain syndrome.” It may be useful to conceptualize delirium as *acute* brain failure and dementia as *chronic* brain failure.

Delirium

Clinical Features

Key Points

- Delirium is characterized by an acute change from usual function and cognition.
- Level of consciousness varies, often dramatically, in patients with delirium.
- Delirium may be hyperactive, hypoactive, or mixed.
- Delirium is often overlooked or misdiagnosed.
- Delirium worsens prognosis and increases length of stay and likelihood of nursing home placement.

Delirium is an acute disorder of global cognitive function involving attention, consciousness, orientation, memory, sensory perception, executive function, and behavior. Misperceptions of any of the senses may occur, but auditory and visual disturbances manifesting as suggestible hallucinations or illusions are common. For example, the delirious patient may interpret spots on the floor tiles as bugs or the sound of the wind as whispering. Delirious patients have abnormal visual perception compared to cognitively normal and demented patients that is independent of the severity of cognitive impairment (Brown et al., 2009).

Delirium cases can be grouped into hyperactive, hypoactive, and mixed subtypes on the basis of psychomotor behavior (Meagher et al., 2008). It has been suggested that the *hypoactive* subtype is more often seen in elderly persons and with delirium caused by hypoxia, metabolic abnormality, and anticholinergic drugs, whereas the *hyperactive* subtype is more common in substance intoxication and withdrawal states. Cognitive impairment and generalized slowing of the electroencephalogram (EEG) are similar in hypoactive and hyperactive subtypes.

Delirium can occur at any age, although advanced age is an independent risk factor. Rather than considering chronologic age in assessing risk, a family physician may best consider biologic age and frailty.

Delirium is often overlooked or misdiagnosed. This lack of diagnostic clarity is concerning given that, independent of other variables, delirium worsens prognosis (Fong et al., 2009; McAvay et al., 2006), often leading to chronic decreased function and cognition. Only 15% of delirious hospitalized patients will regain their baseline function by discharge, and less than half will return to prior function at 6 months (Khan et al., 2009). Delirium increases hospital length of stay by 5 to 10 days (Siddiqi et al., 2006), as well as the likelihood of nursing home placement (Inouye et al., 1998). Finally, mortality increases by 10% to 37% in hospitalized elderly patients (McCusker et al., 2002; Siddiqi et al., 2006). Approximately 40% of patients with delirium during hospitalization who survive to discharge will die within 1 year (Inouye, 2006).

Delirium prevalence and incidence vary greatly across settings of care and populations served. From 10% to 15% of hospitalized elderly patients have delirium on admission, and another 5% to 10% develop it during their stay. More than half of long-term care residents will exhibit delirium on hospital admission. Postsurgical patients (e.g., hip fracture, cardiac surgery) and elderly patients cared for in an intensive care unit (ICU) are at particularly high risk (Khan et al., 2009).

Etiology

Key Points

- Central nervous system immaturity in children and CNS disease in elderly persons may explain the increased prevalence of delirium in these two groups.
- Children generally have a more acute onset of delirium, but a less fluctuating course, than adults.
- Delirium is thought to be caused by an acute cholinergic deficit; other neurotransmitter disturbances are also probably involved.

A stress-diathesis model has been proposed to explain the risk of delirium, depending on the severity of an insult to brain function and the vulnerability of the brain because of immaturity in children and central nervous system (CNS) disease or degenerative disorders most common in elderly persons. This helps explain the highest risk of delirium in the elderly population and more frequent occurrence in children than in young and middle-aged adults.

Although the phenomenology of delirium in adults and in elderly persons differs only in the severity of cognitive symptoms and resilience in recovery, the course and symptomatology in childhood are different. Childhood delirium is often associated with febrile illness and from CNS-toxic medications (anticholinergics) (Lenntjens et al., 2008). Delirium in a child is more likely to have a very acute onset, but a less fluctuating course with less disruption of the sleep-wake cycle, than in adults. Cognitive deficits may be less pronounced in children, whereas hallucinations, delusional thinking, and labile mood may be more pronounced. The different array of causes of delirium in children and adults might explain these differences. In both children and elderly patients with dementia, problematic behaviors caused by delirium are often falsely attributed to irritability associated with illness or oppositional behavior toward caregivers. When a child cannot be comforted by a parent, delirium should be suspected.

The remainder of this discussion focuses on delirium in the elderly patient.

Neurochemical Hypothesis

Cholinergic transmission in the CNS has a major role in cognition and attention, and an acute cholinergic deficit exists in delirium. Dopaminergic transmission is increased in delirium, and this or the imbalance between cholinergic and dopaminergic systems may be etiologic. Disturbances in other neurotransmitters are hypothesized, perhaps explaining subtypes or variations in presentations of delirium. Serotonin may be increased in delirium associated with serotonin syndrome and in hepatic encephalopathy, but decreased in delirium from other causes. Glutamate and γ -aminobutyric acid (GABA) are believed to be increased in alcohol withdrawal and hepatic encephalopathy. Melatonin may be increased or decreased in delirium, which may explain hypoactive and hyperactive subtypes. Norepinephrine may be increased in delirium associated with anoxia and in hepatic encephalopathy. Inflammation may also play a role in causing delirium, either by a direct neurotoxic effect or by causing disturbances in the neurotransmitters. **Figure 48-1** depicts a theoretic explanation for the etiology of delirium.

Diagnostic Process

Key Points

- Tools for diagnosing and managing delirium include Confusion Assessment Method and Memorial Delirium Assessment Scale.
- Dementia is the strongest risk factor for development of delirium.
- Diagnostic testing needs to be informed by a thorough history and careful physical examination.

Diagnostic criteria for delirium are adapted from the American Psychiatric Association's *Diagnostic and Statistical Manual of Mental Disorders*, 4th edition, text revision (DSM IV-TR, 2000) (**Box 48-1**). Given the high prevalence of delirium in certain health care settings and clinical circumstances, diagnosis should not depend solely on a high index of suspicion. Formal evaluation of mental status to detect delirium or dementia should become part of routine assessment of elderly patients presenting with a change of condition. This not only fosters appropriate preventive and therapeutic interventions, but also alerts the *interdisciplinary team* (IDT) to plan care to ensure patient and staff safety, specific patient and family education, carefully considering cognition and function at discharge planning.

*More vulnerable in immature or already impaired brain.

Figure 48-1 Theoretic etiologic hypothesis for delirium.

Box 48-1 Diagnostic Criteria for Delirium (DSM IV-TR)

- Disturbance of consciousness (i.e., reduced clarity of awareness of the environment) with reduced ability to focus, sustain, or shift attention.
- A change in cognition (e.g., memory deficits, disorientation, language disturbance) or the development of a perceptual disturbance that is not better accounted for by a preexisting, established, or evolving dementia.
- The disturbance develops over a short period (usually hours to days) and tends to fluctuate during the course of the day.
- There is evidence from the history, physical examination, or laboratory findings that the disturbance is caused by a general medical condition, a substance intoxication, or a substance withdrawal; is the result of multiple etiologies; is caused by an etiology other than these (e.g., sensory deprivation); or cannot be determined.

Modified from American Psychiatric Association. *Diagnostic and Statistical Manual of Mental Disorders*, 4th ed, text revision. Washington, DC, APA, 2000.

Several standardized instruments have been developed to assess for delirium and monitor severity. The Confusion Assessment Method (CAM) is based on DSM IV-R criteria and has 94% to 100% sensitivity and 90% to 95% specificity, with good interrater reliability when used with formal cognitive testing and administered by trained interviewers (Inyone et al., 1990). Once diagnosed, the 10-item Memorial Delirium Assessment Scale is useful to monitor severity (Breitbart et al., 1997). Other scales are used in specific settings (e.g., ICU). Given the fluctuating course of delirium, it is essential to perform monitoring frequently.

History and Physical Examination

The etiology of delirium is often multifactorial. Therefore the history and physical examination must be detailed and exhaustive; stopping on discovery of one cause is inadequate. The history relevant to delirium is largely a search for risk factors. Risks may be considered as predisposing factors (vulnerability of brain) and precipitating factors (insults to brain). Dementia is the strongest risk factor for delirium (Cole, 2004); two thirds of elderly patients with delirium will also have dementia. This relationship is so strong that if delirium is diagnosed in an elderly person without known dementia, an investigation should be made once the delirium has resolved.

Severe illness, infections, sensory deprivation, medications, and substances of abuse causing either toxicity or withdrawal states can precipitate delirium. Use of medications confers risk both by number and by drug interaction. The risk of delirium is especially high in elders who have three or more medications initiated within a 24-hour period during hospitalization. **Box 48-2** is a compilation of predisposing and precipitating risks for delirium, and Boxes 48-3 and 48-4 list medical illnesses and drugs, respectively, that can cause or contribute to delirium.

A comprehensive physical examination should be completed, emphasizing the neurologic exam, including objective tests of cognition (see Diagnostic Process for dementia).

Box 48-2 Risk Factors for Delirium

Predisposing Factors

Sensory impairment
 Immobility (functional and iatrogenic)
 Psychological stress
 Cognitive impairment (dementia, MCI)
 Lower educational status
 Advanced age
 Past history of delirium, CVA, falls, or neurologic disease
 Multiple medical comorbidities
 Male gender
 Polypharmacy

Precipitating Factors

Medical conditions (see Box 48-3)
 Medications (see Box 48-4)
 Environmental change or stress
 Pain
 Profound sleep deprivation
MCI, Mild cognitive impairment; CVA, cerebrovascular accident (stroke).

An investigation for focal neurologic signs should be done. For example, *asterixis* (flapping of maximally dorsiflexed hands) is characteristic of hepatic encephalopathy, but not unique to it. Tremor may be present in withdrawal states, as are signs of autonomic dysfunction (hypertension, tachycardia, mydriasis, sweating).

Nuances of the history and physical examination are essential to hypothesizing the cause(s) of delirium and to inform decisions to order laboratory and other diagnostic studies and plan specific therapy. Broadly testing without guidance from the history and physical exam is particularly inefficient in determining the cause(s) of delirium. Neuroimaging is of extremely low yield unless done to investigate focal neurologic findings. Furthermore, history of a fall with head trauma and even the finding of a subdural hematoma on computed tomography (CT) might not fully explain a patient's delirium as caused only by acute brain injury if, for example, the fall was caused by a preexisting delirium from recent initiation of a medication.

Other investigations may be needed in specific situations. An EEG is not routinely needed but is helpful in diagnosing

 Hypercarbia
 Sensory deprivation
 Hearing
 Vision
 "ICU psychosis"
 Trauma
 Head
 Other severe injury
 Surgery

toxic encephalopathy, and it is essential in a patient with suspected nonconvulsive status epilepticus.

Prevention

Key Point

- Prevalence of delirium in high-risk settings mandates uniform implementation of unit-wide or facility-wide preventive programs.

An evaluation of risk allows caregivers to apply preventive strategies to avoid development of delirium in high-risk individuals (Box 48-5). However, given the high prevalence in hospitalized elderly patients and in long-term care patients, and the benign nature of many of the strategies for prevention, a standardized facility-wide prevention program may be more appropriate and effective. Prevention involving nonpharmacologic strategies attempts to maintain or normalize sleep patterns, stimulate physical and mental activity consistent with the elderly person's function, maintain or restore orientation to time/person/place, avoid or correct fluid and electrolyte disturbances, maximize the accuracy of sensory perceptions, and minimize the use of catheters and physical restraints.

Benzodiazepines and anticholinergic medications are best avoided when possible. Appropriate pain relief must be balanced with the risk of narcotic-induced delirium. Meperidine creates high risk from short analgesic effect but prolonged elimination of a nonanalgesic but CNS-toxic metabolite. Trials of proactive geriatrics consultation (Marcantonio et al., 2001), nurse-led IDT protocol-based interventions (Milsen et al., 2001), and preemptive low-dose haloperidol (Kalisvaart et al., 2005) have demonstrated decreases in delirium severity in elderly patients hospitalized for repair of hip fractures.

Box 48-4 Drugs that May Cause or Contribute to Delirium

Antiarrhythmics
 Anticholinergics
 Antidepressants
 Antiemetics
 Antiepileptics
 Antihistamines
 Antiparkinsonian agents
 Antipsychotics
 Antineoplastic agents
 Anxiolytics
 Centrally acting antihypertensive agents
 Corticosteroids
 Mood stabilizers
 Muscle relaxants
 Nonsteroidal anti-inflammatory drugs
 Opioid analgesics
 Sedative-hypnotics

From American Medical Directors Association. Delirium and Acute Problematic Behavior Clinical Practice Guideline. Columbia, Md, AMDA, 2008.

KEY TREATMENT

Geriatrics consultation, nurse-led interdisciplinary programs, and preemptive low-dose haloperidol decreased delirium severity (but not incidence) in randomized controlled trials (RCTs) or pre/post trials (Kalisvaart et al., 2005; Marcantonio et al., 2001; Milsen et al., 2001) (SOR: B).

Treatment

Key Points

- Nonpharmacologic management plans should be considered first when treating delirium.
- Indications for pharmacotherapy include delirium-induced behaviors that create a danger to the patient or others, or that interfere with necessary medical therapy.
- Fluctuating nature of delirium makes assessment of treatment efficacy difficult. Assessments must be objective and repeated frequently. Repeat assessment to judge drug efficacy should be consistent with time required for drug to reach steady state.

Treatment of delirium begins with maximized effort to apply strategies outlined in Box 48-5. Identifying and treating one or more potential causes of delirium are equally important (e.g., correcting fluid and electrolyte imbalance, treating an infection *and* discontinuing medications conferring risk). Many delirium-induced behaviors respond well to nonpharmacologic interventions. For example, a delirious elderly patient with repetitive vocalizations disturbing others should be managed by

Box 48-5 Prevention and Treatment Strategies for Delirium

1. Provide reassurance and education.
2. Optimize orientation.
 Minimize potentially ambiguous stimuli (e.g., overhead pager).
 Permit visitation (overnight family stay).
 Minimize room/facility transfers.
 Ensure consistent staff assignment.
 Provide clear instructions.
 Use frequent eye contact.
3. Optimize vision and hearing.
4. Optimize nutrition and fluid intake.
5. Optimize pain management.
6. Optimize mobility within patient's limitations,
 Minimize restraints and catheter use.
 Maximize independent function (e.g., grooming).
7. Optimize sleep hygiene.
 Ensure consistent hour of retirement.
 Use bright light during day, with dark, quiet nights.
 Prevent nocturia.
 Provide pre-retirement routine (warm milk/herb tea, relaxation techniques, back massage).
 Avoid sedative-hypnotics.
8. Provide proactive medication management.
 Avoid drugs that typically cause delirium.
 Minimize polypharmacy.

protecting others from the noise, not by sedating the delirious patient. Having a family member or sitter stay with a restless patient is better than use of physical or chemical restraints.

Pharmacologic treatment becomes necessary when patients have delirium-induced behavior that makes them a danger to self or others, or that interferes with needed medical care (e.g., maintaining bed rest after major surgery, maintaining catheter integrity). Hypoactive delirium might warrant treatment to improve oral intake of food, fluids, and medication or to avoid the medical consequences of inactivity. Additionally, some patients will require treatment for the confusion or hallucinations causing anxiety and fear. Both agitation in hyperactive delirium and lethargy in hypoactive delirium increase the risk for malnutrition and dehydration, aspiration, pressure ulcerations, and deep venous thrombosis or pulmonary embolism. The goal of pharmacologic management should be correction of neurochemical abnormalities, not simply sedation.

No medications are approved by the U.S. Food and Drug Administration (FDA) for treatment of delirium. Benzodiazepines are first-line therapy in patients with delirium induced by alcohol and sedative withdrawal. Antipsychotics are generally considered the drugs of choice in patients with most other types of delirium requiring pharmacologic management. The mode of action for antipsychotics in delirium is probably antagonism of dopamine and the resultant increase in acetylcholine. The choice of antipsychotic should be individualized based on suspected etiology, target symptoms, and patient susceptibility to adverse drug reactions (ADRs) because of age and comorbid conditions. The profile of antipsychotics regarding risk of cardiovascular events and death, QT_c prolongation, anticholinergic effects, sedation, hypotension, and resulting glucose intolerance and movement disorders must be considered when choosing a drug. Higher doses and longer duration of therapy increase the risk of ADRs, as do age, female gender, and preexisting mood disorders or dementia.

Delirious patients, particularly the elderly, often respond to fairly brief courses of low doses of antipsychotics, which decreases the chance of adverse side effects. Benzodiazepines are not recommended, but if used, low doses of short-half-life products (lorazepam, oxazepam) are preferred in elderly patients. Occasionally, methylphenidate is tried in hypoactive delirium. Delivery of medication to a delirious patient can be difficult; rapidly dissolving oral formulations are useful when cooperation with tablets or capsules is problematic. Depot injections of antipsychotics have no role in the treatment of delirium.

The fluctuating course of delirium makes evaluation of drug therapy difficult. Monitoring of mental status and behavior throughout the day using objective measures is required. The use of any of the recognized pharmacologic treatments for delirium risks further impairment of cognitive function, thereby confounding monitoring because the observer has little to differentiate an inadequate response to therapy (and need for uptitration), worsening of the delirium per se, or worsening of cognition from an adverse drug effect, compounding the original delirium.

When treating delirium, the family physician should employ nonpharmacologic strategies, medicate only when

necessary, and use monotherapy. Adjust dose to age/body weight/composition and renal/hepatic function; avoid as-needed dosing; and titrate dose based on repeated objective assessments of delirium severity at intervals consistent with the time necessary for the drug to reach steady state. Treatment for 7 to 10 days after symptoms resolve is usual.

KEY TREATMENT

Benzodiazepines are indicated for the treatment of alcohol withdrawal seizures (SOR: A) but are *not recommended* for treatment of non-alcohol-related delirium (SOR: B) (Cochrane Review). Haloperidol (<3.5 mg/day), risperidone, and olanzapine are equally effective in treating delirium, with few adverse effects (Cochrane Review) (SOR: B). Despite plausible theoretic arguments for efficacy, no convincing evidence supports the use of cholinesterase inhibitors for delirium (Cochrane Review) (SOR: B).

Natural History of Delirium

Delirium is usually of acute onset and transient duration. Delirium often resolves a few days to a few weeks after etiologic insults are corrected. In some patients, however, delirium may persist. When chronic, delirium may result in permanent cognitive deficits, meeting the criteria for dementia (Fong et al., 2009). Hastening the progression of an existing dementia might explain this clinical observation. Delirium is persistent at hospital discharge in almost one third of patients, with almost as many still having symptoms and signs of delirium 6 months after discharge (McAvay et al., 2006; McCusker et al., 2003).

Dementia

Dementia is a syndrome characterized by multiple chronic and progressive cognitive deficits. Deficits in short-term memory and inability to learn new information are typical symptoms that first bring the patient to medical attention. The initial clinical problem is to determine if the presenting concerns are caused by dementia, and if so, to determine the type of dementia.

Clinical Features

Key Points

- Dementia is characterized by multiple areas of cognitive impairment but preserved level of alertness.
- Age-related memory loss, mild cognitive impairment, depression, delirium, and DSM Axis I psychiatric disorders should be considered in the differential diagnosis of dementia.

Dementia is caused by a heterogeneous group of brain disorders that result in global impairment of cognition. In addition to memory impairment, impairment in language (aphasia), inability to carry out motor tasks (apraxia), inability to recognize objects (agnosia), and loss of executive function are seen. Mood, personality, and behavior are often affected. Dementia is distinguished from mental retardation and developmental delay by its onset after a long period of

higher, often normal cognitive function. Dementia must be differentiated from delirium, as noted earlier. Of greatest utility to the primary care physician, attention is preserved in dementia, but it is altered and labile in delirium.

Some elderly persons present with a concern about mild changes in memory (inability to recall names and slower processing of information) but have no functional deficits. This age-related memory loss is thought to be normal. Of more concern is the emerging concept of *mild cognitive impairment* (MCI). Patients with MCI have memory concerns corroborated by an informant, objective but mild memory loss, normal general cognitive function, and intact activities of daily living (ADLs). Many, but not all, patients with MCI progress to Alzheimer-type dementia. Depression in the elderly patient can masquerade as dementia. An elderly patient might present with nondysphoric depression, marked by apathy, decreased cognitive ability, nervousness, somatization, or insomnia. This condition should be recognized and treated as depression. Patients need to be carefully followed because almost half will develop dementia within 5 years (Alexopoulos et al., 1993).

Because psychotic features can occur in delirium, dementia, and depression, psychotic mental illnesses are included in the differential diagnosis of impaired cognitive status. Key features distinguishing the causes of cognitive impairment are summarized in Table 48-1.

Diagnostic Process

Key Points

- Use of clinical tools will improve the precision, efficiency, and usefulness of the clinical evaluation, as well as provide a baseline for comparison because dementia progresses over time.

- Mini-Cog is an efficient and easily interpreted tool for initial cognitive assessment.
- Demonstration of ability to perform ADLs and IADLs will provide insight into the practical problems created by dementia and allow for focused anticipatory guidance relative to patient safety and risk for exploitation.
- Initial laboratory evaluation of the dementia patient includes CBC, urinalysis, chemistry panel, TSH, B₁₂, and perhaps a syphilis serology.
- Structural imaging is appropriate, but functional imaging is still a research tool.

A casual conversation or even a medical interview is unlikely to uncover mild dementia. Patients often maintain social skills and unconsciously develop ego-protective techniques that hide cognitive deficits. Although this observation makes routine screening for cognitive dysfunction attractive, the U.S. Preventive Services Task Force, noting insufficient evidence, does not recommend *routine* screening for dementia (MCI) for any age group (USPSTF, 2003).

On the other hand, multiple guidelines strongly encourage a prompt and systematic response when family members report symptoms suggestive of cognitive decline. Use of screening tools in this context is appropriate. These tools assess cognitive and functional deficits as well as mood. Screening tools provide semiquantitative and reproducible assessments that add diagnostic certainty, document change over time, and facilitate efficient communication with other professional caregivers. The 30-item Mini-Mental State Examination (MMSE) has demonstrated utility in primary care and research settings, but is criticized as being too cumbersome for use in a busy office setting. The Mini-Cog, involving only three-word recall and clock drawing, is an attractive alternative because of its brevity, ease of scoring, and usefulness in ethnolinguistically diverse populations

Table 48-1 Comparison of Presenting Characteristics of Conditions with Altered Mental Status

| Presentation | Delirium | Dementia | Depression | Psychoses* |
|-----------------------|-----------------------------|--|--------------------------------------|---|
| Onset | Acute | Insidious | Insidious | Variable |
| Duration | Short to prolonged | Prolonged, progressive | Variable or recurrent | Chronic with exacerbations |
| Attention | Impaired, fluctuating | Normal except late stage | Normal or impaired | Normal or impaired |
| Consciousness | Impaired, fluctuating | Normal except late stage | Normal | Normal |
| Sensory perceptions | Impaired | Agnosia, misperception | Intact | Impaired |
| Thought content | Disorganized | Paucity of thought | Normal or ruminating | Normal or disorganized |
| Orientation | Impaired, fluctuating | Impaired, mostly stable | Intact | Intact |
| Delusional thinking | Disorganized if present | Secondary to memory loss or misperceptions | Self-deprecating if present | Systematized |
| Participation in exam | Distractable or unable | Tries but fails to perform | Lacks in effort | Variable |
| Hallucinations | Common, visual, suggestible | Uncommon, later stages, visual or global | Not in absence of psychotic features | Common, auditory (e.g., command hallucinations), visual |

*DSM-IV-R Axis I psychotic mental illnesses.

(Borson et al., 2003). The Montreal Cognitive Assessment Test (MoCA) and the St. Louis University Mental Status Test (SLUMS) are more elaborate tools that seek to detect MCI and distinguish MCI from early dementia.

Examination and assessment of function can be accomplished by evaluating ADLs (bathing, dressing, toileting, transfers, continence, eating) and instrumental ADLs (using telephone, shopping, food preparation, housekeeping, laundry, transportation, taking medicine, money management). Functional assessment provides insight into the impact of cognitive impairment on everyday life. The Geriatric Depression Scale (GDS) offers uniform assessment for coexisting depression when MMSE score is 15 or greater. The Cornell Scale for Depression in Dementia, an observer-generated scale, provides a screen for depression in more severely impaired patients. These tests should become a familiar part of the initial evaluation and continuing care provided by the family physician.

History and Physical Examination

When obtaining the medical history, the physician should focus on the onset, trajectory, use of prescription and non-prescription drugs, history of substance abuse, vascular problems or risk factors (especially hypertension), history of head trauma, history of CNS infections or surgery, and family history of dementia. Assessment of ADLs and IADLs, whenever possible, should be demonstrated as part of the physical examination rather than rely on patient or family report. A general physical examination is appropriate to assess the status of comorbid conditions and for evidence of disease states that could be related to dementia. The cardiovascular examination is important to detect the presence of vascular disease. A careful neurologic exam, particularly to identify movement disorders and focal neurologic deficits, will impact the selection of diagnostic tests. ADL and IADL assessments often raise concerns about safety or potential for exploitation and may need to be followed up with a home visit or a referral to social services.

Laboratory and Imaging Studies

Traditionally recommended laboratory studies include a complete blood count (CBC), urinalysis, chemistry panel, thyroid-stimulating hormone (TSH) and vitamin B₁₂ levels, and, if concerns are raised in the history, a syphilis serology. These studies have relatively low yield relative to defining the cause of dementia, but they can be helpful to document the severity of comorbid conditions. They also provide a convenient assessment of the patient's nutritional status. Routine use of apolipoprotein (apo) E genotyping and cerebrospinal fluid (CSF) studies are not recommended for routine use. Structural imaging with non-contrast-enhanced CT or magnetic resonance imaging (MRI) is appropriate in the early evaluation of patients with dementia. Imaging may reveal treatable conditions such as benign or malignant brain tumors or subdural hematomas or suggest normal-pressure hydrocephalus (NPH). Functional imaging remains a research tool and is not recommended in the routine dementia evaluation (Knopman et al., 2001).

Referral for formal neuropsychological testing or EEG can be useful for difficult patients. A systematic evaluation provides a basis for more precise patient and family education, aids in prognostication, and may guide therapy. It can help overcome patient and family denial and decrease "doctor shopping." Box 48-6 summarizes conditions the clinician should consider when approaching a patient with suspected dementia.

Common Types of Dementia

Clinical evaluation will establish that most patients have Alzheimer's disease (AD), Levy body disease (LBD), or vascular dementia (VaD). Autopsy study of brain tissue obtained from persons dying with dementia reveal that most patients actually have mixed dementia, with microscopic changes of AD and VaD most often reported.

Alzheimer's Disease

Key Points

- Alzheimer's disease is the most common type of dementia and the fifth leading cause of death for Americans over age 65.
- Alzheimer's disease is classified as late-onset AD (much more common) and early-onset AD (less common but stronger genetic basis).
- Age is the strongest risk factor for AD.
- Course of AD is one of slow but relentless progression.
- Life expectancy from diagnosis is 4 to 6 years, although some patients live much longer. Clinical indicators of short life expectancy include eating problems and nonremediable weight loss, repeated bouts of pneumonia, and frequent febrile episodes.
- Family medicine's commitment to continuity, a biopsychosocial approach, and recognition of the family as a unit of care allow the family physician to be particularly effective when helping caregivers.

Alzheimer's disease is the most common type of dementia. The exact cause or causes of AD are unknown, but age is the most important risk factor. Given the increasing life expectancy in the United States (and worldwide), and that

Box 48-6 Diagnostic Considerations for Evaluating Patient with Suspected Dementia

- D**—Drugs and toxins (alcohol, neuroleptics, hypnotics, anticonvulsants, analgesics, many others)
- E**—Environmental deprivation (poor vision and hearing, lack of assistive devices); electrolyte disorders (sodium, calcium, magnesium)
- M**—Metabolic and endocrine disorders (hypothyroidism, hyperammonemia); movement disorders (dementia with Lewy bodies, Parkinson's disease)
- E**—Emotional disorders (depression, delirium)
- N**—Nutritional deficiencies (vitamin B₁₂, thiamine, niacin)
- T**—Tumors and trauma (subdural hematoma, normal-pressure hydrocephalus, brain tumors)
- I**—Infections (human immunodeficiency virus, syphilis, Creutzfeldt-Jakob disease)
- A**—Alzheimer's disease, vascular dementia

“baby boomers” (those born between 1946 and 1966) have begun turning 65, family physicians can expect more and more patients and families seeking treatment for AD. Currently, about 5.3 million Americans have AD. Unless new discoveries facilitate prevention, delay the onset, or slow the progression of AD, it is estimated there will be 11 to 16 million persons with AD in 2050.

Most cases of AD develop in people older than 60 years. Genetics appears to have little influence in late-onset AD, although there is great research interest in the apo E E4 allele, located on chromosome 19. Patients not expressing the apo E E4 allele have the least risk for AD, heterozygous patients are at intermediate risk, and homozygous patients are at greatest risk. Apolipoprotein E is involved in lipid transport. It is a risk factor for AD, as well as LBD and VaD. The clinical relevance of this observation is unclear.

Early-onset AD patients often have changes in chromosomes 21, 14, or 1. Persons with Down syndrome (trisomy 21) often develop the symptoms and histologic findings of AD in their 40s and 50s. Other risk factors for AD include head injury with loss of consciousness and lower educational level. Various risk factors for atherosclerosis (diabetes, hypertension) have also been shown to increase the risk of AD, as well as VaD.

Histopathologic markers of AD include extracellular senile plaques (aggregations of abnormal amyloid protein), intraneuronal neurofibrillary tangles (hyperphosphorylated tau protein), and brain cell death. Neurofibrillary tangles are preferentially distributed in the medial temporal lobe, hippocampus, and amygdala, whereas senile plaques are widely scattered throughout the cerebral cortex (Clark and Karlawish, 2003). The AD patient's brain displays shrinking gyri, widening of the sulci (particularly in the frontotemporal region), and enlargement of the ventricular system in proportion to the atrophy of the cortex. Caution should be taken in using these features exclusively for the diagnosis because normal aging occurs in much the same manner, although with more diffuse atrophy and slower progression if serial studies are performed. Decreases in hippocampal volume correlate well with deteriorating clinical status (Jack et al., 2000).

Many neurotransmitters, including norepinephrine, serotonin, somatostatin, and various neuropeptides, show alterations in AD patients. The most prominent neurochemical defect appears to be a deficiency in the enzyme choline *O*-acetyltransferase, resulting in a deficit of acetylcholine. This is most evident in the nucleus basalis of Meynert and the hippocampus. In the absence of cholinergic stimulation from these lower centers of the brain, there is secondary atrophy in the cerebral cortex, leading to memory problems and other deficits in cognitive function. Neurochemical alterations probably contribute to the associated psychiatric symptoms of AD (depression, anxiety, agitation, psychosis). Early in the course of AD, impaired memory is the predominant finding. Changes in mood and personality can also be seen. Later, memory impairment becomes more dramatic, and word-finding difficulty (anomia) appears. These changes can be subtle, and family, co-workers, and physicians might unconsciously adapt to the person's impairment. This is helpful to the patient, but it contributes to delay in diagnosing AD. Eventually, functional performance is affected, with deterioration in skills of driving, handling finances, meal planning, and hygiene. There is further deterioration in

language with disordered syntax. Executive functions, manifesting with impaired judgment, sequencing, and problem solving, become more problematic. Memory loss becomes profound, with loss of recognition of previously familiar persons or things, as illustrated in Figure 48-2.

Influenced somewhat by premorbid personality, psychiatric syndromes can develop at any point in the course of the illness. Paranoia, agitation, frustration, irritability, anxiety or restlessness, socially inappropriate behavior, delusions, and hallucinations are all common. Food preferences may change. In later stages, apraxia and probable decrease in the pleasurable, endorphin-mediated response to eating lead to a decrease in nutritional intake without suffering. Finally, near-coma deteriorates to coma. Seizures and myoclonic jerks are often observed in AD and other dementias (Scarmeas et al., 2009). Life expectancy of AD patients is generally 4 to 6 years after diagnosis (Larson et al., 2004), although some patients live for 10 years and longer. Box 48-7 summarizes diagnostic criteria for dementia and AD.

Pharmacotherapy

Early recognition of AD offers the greatest opportunity for modification of the course of the illness. Pharmacotherapy should be considered only as part of a comprehensive treatment plan that addresses comorbid medical and psychiatric conditions, behavioral management, social interventions, and support and education of caregivers. Goals of pharmacotherapy include improving memory and cognition (or at least slowing cognitive decline), alleviating behavioral disturbances, decreasing caregiver burden, and delaying need for institutionalization.

Two classes of pharmacotherapeutic agents have recognized indications for the treatment of AD, comprising four cholinesterase inhibitors and one *N*-methyl-D- aspartate (NMDA) receptor agonist. The first cholinesterase inhibitor developed, tacrine, has little current use because of inconvenient dosing and need for laboratory monitoring for liver toxicity. The other three, donepezil, galantamine, and rivastigmine, have shown consistent, modest beneficial effects in the domains of cognition and global assessment. Diarrhea, nausea, and vomiting, consistent with expected effects of cholinesterase inhibitors, were the most common side effects. Memantine, the NMDA receptor agonist, improves cognition and global assessment, but effect sizes were small. Other studies suggest improvement in quality of life. Common side effects include nausea, diarrhea, dizziness, and headache (Raina et al., 2008). No clinically important differences among the drugs have been demonstrated. Alternative delivery systems (rapidly dissolving tablets, liquid formulations, transdermal patches) are available.

Based on an exhaustive and comprehensive reviewed of these five FDA-approved dementia treatments, the Joint American College of Physicians/American Academy of Family Physicians Panel on dementia concluded that a decision to start therapy should be based on individual assessment, noting that all the drugs are associated with known adverse events and have shown only modest or even, in some studies, no benefit. The panel also stated treatment with memantine or a cholinesterase inhibitor is not appropriate when the goals of care no longer include slowing decline, a circumstance frequently seen when AD is advanced (Qaseem et al., 2008).

6-21-99

Dear son Dennis,

I am proud that you have your Doctorate. I am kind of Lost mother. I am at good Samaritan Luther Manor and want to call a Taxi to go home. I need you. Your mother is confused. I know too many people with the same name. I am hoping to be home by 8pm tonight. I played the organ tonight and we had fun.

Love,

L

Box 48-7 Diagnostic Criteria for Dementia and Probable Alzheimer's Disease

Dementia

Loss of memory, documented by MMSE or similar testing
and

Evidence of at least one additional impairment including:

- Aphasia
- Apraxia
- Agnosia
- Impairment of executive function

and

Resulting impairment sufficient to interfere with usual social or occupational functioning

Probable Alzheimer's Disease

Typical history, including:

- Insidious onset
- Gradual progression

Documented cognitive loss

Absence, documented by physical exam, laboratory testing, and neuroimaging of other diseases that could cause dementia.

Based on DSM-IV-TR and National Institute of Neurologic and Communicative Disorders and Stroke, Alzheimer's Disease and Related Disorders Association (NINCDS-ADRDA) criteria.

MMSE, Mini-Mental State Examination.

KEY TREATMENT

Three cholinesterase inhibitors and one NMDA agonist are available for the treatment of AD (Raina et al., 2008). Comprehensive literature review shows modest efficacy and predictable non-life-threatening side effects (SOR: B).

Prevention

The absence of clearly effective active treatments has created considerable interest in efforts to prevent AD and other dementias. Numerous vitamins, nutraceuticals, and pharmacologic agents have been examined for use as preventive agents for AD-related memory loss. A double-blind placebo-controlled study of vitamin E and donepezil for the treatment of MCI was unable to demonstrate a benefit from vitamin E and showed only modest and short-term benefit from donepezil (Petersen et al., 2005). No medication, nutraceutical, or vitamin has been shown to prevent AD.

Ginkgo biloba is probably the best studied of the nutraceuticals promoted for the prevention of dementia. Initially encouraging studies have not been supported by subsequent RCTs. A National Institutes of Health (NIH)-funded study involving more than 3000 volunteers age 75 and older concluded that *Ginkgo biloba* "was not effective in reducing the overall incidence rate of dementia or AD incidence in elderly individuals with normal cognition or those with MCI" (DeKosky et al., 2008; Snitz et al., 2009).

Enthusiasm for a preventive role for estrogen and non-steroidal anti-inflammatory drugs (NSAIDs), based on

epidemiologic correlations, have not been supported by follow-up studies. Neither is recommended.

A number of cohort studies suggest that educational and occupational attainment, cognitively stimulating activities such as reading, playing cards or board games, going to museums, playing musical instruments, and dancing are associated with reduced risk of developing AD. Controlled trials have not been done (and will be difficult or impossible to perform) to confirm these associations (Verghese et al., 2002; Wilson et al., 2002). Given the benign nature of the proposed interventions, it would seem prudent to encourage such activities when patients or family members raise questions about prevention.

Given the increasing awareness of the contribution of cerebrovascular pathology to disease burden of all types of dementia, aggressive management of hypertension and diabetes, as well as the management of vascular risk factors through diet, exercise, and preventive pharmacologic agents, is having the added benefit of lowering the risk of dementia (Middleton and Yaffe, 2009).

KEY TREATMENT

Cognitive, physical, and social activity; a diet rich in antioxidants and polyunsaturated fatty acids; and vascular risk factor control (particularly hypertension treatment) may have a role in the prevention of AD dementia (Middleton and Yaffe, 2009; Verghese et al., 2002; Wilson et al., 2002) (SOR: B).

Caregiver Education and Support

Family physicians are often in a particularly powerful position to address caregiver issues. In some cases the family physician is the doctor for both the dementia patient and the caregiver. Family medicine's commitment to continuity and a comprehensive biopsychosocial approach provides a useful framework for understanding and addressing the stresses that affect family members. A meta-analysis of psychosocial interventions for caregivers showed decreased levels of caregiver stress, improved knowledge, and improved patient mood, but no effect on caregiver burden. Involving both the caregiver and the patient in the intervention increased the benefit. At least four studies indicate that caregiver interventions delay nursing home admission (Brodaty et al., 2003).

Knowledge of and referral to community resources is critical to managing caregiver stress and preserving patient quality of life. Adult day care, respite care, medical and non-medical home care, and hospice programs all play a role in the care of the AD patient and family. Particularly helpful are the Alzheimer's Association and the National Institute of Aging's Alzheimer's Disease Education and Referral (ADEAR) Center. Bibliotherapy references include *The 36-Hour Day* (Mace et al., 2006) and *Alzheimer's Disease: the Family Journey* (Caron et al., 2000).

End-of-Life Care

Alzheimer's disease is a terminal illness. It is currently the fifth leading cause of death for persons age 65 and older (Heron et al., 2009). AD progresses slowly, making it difficult to recognize when a patient goes from the advanced to terminal phase of the illness. This in turn makes it difficult

to determine when to initiate discussions with family about shifting to an exclusively palliative care approach and possible involvement of hospice. Potential clinical indicators for the shift include progressive nonremediable weight loss (White et al., 1998), eating problems, repeated episodes of pneumonia, and frequent febrile episodes (Mitchell et al., 2009). The Center for Medicare and Medicaid Services (CMS) has published guidelines to assist in the determination of terminal status in patients with dementia (Box 48-8). Once the terminal stage is recognized by the physician and acknowledged by the family and other caregivers, an appropriate end-of-life care plan can be instituted.

Lewy Body Disease

Lewy body disease (LBD) is emerging as a term to capture both dementia with Lewy bodies (DLB) and dementia associated with Parkinson's disease (PDD). This is useful because the only difference is the timing of dementia. In DLB the dementia is evident before or concurrently with the appearance of parkinsonian symptoms. In PDD, Parkinson's disease is evident for 1 year or more before dementia symptoms appear. Three core clinical features help distinguish LBD from other dementias: (1) fluctuating cognition with pronounced variations in attention and alertness, (2) recurrent visual hallucinations that are typically well formed and detailed, and (3) spontaneous features of parkinsonism (McKeith et al., 2005).

Box 48-8 Medicare Local Coverage Determination (LCD) for determining terminal state of Alzheimer's Disease (AD)*

Patients will be considered to be in the terminal stage of dementia (life expectancy of 6 months or less) if they meet the following criteria. Patients should show all the following characteristics:

1. Stage 7 or beyond according to the Functional Assessment Staging Scale (FAST)† [FAST Stage 7 represents severe AD]
2. Unable to ambulate without assistance
3. Unable to dress without assistance
4. Unable to bathe without assistance
5. Urinary and fecal incontinence, intermittent or constant
6. No consistently meaningful verbal communication: stereotypical phrases only, or the ability to speak is limited to six or fewer intelligible words

Patients should have had one of the following within the past 12 months:

1. Aspiration pneumonia
2. Pyelonephritis or other upper urinary tract infection
3. Septicemia
4. Decubitus ulcers, multiple, stage 3-4
5. Fever, recurrent after antibiotics
6. Inability to maintain sufficient fluid and calorie intake with 10% weight loss during previous 6 months or serum albumin <2.5 g/dL

From Center for Medicare and Medicaid Services (CMS). Local Medical Review Policy. www.cms.hhs.gov. Minor regional variations and modifications over time are anticipated.

*This section is specific for AD and related disorders and is not appropriate for other types of dementia, such as multi-infarct dementia.

†FAST Scale © 1984 by Barry Reisberg, MD.

In advanced stages it can be difficult to distinguish LBD and AD, both clinically and pathologically. It is important to make the diagnostic distinction, however, because use of typical antipsychotic agents in LBD can be associated with severe, even fatal, exacerbations of parkinsonism and autonomic instability. Diagnostic criteria are listed in [Box 48-9](#).

Motor symptoms can be treated with carbidopa-levodopa, starting with low doses and proceeding cautiously. Carbidopa-levodopa itself can cause confusion, and distinguishing an adverse drug reaction from a dementia-related psychotic episode is difficult. Neurochemical changes in LBD are similar to those seen in AD, particularly the deficiency in acetylcholinesterase, suggesting that cholinesterase inhibitors would be particularly effective. Despite positive case reports, systematic review of the evidence notes that “patients with dementia with Lewy bodies who suffer from behavioral disturbances may benefit from rivastigmine, but the evidence is weak” (Wild et al., 2003).

Psychosocial interventions for LBD are similar to those used in AD. Anticipatory guidance for caregivers regarding the likelihood of waxing/waning cognition and dramatic hallucinations, as well as the need to avoid the use of typical antipsychotics, is important.

KEY TREATMENT

Cholinesterase inhibitors should be beneficial in Lewy body disease patients, but evidence supporting their efficacy is modest (Wild et al., 2003) (SOR: B).

Box 48-9 Revised Criteria for Clinical Diagnosis of Dementia with Lewy Bodies (DLB)

- Central features** (essential for a diagnosis of possible or probable DLB)
 - Progressive cognitive decline of sufficient magnitude to interfere with usual social or occupational function
 - Prominent or persistent memory impairment
 - Deficits on tests of attention, executive function, and visuospatial ability
- Core features** (two core features are sufficient for a diagnosis of probable DLB, one for possible DLB)
 - Fluctuating cognition and variations in attention and alertness
 - Recurrent visual hallucinations
 - Spontaneous features of parkinsonism
- Suggestive Features** (one core + one suggestive feature sufficient for diagnosis of probable DLB, with no core features one suggestive feature sufficient for diagnosis of possible DLB)
 - Severe neuroleptic sensitivity
 - REM sleep behavior disorder
- Supportive features** (commonly present in DLB but without proven diagnostic specificity)
 - Repeated falls and syncope
 - Transient, unexplained loss of consciousness
 - Severe autonomic dysfunction (e.g., orthostatic hypotension, urinary incontinence)
 - Systematized delusion, nonvisual hallucinations

Modified from McKeith IG, Dickson DW, Lowe J, et al. Diagnosis and management of dementia with Lewy bodies: Third Report of the DLB Consortium. *Neurology* 2005;65:1863-1872.

REM, Rapid eye movement.

Vascular Dementia

Vascular dementia vies with LBD as the second most common type of dementia in the United States. The rate is higher in areas with higher rates of hypertension. Conceptually, VaD refers to cases in which vascular disease produces cerebral injury severe enough to result in dementia. This fairly simple concept is made clinically challenging by the multiple types of vascular disease and the varying location and degree of the resulting cerebral injury. Cerebral damage may be hemorrhagic, hypoxic, or anoxic. The vascular disease can occur in larger arteries, medium or small arterioles, or capillaries. VaD may be the result of a sentinel infarct, multiple infarcts, Binswager's disease, or vasculitis. Hypoxic damage related to systemic episodes of hypotension can also result in VaD.

Given the variety of causes and manifestations, it is not surprising that there are no uniformly accepted criteria for the diagnosis of VaD. It may be overdiagnosed, given the high prevalence of subclinical cerebrovascular disease seen in elderly persons, or underdiagnosed, given the lack of clear criteria for diagnosis. VaD is the most common second diagnosis in mixed dementia, a finding that has clinical significance: AD + VaD or LBD + VaD = more cognitive and functional deficits than AD or LBD alone (Schneider et al., 2007).

Treatment of the resulting dementia includes off-label use of cholinesterase inhibitors and memantine, as well as treatment directed at the control of vascular risk factors. Psychosocial approaches are similar to those used with dementia in general, as described earlier. Disclosure of the diagnosis of VaD to family members creates an opportune “teachable moment” to discuss familial risk and prevention.

Less Common Causes of Dementia

The vast majority of patients seen in primary care settings will have AD, LBD, VaD, or mixed dementia. The following types are relatively rare and therefore are not discussed in detail. They should be suspected when the presentation or course of the dementia is atypical. Consultation will likely be necessary to confirm the diagnosis.

Frontotemporal Lobar Degenerations

Frontotemporal dementia (FTD), formerly called Pick's disease, is the most common of three frontotemporal lobe degenerations (FTLDs). The other two are progressive aphasia and semantic dementia. FTD often presents with disordered behavior as a result of impairment in executive function, motivation, goal setting, and sequencing of plans. Labile mood and social disinhibition are common even before cognitive testing shows an abnormality. Neuroimaging often shows frontal or temporal lobe atrophy; formal psychometric testing is useful to confirm the diagnosis. There are no specific treatments (Liscic et al., 2007).

Normal-Pressure Hydrocephalus

First described in 1965, NPH is characterized by gait disturbance (magnetic gait), urinary incontinence, and dementia. This triad does not offer help with diagnosis, because the findings are common in other dementias as well. Frequently, this is first suspected when prominent ventriculomegaly is

noted on neuroimaging (Hunter-Smith et al., 2007). There is no effective pharmacotherapy, but some cases respond to ventricular shunting. Selection of patients likely to respond to shunting is difficult, and referral to a center with considerable experience is advised if surgical treatment is being considered.

Creutzfeldt-Jakob Disease

Creutzfeldt-Jakob disease (CJD) is a very rare type of dementia associated with prion infection in the brain. It is characterized by unusually rapid progression. Rapid cognitive decline suggests the diagnosis of CJD. Myoclonus, fatigue, and visual problems are associated symptoms. Precise diagnosis requires a brain biopsy, but characteristic CSF and EEG findings are helpful to increase diagnostic certainty. Iatrogenic CJD occur when prion-contaminated tissue is grafted (dura mater, cornea) or injected (human growth hormone, pituitary gonadotropins) (Prusiner, 2001).

HIV-Associated Dementia

Human immunodeficiency virus (HIV)-associated dementia (HAD) develops late in HIV infection. It is a common cause of dementia worldwide. Motor deficits are observed in addition to cognitive decline. Patients are generally younger than most other dementia patients; HAD has been diagnosed in pediatric HIV patients. The use of highly active antiretroviral therapy (HAART) has decreased the incidence of HAD, and newly diagnosed cases often respond to antiretroviral therapy (McArthur, 2004). Opportunistic CNS infections, particularly toxoplasmosis, can be a contributing factor and must be sought and treated.

Behavioral and Psychiatric Symptoms Accompanying Dementia

Key Points

- It is necessary to understand the behavior from the patient's point of view to develop a treatment plan.
- Treating distressing symptoms, such as pain or constipation, may resolve problematic behaviors.
- As the patient's dementia progresses, behaviors are likely to change.

Behavioral and psychiatric symptoms occur frequently in dementia patients. Behavioral symptoms usually increase the suffering of the patient and are very distressing for both family and professional caregivers. Common problem behaviors include wandering, repetitive movements, verbal or physical aggression, resistiveness, pestering, hoarding, inappropriate sexual behavior, and sleep disturbances.

Many patients display psychotic symptoms at some point in the course of their dementia. Simple delusions, hallucinations, and paranoia may occur because of misperceptions of the environment. True psychotic delusions and hallucinations, which are usually visual rather than auditory, may also occur. Any of these symptoms can cause considerable distress, generating requests for the physician to prescribe antipsychotic or sedating medication with the intent to suppress the problematic behavior.

The genesis of psychotic symptoms in the degenerating brain of the dementia patient probably differs from the psychotic symptoms associated with schizophrenia or other psychotic mental illness, and therefore antipsychotics are only occasionally effective. The FDA has not approved antipsychotic drugs for use in dementia patients. A clinical review concluded "pharmacological therapies are not particularly effective for the management of neuropsychiatric symptoms of dementia" (Sink et al., 2005). The safety of these agents in the frail elderly population is also a concern. In 2008 the FDA notified physicians that "both conventional and atypical antipsychotics are associated with an increased risk of mortality in elderly patients treated for dementia-related psychosis."

For all these reasons, nonpharmacologic interventions are preferred for the management of behavioral and psychiatric symptoms. This requires analysis of the problematic behavior, seeking to understand the behavior from the patient's perspective. Attention to precipitating events and consequences of the behavior can lead to a behavioral modification plan. The dementia patient's profound memory loss may be the basis for some behavioral symptoms. Repeated questioning may reflect extreme short-term memory loss. Paranoia-like verbalizations that people are stealing the patient's possessions occur when the dementia patient cannot remember where possessions are kept. **Box 48-10** provides a guideline to assist the evaluation and management of behavioral problems.

Depression is typically seen in dementia patients and is often the cause of irritability, apathy, anorexia, insomnia, or other symptoms that can drive problem behaviors. Successful treatment of the depression is marked by resolution of the problematic behaviors. Unmet physical needs (e.g., pain, constipation) should also be sought as a possible underlying stimulus for problem behavior.

KEY TREATMENT

Typical and atypical antipsychotics show some benefit in dementia patients, particularly in controlling aggression and psychosis, but also carry significant risk, including increased mortality (Sink et al., 2005). (SOR: B).
If antipsychotics are used, low doses and short duration of therapy are recommended (SOR: C).

Care Settings for the Dementia Patient

Key Points

- Physicians' work will change as dementia progresses and goals of care change.
- When dementia patients are in institutional settings, the physician must consider the needs, capabilities, and risks of the institution (adult daycare program, hospital, nursing home, assisted-living center) to ensure delivery of effective care.

Office Care

Office treatment of medical issues in dementia patients is challenging. The impact of impaired decision making, inability to report adverse events, and problems with adherence can alter usual risk/benefit calculations (Brauner et al., 2000). Family members often need to be involved to help

Box 48-10 A-B-C-D Evaluation of Behavior Problems in Delirium and Dementia

- A. What is (are) the *antecedent(s)* to the behavior?
- B. What exactly is the *behavior*?
- C. What are the *consequences* of the behavior?
- D. What *disaster* might result from the behavior?

Modified from American Medical Directors Association. Delirium and Acute Problematic Behavior Clinical Practice Guideline. Columbia, Md, AMDA, 2008.

weigh the risks, burdens, and benefits of therapy, particularly therapy that does not lead directly to symptomatic improvement. Office care usually involves patients with mild to moderate disease. Goals of care typically include patient and family education and completion of formal advance directives while the patient is still able to have some input into decision-making. An RCT comparing usual care management with “medical home” care using an advanced-practice nurse-led IDT showed fewer behavioral and psychological symptoms among patients and caregivers (Callahan et al., 2006).

Hospital Care

Behavioral symptoms are often precipitated by a move from a familiar to an unfamiliar environment. Hospitals can be a particularly stressful environment for a dementia patient, as can the acute or exacerbating medical illness that creates the need for hospitalization. The physician should communicate the dementia diagnosis to the hospital staff. This knowledge can allow preemptive implementation of measures to decrease the likelihood of delirium (Inouye et al., 1999).

Patients with advanced dementia who are hospitalized with acute illnesses have a dismal prognosis. Explaining the risks and benefits of hospitalization and aggressive therapy,

especially when the physician has had an ongoing relationship with the patient and family, often results in a decision to focus on aggressive symptom management without hospitalization (Morrison and Siu, 2000). A “do not hospitalize” order is often appropriate.

Nursing Home

As dementia progresses, most patients develop severe functional deficits or behavior problems that make living at home impossible, even with the most dedicated family caregivers supported by home health care workers. Nursing home admission is a traumatic experience for the patient and family even in the best of circumstances. The trauma is reduced if the admission can be anticipated and the patient and family have meaningful involvement in the decision-making process.

The physician’s role in caring for the dementia patient in the nursing home includes direct patient care and IDT communication. The physician and family can help the nursing home staff learn the patient’s premorbid status and personality to identify any idiosyncrasies that could be helpful when providing care (e.g., “She always calms down if she has chocolate milk”). Open and efficient communication with nursing home staff enhances patient care and promotes creative problem solving.

It is necessary to see the dementia patient in the facility for most visits because transporting the patient to the office is often burdensome for the patient and can precipitate a florid delirium. On-site visits can also facilitate communication with the nursing home staff. Professional groups have provided formal guidance for nursing home attending physicians (Besdine et al., 1996). Physician and family confidence in the care provided in the nursing home allows for quality end-of-life care without the need for hospital transfer when signs of imminent demise are evident.

Overview

Key Points

- Annual alcoholism-identified health costs are \$246 billion.
- Alcoholic persons are heavy users of health care.
- Primary care screening is inadequate for alcoholic patients.

Alcoholism is a chronic and pervasive medical disorder that adds enormous cost to the U.S. health care system. Alcohol abuse and dependency are among the top-three preventable causes of death. The Centers for Disease Control and Prevention (CDC, 2004) estimates that for every alcohol-attributable death, 30 years of potential life is lost, accounting for 2.3 million years of potential life lost (YPLL) and 75,000 preventable deaths per year from identified cases. The total economic costs attributed to alcohol use disorders are \$246 billion, of which \$218 billion is related to alcohol-related motor vehicle crashes (MVCs), violence, and premature death (Harwood et al., 1998).

Alcoholic patients use health care resources disproportionately compared with other populations. Relative to the general population, alcoholics are heavy users of emergency department (ED) services, trauma-related services, acute hospitalization, diagnostic procedures, transfusions, and psychiatric services (Whiteman et al., 2000).

Estimates of the extent of alcohol involvement in trauma include 39% of MVC fatalities (National Highway Traffic Safety Administration, 2004), 47% of homicides, 29% of suicides (Smith et al., 1999), 20% to 40% for fatal recreational injuries (Mayhew et al., 1986), and 10% to 25% for home injuries (CDC 1983; Fell and Nash, 1989). Alcohol is involved in a substantial percentage of injuries caused by falls, drowning, and burns (Howland and Hingson, 1988). More than 5% of all hospital discharges other than child-birth include at least one alcohol-related diagnosis (Chen et al., 2005).

Cirrhosis of the liver continues to be largely attributable to alcohol abuse, with estimates of 60% to 90% of cirrhosis deaths (Johannes et al., 1987). Comorbidity with hepatitis C is frequently a factor in many of these alcoholic cirrhosis-related deaths. Hospitalizations for acute pancreatitis are frequently associated with alcohol dependency. Psychiatric comorbidity is common in the alcoholic population, especially depression and suicide. These sequelae have major implications for managed care organizations and federal and local payers alike. However, screening for alcoholism in primary care and emergency settings is not universal. The recent prospective data from the National Epidemiologic Survey on Alcohol and Related Conditions (NESARC) have provided annual incidence rates for DMS-IV alcohol abuse at 1.0 per 100 person years and alcohol dependence at 1.7 per 100 person years; data also indicate that the greatest risk for alcohol

use disorders occurs during young adulthood (Grant et al., 2008).

Prevalence

Key Points

- Alcohol abuse is more common than diabetes mellitus.
- Heavy alcohol use is more common in men.
- More screening and brief interventions are needed in primary care settings, which results in decreased drinking.
- Screening in hospitals, EDs, and trauma settings can be valuable, but brief interventions in these settings have produced inconclusive results.

In the United States, an estimated 140 million persons use alcohol, making it the most popular psychoactive substance (Baldwin et al., 1993). A reanalysis of the 1994 national comorbidity study found that 8% to 10% of the U.S. population reported lifetime alcohol abuse or dependence (Narrow et al., 2002). About 61% of the U.S. population drinks alcohol (CDC, 2003). The number of U.S. adults who abuse alcohol or are alcohol dependent rose from 3.8 million (7.41%) in 1991–1992 to 17.6 million (8.46%) in 2001–2002, according to NESARC, a study directed by the National Institute on Alcohol Abuse and Alcoholism (NIAAA, 2003). Heavy use is found more frequently in men (10.3%) than women (2.5%). Ethnic variation is minimal in whites (6.4%), Hispanics (7.3%), and African Americans (4.8%) (OAS, 1995). The prevalence of binge drinking, that is, drinking five or more drinks at least once in the preceding month, is 14.2% (Winick, 1996).

The prevalence of alcohol use disorders (abuse and dependence) is almost 15% in the population who consumes alcohol. Compared with other chronic medical conditions in family medicine, alcohol use disorders appear to be of significant importance for early recognition and intervention. Hypertension is estimated to affect at least 50 million Americans, and diabetes mellitus (DM) type 2 affects more than 2% of the U.S. population, or 5.4 million adults. Alcohol use disorders rank almost as high as hypertension and much higher than DM in terms of prevalence. The key for the family physician is to increase the screening, diagnosis, and treatment of alcohol abuse in the clinical setting to the level of importance attached to hypertension or DM. Screening in hospitals, EDs, and trauma care settings can add value (ACS, 2008; Gentilello et al., 1999; Smothers et al., 2004). However, brief interventions for alcohol use in patients with acute injuries in the ED and in hospital admissions have been inconclusive (Dappen et al., 2007; Emmen et al., 2004). A meta-analysis of *screening and brief intervention* (SBI) was found effective in reducing alcohol consumption at 6 and 12 months among non-treatment-seeking primary care patients, regardless of gender (Fleming, 2002). Some evidence suggests that SBI for prevention is also effective in pregnancy care settings (Floyd, 2007).

Causative Factors; Diagnosis and Classification

See the discussion online at www.expertconsult.com.

Screening and Assessment

Key Points

- Apply CAGE screening to all patients older than 18.
- Be aware of “negative” drinking history.
- Closely follow up positive responses.
- The AUDIT-C is a standard for quantifying alcohol use disorders in medical settings.

There is good evidence to support screening for alcohol dependency and alcohol use disorders when using standard screening tools in practice. For the family physician, the diagnosis of alcoholism often depends on clues from the history and physical examination (Box 49-1). Possible clues may include a history of driving under the influence (DUI) or an MVC; history of repetitive trauma; new-onset hypertension, gastritis, or pancreatitis; other, otherwise unexplained liver disease (AST > ALT); presence of depression; recent loss of employment or separation from family; unexplained tremor; upper gastrointestinal (GI) bleeding; recent falls or accidents; and a history of family or marital violence.

The four CAGE questions (cut down, annoyed, guilty, eye opener) are adequate for screening purposes (Box 49-2), derived from the longer Michigan Alcoholism Screening Test (MAST) questions (see eTable 49-1 online) (Hays and Spickard, 1987; Powers and Spickard, 1984). Two positive responses are considered a positive screen and indicate that further assessment is warranted. An important point is that family physicians should not assume that someone does not have an alcohol use disorder when that person answers negatively to questions about drinking. If such patients do not use alcohol at all, it may indicate that they had to quit because they had problems with alcohol. Given the prevalence of alcohol use disorders, it is recommended that the CAGE questions be applied to all patients older than 18 years. Another brief set of screening questions is the TWEAK questionnaire: tolerance, worries, eye openers, amnesia, and cut down (Box 49-3).

Longer screening questionnaires include the MAST and the Alcohol Use Disorders Test (AUDIT; see eTable 49-2 online) (Saunders et al., 1993). Both are considered higher in predictive value but more difficult to administer. Age-specific and population-specific survey tools are also available, including the Geriatric Alcoholism Screen and an adolescent alcoholism inventory. The 10-item Core questionnaire includes three questions on alcohol consumption (the AUDIT-C) and seven on the impact of alcohol use. The AUDIT has been shown to have good sensitivity and specificity in

Box 49-1 Screening Clues for Alcoholism

“Driving under the influence” (DUI) arrest
 Domestic violence
 Unexplained trauma
 Family stress
 New hypertension
 Gastritis
 Pancreatitis
 Tremor

Box 49-2 Brief Screening Questions for Alcohol Use**CAGE***

1. Have you ever felt you should *cut down*, on your drinking?
2. Have people *annoyed* you by criticizing your drinking?
3. Have you ever felt bad or *guilty* about your drinking?
4. Have you ever had a drink first thing in the morning to steady your nerves or to get rid of a hangover (*eye opener*)?

Scoring: Item responses on the CAGE are scored 0 for “no” and 1 for “yes” answers, with a higher score an indication of alcohol problems. A total score of 2 or greater is considered clinically significant.

The normal cutoff for the CAGE is two positive answers; however, the Consensus Panel recommends that the primary care clinicians lower the threshold to one positive answer to cast a wider net and identify more patients who may have substance abuse disorders. A number of other screening tools are available.

CAGE Questions Adapted to Include Drugs (CAGE-AID)[†]

1. Have you ever felt you ought to cut down on your drinking or drug use?
2. Have people annoyed you by criticizing your drinking or drug use?
3. Have you felt bad or guilty about your drinking or drug use?
4. Have you ever had a drink or used drugs first thing in the morning to steady your nerves or to get rid of a hangover (*eye-opener*)?

*Ewing JA. Detecting alcoholism: the CAGE questionnaire. JAMA 1984;252:1905-1907.

†Brown RL, Rounds LA. Conjoint screening questionnaires for alcohol and drug abuse. Wis Med J 1995;94:135-140.

medical and general populations and has recently been useful for screening patients with major psychiatric disorders and as an assessment instrument for patients seeking treatment for alcohol use disorders (Cassidy et al., 2008; Donovan et al., 2006). The AUDIT-C provides an efficient standardized method for assessing the quantity and frequency of alcohol use and accounts for much of the test’s discriminative power in medical populations (Rodriguez-Marros and Santamarina, 2007).

Biologic Markers**Key Points**

- The MCV is higher than 100 fL.
- The AST level is higher than the ALT level.
- There is a positive response to CDT level.
- Five drinks daily for 2 weeks elevates GGT in most people.
- Using GGT and CDT in combination increases sensitivity over either marker alone by 20% without compromising specificity.

Diagnostic clues from the laboratory include a complete blood count (CBC) with an elevated mean cell volume, elevated γ -glutamyltransferase (GGT), aspartate transaminase (AST) level higher than alanine transaminase (ALT), unexplained leukopenia or thrombocytopenia, and positive response to the *carbohydrate-deficient transferrin* (CDT) level (Borg et al., 1992). It is estimated that 5 drinks/day for two weeks will yield an elevated GGT in most people (USDHHS, SAMSHA, 2006). Using CDT and GGT together increases

Box 49-3 TWEAK Screening For Alcohol Use

TWEAK is a five-item scale developed originally to screen for risk drinking during pregnancy.

Points

(1-2) *Tolerance:* How many drinks can you hold? or How many drinks do you need to feel high?

(1-2) *Worried:* Have close friends or relatives worried or complained about your drinking in the past year?

(1) *Eye-openers:* Do you sometimes take a drink in the morning when you first get up?

(1) *Amnesia* (blackouts): Has a friend or family member ever told you about things you said or did while you were drinking that you could not remember?

(1) *Cut down:* Do you sometimes feel the need to cut down on your drinking?

Administering and Scoring

Before administering TWEAK, drinkers are identified by a positive response to the question, “Do you consume, or have you ever consumed, beer, wine, wine coolers, or drinks containing liquor (i.e., whiskey, rum, or vodka)?”

To score the test, a 7-point scale is used.

The “tolerance-hold” question scores 2 points if the respondent is able to hold six or more drinks.

The “tolerance-high” question scores 2 points if three or more drinks are needed to feel high.

A total score of 2 or more indicates that obstetric patients are likely to be risk drinkers. However, preliminary studies suggest that cutoff points of 3 or 4 are better than 2 for identifying harmful drinking or alcoholism.

sensitivity by 20% of either marker alone without compromising specificity (Hitela et al., 2006). Dose-response relationships are not well established, making it difficult to use these tests as a direct quantifier for alcohol consumption (Allen et al., 2004).

Interview Questions

Guidelines for interviewing adolescents about alcohol have been reviewed (Speraw and Rogers, 1998). An atmosphere of trust and privacy must be conveyed (parents should be excluded). The questioning should be gradually moved from nonthreatening areas about general lifestyle to more specific questions about medications to questions about alcohol use. Standard interview questions for alcohol abuse include quantity of consumption; frequency of consumption; preference of alcoholic beverages; age at onset of drinking; attempts to cut down or quit; time of most recent drink; adverse sequelae related to drinking (or stopping drinking); and pattern of drinking (continuous, daily drinking, binge pattern). Quantity questions can classify binge drinking as never, less than one, one to three, three to five, and more than five per month. Vague or evasive answers, as well as rationalizations, should be “red flags.” Patients can also be asked how much alcohol they purchase and how often. It is important to elicit specific, concrete information and not become derailed by certain responses.

A family history of alcohol problems must be detailed because it is a major predictive variable. When a clinician receives the answer that the patient does not drink at all,

the line of questioning should still be pursued to determine whether cessation was problem based. Once it has been established that the person has a history of binge drinking or continuous daily drinking, follow-up questions are in order. These questions may include role impairment, family concerns, amnesia, self-concern, and hangovers to determine the patient's sentiments about alcohol consumption.

Detailed Assessment

Once it has been established that the patient has problems with alcohol, more detailed assessment is in order. The history should then be focused on the known harmful consequences of alcohol abuse and dependency as related to the patient's history. (For a list of complications, see Woodard, 2009). Major disorders include Wernicke's encephalopathy, withdrawal seizures, cerebellar disease, peripheral neuropathy, cardiomyopathy, cirrhosis, pancreatitis, gastritis, bone marrow suppression, and aseptic necrosis of the hip. A careful history should include an assessment of tolerance and withdrawal symptoms, including shakes, hallucinosis, seizures, and delirium tremens (DTs). The time of the last drink and quantification of daily drinking are prerequisites. A history of stage 2 to 4 withdrawal with or without a history of serious medical complications is in itself justification for acute care hospitalization. Alcohol withdrawal often includes anxiety, nausea, vomiting, diarrhea, tremors, and elevated pulse and blood pressure (BP). A history of blackout or amnesic episodes while drinking must also be elicited. A history of family, social, legal, and occupational complications should be obtained as part of the diagnosis of alcoholism.

A psychiatric evaluation is key in the assessment for alcohol abuse. Screening tools such as the Beck Depression Inventory can help identify underlying depression. Assessment of suicidal ideation must be documented, because alcoholics are at much greater risk for suicide-related deaths. The Mini-Mental Status Examination (MMSE) can be useful for assessing possible dementia or delirium and pointing to the need for more extensive neuropsychiatric testing (see Chapter 48). Cognitive damage may be a factor in denial, a trait that characterizes many patients with known alcohol dependency. A sexual history should be included, with attention to multiple partners and human immunodeficiency virus (HIV) risk assessment. A history of comorbid polysubstance abuse and intravenous (IV) drug use should also be sought. Cough hemoptysis, night sweats, fever, and weight loss suggest the need to investigate for tuberculosis.

Physical Assessment

The physical examination should pay close attention to vital signs. Elevated BP, pulse, or respiration can be a clue to the severity of alcohol withdrawal. The smell of ethanol on the breath will point to acute intoxication; the comorbid "dry mouth" may then be a local effect and not related to dehydration. Skin changes can be seen in alcoholics and may include rhinophyma, red swollen facies, and porphyria cutanea tarda. A thorough neurologic examination is in order, including cranial nerves, extraocular movements, gait, and cerebellar signs, as well as a sensory assessment of the lower extremities. Ataxia and nystagmus can be clues to possible intoxication or Wernicke's encephalopathy. Percussion and palpation

of the liver are important in alcoholism. Examination of the extremities can include visualization of Dupuytren's contractures and palmar erythema. An irregular heart rhythm suggests atrial fibrillation, or "holiday heart."

In women, diagnosis of pregnancy should also be excluded (see Alcohol Use Disorder in Women). Alcoholism in pregnancy has severe perinatal effects. Cardiovascular, liver, GI, neurologic, and other sequelae of alcohol and other drugs of abuse have been reviewed (Gordis, 2003). Alcohol abuse is frequently associated with hypertension.

KEY TREATMENT

Evidence on the effectiveness of counseling to reduce alcohol consumption during pregnancy is limited; however, studies in the general adult population show that behavioral counseling interventions are effective among women of childbearing age. The benefits of behavioral counseling interventions to reduce alcohol misuse by adults outweigh any potential harm (USPSTF, USDHHS, 2006) (SOR: B).

Management

Alcohol Intoxication

Key Points

- Naive alcohol users are impaired at lower levels.
- Always give thiamine to alcoholic patients.
- Urine toxicology is frequently helpful for concomitant drug use.

Alcohol intoxication is frequently seen as a component of trauma, domestic violence, or suicide attempts (McGinnis and Foege, 1993). The degree of intoxication is determined by the amount of alcohol ingested, the duration of the ingestion, and the patient's tolerance, if any, for the alcohol. Subtle effects occur at levels of 20 mg/dL and include mild euphoria, mild impairment of coordination, and mood alterations. At 80 to 100 mg/dL, delayed reaction times and slurred speech may be noted. This 80-mg/dL level is generally accepted as an unsafe level for motor vehicle operation. Between 100 and 200 mg/dL, ataxia, grossly slurred speech, and incoordination occur. As the level climbs to 300 mg/dL, the ataxia becomes more marked, and drowsiness, lethargy, and vomiting may occur. In naive drinkers, levels above 400 mg/dL are associated with coma, respiratory depression, hypothermia, and death from central nervous system (CNS) depression, loss of airway integrity, or pulmonary aspiration. Chronic alcoholics will have different tolerance responses than those just listed and may be in severe withdrawal at substantial levels.

Alcohol-induced coma can be managed by protecting the airway and performing basic resuscitation, if necessary. The patient should be placed in a warm protective environment, with careful monitoring of vital signs. Gastric emptying is rarely helpful because of the rapid absorption of alcohol, but it may be considered if the ingestion has occurred within 60 minutes. Alcohol is eliminated mostly by hepatic metabolism, which follows zero-order kinetics. The rate does

not change with changes in the alcohol blood level. Fructose can enhance elimination but is not typically used. In extreme cases, hemodialysis may be effective in reducing the level quickly. Activated charcoal does not efficiently absorb ethanol but may be given if other toxins have been ingested (Mayo-Smith, 2009).

Thiamine and glucose should always be administered, because chronic alcoholism is associated with hypoglycemia and thiamine deficient states such as Wernicke's encephalopathy (mental confusion, cranial nerve palsies, ataxia). Thiamine should be given immediately before or with glucose to prevent hypoglycemia because glucose is metabolized with the enzyme thiamine pyrophosphorylase. The physician should look for additional drug use in all patients because the effects of other drugs may be obscured by the obvious alcohol intoxication (Mayo-Smith, 2009). A urine toxicology screen may be positive for concomitant intoxicants.

Overview of Alcoholism Treatment

Alcoholics who are actively drinking are among the highest cost users of medical services in the United States. Several studies have documented that alcohol treatment has beneficial effects on health care expenditures, primarily as a result of decreased health care use by alcoholics and their families. A Harvard Study compared 587 lifesaving interventions and ranked all substance abuse interventions, including treatment of alcoholism, in the top 10% (Tengs et al., 1995).

Physicians interface with the medical or behavioral effects of alcoholism when patients deteriorate to the point of trauma, end-organ damage, or behavioral impairment. As with other chronic disorders, alcoholism is slow but progressive. As the disease progresses, the ability to control drinking diminishes, which distinguishes an alcoholic from a nonalcoholic. Many physicians view detoxification as the treatment of this disorder, which is similar to giving diabetics one injection of insulin to control their diabetes. It treats the immediate problem but does little to address the chronic disorder in 1 week or 1 month. Although the goal for an alcoholic is complete abstinence from alcohol, the norm is alcohol consumption in increasing amounts. The family physician can view intermittent periods of abstinence or reductions in alcohol consumption as progress in treatment of the disease and encourage further efforts. Relapse must be evaluated carefully, and keys to change can open the door to further reductions or ongoing abstinence.

The American Society of Addiction Medicine (ASAM) has developed patient placement criteria (PPC) to better guide treatment of alcoholism. (Mee-Lee et al., 2001). The PPC can help to assign the appropriate level of care for detoxification and subsequent rehabilitation of those with alcohol use disorders. The ASAM criteria reflect a consensus of expert opinion for adolescents and adults in treatment. Levels of care are differentiated by three criteria: (1) degree of direct medical management provided; (2) degree of structure, safety, and security provided; and (3) degree of treatment intensity provided. The current criteria are under revision since 2007. Special populations who need consideration include pregnant and nursing women; adolescents; older adults; HIV-positive patients; patients with neurologic, cardiovascular, hepatic, or renal disorders; patients with psychiatric comorbidities; and persons in criminal justice settings (Wright et al., 2009).

Detoxification

The *alcohol withdrawal syndrome* is a somewhat predictable series of events that have a temporal relationship to the use, decrease in intake, or cessation of alcohol consumption. Alcohol withdrawal may occur in a patient who has a reduction in alcohol intake from a previously significant level or an absolute absence of alcohol. The pharmacology of alcohol and its subsequent metabolism is well known and follows zero-order kinetics, primarily through the liver and cytochrome pathways (Mayo-Smith, 2009).

Patients with mild to moderate alcohol withdrawal symptoms and no serious psychiatric or medical comorbidities can be safely treated in the outpatient setting (Asplund et al., 2004). The severity of these symptoms varies greatly among individuals, but in a majority, they are mild and transient, passing within 1 or 2 days (Driessen et al., 2005; Mayo-Smith, 2009). Westerling and colleagues (2006) developed a scale to predict severity of alcohol withdrawal.

The signs and symptoms of alcohol withdrawal vary individually but tend to be repetitive in the same person. Most alcoholics who withdraw from alcohol experience minimal symptoms, such as sleep disturbance or anxiety. A small number may have tremulousness, agitation, diaphoresis, and cognitive impairment. The tremors or shakes typically begin 12 to 14 hours after a period of heavy drinking and are usually noted in the early morning. Tremulousness may be accompanied by *alcoholic hallucinosis*, a misperception of objects in the patient's sensory arena. Other symptoms of withdrawal include nausea, vomiting, poor oral intake, sweats, and anxiety. Seizures during alcohol withdrawal tend to occur as one isolated seizure or a brief cluster of seizures. Seizures are frequently preceded by tremors and tend to recur in a similar pattern in the same patient. Seizures may be the initial manifestation of alcohol withdrawal. Seizure activity is most common 24 to 48 hours after alcohol cessation, although seizures can occur as early as 24 hours or as late as 2 weeks after cessation of alcohol (Victor, 1983) (Box 49-4). Seizures may occur even later with concomitant benzodiazepine abuse. Withdrawal seizures are typically generalized, grand mal, and self-limited. Rarely, seizures may progress to status epilepticus (<3%). Physical signs include an elevated pulse and BP along with signs of autonomic hyperactivity. Researchers have noted increased levels of catecholamine in the locus ceruleus (brainstem) and abnormalities in the neuroinhibitory hormone γ -aminobutyric acid (Mayo-Smith, 2006).

The revised Clinical Institute Withdrawal Assessment for Alcohol scale, revised (CIWA-Ar) is a validated 10-item assessment tool used to quantify the severity of alcohol withdrawal syndrome and to monitor and medicate patients going through withdrawal (Bayard et al., 2004) (Table 49-1). Patients with moderate withdrawal should receive pharmacotherapy

Box 49-4 Alcohol Withdrawal Seizures

Peak seizure risk is 24 to 48 hours after cessation; may occur up to 2 weeks later.

Seizures are brief or occur in a "flurry."

Dilantin is ineffective.

Use caution with medications that lower seizure threshold (e.g., tricyclics, phenothiazines).

to treat their symptoms and reduce the risk of seizures and DTs during outpatient detoxification. Benzodiazepines are the treatment of choice for alcohol withdrawal, according to U.S. and Scottish guidelines (SIGN, 2003). In healthy people with mild to moderate alcohol withdrawal, carbamazepine has many advantages, making it a first-line treatment for properly selected patients (Asplund et al., 2004).

Major alcohol withdrawal, also known as *delirium tremens*, occurs in less than 5% of alcoholics in withdrawal. Delirium tremens is usually preceded by minor withdrawal symptoms, although they may appear frankly in a patient with minimal symptomatology. The delirium often begins 3 to 4 days after the last drink and is characterized by a marked change in sensorium with agitation, frank hallucinations,

Box 49-5 Delirium Tremens (DTs)

Usually preceded by tremor or seizures.
 Usually begin 3 to 4 days after alcohol cessation.
 Delirium with severe disorientation
 Autonomic hyperactivity
 Disturbed sleep
 Worsened by concomitant disorders (e.g., pancreatitis, pneumonia, GI bleed)

and severe disorientation (Box 49-5). Severe and potentially life-threatening autonomic hyperactivity leads to tachycardia, hypertension, and diaphoresis, frequently with low-grade fever. The severe disorientation may lead to self-injury or harm. Typically, the patient's actions may be appropriate to the context of the state of disorientation and hallucinosis. The patient's sleep activity is usually disturbed, along with excessive motor activity. Risk factors for DTs are a high blood alcohol level at the initial evaluation, an alcohol withdrawal seizure early in the withdrawal syndrome, and a previous history of delirium (Victor, 1983). Concomitant infections or additional medical disorders may also predispose to severe alcohol withdrawal. Fever over 101° F (38.3° C) should be evaluated further. Before the treatment of alcohol withdrawal, a complete physical examination should be performed to assess the patient, including analysis for GI blood loss.

KEY TREATMENT

Physicians should always use thiamine supplementation (Mayo-Smith, 2009 (SOR: A)).
 Giving benzodiazepines is the treatment of choice of alcohol withdrawal and is supported by the latest systematic reviews (Ntais et al., 2005) (SOR: A).
 Carbamazepine is first-line treatment for properly selected patients (Asplund et al., 2004) (SOR: C).
 Phenytoin (Dilantin) is ineffective in withdrawal seizures.

Withdrawal Treatment

Treatment of alcohol withdrawal consists of supportive and pharmacologic interventions. Supportive interventions include fostering the patient's desire for abstinence during the withdrawal process. A calm, quiet environment, reassuring and reorienting the patient if confused, decreases the risk of injury or relapse.

The preferred CNS agents for detoxification are the benzodiazepines, according to U.S. and Scottish guidelines (Asplund et al., 2004; SIGN, 2003) and Cochrane review (Ntais et al., 2005). They provide the best side effect profile and have a better risk/benefit profile than other agents. Benzodiazepines are not likely to be fatal in overdose unless mixed with another central depressant (check the urine toxicology screen). Chlordiazepoxide and diazepam are both effective agents. If liver disease is present, or to treat withdrawal in an older patient, oxazepam or lorazepam may be a safer choice because of shorter half-life. Additionally, beta blockers such as atenolol, 50 to 100 mg/day, may decrease tremulousness and sympathomimetic symptoms if there are no contraindications (Table 49-2). A scheduled regimen of chlordiazepoxide, 100 to 300 mg on day 1, followed by daily 50% dose reductions for 3 to 5 days, rather than "as needed" or on a symptom schedule, provides for a smooth withdrawal. Doses must be held for oversedation or somnolence. Monitoring for oversedation is necessary before each dosing (Sullivan et al., 1989). Aggressive regimens support patient comfort, help maintain compliance, and reduce the risk of seizures and major withdrawal. Outpatient detoxification can be performed; without supervision, however, some risk is present (e.g., seizures, self-injury, overdose), and relapse is likely if further alcohol is available.

Anticonvulsants such as phenytoin have not been demonstrated to reduce withdrawal seizures better than benzodiazepines. Anticonvulsants used for detoxification with a history of seizures received a level B of evidence in the Scottish guidelines (SIGN, 2003). Carbamazepine is superior to other anticonvulsants and results in less psychiatric distress, a faster return to work, less rebound symptoms, and reduced

Table 49-2 Alcohol Withdrawal: Stages and Treatment Summary

| Stage | Intervention | Pharmacology |
|--------------|---|--|
| I. Mild | Be supportive. Contact Alcoholics Anonymous. Provide close follow-up. | Thiamine, 100 mg daily Chlordiazepoxide, 25 mg three times daily if necessary, 3 days only |
| II. Moderate | Allow brief inpatient visit. Make observations. Check laboratory test results (e.g., magnesium, phosphate, electrolyte, glucose levels). | As above, <i>plus</i> chlordiazepoxide, 100-300 mg/day, 3 days only Atenolol, 50-100 mg/day, 3 days only |
| III. Severe | Hospitalize in ICU. Delirium tremens, intermediate care. Laboratory tests as above. Monitor fluid status. May need restraint. Monitor for infection. Prevent self-harm. | As above, <i>plus</i> chlordiazepoxide, 100 mg hourly until asleep or subdued, then taper. Antipsychotics: haloperidol, 2-10 mg/day Lorazepam, 1-2 mg intravenously if unable to take orally |

posttreatment drinking (Malcolm et al., 2001). Anticonvulsants are not generally indicated unless a concomitant seizure disorder is present.

Antipsychotic medications such as risperidone, olanzapine, and haloperidol have benefits in patients with hallucinosis and DTs but may reduce the seizure threshold (SIGN, 2003). Ear acupuncture has not shown efficacy in alcohol withdrawal in clinical trials. However, massage therapy has reduced withdrawal scores (Kunz et al., 2007; Reader et al., 2005).

Interventions in Alcohol Disease

Interventions by family physicians have the goal of changing the natural course or outcome of the alcoholic disease process. A family physician typically performs many interventions on patients with chronic disorders over time. Interventions generally follow an assessment and consist of advice about how to manage the disorder, may include a pharmacologic agent, and usually require some type of follow-up or ongoing monitoring.

Brief Interventions

Brief interventions can be very successful in primary care (SIGN, 2003) (Box 49-6). The father of the concept of *stages of change*, Prochaska (2009) reviews motivation to change in alcohol addiction. Family physicians can apply motivational interviewing in helping patients to move to the next level in stages of change. Part of any substance abuse intervention is the physician's assessment of the patient's readiness to change. First described by Prochaska and DiClemente (1983) while studying smokers, assessing the state of change assists the family physician in targeting the interventional approach to the patient. Change consists of the following six states:

1. **Precontemplation.** The physician can plant the seed of how alcohol is harming the patient (think of creative ways to list reasons) physically or emotionally. Written

Box 49-6 Components of Effective Brief Intervention

Feedback of physician's assessment
Emphasis on patient *responsibility*
Clear, direct *advice to change*
Nonconfrontational physician approach
Menu of options provided

From Bien TH, Miller WR, Tonigan JS. Brief interventions for alcohol problems: a review. *Addiction* 1993;8:315-335.

information is helpful, and support to the family and others involved must be offered. Further biologic or historical data should be collected, with follow-up at reasonable intervals and availability to help the patient when ready. A nonjudgmental approach is best.

2. **Contemplation.** The patient is aware that harm is occurring but is not yet ready for action. The physician tries to motivate patient to the action phase by listing more reasons for urgency, such as bleeding, ulcers, pancreatitis, and family violence. The physician offers referral advice if the patient is interested, collects more data, performs follow-up at a short interval, and is ready to help the patient when ready to start.
3. **Preparation.** The physician assists the patient in preparing for reduction or cessation of use.
4. **Action.** The patient is ready for referral, has "hit bottom," or is otherwise ready for change. The physician arranges inpatient or outpatient detoxification and involvement in a treatment program and completes a history and physical examination, with laboratory studies as appropriate.
5. **Maintenance.** The physician performs follow-up on the patient; reviews participation in the self-help program and use of the 12 steps as well as the frequency of Alcoholics Anonymous (AA) attendance; monitors target organ issues; performs mental status and depression screening; counsels regarding relapse prevention; monitors laboratory values (e.g., GGT, CDT); prescribes vitamins, naltrexone, acamprosate, antidepressants, or disulfiram (Antabuse) as needed; monitors urine ethylglucuronide (ETG) to determine alcohol use in the previous 72 hours; monitors and schedules; and performs follow-up regularly, as with any chronic disease.
6. **Relapse.** The physician anticipates relapse with any addictive disorder, is ready to help the patient again with entry into a recovery program, and offers nonjudgmental support.

Brief interventions can be carried out in the context of a routine office visit (Edwards and Rollnick, 1997; Fleming et al., 1999). Interventions can follow assessment of the patient. When the physician sees sufficient evidence to conclude or strongly suspect that an alcohol use disorder is present, the brief intervention can be targeted to the patient's stage of change. An encounter with a precontemplative patient would include presentation of the physician's analysis of the problem in a supportive and nonconfrontational manner, with the goal of moving the patient to another state of change. For example:

Mr. Smith, your recent accident, alcohol use pattern, liver enlargement on physical examination, and abnormal laboratory test results lead me to conclude that your use

of alcohol is a problem. As your family physician, I am concerned about your ongoing health risks. What can we do to deal with this problem?

Alternatively, a patient who is in the contemplation phase of change would be asked a different set of questions, such as:

Mr. Smith, I am glad that you are able to realize the impact that your alcohol drinking is having on your health, but we need to move forward and discuss treatment options.

An effective brief intervention should include *feedback* summarizing the physician's assessment; patient responsibility should also be emphasized, followed by clear, direct advice to change given in a nonconfrontational manner. The patient is given a menu of options from which to choose (Bien et al., 1993). Authoritative approaches are generally less effective than an empathetic approach. This type of approach will take practice and refinement for busy family physicians but can be integrated into the office practice without substantial time or expense. These techniques are more generally known as *motivational interviewing*. Motivational interviewing is effective in helping family physicians to engage patients in a variety of behavioral changes, including alcohol or tobacco abuse. Motivational interviewing has been a successful technique when used with alcohol brief interventions (Vasilaki et al., 2006).

Classic Intervention

When a brief intervention is not effective, or if the circumstances demand more expeditious change, a classic intervention can be planned. The interventional goal is to break through the alcoholic denial system by providing an overwhelming amount of evidence and feedback to the alcoholic patient. Classic interventions need to be carefully orchestrated by professionals trained in chemical dependency treatment. Unless actively involved in alcoholism treatment, most family physicians will consult one of their referral treatment programs for assistance in developing a classic intervention. The family physician may be an appropriate member of the intervention group.

Treatment of Alcoholism

Key Points

- Try the least restrictive treatment first for the alcoholic patient.
- Long-term treatment is favored for alcoholism.
- The presence of other disorders increases acuity needs in the alcoholic.

The treatment options for alcoholism are extensive (Fuller et al., 2003; Kranzler et al., 2009). The medications most widely studied for alcohol use disorders are disulfiram, naltrexone, and acamprosate. Results from the COMBINE study and trials of depot naltrexone formulations and oral topiramate have provided important new information on the use of these medications in alcohol rehabilitation.

A family physician is faced with several decisions when evaluating a patient for treatment of alcoholism after successful detoxification, or if medically supervised detoxification is not needed. Should the patient go through a hospital or a nonhospital (residential) inpatient program, a day treatment program, or any outpatient program? Should the patient receive counseling, attend AA, or be involved in a cognitive program? Inpatient programs offer isolation from the drinking environment, intensive treatment, family involvement, in-depth assessment, and convenience for further medical or psychiatric assessment. However, they carry significant expense, typically occur after detoxification, remove the patient from the real-world environment, and have not been consistently shown to improve long-term outcomes. Patients who are suicidal or who have serious concomitant mental disorders that may impair recovery, as well as those unable to maintain abstinence in a less restrictive environment, should be considered for these facilities. Advantages of day treatment and outpatient treatment include reduced expense, ability to maintain work in some cases, and usually a longer period of treatment in a less restrictive environment. In general, as long as it is safe to try outpatient treatment initially, it is the least restrictive and most cost-effective method.

Access to relapse prevention treatments of established efficacy should be facilitated for alcohol-dependent patients. These therapies include outpatient programs, residential and "halfway house" milieu therapies, and partial hospitalization programs (SIGN, 2003).

Alcohol Dependency and Psychiatric Comorbidities: Dual Diagnosis

Dual diagnosis is defined as alcohol dependency with one or more other psychiatric comorbidities. Frequently, alcoholics abuse other substances, such as crack cocaine, nicotine, and even opiates (Tallia et al., 2005). Comorbidity estimates among alcoholics, gender preferences for addictive substances, and patterns of progression vary widely (Crum, 2009). Assessment of long-term outcomes highlights the impact of comorbidities on level of functioning, educational achievement, occupation, and social relationships (Crawford et al., 2008).

Patients with alcohol problems and anxiety or depression should have their alcohol problem treated first. If depressive symptoms persist for more than 2 weeks after treatment for alcohol dependence, the physician should consider use of a selective serotonin reuptake inhibitor (SSRI) or tricyclic antidepressant (TCA), or referral for supportive psychotherapy and cognitive-behavioral therapy (CBT), along with relapse prevention (SIGN, 2003). CBT has been shown to be efficacious (Longabaugh and Morgenstern, 1999; Project MATCH, 1997).

Patients with psychotic disorder and alcohol dependence should be encouraged to address their alcohol use and may benefit from motivational, CBT, family, and nonconfrontational approaches. Structured settings may offer some advantage for patients with psychotic comorbidities. Another challenge with treating alcoholics with comorbid conditions is *impulse control disorders* (ICDs). Also known as "behavioral addictions," ICDs include pathologic gambling (PG) and many other conditions (Yip and Potenza, 2009). Of interest in the treatment of alcoholics is evidence that patients with

PG can benefit from treatment with naltrexone (Kim et al., 2001).

Drug Treatment Specific to Alcohol Dependency and Recovery

Key Points

- Disulfiram can be regarded as an aversive agent.
- Naltrexone produces a surmountable opiate blockage and diminishes the reinforcing effect of alcohol.
- Depot naltrexone has greater efficacy than oral naltrexone in alcohol use disorders.
- Acamprosate reduces the urge to drink in some patients.

Treatment of alcohol abuse and dependency with medications has long been a challenging and controversial topic. Drug treatment of alcohol abuse can be divided into drugs used for detoxification (see earlier discussion) and those used to reduce or eliminate alcohol consumption after detoxification and for relapse prevention. Pharmacologic interventions for alcoholism have been reviewed (Fuller et al., 2003). The U.S. Food and Drug Administration (FDA) now approves three drugs for alcohol treatment to reduce or eliminate consumption: disulfiram (Antabuse), acamprosate (Campral), and naltrexone (ReVia) as well as long-acting naltrexone (Vivitrol).

Disulfiram

Disulfiram has been available for the treatment of alcohol dependency since the late 1940s. Given as a single daily dose, disulfiram inhibits aldehyde dehydrogenase, the second alcohol degradation enzyme. This inhibition causes acetaldehyde to increase 5 to 10 times the usual level found after alcohol consumption. Symptoms that occur in patients acquiring alcohol from any source include flushing, palpitations, respiratory difficulty, nausea, vomiting, weakness, and general uneasiness. If alcohol consumption continues or a large volume is ingested, hypotension, syncope, loss of consciousness, and death may follow. Minor reactions may occur with inadvertent exposure from nonbeverage alcohol sources such as colognes, over-the-counter (OTC) medications, or foods with uncooked alcohol. Also used in attempted and completed suicides, disulfiram can be thought of as an “incomplete poison” that will become a “complete poison” if alcohol is added.

Disulfiram works on the patient’s understanding and expectation of an adverse experience if alcohol is consumed. It can be given in dosages of 125 to 500 mg daily and can be safely started 24 to 48 hours after alcohol cessation. Avoidance or extreme caution should be used in patients with known or suspected coronary artery disease, those at risk for suicide or with serious mental illness, or those unable or unlikely to comply with a complete treatment plan that includes additional forms of treatment. Disulfiram should not be used as the only treatment for alcohol abuse; it is better considered as an adjunct for carefully selected patients. An often-quoted blinded placebo-controlled study of Veterans Administration patients

found that doses of 250 mg, 1 mg, and no disulfiram produced no significant differences in total abstinence (Fuller et al., 1986). Higher doses were associated with fewer drinking days than in other groups. Adverse reactions include peripheral neuropathy, optic neuritis, drowsiness, fatigue, metallic aftertaste, and infrequent hepatotoxicity, probably resulting from hypersensitivity. Evaluation of liver enzyme levels before therapy and periodically is recommended.

Supervised treatment or directly observed therapy (DOT) with oral disulfiram may be used to prevent relapse. However, patients must be informed that this treatment requires complete abstinence, and they should clearly understand the risks of disulfiram therapy.

Naltrexone

The euphoric effect of alcohol is mediated through the endogenous opioid system, with activation of the prefrontal cortex (Tuhonen et al., 1994). Naltrexone, an opioid antagonist, has documented beneficial effect in reducing relapse and craving in alcoholic patients (O’Malley et al., 1992; Swift et al., 1994; Volpicelli et al., 1992). Alcoholics taking naltrexone report a less pleasurable effect or high from alcohol consumption and do not escalate their drinking as rapidly as control groups (Volpicelli et al., 1995). A decreased craving for alcohol has not been universally reported. Naltrexone is given as a daily 50-mg tablet or a monthly 300-mg injection. This dosage provides a surmountable opioid blockage that will render other opioids ineffective unless given in greatly increased doses. Naltrexone is not an aversive agent. Many alcoholic patients report a less-than-expected pleasurable experience with alcohol consumption, whereas others report some mild aversive symptoms.

Naltrexone undergoes first-pass hepatic metabolism and is hepatotoxic in excessive doses. It should not be given to patients currently addicted to opiates because it will precipitate acute opiate withdrawal (Croop et al., 1997). The most common side effects at the usual dosage include nausea, headache, dizziness, anxiety, and somnolence. Good candidates for naltrexone are those likely to be compliant with therapy, those concomitantly addicted to opiates who have been detoxified and have not received opiate replacement therapy, and those with heavy alcohol cravings at entry to therapy (Volpicelli et al., 1997). Naltrexone should *not* be used as a single treatment agent but rather in conjunction with other behavioral or motivational treatment modalities. Questions remain about the duration of treatment with naltrexone in alcohol use disorders. Generally, prolonged abstinence rates improve after 12 months of continuous abstinence.

Poor compliance with oral naltrexone reduces its potential benefits (Volpicelli et al., 1997). In a pilot study, alcohol-dependent patients treated with subcutaneous depot formulation of naltrexone had detectable plasma concentrations of the medication for more than 3 days after injection and had reduced frequency of heavy drinking compared with the placebo group (Kanzler et al., 1998). A randomized clinical trial with depot naltrexone did not demonstrate reduced incidence of heavy drinking, although it did demonstrate significantly delayed onset of drinking, increased number of abstinent days, and increased abstinence (Kanzler et al.,

2004). The FDA approved long-acting naltrexone (Vivitrol), 380 mg each month intramuscularly (IM) in the buttock, for alcohol dependency in 2006. Patients should be abstinent when they are started on naltrexone.

An alternative opioid antagonist with some success in patients with alcohol dependency, but not as well studied, is nalmefene (Kanzler et al., 2009).

According to the Agency for Health Care Policy and Research, there is good (level B) evidence to support the use of naltrexone to reduce craving and relapse (AHCPR, 1999).

Acamprosate

Acamprosate is one of the newest drugs to be added to the formulary for the treatment of alcohol dependency. The FDA has approved acamprosate for maintenance of abstinence from alcohol in patients with alcohol dependence who are abstinent at treatment initiation. This provision includes that patients also participate in a comprehensive alcohol treatment program. Acamprosate is reasonably well tolerated and without serious adverse effects (AHCPR, 1999). European trials of acamprosate showed efficacy in alcohol dependence; acamprosate enhanced abstinence and reduced drinking days in alcohol-dependent subjects.

Acamprosate is recommended in newly detoxified dependent patients as an adjunct to psychosocial interventions. Acamprosate is approved for use in alcohol-dependent and alcohol-abusing patients. Its mechanism of action is not well known, although there is fair evidence of its benefit. Acamprosate is an analog of homotaurine, a GABA-ergic agonist. The GABA-ergic system appears to affect the action of alcohol-induced behavior. Acamprosate also appears to have effects on glutamate and NMDA receptors. Chronic alcohol exposure is thought to alter the normal balance between neuronal excitation and inhibition, and acamprosate may help restore some of this balance. Several controlled clinical trials have demonstrated the effectiveness of acamprosate as an adjunct to psychosocial therapy for alcoholics who have undergone inpatient detoxification. In these studies, acamprosate was demonstrated to be superior to placebo. Acamprosate does not appear to be effective in the treatment of polysubstance abuse (Bouza et al., 2004; Mann et al., 2004). Evaluation of renal function for those at risk, including elderly patients, is indicated before initiating treatment with acamprosate.

Two U.S. multicenter trials, including the Combining Medications and Behavioral Intervention for Alcoholism (COMBINE) study, failed to show an advantage of acamprosate over placebo on an "intent to treat" basis (Anton et al., 2006; Mason et al., 2006). Discrepancies may be caused by differences in European studies, which included heavier drinkers with longer periods of abstinence before induction in trials (Kanzler et al., 2009).

Summary

Pharmacotherapy for alcohol use disorders with strength of recommendation (SOR) is as follows:

- Naltrexone (A, 1)
- Long-acting naltrexone (Vivitrol) (A, 1)
- Acamprosate (A, 1)
- Disulfiram (B, 2)

Other Medications Used in Alcohol Treatment

Anticonvulsants (Topiramate)

Anticonvulsants likely exert beneficial effects on γ -aminobutyric acid (GABA) receptors. Placebo-controlled studies included carbamazepine (Mueller et al., 1997), divalproex (Brady et al., 2002), and topiramate (Johnson et al., 2003), with a multicenter study confirming the efficacy of topiramate and anticonvulsants for treatment of alcohol use disorders (Johnson et al., 2007). Topiramate was shown to decrease (1) drinks/day, (2) drinks/drinking day, (3) drinking days, (4) heavy-drinking days, and (5) GGT levels (Johnson et al., 2007). Side effects of anticonvulsants include numbness and tingling, metabolic acidosis, fatigue, dizziness, loss of appetite, nausea, diarrhea, weight loss, and difficulty concentrating, with memory, and in word finding. Suicidal thoughts or actions are infrequently reported, as are renal calculi and acute secondary glaucoma (Kranzler et al., 2009).

Baclofen

A GABA-B receptor agonist, baclofen has long been used as an antispasmodic. Only more recently has baclofen been investigated as a treatment for alcohol dependency. In a modest controlled trial of 1 month, baclofen was efficacious in achievement of total abstinent days compared with placebo (Addolorato et al., 2002). A follow-up study demonstrated efficacy in 84 patients with cirrhosis of the liver in maintaining abstinence (71% baclofen vs. 29% placebo) (Addolorato et al., 2007). There is potential for abuse of baclofen and withdrawal reactions, including delirium, which underscores the need for further research (Kanzler et al., 2009).

Serotonergic Agents

Most episodes of postwithdrawal depression will remit without specific treatment if abstinence from alcohol is maintained for days or weeks (Brown et al., 1988; Schukit, 1983). Whereas patients with comorbid depression often require pharmacotherapy, and although the SSRIs have a low side effect profile, they can exacerbate the tremor, anxiety, and insomnia in early-recovering alcoholics. Recovering alcoholics with comorbid depression may actually do better with TCAs (Nunes and Levin, 2004).

Special Populations

Alcohol Use Disorder in Women

Women have lower rates of alcohol abuse and dependency than their male counterparts, 1.5% overall and 1.5% in older adult women (Mouton and Espino, 1999) (Box 49-7). Women generally enter treatment later than men and have more psychiatric symptoms. Women seem to develop many pathologic effects of alcohol more rapidly than men (Blume and Zilberman, 2005), including fatty liver, hypertension, anemia, malnutrition, GI hemorrhage, and peptic ulcer requiring surgery (Zweben, 2009). For women, five to seven drinks daily is sufficient to cause significant disease progression.

Box 49-7 Women Alcoholics

Lower rates of abuse than men.
 More hidden drinking than men.
 TWEAK screening better than CAGE.
 Less alcohol consumption than men may cause significant disease progression.
 Treatment in all-women program is preferred.

Nonmedical use of prescription drugs in general and opioids in particular has been identified as a significant problem since the late 1990s. Women also have higher associated rates with first use of illicit drugs after age 24, serious mental illness, and cigarette smoking (Tetrault et al., 2008). Comorbid conditions for women include drug addiction, sexual abuse, intimate partner violence, borderline personality disorder, eating disorders, mood disorders and anxiety disorders, and HIV infection. Women who drink alcohol may be more sensitive to the behavioral effects of concomitant cocaine use (Zweben, 2009).

Family physicians generally detect alcohol use disorders in women later than in male alcoholics. Screening tests (e.g., CAGE) have less sensitivity in women and need to be interpreted differently, usually with lower cutoff points. This difference may result from the lower volume of alcohol consumed and the social stigmatization of these women (Bradley et al., 1998). Screening tests such as the TWEAK have performed better than the CAGE in women. It is important for physicians to educate women about their greater risk, even highly educated patients (Green et al., 2007). Incarcerated women often begin using drugs and alcohol at very young ages and frequently require significant educational and job-training support to make successful transitions to recovery (Zweben, 2009). Women may have better treatment outcomes if referred to all-women programs or programs specializing in women's addictions (Hodgkins et al., 1997).

Alcohol Abuse and Pregnancy

The Institute of Medicine recognizes alcohol-related birth defects (ARBDs) and alcohol-related neurodevelopmental disorder (ARND) in addition to fetal alcohol syndrome (FAS) as potential effects of alcohol use in pregnancy and the periconception period (Warren and Foudin 2001; Muchowski and Paladine, 2004). A diagnosis of FAS requires characteristic facial anomalies, growth retardation, and neurodevelopmental abnormalities. In *partial* FAS, affected children have some of these characteristics, with no other explanation. ARBD includes a confirmed history of maternal alcohol use plus one or more congenital defects, most often cardiac, renal, vision, hearing, or skeletal. ARNDs require a confirmed history of maternal alcohol use and the neurodevelopment abnormalities or cognitive-behavioral abnormalities found in partial FAS.

The prevalence of FAS in the U.S. population is estimated at 0.5 to 2 per 1000 births, with up to 10 in 1000 newborns having some effect from alcohol exposure. The rate of FAS is more than 20 times higher in the United States compared with other countries, including European countries, partially because of differences in diagnosis (Muchowski

and Paladine, 2004). Whether a safe threshold of alcohol consumption exists before or during pregnancy is controversial. Many U.S. authorities recommend against any alcohol intake before or during pregnancy. The effects of alcohol on a fetus depend on the amount of alcohol consumed at one time, timing of alcohol consumption in gestation, and duration of alcohol use in pregnancy. This is complicated by studies using various definitions of "light" and "heavy" alcohol use, with categories that often overlap among different studies. *Binge drinking*, defined as more than five drinks in a single day, even when episodic, is more dangerous to fetal brain development than non-binge drinking (Muchowski and Paladine, 2004).

Less severe problems can occur, although a high level of alcohol use in pregnancy is associated with more severely affected offspring. A 1984 study of 31,000 pregnancies showed a higher risk of growth retardation if a mother had even one drink a day. A 2001 study of more than 600 urban African American children showed continued behavioral effects of alcohol at age 6 to 7 years with low levels (one drink daily) of maternal alcohol consumption (Muchowski and Paladine, 2004).

Some intervention attempts show promise. A review of trials in which physicians briefly counseled nonpregnant women who were problem drinkers found no consistent decrease in drinking. Trials of personalized advice to pregnant women have also been found to be no more effective than written information alone. A written self-help manual, however, did improve cessation rates in women at a prenatal clinic. The CDC sponsored a pilot project to encourage alcohol cessation and effective contraception in women at risk for alcohol-exposed pregnancy (Muchowski and Paladine, 2004). Although not a controlled trial, this more extensive intervention showed promise. Of the 143 women enrolled, 68.5% had stopped their alcohol consumption or were using effective contraception by the 6-month follow-up. Women should not be discouraged from breastfeeding, if they are not using illicit drugs and do not have specific contraindications such as HIV infection (McCarthy and Posey, 2000).

Applying the Evidence

Written information about the risks of alcohol use in pregnancy should be provided to pregnant women who consume alcohol (Floyd et al., 1999; Muchowski and Paladine, 2004). Data are insufficient to recommend physician counseling for alcohol cessation before or during pregnancy. More comprehensive interventions may be more effective but have yet to be fully studied. No studies have evaluated neonatal outcomes with women counseled on alcohol cessation in the periconception period.

Emergency Contraception

The importance of making information and resources available for emergency contraception deserves more attention for women with addictions. Emergency contraception techniques are widely available and as OTC medications in some states. However, these are underused by women at risk for unintended pregnancy. An emergency hotline is available nationally for emergency contraception access for women: 1-888-NOT-2-LATE (1-888-668-2528) (<http://not-2-late.com> accessed 8-31-06).

Adolescents

Family physicians should develop expertise for recognizing alcohol abuse in adolescents. According to the American Academy of Family Physicians Graham Center, 38% of ambulatory adolescent health visits in the United States are made to family physicians (AAFP, 2001). Specific screening tools are available for adolescents (Comerci, 2002). Alcohol abuse in the family system can create several levels of dysfunction, including the abuse of alcohol or other drugs by adolescents. Approximately 3% of adolescents are addicted to alcohol or other drugs (NIAAA, 1997). Drinking is frequently a family matter, with 82% of drinking families raising children who drink, and 72% of families who abstain raising children to abstain (Johnson and Leff, 1999). Environmental, physiologic, and genetic factors combine to place certain adolescents at risk.

Detection of use or abuse requires reliable information from the adolescent. An atmosphere of trust must be established, and more than one visit is often necessary. Urine drug screening can be effective but is controversial. The American Academy of Pediatrics recommends involuntary testing only in limited emergency circumstances, such as altered mental status, inability to give consent (seizures, coma), acute medical problems putting the adolescent at serious risk, a preadolescent or very young adolescent, and court-ordered monitoring (AAP, 1998; Comerci, 2002). Family physician interventions for adolescents abusing alcohol or other substance must be tailored to the adolescent's specific needs. Appropriate treatment programs should have strong family involvement, total abstinence goals, and professionals experienced in adolescent care.

College student drinking is a major concern on U.S. campuses. An estimated 1700 unintentional college student deaths per year involve alcohol (Hingson et al., 2005). The NIAAA Task Force on College Drinking categorized college student drinking consequences as damage to self, others, or the institution, as well as the overlapping categories of drinking and driving, high-risk sexual behavior, and physical and sexual aggression (NIAAA, 2002). College prevention strategies include cognitive-behavioral skills-based interventions, brief motivation interventions, feedback-only interventions, and environmental interventions. Underage drinking statutes, including penalties for servers, and comprehensive campus-community approaches that involve students, all campus stakeholders, and community leaders have proved beneficial (Larimer et al., 2009).

Treatment of Older Adults

Alcohol use disorders and prescription drug abuse are prevalent in older adults (Blow et al., 2002). Specific "geriatric alcohol use disorder" screening tests can be used by family physicians, including the SMAST-G, MAST-G, AUDIT, and CAGE (see earlier discussion) (Blow et al., 2009). Older adults are often categorized as "binge drinkers." The National Institute on Alcohol Abuse and Alcoholism (NIAAA) and the Centers for Substance Abuse Treatment (CSAT) have published alcohol use guidelines for older adults (Blume, 2009). Often, comorbid affective disorders are present in older adults. Premorbid alcohol use disorders predict a more severe course of affective disorders (Cook et al., 1991).

Concomitant alcohol use disorders and depression increase late-life suicide risk, as does at-risk and problem drinking among elderly persons (Blow et al., 2004). Older persons with alcohol use disorders may respond well to brief interventions and increased socialization. The GOAl study and Health Profile Project found brief interventions in older adults to be efficacious (Blow and Barry, 2000; Blow et al., 2009; Blume, 2009).

Physician with Alcohol Use Disorders

The prevalence of alcohol use disorders among physicians is comparable to the national lifetime prevalence of 13.5% (Reiger et al., 1990). Family physicians, along with anesthesiologists, were overrepresented in a study of 1000 physicians with substance use disorders (Talbot et al., 1987).

Male physicians outnumber female physicians in studies of substance use disorders. Risk factors used in other patient groups apply to physicians as well (see online discussion of causative factors). The pattern of physician abuse differs from that in the general population by the increased use of alcohol, benzodiazepines, and prescription opiates (Hughes et al., 1992). Much of the prescription drug use is self-prescribed. Impairment is generally noted first in the alcohol-abusing physician's family and social life. Marital discord, relationship problems, and heavy drinking at social events can progress to work dysfunction and impairment (Talbot et al., 1987). The physician's thinking initially becomes impaired in spatial and constructive skills, along with negative effects on memory. Verbal skills are maintained, although cognition is affected as drinking continues. An alcoholic physician will frequently turn to benzodiazepines for relief of anxiety or stress symptoms. Further impairment leads to avoidance of responsibility, such as not returning pages while on duty, showing up late, or arriving for patient care responsibilities with alcohol on the breath.

Several studies have shown that alcohol use and abuse patterns are established early in the physician's career (Birch et al., 1998; Clark et al., 1987). In 2001, The Joint Commission (formerly Joint Commission on the Accreditation of Healthcare Organizations) pressured hospital organizations to address the wellness of their medical staff (Joint Commission, 2008). State medical societies and licensing bodies have been active in establishing physician health programs and guidelines, to assist the physician in returning to a productive career (Federation of State Physician Health Programs, 2005). Treatment outcomes for physicians in these structured programs are excellent, with sustained recovery rates of 70% to 80% or better (Paris and Cannavan, 1999). A cohort study of 100 physicians with alcohol use disorders found similar trends and an average sustained abstinence of 17.6 years (Lloyd, 2002).

As with the treatment of any chronic illness, early identification and intervention improve recovery rates of physicians with alcohol use disorders. Posttreatment behavioral and biologic (urine) monitoring, as well as attendance at physician support groups and AA meetings, are important in the recovery process (Galanter et al., 1990). The AAFP (1998) recognizes physician treatment and recovery from alcoholism or other forms of substance abuse and supports physicians who successfully complete treatment programs acceptable to the physician health program of the individual state.

Prevention

Primary prevention is the education of at-risk populations to avoid problems. Family physicians have the power to identify families with alcoholism and provide education to the children and adolescents who are at risk. Primary prevention includes the community; a Chinese proverb says the physician who also cares for the community is the “best physician.” Family physicians can offer universal screening for alcoholism and alcohol abuse; this is an example of the secondary level of prevention in their practice. The evidence for effectiveness of “designated driver” and school-based drinking and driving prevention programs has been insufficient (Ditter et al., 2005; Elder et al., 2005). School prevention programs noted as effective include the Michigan Model for Comprehensive School Health Education (Shope et al., 1996).

Public Policy Recommendations

Family physicians can affect public policy advocacy on issues of alcohol abuse through professional organizations such as the AAFP and state academies. The CDC (2004) recommends that states and local jurisdictions consider adoption of effective strategies aimed at reducing excessive drinking. Family physicians can advocate policies that include (but are not limited to) increasing alcohol excise taxes, reducing DUI limits to the 0.04 blood alcohol level, toughening DUI

penalties, restricting advertising along highways or in ethnic minority communities, zoning restrictions on placement of points of sale, and increasing opportunities for screening in various settings (e.g., courts, jails, EDs).

Public policy interventions can be categorized as (1) measures to reduce the availability of alcohol, such as control of hours and days of sales, outlet-density restrictions, monopoly regulatory systems, and minimum-age drinking laws, or as (2) penalties, such as increased DUI enforcement, server-liability laws, and altering the server environment through training. “Ecologic research” on environmental changes and prevention of alcohol abuse includes the Communities Mobilizing for Change on Alcohol Project, the Community Trials Project, and the Sacramento Neighborhood Alcohol Prevention Project (Treno et al., 2009). This emerging body of evidence should help communities in the future as they strive to create environments that reduce the frequency of alcohol use disorders.

KEY TREATMENT

Screening in primary care settings can accurately identify patients whose levels or patterns of alcohol consumption do not meet criteria for alcohol dependence, but place them at risk for increased morbidity and mortality. Brief behavioral counseling interventions with follow-up produce small to moderate reductions in alcohol consumption that are sustained over 6 to 12 months or longer (USPSTF, USPHS, 2000) (SOR: B).

Overview

Key Points

- Tobacco use is the leading cause of death in the United States.
- Toxins from cigarette smoke cause disease in most organs of the body.
- Smokers die an average of 13 or 14 years earlier than nonsmokers, and 50% of continuing smokers will die of a tobacco-related disease.
- Smoking is responsible for 40% of all deaths from cancer and 21% of deaths from cardiovascular disease.
- Almost 10% of deaths attributable to smoking occur in nonsmokers exposed to secondhand smoke.

The power of nicotine addiction became clear when I saw malnourished and hungry people trading food rations for cigarettes.

William Foege (1989), commenting on refugee camps during the Nigerian Civil War

Tobacco smoking leads to a dependence on nicotine that is indistinguishable from other forms of drug dependence. The revised fourth edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-IV-TR) of the American Psychiatric Association (APA, 2000) classifies tobacco dependence as an *addiction*. In such a dependency, the drug is needed to maintain an optimal state of well-being. *Nicotine*, the addictive constituent of tobacco, meets these criteria because a typical withdrawal syndrome occurs after smoking cessation, tolerance to its use develops, and most importantly, use persists

after developing symptoms attributable to the substance and in the face of its known harm. Some believe that nicotine is more addictive than cocaine or alcohol (Krasnegor, 1979; Lee and D'Alonzo, 1993; Kandel et al., 1997). However, a substantial fraction of daily smokers, perhaps as many as half, do not meet the DSM-IV criteria for nicotine dependence (Hughes et al., 2006; Donny and Dierker, 2007).

Nicotine acts on specific $\alpha 4\beta 2$ nicotinic acetylcholine receptors in the mesocorticolimbic system, through neural pathways that are now seen as a common pathway for addictive drugs. Nicotine modulates the release of dopamine in the brain's reward centers in the ventral tegmental area and the nucleus accumbens, decreasing the normal rate of degradation of dopamine as well. High concentrations of nicotine are delivered to the central nervous system (CNS) within seconds of a puff during smoking, with complete saturation of nicotinic receptors with as few as three cigarettes, and lasting as long as 3 hours (Brody, 2006).

It may take only one cigarette to hook an adolescent. About one fourth of young people experience a *first-inhalation relaxation experience* (FIRE) with their first cigarette, a large percentage of whom become addicted (DiFranza et al., 2007).

For tobacco-dependent persons, craving results when nicotine occupancy on receptors declines over time (e.g., during sleep at night). Relief from craving requires that the smoker replenish the nicotine within the receptor as completely as possible, which is why the first cigarette of the morning is often the most "satisfying" to addicted smokers. Since the cigarette is the most efficient rapid-delivery device for nicotine and the concurrent relief of craving, physicians and patients need to understand that medicinal nicotine replacement products are quite inefficient, by comparison, delivering

lower concentrations of nicotine and incompletely resolving cravings.

The sheer number of nicotine doses is also highly reinforcing. A typical one-pack-daily smoker receives about 100,000 reinforcing hits a year, much more than with cocaine or heroin (Brunton, 1999).

Tobacco contributes to about 443,000 deaths annually in the United States and has rightly been dubbed the “leading cause of death in the United States” (McGinnis and Foege, 1993; Mokdad et al., 2004). One third of these smoking-related deaths are from cardiovascular disease and cerebrovascular accident (CVA, stroke), 29% from lung cancer, 20% from chronic respiratory disease, and at least 8% from cancers other than lung (Fig. 50-1). Just over 10% of deaths attributable to smoking occur in nonsmokers exposed to secondhand smoke, most from cardiovascular causes (CDC, 2008). Each year, smoking is responsible for 18% of the total deaths in the United States—seven times more Americans than were killed in the Vietnam War. Smoking has killed more Americans during the 20th century than were killed in battle or died of war-related diseases in all U.S. wars ever fought (Pollin and Ravenholt, 1984). Furthermore, cigarettes kill more Americans than alcohol, car accidents, suicide, AIDS, homicide, and illegal drugs combined (ACS, 2005).

As shown by the grim, disease-specific facts, most smokers do not understand the implications for longevity involved in continued tobacco use. On the average, male smokers in the United States die 13.2 years earlier and females 14.5 years earlier than nonsmokers (Manson et al., 2000). Half of all continuing adult smokers will die of a cigarette-related illness (Doll et al., 2004). This relative lack of knowledge about tobacco harm may be in part because

of the lack of publicity given to celebrities who die from smoking-related diseases (see eTable 50-1), although the death of news anchor Peter Jennings from lung cancer in 2005 received considerable attention and spurred increased interest in cessation.

The Centers for Disease Control and Prevention (CDC; 2009) estimated that in 2007, 19.8% of American adults smoked cigarettes (21.3% of men and 18.4% of women). Smoking prevalence is lowest among Asians (9.6%) and Hispanics (13.3%) and highest among American Indians and Alaska Natives (36.4%). Smoking prevalence is also higher among adults living below the poverty level (28.8%). Higher educational status confers additional protection against smoking, with persons holding a graduate degree smoking the least (6.2%). Thus, cigarette-related disease is increasingly becoming a set of afflictions suffered by the poor and undereducated, persons who understand the least about their risks and who have the poorest access to medical care resources (CDC, 2008).

In 2008, about one in five (20.4%) high school seniors smoked, the lowest level since monitoring started in the 1970s. Boys smoke more than girls in high school, (21.3% vs. 18.7%), and many more boys use smokeless tobacco (13.6% vs. 2.2%). The tobacco industry spends more than \$12 billion annually on marketing (>\$42 million/day) (Campaign for Tobacco-Free Kids, 2008).

Although few people start smoking as adults, each day 4000 children and adolescents try smoking for the first time, and 3000 of them become regular users of tobacco. Half of high school seniors who smoke started by age 14. Most smokers start smoking before 18, and only 5% start after age 20. Each year, 70% of those who smoke say that they would like to stop, and about 50% attempt to quit, but less than 5% succeed (Fiore et al., 2008). The likelihood of success in smoking cessation increases with the number of attempts, and those with a college education are twice as likely to succeed as less educated smokers. Family physicians must view tobacco addiction as a chronic disease that requires frequent intervention.

* Average annual number of deaths, 2000—2004.

Figure 50-1 Deaths attributable each year to smoking. (From CDC Office on Smoking and Health. http://www.cdc.gov/tobacco/data_statistics/tables/index.htm)

Health Risks Associated with Smoking

Toxins from cigarette smoke go everywhere the blood goes and cause disease in almost every organ of the body.

Cancer

Key Points

- A dose-response relationship exists between the number of cigarettes smoked and the risk of cancer. Those smoking more than one pack a day have 20 times the risk of nonsmokers.
- Smoking formerly labeled “low-tar” and “low-nicotine” cigarettes provides no benefit over smoking regular cigarettes.
- Less than half of all smoking deaths are from cancer; the rest are from heart disease, chronic lung disease, and stroke.
- Tobacco use increases the risk of cancer in most organs.

About 30% of all cancer deaths are attributable to cigarette smoking, with the evidence increasingly stronger. Box 50-1 lists diseases, including many cancers, for which the

Box 50-1 Evidence-Based Relationship between Smoking and Disease**The evidence is sufficient to infer a causal relationship between smoking and:**

Cancer of the bladder, cervix, esophagus, kidney, larynx, lung, oral cavity, pharynx, pancreas, stomach
 Acute myeloid leukemia
 Abdominal aortic aneurysm
 Subclinical atherosclerosis
 Stroke (cerebrovascular accident)
 Coronary heart disease
 Chronic obstructive pulmonary disease (COPD)
 Acute respiratory infections, including pneumonia
 Reduced lung function in infants
 Impaired lung growth during childhood and adolescence
 Respiratory symptoms in children and adolescents, including cough, phlegm, wheezing, and dyspnea
 Asthma-related symptoms (e.g., wheezing) in childhood and adolescence
 Premature onset of age-related decline in lung function
 All respiratory symptoms among adults, including coughing, phlegm, wheezing, and dyspnea
 Poor asthma control
 Sudden infant death syndrome (SIDS)
 Reduced fertility in women
 Fetal growth restriction and low birth weight
 Premature rupture of membranes, placenta previa, and placental abruption
 Preterm delivery and shortened gestation
 Cataracts
 Increased absenteeism from work

Adverse surgical outcomes related to wound healing and respiratory complications
 Hip fractures

Low bone density in postmenopausal women
 Peptic ulcer disease

The evidence is suggestive of a causal relationship between smoking and:

Colorectal cancer
 Liver cancer
 Increased prostate cancer mortality
 Acute respiratory infections in persons with COPD
 Increased lower respiratory tract illnesses during infancy
 Impaired lung function in childhood and adulthood (with maternal smoking)
 Poorer prognosis for children and adolescents with asthma
 Increased nonspecific bronchial hyperresponsiveness
 Ectopic pregnancy
 Spontaneous abortion
 Cleft palate
 Low bone density in older men
 Dental caries
 Erectile dysfunction
 Macular degeneration
 Graves' disease

From US Surgeon General. The Health Consequences of Smoking: a Report of the Surgeon General, 2004. Rockville, Md, US Department of Health and Human Services, Public Health Service, Office of the Surgeon General, 2004.

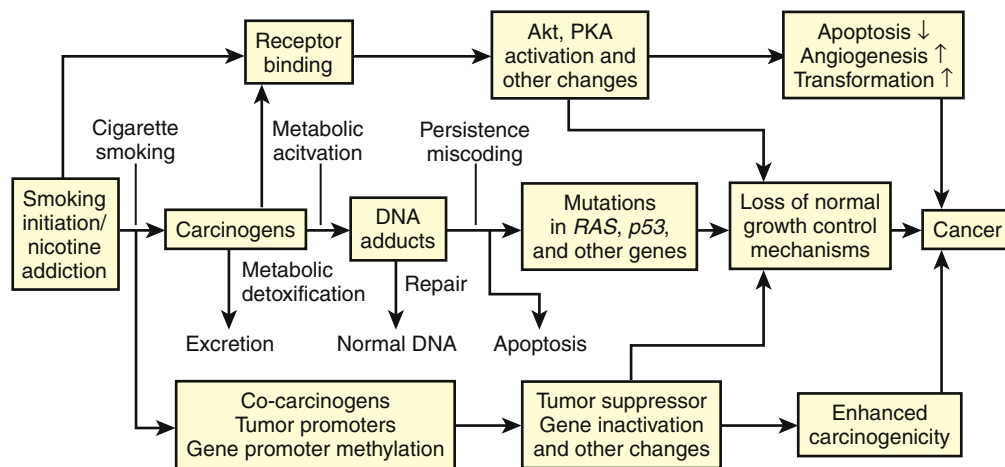

Figure 50-2 Mechanisms that contribute to tobacco-caused cancer. (From American Chemical Society, for Stephen S. Hecht. *Progress and Challenges in Selected Areas of Tobacco Carcinogenesis*.)

evidence is sufficient to *infer* a causal relationship, as well as those for which the evidence is sufficient only to *suggest* a causal relationship. Reviewing tobacco's role in carcinogenesis, Hecht (2008) discusses several mechanisms that contribute to cancer, including metabolic changes in DNA and formation of DNA-carcinogen adducts, leading to mutation; inhibition of genes such as *p53*, a tumor suppressor; and mutations in the *K-RAS* oncogene (Fig. 50-2).

Lung

A clear dose-response relationship exists between lung cancer risk and daily cigarette consumption. From 1950 to 1990, the U.S. mortality rate for lung cancer increased fourfold for men and sevenfold for women. Although the mortality rates in men have been declining since 1990, lung cancer is still the principal cause of cancer death for both genders.

Figure 50-3 **A**, Annual age-adjusted cancer death rates among males for selected cancers, United States, 1930–2005 (rates are age-adjusted to the 2000 U.S. population). Because of changes in *International Classification of Disease* (ICD) coding, numerator information has changed over time. Rates for cancers of the lung and bronchus, colon and rectum, and liver are affected by these changes. **B**, Annual age-adjusted cancer death rates among females for selected cancers, United States, 1930–2005 (rates are age-adjusted to the 2000 U.S. standard population). *Uterus includes uterine cervix and uterine corpus. Because of changes in ICD coding, numerator information has changed over time. Rates for cancers of the uterus, ovary, lung and bronchus, and colon and rectum are affected by these changes. (**A** from US mortality data, 1960 to 2005, *US Mortality 1930–1959*, National Cancer Institute, CDC, 2008. *CA Cancer J Clin* 59:233, 2009; **B** from US mortality data, 1960 to 2005, *US Mortality 1930–1959*, National Center for Health Statistics, CDC, 2008. *CA Cancer J Clin* 59:234, 2009.)

In 1988, lung cancer passed breast cancer as the leading cause of death from cancer in women (Fig. 50-3). Although the lung cancer death rate has leveled off in U.S. women, in some states it is still increasing (Fig. 50-4).

Unfortunately, early detection does not improve the survival rate for lung cancer. The 5-year survival rate is only 15%

and has improved only slightly since the early 1960s (ACS, 2005). Almost 60% of lung cancer patients die within a year and 85% within 5 years. By the time the diagnosis is made, three of four patients already have metastases. However, the risk of death from lung cancer is substantially reduced when smoking is discontinued. Reducing smoking from an average

Figure 50-4 Trends in age-standardized lung cancer death rates for the United States and select states by gender, 1975–2005. (From Cokkinides V et al. *CA Cancer J Clin* 59:357, 2009.)

of 20 cigarettes a day to less than 10 per day reduces the lung cancer risk by 25% (Godtfredsen et al., 2005). A diminished risk for lung cancer is experienced in former smokers after 5 years of cessation; however, the risk remains higher than that of nonsmokers for as long as 15 to 20 years (US Surgeon General, 2004).

Although the amount of tar in cigarettes has declined in recent years, the risk of lung cancer has not changed. Smoking formerly labeled “low-tar” and “low-nicotine” cigarettes provides no benefit over smoking regular cigarettes, and the uptake of carcinogens is no different in “regular,” “light,” and “ultralight” smokers (Hecht et al., 2005), as previously marketed. However, surveys show that most people believed “light” cigarettes to be less dangerous than regular cigarettes and regular cigarettes much more likely to cause illness. The recent federal legislation banning the use of words such as “light” from tobacco advertising is beginning to dispel this myth.

Increasing data regarding the genetic predisposition to lung cancer are emerging (see Smoker’s Genetics). Family aggregation related to lung cancer is likely multifactorial, including exposure to secondhand smoke, major genetic factors (e.g., chromosome 6p locus, *CYP1A1* gene), other genes that modify risk of lung cancer, and genes that may enhance nicotine addiction or modify nicotine metabolism (D’Amico, 2008; US Surgeon General, 2004).

Larynx

The risk for laryngeal cancer is 20 to 30 times greater in smokers. About 70% of oral and 85% of laryngeal cancer deaths are directly attributable to smoking. The risks of cancer of the oral cavity, pharynx, and larynx drop sharply during the first 10 years after smoking cessation. There appears to be a synergistic, multiplicative effect between smoking and drinking,

such that the risk for development of cancer of the larynx is as much as 75% higher in people who use tobacco and alcohol versus those exposed to either substance alone (US Surgeon General, 1990, 2004).

Esophagus

Cigarette smoking is a casual factor in both squamous cell carcinoma and adenocarcinoma of the esophagus. Heavy smokers (more than one pack per day) have 10 times the mortality from esophageal cancer as do nonsmokers.

Head and Neck

Cancers of the head and neck account for about 5% of all cancers diagnosed and 3% of cancer mortality each year. Tobacco use, whether smoking or chewing, is a key causal factor, with excess risks ranging from 5 to 25 times that of persons not using tobacco. Smoking accounts for 45% to 75% of all head and neck cancers (Freedman et al., 2007). The risks are dose dependent, and concurrent alcohol use multiplies the risks of developing head and neck cancer.

Pancreas

An equally dismal picture occurs with cancer of the pancreas, for which the 5-year survival rate is only 2%. Because of the nonspecific nature of the initial symptoms and the difficulty in making a diagnosis, the mean survival time after diagnosis of pancreatic cancer is less than 6 months. Smokers have two to three times the risk of pancreatic cancer as nonsmokers, and the risk is proportional to the amount smoked. Increased risk persists at least 10 years after quitting. More than one fourth of pancreatic cancer cases (27%) are attributable to cigarette smoking (Silverman et al., 1994; US Surgeon General, 2004).

Cervix Uteri and Ovary

Women who smoke cigarettes have four times the risk of cervical cancer as nonsmokers. Even women who smoke only 100 cigarettes during their lifetime more than double their risk of cervical cancer. The risk from smoking is greater in women younger than 30 than in those older than 30 (Slattery et al., 1989). Constituents from cigarette smoke, including mutagens and the carcinogen 4-(methylnitrosamino)-1-(3-pyridyl)-1-butanone (NNK), have been detected in the cervical mucus of smokers at levels 40 to 50 times those in serum. Smoking is a risk factor for cervical intraepithelial neoplasia (CIN) and cervical cancer among women who test positive as well as negative for human papillomavirus (HPV). The relative risks for CIN and cervical cancer are two to four times greater for current and former smokers compared with never-smokers (US Surgeon General, 2004). Although the risk of some types of ovarian cancer has been shown to be as much as three times greater in women who smoke cigarettes (Qian et al., 1989; Tworoger et al., 2008), the evidence is inadequate to confer a causal relationship (US Surgeon General, 2004).

Bladder and Kidney

Forty percent of bladder cancers are smoking-related, and higher rates of kidney cancers are also noted in smokers. Smokers have two to four times the risk of bladder cancer as those who never smoked. The risk for kidney cancer is strongly dose dependent. Even one to nine cigarettes per day creates a 60% excess risk of renal cell cancer in men, and the risk doubles for men smoking more than a pack a day. Overall, the relative risk (RR) for women smokers is about 1.38, and for men 1.54 (Hunt et al., 2005). Smoking accounts for most cancers of the renal pelvis and ureter in the United States (McLaughlin et al., 1996; US Surgeon General, 2004). The kidneys and bladder are the final common pathway for the concentration of toxic products of tobacco smoke and provide the longest direct exposure to carcinogens and radioactive substances, such as polonium 210, in tobacco smoke (Winters and DiFranza, 1982).

Colon and Rectum

A strong relationship has been noted between smoking and colorectal cancer, but the induction period is about 35 years. This lengthy induction would explain why it is just beginning to show up in women and indicates that efforts to prevent smoking among young people should be intensified (Giovannucci et al., 1994). The increased risk is about 20% higher for current smokers, and appears to be stronger for rectal cancer. Although the evidence is suggestive but not conclusive, a causal relationship would mean that about 12% of the colorectal cancer burden would be attributable to smoking (Tsoi et al., 2009; US Surgeon General, 2004).

Liver

Although the 2004 Surgeon General's Report concludes that the relationship between smoking and liver cancer is suggestive but not causal, a meta-analysis from the World Health Organization (WHO) International Agency for Research on

Cancer found an RR of 1.55 among current smokers and 1.2 among former smokers for development of liver cancer (Lee et al., 2009).

Leukemia

Overall, smoking cigarettes increases a person's risk for leukemia by 30%. Mortality from leukemia is increased 50% in cigarette smokers (RR, 1.53), and the response is dose related. The risk is greatest for myeloid leukemia. The potent carcinogen *benzene*, a constituent of cigarette smoke, seems to be the major toxin responsible for leukemia among smokers. Approximately 14% of all cases of leukemia in the United States may be caused by cigarette smoking (Brownson et al., 1993).

Second Primary/Recurrent Cancers

Continued smoking interferes with both radiotherapy and chemotherapy used for cancer treatment. An increase in second primary tumors among continuing smokers is seen in lung (Lin et al., 2005) and head and neck cancer (Chuang et al., 2008). The emergence of contralateral breast cancer has also been linked to continued smoking among women (Li et al., 2009).

Chronic Obstructive Pulmonary Disease (COPD)

Key Points

- COPD is the leading cause of disability in the United States, and cigarette smoking is its main cause.
- The risk of COPD is directly proportional to the number of cigarettes smoked, but lung function improves with cessation of smoking, even after age 60.

Cigarette smoking is the main cause of COPD, which includes emphysema and chronic bronchitis. COPD is the fourth leading cause of death and the leading cause of disability in the United States. Women smokers are 13 times more likely to die from COPD, and male smokers have about a 12-fold increased risk (US Surgeon General, 2004). During their lifetime, smokers have about a 40% chance of developing chronic bronchitis. There may also be important racial differences, with African Americans, particularly females, having a higher risk than white smokers (Dransfield et al., 2006; Pelkonen, 2008). COPD among women is rising more quickly than among men, and since 2000, more women than men have died each year from COPD (CDC, 2008).

Changes in bronchi and the lung parenchyma are proportional to duration and intensity of smoking. Cigarette smoke inhibits ciliary activity of the bronchial epithelium and phagocytic activity of macrophages in the alveoli, resulting in decreased clearance of foreign material and bacteria from the lung, which leads to increased infection and tissue destruction. Smoking also releases inflammatory mediators, including oxidases and proteases, and inhibits pulmonary repair mechanisms. Even after age 60, smokers who quit have better pulmonary function than those who continue smoking. Lung function is inversely related to the number of cigarettes smoked over a lifetime. The rate of decline in pulmonary function is arrested by smoking cessation, the earlier the better.

Cardiovascular Disease

Key Points

- The risk of myocardial infarction is proportional to the number of cigarettes smoked.
- More than half of deaths from coronary artery disease are sudden, but the risk of sudden death is reduced immediately on cessation of smoking.
- Filter cigarettes and those with “low tar” or “low nicotine” do not reduce the risk of myocardial infarction.

Coronary Heart Disease

Heart disease is the leading cause of death in the United States, and tobacco use is a major risk factor. Up to 30% of all deaths from heart disease are caused by smoking, with a strong dose-dependent relationship. In general, smokers have two to four times the risk of coronary heart disease as nonsmokers. For women smokers, the risk may be even higher. Women who smoke only one to five cigarettes a day have 2.5 times the risk of developing coronary heart disease as nonsmokers, rising to 75 times the risk in those who smoke 40 or more cigarettes a day. Three fourths of myocardial infarctions in women younger than 50 have been attributed to smoking (Dunn et al., 1999; Slone et al., 1978). Women who smoke and use oral contraceptives (OCs) have up to 10 times greater risk of heart attack than women who do neither, depending on which generation of OC is used.

Smoking acutely raises systolic blood pressure, heart rate, and cardiac output and causes vasoconstriction. It increases inflammation, promotes thrombosis and platelet aggregation, increases atherogenesis and plaque destabilization, and promotes oxidation of low-density lipoproteins (LDLs). Both active and secondhand smoke exposure cause endothelial dysfunction, a key element in early atherogenesis. Increased levels of C-reactive protein (CRP) are found in smokers, and the low-grade inflammatory response associated with smoking also results in increased leukocyte counts. Increased blood viscosity and lower oxygen-carrying capacity from carbon monoxide (CO) in cigarette smoke further decrease the coronary reserve. CO has an affinity for hemoglobin (forming carboxyhemoglobin) that is 245 times stronger than that of oxygen. Thus, CO reduces oxygen delivery to the myocardium and has a decidedly negative inotropic effect. Carboxyhemoglobin also lowers the threshold for ventricular fibrillation and could help explain the higher incidence of sudden death in those who smoke.

More than half of all deaths from coronary heart disease are sudden deaths caused by cardiac arrhythmia. Nicotine is arrhythmogenic, because it increases serum catecholamine concentration. Those who quit smoking reduce their risk of sudden death immediately; the decline is not time dependent (Goldenberg et al., 2003).

The risk of myocardial infarction (MI) is proportional to the number of cigarettes smoked, but as few as one to four cigarettes a day raises the risk of dying from ischemic heart disease by 2.7 times in men and 2.9 times in women (Bjartveit and Tverdal, 2005). The risk of MI increases progressively to as much as 20-fold in persons smoking 35 or more cigarettes per day. Persons who smoke cigarettes

containing “low” amounts of nicotine have the same degree of MI risk as those who smoke cigarettes containing larger amounts. Smokers of these “low-dose” cigarettes still have three times the MI risk as nonsmokers (Kaufman et al., 1983). Within a few years of stopping, the risk of MI decreases to a level similar to that in men who have never smoked, even in heavy smokers who have a positive family history of coronary heart disease (Rosenberg et al., 1985). The risk of coronary heart disease is reduced by about half after the first year of cessation, falling to that of never-smokers after 15 years of abstinence (US Surgeon General, 1990). Those who have coronary heart disease and stop smoking have a reduction of about 36% in both all-cause mortality and nonfatal MI (Crichley and Capewell, 2004). Women who follow lifestyle guidelines involving diet, exercise, and not smoking have a very low risk of coronary heart disease (Stampfer et al., 2000).

“Silent” ischemia probably accounts for most cardiac ischemic events. Patients with coronary heart disease who smoke have three times as many episodes of silent ischemia as nonsmokers, and the duration of each is 12 times longer (Barry et al., 1989). Frequent episodes of myocardial ischemia, even though asymptomatic, must damage the heart. Because smoking also increases platelet adhesiveness, increases levels of triglycerides and LDL cholesterol, and lowers high-density lipoprotein cholesterol, a higher incidence of MI would be expected (Chelland et al., 2008).

Benefits from stopping smoking can be demonstrated at all ages. No decrease in benefit is seen with age, so it is still worthwhile for someone older than 65 to break the addiction (Hermanson et al., 1988; LaCroix et al., 1991). This benefit can be demonstrated in the cerebral as well as the coronary circulation. Older adults who stop smoking have significantly higher cerebral perfusion levels than those who continue to smoke. Even those who have smoked for 30 to 40 years have improved cerebral circulation within a relatively short time after stopping smoking (Rogers et al., 1985).

Stroke (Cerebrovascular Accident)

Key Points

- Risk of stroke is six times greater in smokers (>1 pack/day).
- Smokers who are also hypertensive have a 20 times greater stroke risk.
- Risk of CVA declines rapidly after smoking cessation, and at 5 years is the same as for a nonsmoker.

Stroke (CVA) is the third most common cause of death in the United States. Although hypertension is the greatest risk factor for stroke, cigarette smoking is also significant. The incidence of stroke in smokers is two to four times higher than in nonsmokers. Among those screened in the Multiple Risk Factor Intervention Trial (MRFIT), smokers had twice the risk of a nonhemorrhagic stroke, and smoking was strongly associated with all forms of stroke (Neaton et al., 1993).

The risk of stroke increases in proportion to the amount of smoking. Those who smoke more than 40 cigarettes/day have twice the stroke risk of those who smoke less than 10 cigarettes/day. Compared with women who have never smoked, the risk of stroke increases 2.2-fold in women smoking 1 to 14 cigarettes/day and 3.7-fold in women

smoking 25 or more cigarettes/day (Colditz et al., 1988). Noting a clear dose-response relationship, Bonita and associates (1986) found a threefold increase in the risk of stroke in smokers versus nonsmokers (see eFig. 50-1 online). The risk is 5.6 times higher in persons smoking more than one pack daily. Cigarette smokers who are also hypertensive have a 20-fold increased risk of stroke (US Surgeon General, 2004).

Sclerosis of the carotid arteries is directly proportional to the amount of smoke exposure. Smoking increases the risk of ischemic heart disease and cerebrovascular disease regardless of the level of serum cholesterol. Low cholesterol level did not protect against smoking-related arteriosclerotic cardiovascular disease in patients in South Korea, where the prevalence of smoking is among the highest in the world (72% of men) (Jee et al., 1999). Smoking may increase the likelihood of thrombosis by increasing serum fibrinogen, enhancing platelet aggregation, and increasing blood viscosity.

The risk of stroke declines rapidly after cessation of smoking. After 5 years, risk of CVA is at the level of nonsmokers, which emphasizes that “it is never too late to quit,” no matter how long the patient has been smoking.

Subarachnoid Hemorrhage

A recent systematic review of the risk factors for subarachnoid hemorrhage (SAH) shows that smoking doubles the risk for SAH (Feigin et al., 2005). About one third of all SAH was found to be attributable to smoking in a smaller case-control study, and, although the risk dropped within a few years after quitting, it may remain increased for up to 15 years in the heaviest women smokers (Anderson et al., 2004).

Older studies involving high-dose estrogen OCs showed a significant interaction with smoking, increasing the risk for stroke and SAH among women who both smoked and used OCs. Studies of women who use second and third-generation OCs find no increased risk of stroke, even among smokers (Yang et al., 2009). However, the American College of Obstetricians and Gynecologists states that “practitioners should prescribe combination hormonal contraceptives with caution, if at all, to women older than 35 years who smoke” (ACOG, 2006).

Peripheral Vascular Disease

Smoking is strongly associated with other forms of cardiovascular disease, including abdominal aortic aneurysm (AAA) and peripheral vascular disease in both men and women. Smoking causes as much as half of all peripheral artery disease, and significantly increases the failure rates after lower-limb bypass surgery. The risk of AAA rises in proportion to duration and intensity of smoking and is up to sevenfold greater at 20 pack-years (US Surgeon General, 2004). The U.S. Preventive Services Task Force (USPSTF) has recommended one-time screening for AAA by ultrasonography in men age 65 to 75 who have ever smoked. Consideration should also be given for screening women over age 65 with a history of smoking (Derubertis et al., 2007), because about 40% of the annual deaths from AAA occur among women, in whom the disease is more deadly than men. Smoking is also an independent risk factor for erectile dysfunction, an additional fact that may help motivate men to stop smoking.

Other Diseases and Conditions

Alzheimer’s Disease

Studies show conflicting evidence linking smoking with Alzheimer’s dementia and other causes of cognitive decline. However, a meta-analysis found that compared with never-smokers, current smokers had RRs of 1.79 for Alzheimer’s disease (AD) and 1.78 for vascular dementia. Smokers in this study also had greater yearly declines in Mini-Mental State Examination (Anstev et al., 2007). Another systematic review and meta-analysis also found significant risk for AD among smokers (RR, 1.59) but less risk for developing vascular dementia (1.35) and cognitive decline (1.20) compared with never-smokers (Peters et al., 2008).

Graves’ Disease

Smoking appears to be one of the many factors causing Graves’ disease, particularly among women, and includes a higher risk of Graves’ ophthalmopathy as well (Vestergaard, 2002).

Diabetes Mellitus

Diabetes is a rapidly growing worldwide pandemic, and cigarette smoking is responsible for about 10% of the incidence of type 2 diabetes. A dose-response relationship exists, with the risk increasing in direct proportion to the number of cigarettes smoked. People who smoke more than one pack a day have about double the risk for diabetes as nonsmokers, and the risk is still 1.5 times greater for those who smoke only 1 to 14 cigarettes a day (Manson et al., 2000; Willi et al., 2007). Smoking increases the risk for development of the metabolic syndrome and its attendant cardiovascular consequences (Chiolerio et al., 2008).

Patients with diabetes who smoke are at increased risk for both micro- and macrovascular complications. Cigarette smoking increases the risk for diabetic nephropathy, retinopathy, and neuropathy. This association is strongest in patients requiring insulin for control. Smoking cessation is essential for preventing diabetic complications.

Depression

Smokers are more likely to experience major depression than nonsmokers, and the incidence increases steadily with the number of cigarettes smoked. This increased risk may result from genes that predispose to both conditions (Kendler et al., 1993). Smoking may predispose to depression and, conversely, may be an antecedent to smoking, in the adolescent population (Brook et al., 2004; Goodman and Capitman, 2000).

Wrinkles

We are not very effective in getting the message about tobacco’s hazards across to adolescents. By talking about disease, we may not be speaking their language. The fact that smoking causes wrinkles, bad breath, and yellow teeth may be a more effective message than evidence that smoking kills. Premature wrinkling (crow’s feet) increases with the number of cigarettes smoked; heavy smokers are five times more likely to have wrinkles than nonsmokers (Kadunce et al., 1991).

Macular Degeneration and Cataract

Macular degeneration is the leading cause of blindness after age 65, and nothing prevents or delays its progression. Smoking 20 or more cigarettes a day increases the risk of macular degeneration two- to threefold. As with other smoking-related disorders, macular degeneration also appears to be dose related, with the incidence increasing with the number of pack-years (Christen et al., 1996; Thornton et al., 2005). Smoking is also a cause of nuclear cataract, with smokers having two to three times the risk of never-smokers.

The Myth of Filtered Cigarettes

There is a mistaken popular belief that filtered brands of cigarettes, which now account for more than 97% of those sold in the United States, are safer than nonfiltered cigarettes and that formerly labeled “light” cigarettes convey a degree of health protection. “Low-tar” and “low-nicotine” filtered cigarettes are now the most commonly purchased products. Because the addiction is to nicotine, people who smoke low-nicotine cigarettes undergo “compensatory smoking,” in which they inhale more frequently and more deeply to maintain their blood nicotine levels. As a result, tar intake increases, so the cigarette changes from the low-tar to the high-tar category. Smokers who take 14 puffs per cigarette inhale 58% more tar than those taking the standard 8.7 puffs per cigarette. Most manufacturers create tiny perforations in the filter to dilute the smoke with air, thus creating their “light” and “ultralight” cigarettes. Many smokers, however, block the holes with their lips or their fingers to obtain undiluted smoke with a higher concentration of nicotine (Kozlowski et al., 1980).

Cigarettes with reduced yields of nicotine and CO are not safer. The fourfold increased risk of MI does not vary according to the nicotine content. The degree of risk is proportional to the number of cigarettes smoked (Palmer et al., 1989). Similar myths about “natural” and “organic” cigarettes should be dispelled, since there is absolutely no evidence that these tobacco products confer any health protection compared with other brands.

Cigars

Key Points

- Cigars are not a safe alternative to cigarettes, causing both cancer and heart disease.
- Cigar-related health risks are related to number smoked and depth of inhalation.
- Risk of tobacco-related disease is increased when smoking is combined with alcohol consumption.

In 2004 the CDC estimated that about 9.4% of men, 1.9% of women, and 14.8% of students grades 8 to 12 were current cigar smokers. The mortality patterns from cigar smoking relate in part to the degree of inhalation by the smoker. Primary cigar smokers, or those who have never or rarely smoked cigarettes, inhale much less than secondary cigar smokers—those who have switched from or are concurrent cigarette smokers. The main reason for the difference is the

pH of the smoke, which in cigars is higher than in cigarettes, allowing nicotine to be absorbed across the oral mucosa. Secondary cigar smokers, however, have learned to inhale smoke, and increase their risk of cancer and heart disease.

Cigar smokers have a risk of oral and pharyngeal cancer that is similar to cigarette smokers; their risk of esophageal cancer is several times that of never-smokers. As with cigarette smoking, the use of alcohol multiplies the risk of these cancers, accounting for about 75% of cases in developed nations (Pelucci et al., 2008).

Lung cancer risk varies with depth of inhalation and number of cigars per day. Primary cigar smokers with no or slight inhalation have about a 1.8 mortality ratio of lung cancer; moderate-deep inhalers increase this to 4.9, with an overall mortality ratio of 2.11 compared with nonsmokers. Secondary cigar smokers have a mortality ratio of 5.4; moderate-deep inhalers in this group increase the risk to 9.77. Combined cigarette-cigar smokers have an overall lung cancer mortality ratio of 11.20 (NCI, 1998).

Cigar smokers are also at higher risk for both COPD (RR, 1.45) and coronary artery disease (RR, 1.27) compared with nonsmokers (Iribarren et al., 1999). As with the cancer risk, the level of inhalation increases risk; for example, secondary cigar smokers with moderate-deep inhalation patterns have a fivefold increased risk for COPD (NCI, 1998).

Electronic Cigarettes

Electronic cigarettes (e-cigarettes), first developed in China in 2003, consist of a metal tube resembling a normal cigarette, a battery, an atomizer, and a replaceable cartridge containing liquid nicotine, propylene glycol, and flavoring. Examples of flavorings are chocolate, cherry, and bubblegum, all of which can be enticing to children. When a user puffs on the e-cigarette, an indicator light at the tip glows and the heating element vaporizes the solution from the cartridge containing nicotine and other substances. A mist is produced that is similar to cigarette smoke and contains the propylene glycol, a known pulmonary irritant used in antifreeze.

To date there are no published clinical trials and there is no quality control to limit the amounts of chemicals in e-cigarettes, including known carcinogens. The sale of electronic cigarettes containing nicotine is illegal in Australia. In the United States the American Cancer Society (ACS) and other professional organizations have called for e-cigarettes to be illegal. The U.S. Food and Drug Administration (FDA) has not approved these devices and has halted shipments of them from entering the country, but Internet sales are growing.

In 2009 the U.S. Congress granted the FDA the power to regulate tobacco products, including the authority to stop e-cigarettes from entering the country. Electronic cigarettes, even though smokeless, may contain known carcinogens and toxic chemicals. There is considerable debate as to whether these products might deliver nicotine with minimal additional harm to the smoker, becoming a “harm reduction” instrument that enables smokers to continue their nicotine dependence and reduce risk or enhance quit attempts. On the other hand, these products have little quality control; nicotine delivery is inconsistent; FDA-type testing has not yet been done; and long-term risks are not known.

Smokeless Tobacco

Key Points

- Snuff users have a 50-fold increased risk of cancer of the cheek and gum.
- The carcinogens in smokeless tobacco have a greater concentration than in cigarette tobacco; the level of nitrosamines is more than 10,000 times that allowed in bacon and beer.

Smokeless tobacco comes in two types: *snuff*, which is dry or moist, and *chewing* (spitting) tobacco, which comes as a loose leaf, plug, or twist. Smokeless tobacco contains many of the same carcinogens as cigarette tobacco, but some are present in much greater concentrations. *Nitrosamines*, which are powerful chemical carcinogens, are present at levels up to 14,000 times higher than the federal government allows in bacon and beer (Connolly et al., 1986).

A variation on smokeless tobacco is called *snus*, which contains powdered, flavored tobacco in small sachets placed under the lip, releasing nicotine through the buccal mucosa. Because of differences in manufacturing, snus has comparatively small levels of the carcinogenic compounds found in traditional smokeless products. No spitting is required. Snus marketing campaigns emphasize its use when smoking is not allowed, and most U.S. snus users also smoke cigarettes. In Sweden, snus use has eclipsed smoking, and many smokers have used snus to quit smoking but have continued using snus, and many appear to be dependent. Again, in the United States, this has sparked a fierce debate about the use of snus and similar products as agents for “harm reduction,” and whether smokers should be advised to switch as a means of smoking cessation, since exclusive smokeless tobacco use avoids many of the dangers of combustible tobacco.

Treatment of smokeless tobacco use is difficult, because none of the standard medications used for smoking cessation has shown effectiveness for smokeless tobacco users, although behavioral counseling has a modest effect (Fiore et al., 2008). The nicotine patch and lozenge have been suggested, and clinical trials of combination therapy are ongoing. Behavioral interventions such as mailings, oral or dental screenings, group discussions, workplace interventions, and telephone support showed the best evidence for smokeless tobacco cessation (SOR: B). There was no benefit from the use of bupropion SR or nicotine patches or gum (Cayley, 2009; SOR: A).

Use of smokeless tobacco increases the frequency of oropharyngeal cancer and causes gum recession and tooth loss. Overall, the RR for oral cancer among snuff users is 2.6; for esophageal and pancreatic cancer, 1.6 (Boffetta et al., 2008). Leukoplakia is found in 18% to 64% of users (Connolly et al., 1986). Snus has been associated with a higher risk of oropharyngeal cancer in some studies (Roosar et al., 2008), but not others (Luo et al., 2007), and also has a small risk of pancreatic cancer. A systematic review and meta-analysis of the risk for myocardial infarction and stroke among current smokeless tobacco users found small increases in relative risk for these conditions (Boffetta and Straif, 2009).

Although educational programs have been launched by the National Cancer Institute and Major League Baseball, smokeless tobacco use has trended upward in adolescents. College athletes often believe that male peers, coaches, and

professional athletes are indifferent to the use of spitting tobacco (Hilton et al., 1994). An estimated 8.6% of high school students are current smokeless tobacco users. Smokeless tobacco is more common among high school boys (14%) than girls (2.2%). As with college students, many high school spit tobacco users participate in organized sports. Enlisting the support of coaches to help with tobacco use prevention is an untapped resource that should be explored.

Involuntary (Passive) Smoking

Key Points

- Secondhand smoke contains 4000 different chemicals, of which more than 60 are carcinogenic.
- About one third of lung cancers occur in nonsmokers who live with a smoker or work in a smoky environment.
- Passive smoking is the third leading preventable cause of death, after alcohol and smoking itself.
- Passive smoking increases the risk of SIDS in infants and otitis media, cancer, and respiratory disease in older children, in direct proportion to smoke exposure.

Secondhand smoke, also called *environmental tobacco smoke* (ETS), is the combination of smoke emitted from the burning end of a cigarette, cigar, or pipe and the smoke exhaled by a smoker. Two thirds of the smoke from a burning cigarette never reaches a smoker’s lungs, but instead goes directly into the air. *Sidestream smoke* is emitted into the air from a smoldering cigarette or cigar between puffs, and *mainstream smoke* is what the smoker inhales directly—the exhaled smoke also contributes to ETS. Although diluted by air before being inhaled, sidestream smoke contains greater concentrations of toxic substances than mainstream smoke because of a lower combustion temperature and lack of filtration through the cigarette.

The 2006 Report of the Surgeon General, *The Health Consequences of Involuntary Exposure to Tobacco Smoke* (USHHS, 2006), concludes the following:

1. Secondhand smoke causes premature death and disease in children and adults who do not smoke.
2. Children exposed to secondhand smoke are at increased risk for sudden infant death syndrome (SIDS), acute respiratory infections, ear problems, and more severe asthma. Smoking by parents causes respiratory symptoms and slows lung growth in their children.
3. Exposure of adults to secondhand smoke has immediate adverse effects on the cardiovascular system and causes coronary heart disease and lung cancer.
4. The scientific evidence indicates that there is no risk-free level of exposure to secondhand smoke.
5. Eliminating smoking in indoor spaces fully protects nonsmokers from exposure to secondhand smoke. Separating smokers from nonsmokers, cleaning the air, and ventilating buildings cannot eliminate exposures of nonsmokers to secondhand smoke.

Tobacco smoke contains more than 4000 different chemicals, at least 60 of which are known carcinogens (National Toxicology Program, 2005). The U.S. Environmental Protection Agency, (EPA) the National Toxicology Program, the U.S. Surgeon General, and the International Agency for Research on Cancer have determined that environmental

tobacco smoke is a class A (known) human carcinogen, in the same class as asbestos, mustard gas, arsenic, and benzene. In addition to the 3000 lung cancer deaths a year in nonsmokers, almost 40,000 heart disease deaths each year are linked to secondhand smoke. Secondhand smoke exposure also causes chronic otitis media, cough, and lower respiratory illnesses in children, such as asthma, bronchitis, and pneumonia. It is estimated that tobacco smoke in the home and workplace could be responsible for the deaths of about 50,000 nonsmokers annually in the United States, making passive smoking the third leading preventable cause of death, after those from direct smoking and alcohol (Air Resources Board, 2005).

In a classic study, Hirayama (1981) was among the first scientists to demonstrate an increased risk of lung cancer in nonsmoking housewives exposed to the secondhand cigarette smoke of their husbands (see eFig. 50-2 online). Since then, many studies have shown an association between being married to a smoker and having an increased risk of lung cancer. Overall risk of lung cancer increases 20% to 30% in nonsmokers exposed to ETS in the home; combined home and work exposure further increases the risk (USDHHS [Report of the Surgeon General], 2006).

A report from the California EPA's Air Resources Board is another well-researched review of the health effects of passive smoking. Their meta-analyses of the breast cancer risk indicate that the RR for breast cancer, particularly among premenopausal women, is between 1.68 and 2.20 (Air Resources Board, 2005; Miller et al., 2006). A 2009 Canadian task force report found a causal link between passive smoke exposure and breast cancer, especially in younger, premenopausal women, and a causal relationship between active smoking and breast cancer at all ages (Johnson et al., 2011).

It is estimated that the risk of MI is up to 70% greater for a woman whose husband smokes (Wells, 1994). Relative risk estimates from meta-analysis indicate a 25% to 30% increase in the risk for coronary heart disease in exposed nonsmokers; as with lung cancer, multiple sites of exposure increase the risk (USDHHS [Report of the Surgeon General], 2006). The cardiovascular effects of even brief exposure to secondhand smoke are often nearly as great as those of direct smoking, with platelet aggregation and arterial endothelial damage occurring within 30 minutes of exposure; furthermore, secondhand smoke induces oxidative stress and promotes vascular inflammation (Barnoya and Glantz, 2005). Exposure to secondhand smoke is associated with increased levels of inflammatory markers related to the development of atherosclerosis. People exposed have higher white blood cell counts and elevated CRP levels, oxidized LDL cholesterol, homocysteine, and fibrinogen. Even occasional exposure results in elevated levels. These increases are similar to those seen in active smokers.

Reports show that the health benefits of banning smoking in public places and the workplace include a reduction in heart attacks. Examination of community MI rates after implementation of strong smoke-free legislation found a pooled random-effects estimate of the rate of acute MI hospitalization 12 months later to be 0.83 (95% CI, 0.80-0.87), with growth of this benefit expected over time (Lightwood and Glantz, 2009). With similar findings, systematic review and meta-analysis of 10 locations with smoke-free legislation concluded that the acute MI risk decreased by 17% overall,

with the greatest effect in younger individuals and nonsmokers (Meyers et al., 2009).

Secondhand Smoke: Effects on Children

Over 50% of children younger than 5 years of age live in homes with at least one adult smoker. Children of smoking parents have more bronchitis and pneumonia during their first year of life and more otitis media when older. They have increased incidence of cough, bronchitis, and pneumonia proportional to the number of cigarettes smoked by the parents, particularly the mother. In fact, children of parents who smoke at least a half-pack a day have almost twice the risk of hospitalization for a respiratory illness. Secondhand smoke causes new-onset asthma in exposed children, and young persons with asthma have more asthma episodes (Charlton, 1994; Rantakallio, 1978; USHHS [Report of the Surgeon General], 2006).

Passive smoking also increases the risk of sudden infant death syndrome. Infants exposed to secondhand smoke have twice the risk of SIDS, and infants whose mothers smoke before and after birth are three to four times more likely to die from SIDS (US Surgeon General, 2004, 2006).

Small children are victimized more by passive smoking than adults. Because of their more rapid breathing, children inhale larger amounts of harmful substances. Children exposed to their parents' cigarette smoke have six times the average number of respiratory infections. They also have deficits in growth and in intellectual and emotional development, as well as more behavior disorders, such as hyperactivity.

Physicians and health care providers who care for children should advise parents to quit smoking to limit their children's exposure to secondhand smoke, and advocate for smoke-free indoor air both at home and in cars when children are passengers, since these two locations account for the majority of childhood exposure to secondhand smoke.

Thirdhand Smoke

Thirdhand smoke occurs when cigarette smoke reacts with nitrous acid on surfaces to form *tobacco-specific nitrosamines* (TSNAs). Nitrous acid is a common indoor pollutant and, when combined with cigarette smoke, forms a carcinogen that becomes more potent over time. Thus, nicotine is converted to a dangerous carcinogen after it is absorbed on indoor surfaces in automobiles and furniture. This can be especially hazardous to infants and children who live close to the floor because the TSNAs are especially concentrated in dust and carpeting. Smokers believed that smoking only when others were not present (e.g., in car or home) created no risk to the nonsmoker who arrives later. In fact, the smoke clings to upholstery, cotton, and carpeting and actually builds up over time, exposing the nonsmoker to potent carcinogens. This thirdhand smoke can be especially dangerous because TSNAs cannot be simply inactivated by dry cleaning or washing with soap and water. Most soaps are alkaline and cleansers that dissolve nicotine must be acidic. Thus, it is almost impossible to remove TSNAs from carpeting, which will continuously uptake nicotine. Even washing smooth stone and metal with an alkaline soap will not remove nicotine residue (Dreyfuss, 2010; Sleiman et al., 2010).

Pregnancy

See the discussion online at www.expertconsult.com.

Key Points

- The more a pregnant woman smokes, the greater the risk of premature delivery and low-birth-weight infants, unless she stops smoking by the fourth month of gestation.
- Smoking during pregnancy increases the risk of congenital abnormalities, mental retardation, learning problems, and attention-deficit/hyperactivity disorder (ADHD).
- The risk is increased for spontaneous abortion, placenta previa, and premature rupture of membranes.
- Reduced fertility is proportional to the number of cigarettes smoked.

KEY TREATMENT

Because of the serious risks of smoking to the pregnant smoker and the fetus, whenever possible pregnant smokers should be offered person-to-person psychosocial interventions that exceed minimal advice to quit (Fiore et al., 2008) (SOR: A). Although abstinence early in pregnancy will produce the greatest benefits to the fetus and expectant mother, quitting at any point in pregnancy can yield benefits. Therefore, physicians should offer effective tobacco-dependence interventions to pregnant smokers at the first prenatal visit and throughout pregnancy (Fiore et al., 2008) (SOR: B).

Smoking and Mental Health

Mental illness and substance abuse puts patients at particular risk for dying of tobacco-related illness because they are more likely to smoke, and smoke more heavily, than others in the population. Patients with psychiatric illness consume up to 70% of the cigarettes smoked in the United States, with two to four times the general prevalence of smoking (Grant et al., 2004; Kalman et al., 2005). Among mentally ill and substance-abusing patients, as many as 200,000 die each year from tobacco-related causes—almost half the total U.S. tobacco-related mortality (Williams et al., 2004). Individuals in this special population of smokers do express strong interest in quitting smoking, however. Counseling and pharmacology that is useful with other smokers is effective in mentally ill and substance-abusing patients who smoke (Ranney et al., 2006), and just as with other smokers, this part of their health care must not be neglected.

Social and Legal Action

See online text for discussion.

Smoking Cessation

Key Points

- Patients who smoke should receive advice and encouragement to stop at every visit.
- Take advantage of the teachable moment, when a patient who smokes is being treated for any medical condition.

- Multiple strategies and persistence are usually needed for successful cessation because tobacco dependence is a chronic disease.
- Brief counseling, usually lasting less than 3 minutes, is an effective way to begin intervention.

Family physicians are in a unique position to assist their patients in smoking cessation. Because 7 of every 10 smokers visit their physician at least once a year, this is a golden opportunity that should not be missed. Among smokers, 70% want to quit and about 40% make an attempt each year, but less than 5% succeed. Even brief physician advice can double the quit rate (Fiore et al., 2008). Of those who try to quit on their own and do not use recommended cessation methods, most relapse within 8 days (CDC, 2008).

A survey by the Association of American Medical Colleges (AAMC, 2007) about physician behavior related to smoking cessation is summarized as follows:

Most physicians consistently ask patients who smoke about their smoking status and advise them to stop (86%), but only 13% say they usually refer smokers to others for appropriate treatment and only 17% say they usually arrange for follow-up visits to address smoking. Only 31% “usually” advised use of nicotine replacement therapy, and 25% “usually” prescribed other medication for cessation. Only 7% regularly referred patients to a quit line.

Physicians regard current smoking cessation tools as inadequate, citing the following:

- Insufficient services, resources, and organizational support
- Interventions that have only limited effectiveness
- Limited education and training for physicians on addressing tobacco use and cessation interventions

The five factors cited most often by physicians as significant barriers to successful interventions are lack of patient motivation (63%), limited coverage for interventions (54%), limited reimbursement for a physician's time (52%), time with patients is limited (41%), and too few available cessation programs (39%).

Patients should be asked about tobacco use at every visit because repeated screening increases rates of clinical intervention. Tobacco users should be advised to quit at every visit (SOR A), because there is a dose-response relationship between the number of contacts and abstinence. Tobacco use screening coupled with brief advice is one of the top-three clinical prevention measures and is cost-effective as well (Maciosek et al., 2006). Tobacco-cessation treatment may include a variety of components: counseling for behavior change in both individual and group settings, such as motivational interviewing and problem solving/skills training; use of evidence-based pharmacotherapy; and proactive telephone quit line counseling (Fiore et al., 2008; USPSTF, 2009). Patients should receive at least minimal advice and encouragement at every visit based on the five “As” approach (Box 50-2). The American Academy of Family Physicians (2005) has a campaign to encourage its members to engage themselves in smoking cessation interventions. Using two As, “Ask and Act,” the AAFP program emphasizes brief counseling and effective follow-up.

Box 50-2 Five As for Tobacco Users Willing to Quit

- Ask about tobacco use at every visit.
- Advise to quit through clear personalized messages.
- Assess willingness to quit.
- Assist efforts to quit.
- Arrange follow-up and support.

As part of taking the history from a patient who smokes, clinicians should ask the following three questions to assess the patient's degree of nicotine addiction:

1. How much do you smoke? (How many cigarettes or cans of "dip" per day, for how many years?)
2. When do you smoke the first cigarette of the day?
3. How long is the period between cigarettes before craving another smoke?

Patients who smoke more than 20 cigarettes a day, who light their first cigarette within 30 minutes of waking, and who have cravings within 1 hour of the most recent cigarette are likely to have significant physiologic addiction to nicotine. Smoking fewer than 10 cigarettes a day suggests less addictive behavior, and a few patients report that they smoke only during social situations and only 5 to 10 cigarettes a week. Determining the patient's pattern of smoking will provide clues into the level of addiction.

Office spirometry to obtain a forced expiratory volume in 1 second (FEV₁) can also be useful in motivating smokers to quit. Comparing the smoker's "lung age" to the age of a healthy individual who has the same FEV₁, then showing the smoker a graphic display (Fig. 50-5, A), more than doubled the rate of quitting smoking after 12 months (13.6% vs. 6.4%) (Parkes et al., 2008). For example, a 52-year-old smoker with a 20-pack-year history (1 pack/day for 20 years) may have the lung age of a 75-year-old. Probable age at disability and death if the person continues smoking or stops smoking can be shown (Fig. 50-5, B). Such a visual presentation is often effective in achieving cessation even if smokers have a normal lung age because they may think it is not too late for them to quit.

Stages of Change

Patients who begin any major behavioral or lifestyle change go through successive stages in the process, as follows:

Precontemplation: Patient is not interested in quitting smoking in the near future (within 6 months).

Contemplation: Patient is thinking about quitting within the next few months, but has taken no action.

Preparation: Patient is planning to quit in the next 30 days.

Action: Patient is in the process of quitting, or has quit during the last 6 months.

Maintenance: Patient has abstained for more than 3 months.

Family physicians should emphasize progression through the process of change to facilitate the patient's efforts to stop smoking. When a patient reaches the preparation stage, the physician can play a major role in motivating the patient, including counseling and routine use of pharmacotherapy. However, recent research indicates that many smokers do not go through sequential stages and are often successful in quitting during spontaneous, unplanned attempts, perhaps sparked by an illness or by policy changes such as price increases or clean indoor air laws. Physicians' continued

support and encouragement may help increase the frequency and success of these efforts (Ferguson et al., 2009).

Helping to Change Behavior

In addition to the support for smoking cessation activity described by the U.S. Public Health Service (Fiore et al., 2008), *motivational interviewing* is a patient-focused approach to discussing patients' ambivalence about changing their tobacco use behavior. Motivational interviewing uses empathy and a nonjudgmental style to open a dialogue that can show the importance of change and build a patient's self-motivation. Patients can build on prior success (even brief) and become more active partners in the path to abstinence (Mallin, 2002; Miller and Rollnick, 2002). A clear relationship exists between the intensity of counseling and its effectiveness. Although even brief counseling (≤ 3 minutes) doubles the spontaneous quit rate, intensive therapy can be more effective and should be used whenever possible (Fiore et al., 2008).

Both physicians and their patients who smoke should think of nicotine dependence as a chronic disease, usually characterized by many episodes of remission and relapse. A number of strategies are often needed, and expectations must be realistic, because smokers usually do not succeed on their first or even second attempt. Clearly, however, the chances of success increase with each attempt, and relapse should not be considered a sign of failure.

Intensive counseling is associated with a 22% smoking-cessation success rate and even minimal counseling (< 3 minutes) has a 13% quit rate (Schroeder, 2005). Physicians should take advantage of the teachable moment, such as when a smoker is being seen for a respiratory or cardiovascular problem, an asthma attack in a smoke-exposed child, or the smoking-related death of a loved one (Miller and Wood, 2003). One of the most productive times for cessation advice to be received and effective is during prenatal care or after a nonfatal cardiac event. When intensive counseling and follow-up are provided to patients recovering from coronary bypass graft surgery or a heart attack, more than 60% stop smoking and stay off cigarettes, almost twice the rate of those who receive less definitive advice (Smith and Burgess, 2009; SOR A). A Cochrane review of cessation interventions among hospitalized patients shows that intensive interventions that begin in the hospital and have at least one supportive contact after discharge increase the odds of successful tobacco abstinence (Rigotti et al., 2007).

Pharmacotherapy

The updated clinical practice guideline, Treating Tobacco Use and Dependence (Fiore et al., 2008), discusses the use of the different forms of nicotine replacement therapy

KEY TREATMENT

Tobacco users attempting to quit should be prescribed one or more effective first-line pharmacotherapies for tobacco use cessation, including five nicotine replacement therapies (NRTs) (transdermal patch, gum, nasal spray, lozenges, or vapor inhaler) and nonnicotine replacement (bupropion sustained release [SR], or varenicline) (Eisenberg et al., 2008; Fiore et al., 2008) (SOR: A). Brief counseling (≤ 3 minutes) doubles the spontaneous quit rate; intensive therapy can be even more effective and should be used whenever possible (Fiore et al., 2008) (SOR: A).

Figure 50-5 **A**, Explaining lung age to participants. **B**, Graph of lung function against age showing how smoking accelerates age-related decline in lung function. (From Parkes G et al. *BMJ* 336:598-600, 2008, Figs. 1 and 2.)

and the other two FDA-approved prescription medications used for tobacco cessation, bupropion and varenicline (Box 50-3). Effective second-line agents include clonidine, delivered transdermally or orally, and nortriptyline (Fiore et al., 2008), but neither is FDA approved for this indication. All these medications in randomized clinical trials have two to

four times the odds ratio for success compared with placebo for smoking cessation. Medication and treatments to avoid include antidepressants such as SSRIs, benzodiazepines, mecamylamine, hypnosis, acupuncture, laser therapy, and beta-adrenergic blocking agents, none of which has been found to have a beneficial effect (Fiore et al., 2008).

Box 50-3 Clinical Guidelines for Nicotine Withdrawal**Nicotine Patch**

Patches should be applied as soon as patients waken on their quit day. At the start of each day, the patient should place a new patch on a relatively hairless location between the neck and waist. There should be no activity restrictions while using the patch. Treatment for 8 weeks or less is as effective as longer treatment periods. New research indicates that starting the patch 2 weeks before quit day increases success.

Dosage

Nicoderm, Habitrol: 21 mg/24 hr for 4 wk, then 14 mg/24 hr for 2 wk, then 7 mg/24 hr for 2 wk

Nicotrol: 15 mg/16 hr for 4 wk, then 10 mg/16 hr for 2 wk, then 5 mg/16 hr for 2 wk.

ProStep: 22 mg/24 hr for 4 wk, then 11 mg/24 hr for 4 wk

Nicotine Gum

Gum should be chewed slowly until a peppery taste emerges, then parked between the cheek and gum to facilitate nicotine absorption through the oral mucosa. The gum should be slowly and intermittently chewed and parked for about 30 minutes.

Acidic beverages (e.g., coffee, juices, soft drinks) interfere with the buccal absorption of nicotine, so eating and drinking anything except water should be avoided for 5 minutes before and during chewing.

Instructing patients to chew the gum on a fixed schedule may be more beneficial than ad lib use. Patients often do not use enough gum to obtain the maximum benefit.

Dosage

Nicorette: Available as 2 mg and 4 mg per piece. Smokers of more than one pack a day, those who smoke within 30 minutes of awakening, and those with a history of severe withdrawal symptoms should use 4 mg; light smokers should use 2 mg.

Chew one piece every 1-2 hr (at least 9/day) for 6 wk, then one piece every 2-4 hr for 3 wk, then one piece every 4-8 hr for 3 wk, then discontinue.

For the 2-mg dose, do not exceed 30 pieces/day; for the 4-mg dose, 20 pieces/day.

Nicotine Lozenge

Each lozenge is one 2-mg or 4-mg dose and should be dissolved in the mouth when the urge to smoke starts; lasts 20-30 minutes.

Use 9-20/day for up to 12 weeks.

No eating or drinking during use or 15 minutes before use.

Side effects include sore teeth or gums, indigestion, throat irritation, and other symptoms similar to those with the nicotine gum.

Dosage

Commit lozenge: 2 mg and 4 mg per piece. Smokers of more than one pack a day who smoke within 30 minutes of waking, and those with prior history of severe withdrawal, should use the 4-mg form. Light smokers should start with the 2-mg strength. Do not swallow, bite, or chew the lozenge.

Nicotine Inhaler

Local irritation in the mouth and throat occurs in 40% of patients. Coughing and rhinitis are also common. The severity and frequency of these symptoms decline with continued use.

In cold weather, the inhaler and cartridges should be kept in an inside pocket or warm area, because nicotine delivery declines significantly at temperatures below 40° F (4.4° C).

Dosage

Nicotrol Inhaler: 10 mg/cartridge (4 mg delivered and 2 mg absorbed). Each cartridge lasts about 20 minutes with frequent puffing and is equivalent to about two cigarettes. Use 6 to 16 cartridges/day for the first 12 wk, then reduce gradually over 12 wk.

Nicotine Nasal Spray

Moderate nasal irritation for first 3 weeks or longer. Nasal congestion and transient changes in sense of smell and taste may also occur.

Should not be used in patients with severe reactive airways disease.

Do not sniff, swallow, or inhale through nose while administering doses.

Deliver with head tilted slightly back.

Dosage

Nicotrol NS: One spray (0.5 mg) to each nostril (1.0 mg total). Use 1-2 doses/hr and 8 to 40 doses/day (maximum, 5 doses/hr). Each bottle contains 100 doses. Usual maximum, 12 weeks.

Bupropion SR

Contraindicated in patients with a history of significant head trauma, seizure disorder, or eating disorder, and in those who have used a monoamine oxidase inhibitor (MAOI) in the past 14 days.

Side effects are insomnia and dry mouth. If insomnia is present, take the evening dose in the afternoon, but at least 8 hours after the first dose.

Dosage

150-mg tablets; one every morning for 3 days and then twice daily. Start 2 weeks before the target quit date and continue for 12 weeks.

Side effects are nausea (30% of patients), abnormal dreams, insomnia, headache, taste aversion, and flatulence.

Varenicline

Start 1 week before quit date.

Side effects are nausea (30% of patients), abnormal dreams, insomnia, headache, taste aversion, and flatulence. FDA warning addresses behavior changes and suicidal ideation.

Dosage

Chantix: 0.5 mg (white tablet) once daily for 3 days, then twice daily for 4 days, then 1.0 mg (blue tablet) twice daily, for total of 12 weeks.

Comments

Some patients may prefer the nasal spray or inhaler, because the more rapid delivery of nicotine better simulates smoking.

Others may prefer bupropion because it is nonnicotine therapy.

Bupropion should be considered especially in those with a history of depression.

Modified from US Department of Health and Human Services. Treating Tobacco Use and Dependence: Clinical Practice Update. Rockville, Md, Agency for Health Care Policy and Research, Public Health Service, 2008.

Nicotine Patch

The nicotine patch is a mainstay of treatment, often combined with other forms of replacement or psychotropic medication and counseling. The main advantages of the patch are consistent delivery, easy use, and concealment. The major disadvantage is insomnia, which can be avoided by not wearing the patch at night.

In a study by Cornish and Gariti (2002), by the second day of patch use, nicotine levels are about half or greater than those achieved by smoking. Quit rates at 4 to 8 weeks (depending on the study) are about double the rate of success for placebo—that is, up to 70% for the nicotine patch versus up to 40% for placebo. After 1 year, the abstinence rates are about 25% for the gum and patch compared with 12% for placebo. The combination of a short-acting form of NRT (gum, lozenge, nasal spray) added to the patch increases the odds of success, because it helps control cravings and gives the smoker the ability to titrate the dose. Recent evidence also indicates that smokers who begin the patch 2 weeks before the quit date may double the rate of abstinence (Rose et al., 2009).

Nicotine Gum

To obtain maximal results, the gum must be chewed slowly and then parked between cheek and gum to allow for buccal absorption. Although 2-mg and 4-mg strengths are available, the 4-mg strength is recommended for patients who smoke more than one pack a day. Absorption is decreased if the mouth is acidic, so the patient should avoid beverages such as coffee, tea, soda, and fruit juice. Abstinence rates at 4 to 6 weeks are 73% for nicotine gum compared with 49% for placebo gum. The duration of treatment, as with other NRT, should be at least 6 weeks, although a Cochrane review did not find evidence of enhanced success for the patch beyond 8 weeks (Stead et al., 2007).

Nicotine Inhaler and Nasal Spray

The nicotine inhaler resembles a cigarette and mimics the act of smoking, thus permitting perpetuation of a behavioral ritual, but the nicotine is absorbed through the buccal mucosa rather than the lungs. Its efficacy is similar to that of the patch. The nicotine nasal spray is more rapidly absorbed than the other forms of NRT and should be a first-line treatment for heavier smokers. As monotherapy, the nasal spray has a higher odds ratio for success than the other NRT used alone (Fiore et al., 2008).

Nicotine Lozenges

Nicotine lozenges deliver slightly more available nicotine than nicotine gum, are easier to use, and have fewer gastric side effects. The lozenge comes in several flavors and should be sucked like candy, slowly, until the flavor becomes intense. It is then held between the cheek and gums, like nicotine gum, and sucked again after the flavor has diminished. It should not be chewed or swallowed. The 4-mg strength lozenge should be used for those whose first cigarette is within 30 minutes of waking, with the 2-mg strength used

for lighter smokers. Smokers should use seven or eight lozenges or more per day, up to 20.

Bupropion

Bupropion is a monocyclic antidepressant, thought to inhibit the reuptake of both dopamine and norepinephrine. It may exert multiple mechanisms, producing craving relief from dopaminergic activity, and antagonism of nicotinic acetylcholine receptors. The U.S. Public Health Service (PHS) guidelines and other analyses show that bupropion doubles long-term abstinence compared with placebo (Eisenberg et al., 2008; Fiore et al., 2008). Dosing begins 1 week before the quit date: 150 mg for 3 days, then 150 mg twice daily for the remainder of the week until quit day, and long-term maintenance at that dose. Bupropion may also be effective in relapse prevention, although a recent Cochrane review questions that conclusion (Hajek et al., 2008). Bupropion carries a small risk of seizures, as with other antidepressants, and is contraindicated in patients with a significant history of head trauma, eating disorders, or seizure disorders. Bupropion is effective in delaying weight gain associated with smoking cessation. The FDA has issued a black-box warning for both bupropion and varenicline, highlighting the risk of serious mental health events, including changes in behavior, depressed mood, hostility, agitation, suicidal thoughts, and attempted suicide.

Combination Therapy

Just as long-acting and short-acting NRT can be combined to augment cessation success, bupropion can be used with the patch or other forms of NRT. Combination therapy appears to be a promising approach. A 9-week study combining bupropion SR with transdermal nicotine found much greater efficacy than with either medication alone (Jorenby et al., 1999), and subsequent review in the PHS guidelines confirms the utility of combination therapy (Fiore et al., 2008). One might think of bupropion or the patch as the “controller” medication and the short-acting NRT as the “rescue” drug, much as dual therapy is used in asthma control. A recent trial of “triple therapy” using the patch, bupropion, and the nicotine vapor inhaler for up to 6 months showed a 2.57 odds ratio for abstinence compared with patch alone (Steinberg et al., 2009).

Clinicians at the Mayo Clinic Nicotine Dependence Center have routinely used combination therapy and base initial NRT patch dosing on venous cotinine levels. If that is not available, the intensity of smoking or spit tobacco use can be a useful guide (Table 50-1) (Dale et al., 2000).

Table 50-1 Recommended Dosages for Nicotine Replacement Therapy

| Cigarettes (per day) | Nicotine Patch Dose (mg/day) |
|----------------------|------------------------------|
| Less than 10 | 7-14 |
| 10-20 | 14-22 |
| 21-40 | 22-44 |
| More than 40 | 44+ |

Varenicline

Varenicline is a partial agonist/antagonist that is selectively bound to the $\alpha 4\beta 2$ nicotinic receptors, thus blocking nicotine from these brain cells, as well as stimulating them to release dopamine at lower levels than does nicotine itself. This leads to reduced cravings and fewer symptoms of nicotine withdrawal. A Cochrane review of its effectiveness concludes that it increases the odds of successful cessation two to three times more than attempts not using pharmacotherapy, with a pooled RR at 1 year compared to bupropion of 1.52 (Cahill et al., 2008). Varenicline is titrated over 1 week, mainly to help overcome its major side effect of nausea, ameliorated by taking varenicline with meals. Begin with 0.5 mg daily for 3 days, then 0.5 mg twice daily, then 1 mg twice daily on day 8, which is quit day for the patient. Treatment should continue for at least 12 weeks; an additional 12 weeks may be useful in patients who are insecure in their attempts and are at high risk for relapse. The longer dosing schedule was shown to increase success in clinical trials.

Concern has been raised about varenicline and its potential to cause behavior changes and suicidal thoughts. In July 2009 the FDA issued a black-box warning for both varenicline and bupropion saying that patients taking either of these drugs should be observed for symptoms of behavior change, including hostility, aggression, depressed mood, and suicidal ideation or attempts. Patients should stop taking varenicline and contact their physician if these or other unusual neuropsychiatric symptoms occur. In addition, patients should take precautions when driving or operating machinery until they know whether varenicline might adversely affect them. Pilots, air traffic controllers, and persons with commercial motor vehicle licenses cannot use varenicline, according to federal rules issued in 2008. A cohort study of more than 80,000 persons using different medications for smoking cessation, however, found no clear evidence that varenicline caused suicide or depression (Gunnell et al., 2009).

Early evidence shows that using varenicline in combination with the nicotine patch and with bupropion appears to be safe and well tolerated; however, more investigation is needed before these combinations become a mainstay of smoking-cessation therapy (Ebbert et al., 2009a, 2009b).

Second-Line Medications

Clonidine and nortriptyline are listed in the PHS guidelines as second-line drugs, and both have been shown to have significant effects on cessation compared with placebo (Fiore et al., 2008). Nortriptyline is generally titrated up to 75 to 100 mg/day and used for 8 to 12 weeks. It has the advantage of being quite inexpensive, but drug levels may be needed to avoid toxicity. Clonidine patches, 0.2 mg/day, are recommended for up to 10 weeks and should be started 1 week before the quit date. Clonidine's side effects of drowsiness may limit its usefulness in many patients. Neither is FDA approved for smoking cessation.

Quit Lines

One of the least used methods, yet one of the most effective, is telephone quit lines. Surveys have shown that 70% to 85% of smokers prefer to use a quit line to seeing a clinician, perhaps because of the convenience, anonymity, and ability to obtain

counseling in their native language. The toll-free number, 1-800-QUITNOW (1-800-784-8669), is a single access point to the National Network of Tobacco Cessation Quit Lines. Callers are automatically routed to a state-run quit line, if one exists in their area. If there is no state-run line, callers are routed to the National Cancer Institute (NCI) quit line, where they may receive cessation services and other information. Quit lines are available in almost every state (Schroeder, 2005). There is also a California Smoker's Helpline at 1-800-662-8887, which links people nationwide to counselors who will give one-to-one support. Quit lines are even more effective when combined with NRT (Bush et al., 2008)

Relapse Prevention

Perhaps the most poorly understood element in smoking cessation is preventing relapse. Follow-up and ongoing contact with patients is essential, especially in the first few weeks of a cessation attempt. The first 2 weeks are the most crucial period, when smoking even one cigarette is a strong predictor of a return to regular smoking within 1 year. A return visit, proactive telephone call, or regular sessions with a quit line counselor in the early stages of cessation should be integrated into the patient's treatment. To be truly successful, family physicians should integrate tobacco-dependence treatment into their practice (Solberg, 2000). The Cochrane review on relapse prevention found that while no definitive evidence yet exists for specific interventions to sustain abstinence, efforts to help smokers identify and deal with "tempting situations" show promise (Hajek et al., 2008). However, an excellent series of materials for patients is available from the National Cancer Institute website and may be very useful in helping patients with discussions of relapse issues ("Forever Free" at www.smokefree.gov/resources.aspx).

Current Developments

Smoker's Genetics

Genetic testing may be able to indicate persons most susceptible to becoming addicted to nicotine. Addictive individuals who have a particular gene and are trying to quit may be more responsive to nicotine patches than nonnicotine measures such as bupropion (Zyban). Multiple genes are involved, however, and considerable research will be needed to create practical applications for these discoveries.

Much work is currently underway regarding genes and gene mutations that predispose cigarette smokers to lung cancer. *Gene methylation* is a chemical modification that may be a marker for the early detection of lung cancer. The gene *GPC5* has an important tumor suppressor-like function that, if insufficient, can promote lung cancer development. A variant of this gene has been found in one third of nonsmokers who develop lung cancer (Yang, 2010).

Diet

Diet may protect against gene changes in smokers. Some vitamins and green leafy vegetables serve as protective factors against lung cancer, as for colorectal cancer. Increased variety in fruit and vegetable intake may confer some protection against lung cancer among smokers (Buchner et al., 2010).

Scope of the Problem

Key Points

- About 8.0 % of the U.S. population, or 20.1 million Americans, reported using illicit drugs in 2008.
- Marijuana has remained the most frequently used illicit drug in the United States.
- The prevalence of illicit drug use has been greatest in those 18 to 20 years of age.
- With the exception of hallucinogens such as “ecstasy,” prevalence of drug use in teenagers age 12 to 17 has decreased since 2002.
- Illicit drug use is significantly higher among people with serious mental illness.

According to the 2008 Substance Abuse and Mental Health Services Administration (SAMHSA) National Survey on Drug Use and Health, an estimated 20.1 million Americans age 12 or older were current users of illicit drugs or reported having used an illicit substance 1 month before the survey. This represented 8.0% of the U.S. population. This rate has remained essentially stable since 2002. With an estimated 15.2 million current users, marijuana was the most frequently used illicit drug. Among people who used illicit drugs, marijuana was used by an estimated 75.7% of current illicit

drug users. Following marijuana were nonmedical use of prescription psychotherapeutic drugs (6.2 million), cocaine (1.9 million), hallucinogens (1.1 million), and methamphetamine (314,000).

The age group with the greatest prevalence of illicit substance abuse was individuals age 18 to 20, at 21.5%. Rates of illicit drug use among youths age 12 to 17 decreased from 11.6% in 2002 to 9.3% in 2008. The rate of substance abuse or dependence for males age 12 and older was almost twice as high as that for females (11.5% vs. 6.4%). However, males and females had similar rates of nonmedical use of psychotherapeutic drugs, pain relievers, stimulants, and sedatives.

The prevalence of illicit drug use varies by race and ethnicity. Illicit substance use was highest among people reporting two or more races, at 14.1%. An estimated 10.1% of blacks, 9.5% of American Indians or Alaska Natives, 8.2% of whites, 7.3% of Native Hawaiians or other Pacific Islanders, 6.3% of Hispanics, and 3.6% of Asians were current illicit drug users in 2008. Illicit drug use also varies by education level. Among adults age 18 or older, the prevalence of current illicit drug use was 9.4% of adults with some college education, 8.1% of adults who did not complete high school, 8.6% of high school graduates, and 5.7% of college graduates. In 2008 an estimated 8000 people used an illicit substance for the first time each day. Most initiates were female and younger than 18. Between 2003 and 2008, the number of daily new

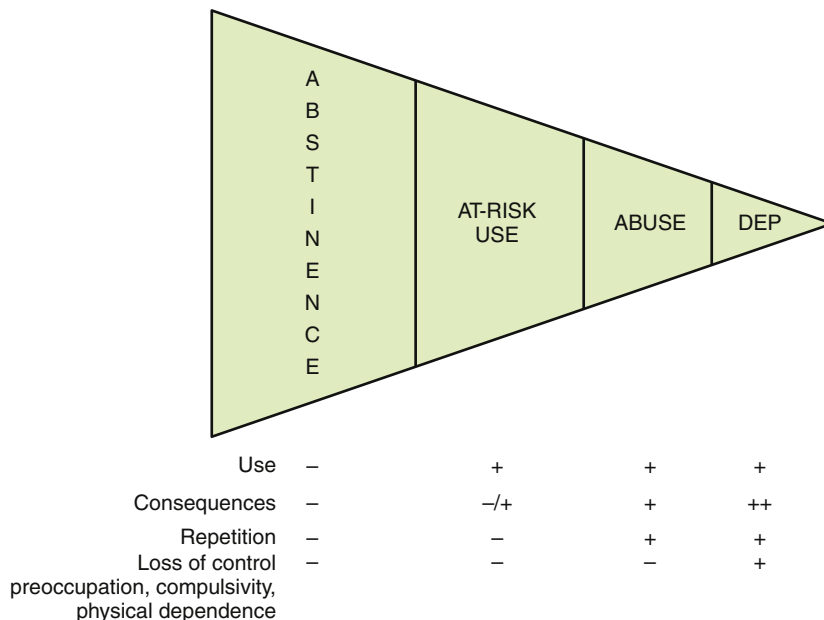

Figure 51-1 Continuum of drug use in patients with substance use disorders. (Modified from Association for Medical Education and Research in Substance Abuse.)

users of cocaine, psychotherapeutic drugs and inhalants had decreased. During the same 5-year interval, the number of people initiating use of hallucinogens, ecstasy, and LSD had increased significantly. Approximately, 19.6% of unemployed individuals age 18 and older were current illicit drug users. This was significantly higher than the prevalence of current drug use among individuals employed full time (8.0%) and part time (10.1%).

The prevalence of substance of abuse was also significantly higher among individuals with serious mental illness. Use of illicit drugs in the past year among adults age 18 or older with serious mental illness was 30.3%, whereas use among same-age adults without serious mental illness was 12.9%.

Terminology

The term “substance use disorder” (SUD) implies a continuum of use: from abstinence to at-risk use to abuse and dependence (Fig. 51-1). The majority of the general population, as well as family medicine patients, are “abstainers.” The majority of users of illicit substances do not meet criteria for the diagnosis of abuse and dependency. This model of substance use is important for family medicine physicians to keep in mind as they talk with their patients about substance use issues. It highlights the key role played by screening for substance use and early intervention at the at-risk use level, before specialized treatment services are more likely needed. For illicit substances, unlike alcohol, no amount of use can be considered safe or healthy, in part because any use is illegal.

Box 51-1 lists the DSM IV diagnostic criteria for substance abuse and dependence. Of note, physical dependence alone does not make a diagnosis of substance abuse or dependence, nor does lack of physical dependence exclude the diagnoses.

Table 51-1 shows some common drug street names. Comprehensive lists can be found on the Office of National Drug Control Policy website, www.whitehousedrugpolicy.gov. Street names vary by region and user group. The most useful

Box 51-1 Diagnostic Criteria for Substance Abuse and Dependence (DSM IV)*

A maladaptive pattern of substance use leading to clinically significant impairment or distress, as manifested by:

Abuse

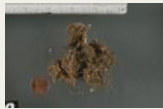

- One or more of the following, occurring in a 12-month period, and these symptoms have never met the criteria for Substance Dependence:
 - Recurrent substance use resulting in a failure to fulfill major role obligations at work, school, or home
 - Recurrent substance use in situations in which it is physically hazardous
 - Recurrent substance-related legal problems
 - Continued substance use despite having persistent or recurrent social or interpersonal problems caused or exacerbated by the effects of the substance

Dependence

- Three or more of the following, occurring in the same 12-month period:
 - Tolerance*, as defined by either of the following: a need for markedly increased amounts of the substance to achieve intoxication or desired effect or markedly diminished effect with continued use of the same amount of substance
 - Withdrawal*, as manifested by either of the following: the characteristic withdrawal syndrome for the substance or the same (or a closely related) substance is taken to relieve or avoid withdrawal symptoms
 - The substance is often taken in larger amounts or longer than intended.
 - There is a persistent desire or unsuccessful efforts to cut down or control substance use.
 - A great deal of time is spent in activities to obtain the substance, use the substance, or recover from its effects.
 - Important social, occupational, or recreational activities are given up or reduced because of substance use.
 - The substance use is continued despite knowledge of having a persistent or recurrent physical or psychological problem that is likely to have been caused or exacerbated by the substance.

information is obtained on the local level, simply by asking patients what they call the drug they are using.

Screening

Screening, brief intervention, and referral to treatment (SBIRT) for alcohol use disorders in primary care has been well studied and is recommended for incorporation into routine

primary care by the U.S. Preventive Services Task Force (USPSTF, SOR B). However, SBIRT in primary care for drug use has been less studied to date, and USPSTF states that there is currently insufficient evidence to recommend for or against routine screening for drug use in primary care.

With the recent increase in prescription drug misuse and abuse, interest in drug-use SBIRT incorporation into primary care has broadened and is being studied for efficacy (Insight Project, 2009). Limitations on drug-use SBIRT in primary

Table 51-2 CRAFT Screening Tool for Adolescents

| CRAFT | Question |
|---------|---|
| Car | Have you ever ridden in a car by someone (including yourself) who was “high” or had been using alcohol or drugs? |
| Relax | Do you ever use alcohol or drugs to relax , feel better about yourself, or fit in? |
| Alone | Do you ever use alcohol or drugs while you are by yourself, or alone ? |
| Forget | Do you ever forget things you did while using alcohol or drugs? |
| Friends | Do family members or friends ever tell you that you should cut down on your drinking or drug use? |
| Trouble | Have you ever gotten into trouble while you were using alcohol or drugs? |

Scoring:
 A “no” response = 0 points; a “yes” response = 1 point.
 0-1 point = negative screen.
 2-6 points = positive screen; consider a safety contract for “yes” response to “car” question regardless of total score.

care include lower prevalence of drug use in primary care patients compared with alcohol use as well as concerns about the practicality of use and positive predictive value (PPV) of available screening instruments in the primary care setting. The American Academy of Pediatrics (AAP), the Bright Future Initiative, and American Medical Association (AMA) Guidelines for Adolescent Preventative Services (GAPS) all recommend at least annual screening of adolescents for drug use. The American College of Obstetricians and Gynecologists (ACOG) advocates regular, periodic screening for all patients, regardless of pregnancy status, although no specific screening instrument is recommended and, to date, no screening instrument has been validated for pregnant women (Lanier and Ko, 2008). Common validated screening instruments for drug use are briefly discussed below.

The CRAFT is the only screening instrument validated for adolescents and has shown an 83% PPV (Table 51-2). It screens for alcohol as well as drug use (Knight et al., 2002).

The ASSIST, CAGE-AID, and DAST have been validated in nonpregnant adults. PPVs for the Alcohol, Smoking and Substance Involvement Screening Test (ASSIST) are not currently available (Newcombe et al., 2005). It screens for tobacco and alcohol in addition to drugs. The ASSIST is available at no cost from the World Health Organization (WHO).

The CAGE-Adjusted to Include Drugs (CAGE-AID) has shown 12% to 78% PPV, with PPV increasing with increasing prevalence of drug use in the study population (Brown and Rounds, 1995). It screens for both alcohol and drug use (Table 51-3).

The Drug Abuse Screening Test (DAST) has similarly shown a wide PPV range of 23% to 75% and is also in the public domain. It screens for drug use only (Staley and El-Guebal, 1990).

The ASSIST and DAST are more lengthy screens than the CAGE-AID and CRAFT and consequently have not been reproduced here. The SAMHSA SBIRT initiative recommends both

Table 51-3 CAGE-AID Screening Tool for Adults

| CAGE | Question |
|------------|---|
| Cut down | Have you felt you ought to cut down on your drinking or drug use? |
| Annoyed | Have people annoyed you by criticizing your drinking or drug use? |
| Guilty | Have you felt bad or guilty about your drinking or drug use? |
| Eye opener | Have you ever had a drink or used drugs first thing in the morning to steady your nerves or to get rid of a hangover (eye opener)? |

Scoring:
 A “no” response = 0 points; a “yes” response = 1 point.
 0-1 point = negative screen.
 2-4 points = positive screen.

Box 51-2 FRAMES intervention technique

Feedback about personal risk
 Responsibility of the patient for change
 Advice to change
 Menu of strategies
 Empathy: express empathy.
 Self-efficacy: elicit and support patient’s self-efficacy for change.

Box 51-3 Five “A’s” Intervention Technique

Assess the risk of the behavior for the patient.
 Advise the patient on their risk and how to modify.
 Agree: come to an agreement with patient on treatment.
 Assist the patient with the treatment plan.
 Arrange follow-up or referral to treatment.

the ASSIST and the DAST for drug screening. (Lanier and Ko, 2008). SBIRT models vary but typically involve a brief screen of several questions regarding tobacco, alcohol, and/or drug use, conducted by frontline staff. Recently a single-question screen for drug use has been validated for primary care: “How many times in the past year have you used an illegal drug or used a prescription medication for nonmedical reasons?” An answer of one or more is a positive screening response (Smith et al., 2010). With sensitivity of 100% and specificity of 73.5%, this single-question screen is comparable to the four-question CAGE-AID.

Patients screening positive receive more in-depth screening with a self-administered or provider-administered screening instrument, such as the DAST or ASSIST, which both allow for stratification of each patient along the SUD continuum. The physician then scores the formal screen and reviews the results with the patient. Patients screening negative are given brief feedback about the results of their screen, and their healthy choices regarding substance use are reinforced by the physician. Patients screening positive for at-risk use, but who do not meet criteria for abuse or dependence, receive a brief intervention, often using the FRAMES model (Box 51-2) or the “Five A’s” model (Box 51-3). Both are useful for patients receptive to change. Motivational interviewing techniques may be more

useful than the FRAMES or Five A's techniques for patients who are more ambivalent about change (Searight, 2009).

Patients screening positive and meeting criteria for abuse or dependence are offered referral to onsite or, more typically, community drug treatment programs. Referral to treatment can be time-consuming and therefore is often done by ancillary staff with knowledge of local treatment resources, or by referring the patient to a community-based agency that provides treatment-matching services.

Laboratory Testing

Key Points

- Any drug testing method involves several important considerations:
- Samples can be adulterated to mask true results: creatinine, pH, specific gravity, and temperature are often used to detect urine sample adulteration.
- A single test result is a marker of use at one point in time and does not itself make a diagnosis of abuse or dependence; laboratory detection of drug use is one tool that may be used during screening, diagnosis, treatment, and relapse prevention of substance use disorders.
- Rates of false positives and false negatives depend on the drug ingested, quantity ingested, duration of use, and specific laboratory cutoffs used; it is important to know the cutoff values of the laboratory used and to obtain a comprehensive history of drug ingestion quantity and frequency over time.

Laboratory testing is frequently used in SUD screening, treatment, and monitoring for relapse. The most common testing method is the *urine drug test*. Other options include blood,

sweat, hair, and oral fluid testing. Table 51-4 lists the advantages and disadvantages of each method (Ries et al., 2009).

Table 51-5 details typical detection times and causes of false-positive results for drugs that can be detected by readily available urine drug testing. Most urine drug tests use immunoassays because these are inexpensive, fast, and easily automated. Gas chromatography with mass spectroscopy (GC/MS) is typically reserved for confirmation of a positive result. Methadone is not a part of most urine drug screen panels and does not show as a positive opiate test. Separate testing for methadone is available. Separate testing is also needed for most "club drugs," including 3,4-methylenedioxymethamphetamine (MDMA), ketamine, and γ -hydroxybutyrate (GHB). Benzodiazepines have a wide range of potencies, half-lives, and metabolites, which makes urine drug screen results less reliable (Ries et al., 2009).

Table 51-5 Urine Drug Testing: Detection Times and Drugs Causing False Positives

| Drug | Detection Time | False-Positive Result |
|-------------------------------|--|---|
| Amphetamines, methamphetamine | 1-3 days | Bupropion, chloroquine, chlorpromazine, ephedrine, labetalol, phenylpropranolamine, propranolol, pseudoephedrine, ranitidine, selegiline, trazodone, tyramine, Vick's inhaler |
| Barbiturates | Short acting: 1-4 days Long acting: several wks | Phenytoin |
| Benzodiazepines | Highly variable | Oxaprozin, sertraline |
| Cocaine | 3 days | None |
| LSD | 2-5 days | Amitriptyline, chlorpromazine, doxepin, fluoxetine, haloperidol, metoclopramide, risperidone, sertraline, thioridazine, verapamil |
| Marijuana (THC) | Single joint: 2 days Heavy use: 27 days | Efavirenz, pantoprazole, quinaprine |
| Methadone | 2-3 days | Quetiapine |
| Opiates | 1-2 days | Gatifloxacin, levofloxacin, ofloxacin, papaverine, rifampicin, poppy seeds |
| Phencyclidine | 7 days | Dextromethorphan, diphenylhydramine, thioridazine, venlafaxine |
| Propoxyphene | 6 hours to 2 days | Cyclobenzaprine, diphenylhydramine, doxylamine, imipramine, methadone |

Table 51-4 Drug-Testing Methods: Advantages and Disadvantages

| Test | Advantages | Disadvantages |
|-------------|---|--|
| Blood | Difficult to adulterate; detects very recent ingestion | Invasive; drugs clear blood more quickly after ingestion than urine |
| Hair | Noninvasive; difficult to adulterate; detects patterns of use over time; frequently used in forensics and research | Not useful for recent ingestion; more difficult to process than other methods |
| Oral fluids | Noninvasive; direct observation easy and makes adulteration more difficult; detects recent ingestion; rapid results | Unintentional contamination from recently ingested substances; drugs clear quickly after ingestion (see Urine) |
| Sweat | Noninvasive; uses patch for collection; monitor for use over extended period | Quantification of drug levels difficult |
| Urine | Noninvasive; rapid results; relatively inexpensive vs. other methods | Easy to adulterate sample, even when observed collection method used |

Pharmacology

Cocaine

Cocaine is a powerful and highly addictive stimulant derived from the leaf extract of the *Erythroxylon coca* bush. In 2008, there were an estimated 1.9 million current users of cocaine, or 0.7 % of the U.S. population. Cocaine use is highest among individuals 18 to 25 years of age.

Cocaine causes a brief, intense feeling of euphoria by blocking the reuptake of dopamine, a neurotransmitter that is associated with pleasure and movement. This blockage accordingly increases the level of dopamine in the central nervous system (CNS). The more rapidly cocaine is absorbed into the bloodstream and delivered to the CNS, the more intense the "high" experienced by the user. Cocaine can be inhaled, injected, or smoked. Injecting or smoking cocaine produces an intense, 5- or 10-minute high that is much stronger than the sensation produced by snorting powder cocaine. The euphoria induced by snorting powder cocaine typically lasts 15 to 30 minutes but is slower in onset than injecting or smoking cocaine. Small amounts of cocaine give users feelings of euphoria, increased mental alertness, and energy.

Symptoms of cocaine intoxication include euphoria, agitation, impaired judgment, bizarre behavior, paranoia, tachycardia, elevated blood pressure, dilated pupils, and diaphoresis. Increased doses of cocaine cause some cocaine users to experience auditory hallucinations, tactile hallucinations, delusions, and aggressive behavior. Sudden cardiac arrest, seizures, and respiratory arrest are examples of fatal complications from cocaine overdose. Tolerance to cocaine causes addicts to binge on cocaine or take more cocaine at increasingly frequent intervals. Withdrawal from cocaine begins with a "crash" or excessive sleep. After 1 to 2 days, the user may feel anxious, irritated, fatigued, and depressed from the absence of cocaine and decreased dopamine levels, which can also cause intense cravings, depression, and suicidal ideation.

Although cocaine has legitimate medical uses, such as local anesthesia in eye, ear, and throat surgery, nonmedical use and importation were banned by the Harrison Act in December 1914.

Marijuana

Derived from a mix of flowers, stems, seeds, and leaves of the plant *Cannabis sativa*, marijuana is the most commonly abused illicit drug in the United States. In 2008, approximately 15.2 million people over 12 years of age were current users of marijuana. Nerve cells in the brain have receptors for THC (delta-9-tetrahydrocannabinol), the main active chemical in marijuana. Once the drug enters the brain, THC causes the release of dopamine and produces feelings of euphoria. Smoking marijuana can produce a high that lasts 1 to 3 hours. Ingesting marijuana that has been mixed with food or brewed with tea can cause a longer high that lasts up to 4 hours. While high on marijuana, users may experience pleasant feelings, a feeling that time passes more slowly, and perceptions of heightened sensation with color and sound stimuli. Marijuana users may also have sudden hunger, thirst, and feelings of paranoia and anxiety. As the euphoria

passes, marijuana users may feel depressed or sleepy. Long-term marijuana use can cause damage to short-term memory by altering the manner in which information is processed in the hippocampus. Marijuana can also cause respiratory problems such as chronic cough, recurrent lung infections, and lung cancer.

Methamphetamine

Methamphetamine is a highly addictive stimulant that can cause increased alertness and increased physical activity with small doses by causing the release of high levels of the neurotransmitter dopamine in the brain. Abusers of methamphetamine experience a brief "rush" by smoking or injecting methamphetamine. Oral ingestion or snorting methamphetamine can produce a high that can last approximately half a day. Due to tolerance, chronic users of methamphetamine may take higher doses of the drug or binge for several days. Long-term use of methamphetamine can cause functional and molecular changes to the brain. Chronic methamphetamine users may exhibit anxiety, violent behavior, and symptoms of psychosis, such as hallucinations, paranoia, and delusions. Fortunately, the use of methamphetamine in the United States has been decreasing. In 2008, there were approximately 314,000 users of methamphetamine, or half the number of users as in 2006.

Hallucinogens

Hallucinogens alter mood and perception. Commonly abused hallucinogens include LSD, PCP, MDMA, and hallucinogenic mushrooms. In 2008, there were 1.1 million current users of hallucinogens in the United States; use increased among youths 12 to 17 years old. *Lysergic acid diethylamide* (LSD) is sold as tablets, capsules, or liquids. It is often added to absorbent paper and dosed in small, decorated squares. Users of LSD experience unpredictable sensations of sound, color, hallucinations, and delusions. Long-term consequences of LSD usage include flashbacks, depression, and long-lasting psychosis. Users of *phencyclidine* (PCP) may smoke, ingest, inject, or snort it to experience hallucinations. PCP use may cause violent behavior, anxiety, and paranoia.

"Club Drugs"

Ketamine, MDMA, GHB, and flunitrazepam (Rohypnol) are substances used in nightclubs, "raves," and dance parties to enhance feelings of intimacy and sensory stimulation. "Ecstasy," or MDMA, produces distorted perceptions of time, enhanced enjoyment of tactile sensations, and feelings of increased energy by increasing the release of serotonin, dopamine, and norepinephrine. The sympathetic overload caused by MDMA can produce hypertension, tachycardia, tremor, diaphoresis, and arrhythmias. MDMA intoxication is also associated with a potentially fatal serotonin syndrome that causes hyperthermia, autonomic instability, and myoclonus. Users of MDMA will typically experience severe depression 2 days after its ingestion.

Ketamine is a dissociative anesthetic derived from PCP. Usually stolen from veterinarians and physician offices, illicit supplies of ketamine are dried in powder form and smoked in

nightclubs with tobacco and marijuana or inhaled. “Special K” can produce sensations of floating outside one’s body, visual hallucinations, and dreamlike states that last for 30 to 45 minutes after ingestion.

Gamma-hydroxybutyrate (GHB) can cause euphoria at lower doses and drowsiness, dizziness, visual disturbances, hypotonia, and amnesia at higher doses. Overdoses of GHB can cause seizures, severe respiratory depression, coma, and death. Because of its sedative and amnesic effect, GHB has been used as a “date rape” drug.

Flunitrazepam (Rohypnol) is a powerful benzodiazepine with 10 times the strength of diazepam that is capable of reducing anxiety, muscle tension, and inhibition. Higher doses of flunitrazepam can produce lack of muscle control, loss of consciousness, and anterograde amnesia. As with GHB, flunitrazepam has been used as a “date rape” drug (Gahlinger, 2004).

Benzodiazepines

Benzodiazepines are a family of depressants used therapeutically to produce sedation, relieve anxiety, induce sleep, control seizures, and alleviate muscle spasms. Abusers of benzodiazepines experience reduced inhibition and impaired judgment. Users of cocaine and amphetamines may take benzodiazepines to counter the stimulant effects. Concurrent use of benzodiazepines with alcohol and other depressants can be life threatening. Abrupt cessation of benzodiazepine use can cause seizures and a withdrawal syndrome similar to delirium tremens.

Opiates (Nonmedical Use of Prescription Drugs)

Hydrocodone (Vicodin) is the most frequently prescribed opioid in the United States. Oxycodone (Oxycontin) and hydrocodone are prescribed in the treatment of acute and chronic pain. Abusers of hydrocodone and oxycodone experience euphoria, relaxation, and sedation. Long-term use can result in tolerance. Abusers may overdose as they take increasing doses of the medication while pursuing euphoric sensations that they previously experienced. Overdoses may result in severe respiratory depression, hypotension, coma, and death. Recently, methadone, primarily diverted from prescriptions for chronic pain and not methadone maintenance treatment, has been linked to increased opiate overdoses as well. Its relatively long onset of action and long half-life make methadone-naïve individuals more prone to overdose as they seek a stronger high with escalating doses, which accumulate, causing overdose.

Heroin

Heroin, or diacetylmorphine, is a synthetic opiate, first created by Bayer in the late 1800s and marketed for pain relief and treatment of morphine addicts. It has a high abuse potential because of its rapid onset of action and short half-life. Heroin is therefore a Schedule I substance (i.e., not available for therapeutic use in the United States). Heroin can be injected intravenously (IV), subcutaneously (SC, “skin popping”), or snorted intranasally, as well as smoked in freebase form. Use of the intranasal route has greatly increased, along with the purity of street heroin and

awareness of human immunodeficiency virus (HIV) infection risk associated with injecting. Heroin itself is an inactive prodrug with two active metabolites, one of which is morphine, and both of which are active at the mu opioid receptor. After intravenous (IV) injection, users describe an intense rush within 1 to 2 minutes, followed by a period of euphoric sedation lasting about 1 hour. In dependent users, withdrawal symptoms can begin within 4 to 6 hours (Ries et al., 2009).

Intoxication and Withdrawal

Signs and symptoms of intoxication and withdrawal and treatments are based on drug class. Generally, withdrawal symptoms are characterized by the opposite of intoxication, with their intensity inversely proportional to the duration of action of the drug and proportional to chronicity of use. Symptom onset is proportional to the half-life of the drug.

Treatment of intoxication for most substances is supportive and symptomatic and typically occurs in inpatient settings. Receptor antagonists are available for both opiate and benzodiazepine intoxication, with use reserved primarily for the overdose state. Treatment of withdrawal usually follows one of two principles: substituting a longer-acting less reinforcing equivalent, then tapering, or symptom control. Withdrawal treatment may occur in the inpatient or outpatient setting depending on the severity of the withdrawal anticipated, the underlying mental and physical health issues of the patient, and level of support available to the patient in the outpatient setting.

Opiates

Intoxication with opiates causes miotic pupils, euphoria, altered level of consciousness, constipation, and respiratory depression. Treatment of opiate overdose involves providing respiratory support and administering naloxone, a pure opiate antagonist. Naloxone is typically administered IV but may also be administered SC, intramuscularly (IM), via endotracheal tube, or intranasally until IV access is established (Barton et al., 2005). The initial dose is typically 0.4 to 0.8 mg, with a 2-minute onset of action when given IV. Doses are repeated and escalated as needed to reverse the overdose. After reversal, patients need to be monitored for 1 to 3 hours for repeated dosing, and sometimes longer if longer-acting opiates such as methadone have been used in the overdose. Naloxone treatment can initiate a rapid and intense withdrawal syndrome (Ries et al., 2009).

Opiate withdrawal is rarely fatal but is extremely uncomfortable and typically is accompanied by strong cravings. Withdrawal signs and symptoms include vomiting, diarrhea, body aches, rhinorrhea, thermoregulation, insomnia, anxiety, dysphoria, gooseflesh, yawning, and pupil dilation. Treatment can be symptomatic, as with the alpha-2-adrenergic agonist clonidine, or can involve receptor agonist or antagonist activity. Methadone can be used with short- or long-taper protocols. Buprenorphine, a partial opiate agonist can similarly be used. The antagonist, naltrexone in combination with clonidine has been used effectively in both inpatient and outpatient settings (Ries et al., 2009).

Sedative-Hypnotics (including Benzodiazepines)

Intoxication with the sedative-hypnotic drug class causes slurred speech, ataxia, respiratory depression, stupor, coma, and death (mostly with mixed overdose). Treatment of overdose involves providing respiratory support and gastrointestinal (GI) tract evacuation. Activated charcoal is particularly helpful for barbiturate overdose, as is urine alkalization for phenobarbital overdose. Flumazenil, a benzodiazepine receptor antagonist, can be used in benzodiazepine overdose, but with caution because it can dramatically increase the risk of seizures and cardiac arrhythmias, especially in mixed overdoses and in patients physiologically dependent on benzodiazepines (Ries et al., 2009).

Withdrawal signs and symptoms from sedative-hypnotics include tachycardia, hypertension, fever, agitation, anxiety, hallucinations, insomnia, irritability, nightmares, sensory disturbances, tremor, tinnitus, anorexia, diarrhea, nausea, seizures, delirium, and death. Most sedative-hypnotic withdrawal is managed by either simple, slow, fixed-dose taper or substitution and taper. A *simple taper* involves decreasing the dose by no more than 10% every 1 to 2 weeks until the starting dose has been 75% decreased, then by 5% every 2 to 4 weeks for the last 25% until the taper is completed. *Substitution and taper* involves substituting a long-acting benzodiazepine (e.g., clonazepam) or phenobarbital for a shorter-acting drug and tapering as above. Conversion tables are available to calculate an approximate equivalent dose, and the dose is titrated over several days to a week, to achieve good relief of withdrawal symptoms before tapering is begun of the substitute, as with the simple taper method. Other adjunctive medications that have shown positive effects include carbamazepine, sodium valproate, propranolol, and trazodone. Because many patients dependent on benzodiazepines in particular have underlying anxiety and other psychiatric comorbidities, and because withdrawal protocols are typically prolonged, anticipation and treatment of reemergence of these symptoms must be anticipated, or relapse is more likely (Ries et al., 2009).

Other Drugs

Table 51-6 lists the signs and symptoms of intoxication and withdrawal of other drugs. There are no specific antidotes or reversal agents for the remaining drug classes. Care of the overdose patient is largely supportive and aimed at treating the medical effects of the particular overdose, such as treatment of myocardial ischemia resulting from cocaine overdose. Currently, no FDA-approved medications are available for stimulant (including cocaine and methamphetamine), marijuana, hallucinogen (e.g., LSD, PCP), or club drug (e.g., MDMA) withdrawal. Behavioral therapies are the mainstay of treatment.

KEY TREATMENT

Naloxone at 0.4 to 0.8 mg initial dose and repeated as needed is effective for opiate-intoxicated patients with inadequate spontaneous ventilation (Ries et al., 2009) (SOR: A).
Sedative-hypnotic withdrawal is managed by simple taper or substitution to phenobarbital or longer-acting benzodiazepine and taper. (SOR: C).

Medical Management (beyond Withdrawal)

Medical management of SUD after the acute withdrawal period for opiate dependence has a relatively long history, with various opioids being tried as maintenance therapies from the late 1800s until passage of the Harrison Act of 1914, which effectively outlawed prescribing opiates for treating addiction for nearly half a century. Currently, three pharmacologic interventions predominate: methadone, buprenorphine, and naltrexone. Of these three therapies, methadone is the most studied and the standard of care for patients with chronic relapsing opiate dependence. However, methadone

Table 51-6 Signs and Symptoms of Intoxication and Withdrawal

| Drug | Intoxication | Withdrawal |
|-------------------------------|--|--|
| Stimulants, including cocaine | Pupil dilation, headache, hyperventilation, dyspnea, cough, chest pain, wheezing, hemoptysis, bronchospasm, pulmonary edema, psychosis, tremor, hyperreflexia, tics, myoclonus, seizures, cerebral hemorrhage or infarct, cerebral edema, nausea, vomiting, bowel infarction or perforation, diuresis, myoglobinuria, acute renal failure, fever, malignant hyperthermia, rhabdomyolysis | Depression, anxiety, fatigue, anhedonia, increased appetite, hypersomnolence, increased dreaming, increased drug craving |
| Marijuana | Pupil constriction, conjunctival injection, headache, tachypnea, tachycardia, orthostatic hypotension, tremor, ataxia, increased appetite, urinary retention | Irritability, insomnia, anxiety, depression, restlessness, anorexia, vivid dreams, chills, nausea, diaphoresis |
| PCP | Horizontal nystagmus, increased tear and saliva production, lost corneal reflex, eyes open coma, pupil dilation, absent laryngeal/pharyngeal reflexes, diaphoresis, flushing, apnea, pulmonary edema, tachypnea, tachycardia, hypertension, high output cardiac failure, stupor, hyperreflexia, nausea, vomiting, acute renal failure, malignant hyperthermia, rhabdomyolysis | Depression, anxiety, irritability, hypersomnolence, diaphoresis, tremor, dysphoria, craving |
| MDMA | Bruxism, headache, dry mouth, diaphoresis, flushing, tachycardia, hypertension, tremor, increased muscle tone, nausea, anorexia, acute renal failure, malignant hyperthermia, rhabdomyolysis | Depression, anxiety, fatigue, difficulty concentrating, muscle pain |
| LSD | Pupil dilation, piloerection, diaphoresis, hypertension, tachycardia, hyperreflexia, tremors, seizures, nausea, vomiting, urinary retention, thermoregulation | Fatigue, irritability, anhedonia |

is also the most stigmatized and has many regulatory barriers to access.

Naltrexone works as a competitive opiate receptor antagonist to block the effects of opiate agonists. It has been shown to be most useful in patients with a strong external motivator for treatment adherence, such as professionals with ongoing licensing board monitoring. In more generalized patient populations, retention in treatment with naltrexone is only 20% to 30% at 6 months. The usual dose of naltrexone is 50 mg daily or 350 mg weekly divided into three doses (100, 100, 150 mg). A reduced starting dose of 25 mg on day 1 is used to minimize GI side effects such as nausea and vomiting, which occur in 10% of patients. Liver enzymes are monitored because liver toxicity is a rare but more serious side effect, shown to resolve after stopping naltrexone (Reis et al., 2009). A monthly depot injectable form of naltrexone was approved by the U.S. Food and Drug Administration (FDA) for treating opiate-dependent patients in 2010. Studies of longer-acting naltrexone implants are ongoing for FDA approval.

Methadone is a long-acting opiate receptor agonist with strong affinity for its receptor and can be dosed once daily for most opiate-dependent patients. Currently, methadone may be used for treating opiate dependence in hospitalized patients (i.e., for withdrawal) or in licensed methadone treatment facilities. Take-home doses are regulated and depend on length of time in treatment and treatment response, including good attendance, adherence to program rules, lack of diverting behaviors, and abstinence, as verified by drug test results. Generally one take-home dose a week is allowed from the outset (many programs are closed on Sundays). Progression to increased take-home doses is determined by state and federal regulations, with the more restrictive statute taking precedent. For family physicians with patients in methadone maintenance, knowing a patient's take-home schedule can provide insight into how well they are doing in treatment. Recent increases in overdose deaths involving methadone have been explored and are more likely caused by an increase in misuse or diversion of methadone prescribed to treat chronic pain, and less likely from an increase in opiate agonist treatment facility diversion (CSAT, 2004).

Buprenorphine is a partial opiate agonist that causes a 50% activation of the opiate receptors. This is typically enough to alleviate withdrawal symptoms and prolonged abstinence symptoms, but not enough to induce euphoria for patients with opiate dependence. It binds more tightly than any of the opiate agonists and has a long half-life, making it a good candidate for blockade therapy. Buprenorphine is given as a sublingual tablet or film, most often compounded with naloxone (Suboxone), to discourage intravenous use, since the naloxone, a potent opiate antagonist, has little effect unless injected. Buprenorphine comes in 2-mg and 8-mg strengths. Unlike methadone, the Drug Abuse Treatment Act of 2000 allows physicians to prescribe buprenorphine outside a methadone treatment facility, with the goal of bringing the treatment of opiate dependence into primary care, greatly expanding treatment availability. To prescribe buprenorphine for opiate dependence, a physician needs to take an 8-hour course, now available online, and submit their application for an additional "X" number from the U.S. Drug Enforcement Administration (DEA). Physicians also need to have a way to refer or provide behavioral health-based addiction treatment for their patients. The number of patients is proscribed by

statute to 30 the first year and up to 100 patients at any given time past the first year if an additional waiver is submitted. Typical doses of buprenorphine range from 8 to 16 mg daily.

Many pharmacologic interventions have been studied for stimulant dependence, but to date, none has been FDA approved. Several anticonvulsants, baclofen, disulfiram, and antidepressants have shown promise in select patient populations, have shown little effect, or are still in clinical trials. Research in treating stimulant dependence also includes maintenance therapy, with sustained-released preparations of slow-onset stimulants such as modafinil (Ries et al., 2009). Vaccine therapy also currently being studied, involves stimulating the patient's immune system to produce antibodies; for example, when bound to cocaine, antibodies prevent the drug from crossing the blood-brain barrier (Martell et al., 2009).

There is even less evidence for use of medications in the long-term management of other substances of abuse, such as hallucinogens, marijuana, and club drugs. Currently, behavioral therapies are the mainstay of treatment (Ries et al., 2009).

KEY TREATMENT

Methadone maintenance is the most studied and effective medical treatment for opiate dependence (National Consensus, 1998) (SOR: A). Buprenorphine maintenance therapy, an alternative to methadone for treating opiate dependence, can be prescribed by appropriately trained and certified primary care physicians, but is somewhat less effective than methadone prescribed at adequate doses (Mattick et al., 2008) (SOR: A). Oral naltrexone is typically reserved for use in patients with strong external motivators for treatment adherence, such as licensed professionals, because treatment retention is otherwise poor, and relapse is common (Minozzi et al., 2006) (SOR: B).

Behavioral Therapies for Substance Use Disorders

Behavioral therapies are a mainstay of SUD treatment. Common modalities include cognitive-behavioral therapy, contingency management, motivational enhancement therapy (MET), "therapeutic communities," and 12-step facilitation. Except for MET, these have not been adapted for use by family medicine physicians in routine office practice, but are usually available as community-based referrals.

Cognitive-Behavioral Therapy

Cognitive-behavioral therapy (CBT) is based on the assumption that the learning processes used by patients to initiate and continue their drug use behaviors can also be used to reduce or stop their drug use. CBT has been extensively studied, especially with cocaine users, and has shown good results. CBT is primarily used in the outpatient setting, usually with weekly individual sessions over several months. Sessions focus on patients learning to recognize the situations in which they are most likely to use drugs, learning to avoid those situations, and learning to cope with their problems without resorting to drug use. These lessons are accomplished through functional analysis and skills training. In functional analysis, each episode of drug use is analyzed

in terms of what the patient was feeling, thinking, or doing before and after the use. This helps identify high-risk situations or coping issues. Skills training involves working on ways to avoid these situations and learn new (or reconnect with past) coping mechanisms for handling high-risk situations and other life stressors without using drugs (Carroll, 1998).

Contingency Management

Contingency management (CM) is based on operant conditioning and involves a structured and consistently administered system of consequences that are used to reinforce behaviors consistent with treatment goals. Basic principles include close temporal proximity of consequence to targeted behavior, performance of targeted behavior easy to verify and verified often, positive consequence given and escalated for continuous positive behavior change, and positive consequence removed when targeted behavior not performed. CM has been shown to be more effective when a single targeted behavior is addressed at a time and when resumption of continuous positive change is reinforced after a brief slip. Barriers include funding sources to cover the cost of rewards and determining appropriate length of treatment for this method. Advantages of CM include the breadth of behavioral changes that can be targeted and its demonstrated success in patients with severe and complex substance use disorders (Petry et al., 2001).

Motivational Enhancement Therapy

Motivational enhancement therapy (MET) engages patients in increasing their internal motivations for making healthy changes in their drug use, building on a patient's strengths and resources in making prior behavioral changes. Goals are set by the patient, although the counselor may advise specific goals when appropriate. This approach is nonconfrontational. The counselor seeks to have the patient talk about the pros and cons of the substance use, reflecting and summarizing as an active listener in a way that highlights discrepancies between the patient's life goals or beliefs and current drug use behaviors. These discrepancies are then used to increase the patient's internal desire for change or discomfort with the status quo. A patient's stage of readiness to change, whether precontemplative, contemplative, preparation, action, maintenance, or relapse, is also determined at each session. In addition, a patient's self-efficacy for change is assessed, and the patient is guided to talk about prior successful behavioral changes, and any optimism for change is reflected and highlighted (Prochaska et al., 1992). MET has been used in both inpatient and outpatient settings, from one session (brief intervention) to several months of weekly sessions.

Therapeutic Communities

Therapeutic communities (TCs) are traditionally residential facilities in which the community structure and function are agents of change, and 12-step-based self-help programs guide individual recovery. Average lengths of stay are about 12 months (6-24 months). Community members progress through varying roles and responsibilities in their recovery

and collectively ensure day-to-day functioning of the community. Days are highly structured and involve group and individual sessions, as well as time for community and personal chores and self-development, such as exercise, vocational time, and educational time. TCs have been successfully adapted to serve special needs populations, such as adolescents, patients with concomitant mental health disorders, patients with HIV infection, and women with children. Successful completion of a TC program has been shown to lead to a significant decrease in SUD behaviors. Day treatment or nonresidential TCs are also available and may be more cost-effective for patients with less severe social problems to address (NIDA, 2002).

Twelve-Step Facilitation

Twelve-step facilitation (TSF) is a modality that seeks to increase the SUD patient's attendance and active involvement in 12-step self-help groups such as Cocaine Anonymous (CA) and Narcotics Anonymous (NA). TSF is used in residential treatment programs as well as outpatient settings. Sessions are highly structured, often workbook guided, and cast the counselor in the role of facilitator of change, with patient involvement the true agent of change. The underlying 12-step principles are the same: the patient's lack of control must be accepted, willpower is insufficient to stop use, and abstinence is desired. Research has shown that the more 12-step self-help group involvement, both in terms of number of meetings attended and, more robustly, the degree of active participation, the greater the success of achieving abstinence and recovery (McIntosh, 2009).

Formal TSF counseling is outside the scope of most family medicine practices. However, physicians making a 12-step self-help group referral can increase the likelihood the patient will engage by (1) contracting with the patient to attend a certain number of meetings weekly, (2) having the patient call the local CA or NA hotline during the visit to set up his or her first meeting, and (3) encouraging attendance at several different meetings to ensure a "good fit." Checking in with patients previously referred or in long-term recovery on meeting attendance and 12-step involvement, such as sponsorship and step work, is supportive of recovery and easily integrated into the primary care visit.

KEY TREATMENT

Cognitive-behavioral therapy and contingency management decrease cocaine use and increase treatment retention (Knapp et al., 2007) (SOR: B).

Twelve-step involvement positively correlates with achieving abstinence and recovery (McIntosh, 2009) (SOR: C).

Primary Care of SUD Patients

The primary care of SUD patients must take into account the systemic effects of the drug(s) ingested, route of administration, methods of drug procurement, illicit drug-prescription drug interactions, and typically, higher rates of nonadherence to follow-up and prescribed regimens (Ries et al., 2009). Infectious diseases (e.g., HIV, hepatitis B and C, tuberculosis) and sexually transmitted infections (e.g., gonorrhea,

chlamydia, herpes, syphilis, human papillomavirus) are more common in SUD patients than in the general population, and patients should be screened routinely. Other infections common in IV drug users include skin abscesses, cellulitis, infectious endocarditis, and pneumonia.

Cocaine and other stimulants can cause myocardial infarction and stroke, raise blood pressure, and make essential hypertension resistant to treatment. Crack cocaine use, inhaled methamphetamines, and marijuana can lead to lung injury, chronic obstructive pulmonary disease, fibrosis, and pulmonary hypertension. Seizures can stem from stimulant use, benzodiazepine withdrawal, "ecstasy" and other "club drug" intoxication (Ries et al., 2009).

Treatment for asthma, hypertension, chronic pain, and diabetes is complicated by the concomitant SUD. Patient adherence to treatment regimens is often compromised by the SUD, with "getting high" and minimizing withdrawal symptoms becoming the focus of their activities. Regular and nutritious meals may be difficult to access or may not be a priority for SUD patients, along with hygienic activities. Sleep disorders are common and can exacerbate health problems and their management. SUD patients' ability to store their medications safely and securely can be compromised by homelessness, diversion, and unsafe living environment.

Ongoing SUDs can mask symptoms, leading to late presentation of diseases such as cancer. This masking often is compounded by lack of access or utilization of primary care and preventive services by SUD patients.

Special Populations

Adolescents

In 2008, approximately 9.3% of youths age 12 to 17 were current users of illicit drugs. This continued a trend of decreased illicit substance use among adolescents. Compared with 2002 data, the prevalence of illicit drug use had decreased for several drugs, including marijuana (8.2% to 6.7%), nonmedical use of prescription drugs (4.0% to 2.9%), cocaine (0.6% to 0.4%), and methamphetamine (0.3% to 0.1%). The use of hallucinogens such as ecstasy, LSD, and PCP had slightly increased (0.7% to 1.0%). Concern about performance-enhancing agents and steroid use among high school and junior high school students has led to surveillance of steroid use among teenagers since 1989. Compared to previous years, overall use of anabolic steroids had decreased. Although predominantly found among young males, the proportion of anabolic steroid use attributable to young females had increased. Among teenagers, African Americans had significantly lower rates of illicit drugs compared to Caucasians. Hispanics in the 12th grade reported the highest rates of some use of crack, heroin, and crystal methamphetamine.

Most youths reported that drugs are readily available. For example, approximately 49% of teenagers 12 to 17 years old reported that it would be "fairly easy" to obtain marijuana, 22.1% reported they could obtain cocaine, and 13.8%

reported that they could obtain LSD. In 2008, 13.7% of adolescents reported that they had been approached by someone selling drugs within the past month.

Because peer pressure is a significant factor for adolescents, their perceptions of risk associated with substance abuse and peer disapproval have also been surveyed. A majority of teenagers have strongly disapproved or somewhat disapproved of illicit drug use by their peers. However, the perceived risk of using marijuana, cocaine, hallucinogens, and other drugs has been lower in recent years. Teenagers may possess less knowledge about adverse drug effects than their predecessors and may display some "generational forgetting" (Johnston et al., 2009).

Racial and Ethnic Minorities

In 2008 the rate of current illicit drug use varied significantly among people of seven different major racial categories. Current drug use was highest among people who reported having two or more races (14.1%). An estimated 10.1% of blacks, 9.5% of American Indians or Alaska Natives, 8.2% of whites, 7.3% of Native Hawaiians or other Pacific Islanders, 6.3% of Hispanics, and 3.6% of Asians were current illicit drug users in 2008.

Pregnant Women

Approximately 5.1% of pregnant women age 15 to 44 were current users of illicit substances in 2008. Compared with nonpregnant women, the rate of drug use is significantly lower for all age groups, with the exception of adolescent women 15 to 17 years old. The rate of illicit substance use was higher among pregnant adolescents age 15 to 17 compared to same-age nonpregnant adolescents (21.6% vs. 12.9%). Use of cocaine, heroin, methamphetamine, marijuana, MDMA, inhalants, and nicotine during pregnancy has been associated with adverse outcomes such as intrauterine growth retardation, delayed cognitive development, and difficulty with attention and learning. Effects vary by substance ingested, quantity and frequency of ingested drug or drugs, and stage of fetal development when ingestion occurs. Currently, methadone maintenance is the treatment of choice for opiate dependency during pregnancy, although buprenorphine has been used when methadone is not available. Newborns are monitored for signs of withdrawal and treated if symptoms are noted.

Mental Health and Substance Abuse

The prevalence of illicit substance abuse or dependence among patients with serious mental illness was 25.2%, or an estimated 2.5 million people, in 2008. Similarly, adults age 18 and older with an episode of major depression within the last year had higher rates of illicit drug use than adults without a major depressive episode (27.2% vs. 13.0%). Having a major depressive episode within the past year was also associated with higher prevalence of dependence on illicit drugs.

In 1994, in response to pressure from both consumers and the supplement industry, the U.S. Congress passed the Dietary Supplements Health and Education Act (DSHEA). Under DSHEA, herbs, vitamins, minerals, and other “natural health” products are regulated differently from pharmaceuticals. After passage of DSHEA, the supplement market boomed, with sales climbing from \$8.8 billion in 1994 to \$15.7 billion in 2000 (Blendon et al., 2001) and \$21 billion in 2008 (Thurston, 2008).

Trends in Supplement Use: Family Physician's Role

Key Points

- Under DSHEA, supplements are regulated differently from pharmaceuticals, with less governmental safety monitoring.
- The use of supplements is widespread.
- Patients should be encouraged to list their supplements whenever they are asked to list their medications.
- Patients may not always discuss supplement use with their health care providers.

The National Health Information Survey (NHIS) gathered data on complementary and alternative (or integrative) medicine (CAM) use and found that 17.7% of 23,393 adults and 3.9% of 9417 children had used nonvitamin, nonmineral natural products in the past 12 months (Barnes et al., 2008). Supplements have become a familiar sight in pharmacies, health food stores, and supermarkets. They are also widely available online, and many food products have them as added ingredients. The sheer number of available products and advertising claims can lead to confusion for patients and health care professionals alike.

Advising patients regarding supplement use can be challenging. Product safety and standardization are often variable. Research may be of poor quality or difficult to interpret. Supplement-drug interactions and other adverse effects are an ever-present concern. Furthermore, most physicians have received little formal teaching about supplements, and becoming familiar with the many popular products can seem daunting.

Despite these challenges, it is vital that family physicians have a working knowledge of appropriate supplement use. Although large numbers of people take supplements, many believe it is not useful to share this information with their physician. The 2002 NHIS found that only one third of the estimated 38 million American adults who use supplements were likely to report doing so to their physician. Disclosure rates were found to be lowest among males, younger adults, minorities, and less frequent users of Western medical care (Kennedy et al., 2008). Results from multiple public surveys, including telephone surveys of more than 2200 people, revealed that almost half of regular supplement users believed that their physicians were prejudiced against supplement use. About 44% thought their physicians had limited knowledge about such products (Blendon et al., 2001).

Specifically asking about herb and other supplement use when gathering a patient history is essential, given that patients may not always volunteer this information. Helping patients make choices regarding supplement use often involves negotiation. Of 1196 supplement users, 66% stated that they would keep taking the supplement they were taking most often, even if the U.S. Food and Drug Administration (FDA) reported it as ineffective (Blendon et al., 2001). People who take supplements often value their independence in making health care decisions, and many have spent much time researching various products online. [Table 52-1](#) summarizes findings

Table 52-1 Main Reasons Patients Use Dietary Supplements

| Kennedy (2007)* (n = 23,393 adults) | ConsumerLab.com† (n = 3226) | Kaufman et al.‡ (n = 2590) |
|--|------------------------------|-----------------------------------|
| 1. Back pain | 1. General health (67%) | 1. "To supplement the diet" (45%) |
| 2. Neck pain | 2. Colds (53%) | 2. General health (16%) |
| 3. Joint pain (5.2%) | 3. Osteoarthritis (39%) | 3. Arthritis (7%) |
| 4. Arthritis (3.5%) | 4. Energy enhancement (37%) | 4. Memory impairment (6%) |
| 5. Anxiety (2.8%) | 5. Cholesterol control (29%) | 5. Energy (5%) |
| 6. Cholesterol (2.1%) | 6. Cancer prevention (28%) | 6. Immune system enhancement (5%) |
| 7. Head/chest cold (2.0%) | 7. Allergies (27%) | 7. Other joint issues (4%) |
| 8. Other musculoskeletal conditions (1.8%) | 8. Weight management (25%) | 8. Sleep aid (3%) |
| 9. Severe headache or migraine (1.6%) | | 9. Prostate problems (3%) |

As often occurs with complementary and alternative/integrative medicine (CAM) modalities, use is most common for disorders (often chronic) that Western medical approaches may not be able to treat as safely or effectively.

*National Health Information Survey of reasons for CAM use in general, 2008.

†In 2002 study on reasons for supplement use, 54% of respondents indicated they were taking supplements for four or more simultaneous conditions. Respondents could give multiple reasons for taking supplements. Respondents were users of the ConsumerLab.com website and likely high-frequency herb users.

‡Results are based on a 2002 telephone survey of why people take supplements. The definition of "supplement" used for respondents excluded vitamins and minerals; 25% answered either "don't know" or "no reason specified" when asked about supplement use. Respondents could give multiple reasons for taking supplements.

on the reasons people give for taking dietary supplements. Many supplements have been used for thousands of years, and for some patients, this alone constitutes evidence that supplements are safe and beneficial. Native Americans had medicinal uses for more than 2500 different plant species (Moerman, 1998), and various "supplements" have been used as part of traditional medical practices in most cultures throughout history. In the United States before 1930, herbs constituted a significant proportion of the remedies listed in the *United States Pharmacopeia* (Blumenthal, 2003).

Only in recent decades have more scientifically based studies of supplement efficacy and safety been conducted. With the development of the National Center for Complementary and Alternative Medicine (NCCAM) in October 1998 within the National Institutes of Health (NIH), supplement research funding in the United States has grown dramatically. In other countries, groups such as the European Scientific Cooperative on Phytomedicines (ESCOP, www.escop.com) and Edzard Ernst's team at the University of Exeter have been gathering and analyzing data from hundreds of well-designed randomized trials. It is no longer legitimate during a patient encounter to make sweeping statements discouraging supplement use because, "We just don't know enough about them." To state that all supplements are dangerous is just as inaccurate as claiming, as many manufacturers do, that dietary supplements are consistently safe and effective. Some supplements have shown great promise in helping to prevent or treat various illnesses. Others have been proven harmful enough that their use should be discouraged. Ideally, physicians should be as informed and actively involved in patients' decisions regarding dietary supplements as they are with their decisions regarding prescription medications. **Box 52-1** offers guidelines for discussing supplements with patients.

Supplement Safety

Key Points

- It is as inappropriate to generalize about supplements being dangerous or having unknown effects as to assume that all supplements are safe because they are "natural."
- Although rarely observed, physicians must still be aware of herb-drug interactions and adverse supplement effects.
- Supplements can affect blood pressure, serum glucose levels, and coagulation, which can be therapeutically useful or dangerously adverse.
- Use supplements with caution in certain patient populations, including pregnant and lactating women, children, patients taking warfarin, and those with renal or hepatic failure.

Until 2007, supplement manufacturers had few requirements for evaluating the safety of their products. In late 2007, it was mandated that all dietary supplement-related adverse events must be reported to the FDA. Deadlines were set for when companies of various sizes would be required to evaluate the identity, purity, strength, and composition of their products. The last deadline, for companies with 20 or fewer employees, was set for June 2010. However, there is no requirement that the FDA verify efficacy of herbal supplements. Proponents of natural remedies often hold that it is reasonable to keep regulation loose, claiming that "natural" products are, as a general rule, safer than pharmaceuticals. Although this seems true, more than 25% of medications are based on compounds derived from natural substances (Schulz et al., 2001). The line between what is "natural" and what is a "drug" is often blurred. Many herbal products are key ingredients in over-the-counter (OTC) drugs, including capsicum from hot peppers (for herpes skin outbreaks), witch hazel

Box 52-1 Considerations When Evaluating Supplement Safety

Recognize that patients often do extensive research regarding supplements and may often be quite knowledgeable about indications for use and safety risks.

It is acceptable to offer to review supplements' safety after the visit and discuss its use further with a patient in follow up, if there is uncertainty about a particular product or if clinic visit time is limited.

Although severe complications from using herbs are rarely reported, "natural" does not always mean "safe." Many natural products can be quite dangerous.

If a supplement has the potential to interact with serum levels of a medication, this should be discussed with the patient.

Some supplements (e.g., St. John's wort, grapefruit) can alter the activity of cytochrome P-450 enzymes in the liver, affecting other drug levels. Others can affect coagulation, serum glucose, and blood pressure (see Boxes 52-3 to 52-5).

The effects of supplement use on the environment must be considered.

Some herbs, such as American ginseng, slippery elm, and golden-seal, are endangered in the wild.

The popularity of shark cartilage in the 1990s contributed to sharp declines in shark populations.

The U.S. Dietary Supplements Health and Education Act (DSHEA) effectively gave the Food and Drug Administration (FDA) the burden of proving that a given supplement is unsafe. Good manufacturing practices have been required for large companies since 2007 and all companies as of 2010.

As a general rule, many of the mass-produced herb brands seem to score better in product quality than those from small-scale industries, but this is variable.

Finding reliable products and knowledgeable vendors is important; it may help to become familiar with a few manufacturers so that a few specific, reliable products can be recommended.

Some supplements actually improve the body's ability to metabolize or tolerate certain medications.

For example, milk thistle has been found in some studies to protect the hepatocytes from damage secondary to hepatotoxins (Blumenthal, 2003).

Supplements, particularly herbs, should be used with caution in pregnant or lactating women and children. (See Brinker, 2001, for additional guidelines in special patient populations.)

Many supplement prescribers prefer to recommend products made by companies who have actually invested in research related to efficacy and safety. Manufacturers and product names are often mentioned in the "Methods" sections of randomized controlled trials (RCTs).

Data from Blumenthal M. American Botanical Council. The ABC Clinical Guide to Herbs. New York, Thieme, 2003; Brinker F. Herb Contraindications and Drug Interactions, 3rd ed. Sandy, Ore, Eclectic Publications, 2001; NIH Office of Dietary Supplements, 2009; Natural Medicines Comprehensive Database, 2009; and Rotblatt M, Ziment I. Evidence-Based Herbal Medicine. Philadelphia, Hanley & Belfus, 2002.

(hemorrhoid treatments), and psyllium seed (laxatives). Conversely, some natural compounds can be highly poisonous, such as daffodil bulbs, oleander leaves or branches, and castor beans (just one or two beans can kill an adult, even though castor oil is relatively safe and often used).

When advising patients regarding herb safety, it must be remembered that pharmaceutical use is itself associated with significant morbidity and mortality. For example, data from 39 prospective studies estimated that adverse drug reactions are implicated in more than 100,000 inpatient deaths per

year (Lazarou et al., 1998). In contrast, adverse event reports are much less common for herbs (Brinker, 2001). In 2008, 6 months after supplement adverse event reporting began, the FDA had received 600 adverse event reports; this is in contrast to the 482,154 reports it had received for pharmaceuticals during a 1-year period (Perez, 2008). It is unclear whether this relatively low number of reports is caused in part by limitations in reporting mechanisms. A significant portion of available supplement safety data is based on isolated case reports or extrapolations from pharmacokinetic, *in vitro*, or animal data.

Patients should be encouraged to bring the supplements they are taking with them to clinic visits. They should be reminded to list supplements whenever they list their medications, particularly on hospital admission. Often, patients will hand their physician the packaging for a particular product; Box 52-2 discusses how to evaluate a product's quality based on its packaging information.

The challenges associated with placing the burden of proof for product safety on the FDA surfaced with the events leading to the April 2004 ban on ephedra, a naturally derived, amphetamine-like stimulant. Only after linking ephedra to 155 deaths, including the death of a well-known athlete, and dozens of heart attacks and strokes was the FDA finally able to justify putting the ban into effect (Natural Database, 2009; Wong, 2009). Ephedra has been used in various forms in China for thousands of years, but not at the high dosage levels found in many of the products linked to harmful outcomes. Many of the negative effects of ephedra were associated with its use in combination with other compounds, such as caffeine. Some supplement manufacturers seem to assume that "if a little bit is good, more is even better." Table 52-2 summarizes some herbal supplements that, based on the current level of research, should be avoided or used only under professional supervision.

Advising patients regarding supplement safety can be difficult. For example, vitamin E has been widely touted as having a number of potential health benefits, including cancer prevention, lowering heart disease risk, slowing age-related macular degeneration, and reducing dementia progression; results of some studies have been quite favorable (Natural Database, 2009). However, a significant body of research questions vitamin E supplementation. A Johns Hopkins meta-analysis concluded that dosing over 400 international units (IU) daily "may increase all-cause mortality and should be avoided" (Miller, 2005). Other research suggests a potential link between vitamin E consumption and risk of heart failure in patients with vascular disease or diabetes (Lonn et al., 2005). In the Women's Health Study, vitamin E supplementation did not seem to affect the incidence of cancer or major cardiovascular events, although cardiovascular mortality in younger women was reduced (Lee et al., 2005). For Parkinson's disease, vitamin E appears beneficial for prevention if eaten in the diet, but not taken as a supplement (Zhang et al., 2002). It is frequently argued that the types of tocopherols taken (alpha vs. gamma vs. mixed) can alter vitamin E's efficacy and safety.

How does the family physician weigh the risks and benefits of a supplement when faced with such a hodgepodge of information? First, it is important to encourage patients to obtain as many nutrients as possible directly through the foods they eat. If they choose to take additional supplements,

Box 52-2 Considerations When Reviewing a Supplement's Packaging

It should be clear what ingredients the product contains.

For botanicals, Latin names of component plants should be listed, because many species have multiple common names.

Use caution with Chinese and Ayurvedic herbs that do not clearly state their ingredients' names in English or Latin.

According to the U.S. Dietary Supplements Health and Education Act (DSHEA), a supplement's label may make "structure/function claims" provided they are not misleading and have been validated by some form of scientific research.

Examples of such claims include "supports digestive health" or "helps maintain prostate health."

Products may not claim to cure, treat, or prevent disease and must state on the label that any claims "have not been evaluated by the FDA."

If a product does not follow these guidelines, avoid it.

For herbal remedies, note the type of formulation, such as tincture versus crude herb versus infusion. These formulations can have different properties and effects (see Table 52-3).

The numbers of tablets or capsules in the package and the weight of each, as well as a breakdown of nutritional content of the supplement, should be listed.

Look for how the product's contents are standardized.

Many botanicals will be standardized to a specific percentage content of one particular chemical.

For example, ginseng may be standardized by *ginsenoside* content and horse chestnut extract by level of *aescin*.

Different companies may standardize for the same herb using different chemical compounds; for example, St. John's wort may be standardized to either *hypericin* or *hypericum* levels.

In many cases the chemical component used for standardization is *not* a known physiologically active constituent of the product.

For combination products, the amount of each component of a supplement must be listed, unless the product is a proprietary blend (as many herbals are).

With a proprietary brand, only the total amount of the blend is legally required to be listed.

Use of combination products requires additional caution. Some supplements (including many megavitamins, which add herbs or nonvitamin nutrients to the usual array of vitamins they contain) can contain dozens of individual ingredients.

Consider each ingredient individually for safety and efficacy.

Expiration dates on supplement packaging are assigned by the manufacturer and are often arbitrarily set at 2 years after the manufacture date for herbal remedies.

The manufacturer's name and address should be seen on the label.

For herbals, *where* a plant was grown may influence its potency, and the user may not be able to determine this by reading the label.

Supplements containing various organ tissues (e.g., thymus, gonads, adrenals) should be used with caution, given the potential risks of electrolyte disturbances or prion-borne disease.

Typically, patients taking multiple supplements will not be aware that they may be exceeding safe intake levels for certain compounds.

In particular, note cumulative doses of vitamin A, vitamin E, vitamin B₆, selenium, magnesium, and calcium. Keep recommended upper intake levels in mind.

This is also important for supplements that affect serum glucose levels, blood pressure, or coagulation status.

Pay close attention to price, which need not always correlate with quality.

Some supplements can be as expensive as drugs, if not more so.

Data from Blumenthal M. American Botanical Council. The ABC Clinical Guide to Herbs. New York, Thieme, 2003; Brinker F. Herb Contraindications and Drug Interactions, 3rd ed. Sandy, Ore, Eclectic Publications, 2001; NIH Office of Dietary Supplements, 2009; Natural Medicines Comprehensive Database, 2009; and Rotblatt M, Ziment I. Evidence-Based Herbal Medicine. Philadelphia, Hanley & Belfus, 2002.

patients should keep intake at a reasonably safe range (e.g., no more than 400 IU of vitamin E daily). Keep informed. As with hormone replacement therapy (HRT) and use of cyclooxygenase-2 (COX-2) inhibitors, recommendations regarding supplements may also change dramatically with emerging research findings. Ultimately, decisions about supplement use must be informed by knowledge of individual patients' circumstances and personal preferences, once they are made fully aware of potential risks and benefits.

Herb-Drug Interactions

An important concern for many clinicians is the possibility of herb-drug interactions. Fugh-Berman and Ernst (2001) compiled case reports and other data from three research databases and contacted 10 supplement manufacturers, ranking studies according to a 10-point scoring system, based on how clearly the report accounted for comorbidities and

adequately described the circumstances surrounding the interactions. Of 108 reported interactions, 14 were classed as "likely to exist," 20 were deemed "possible," and 74 were classed as "unevaluable." Many of the most likely herb-drug interactions involved St. John's wort, an herb used in the treatment of depression. This botanical affects the cytochrome P-450 3A4 system, potentially lowering the serum levels of several drugs, including oral contraceptives and cyclosporine (Brinker, 2001).

One of the most common adverse effects of many herbal remedies is alteration of coagulation. Levels of warfarin, heparin, or antiplatelet agents are altered by some herbs. **Box 52-3** lists common supplements that affect coagulation and fibrinolysis. **Box 52-4** lists herbs that may affect serum glucose levels, and **Box 52-5** lists herbs with potential effects on blood pressure. A recent review of available case studies summarizes possible interactions among several popular herbal remedies, including echinacea, garlic, ginkgo,

Table 52-2 Potentially Dangerous Supplements*

| Herb Names | Why Avoid |
|--|--|
| Herbs that Are Generally Contraindicated | |
| Birthwort (<i>Aristolochia</i> spp.) Other names: snakeweed, serpentary, sangrel, sangree root | Contains aristolochic acid, a carcinogen and known cause of renal failure. Deaths have been attributed to consumption |
| Wild ginger (<i>Asarum canadense</i>) | Banned in seven European countries, Egypt, Japan, and Venezuela |
| Comfrey (<i>Symphytum</i> spp.) Other names: ass ear, black root, blackwort, bruisewort, consound, gum plant, knitback, salsify, slippery root, wallwort | Liver damage FDA advised removal from market in 2001 |
| Chaparral (<i>Larrea tridentata</i> , <i>L. divaricata</i>) Other names: creosote bush, greasewood, jarilla | Liver damage Death FDA warning issued in 1992 |
| Germander (<i>Teucrium chamaedrys</i>) | Liver damage Banned in France and Germany |
| Kava (<i>Piper methysticum</i>) Other names: ava, awa, gea, gi, intoxicating pepper, kao, kawa pfeffer, kew, long pepper, malohu, milik, sakau, tonga, yagona | Safety controversial (use only with experience) Has antianxiety and sedative properties, and can reduce coordination and judgment Liver damage; but as is often the case, this was likely caused by a specific product that contained adulterants. FDA warning issued 2002 Banned in Canada, Germany, Singapore, South Africa, Switzerland |
| Ephedra (<i>Ephedra sinica</i> or <i>E. equisetum</i>) Other names: ma huang, amsania, Brigham tea, budshur, chewa, Chinese joint fur, desert herb, epitonin, horsetail, hum, huma, khama, mao, mao-kon, natural ecstasy, phok, popotillo, sea grape, shrubby, squaw tea, teamster's tea, yellow astringent | Arrhythmia CNS excitation Hypertension MI Stroke |
| Herbs Rated as Likely Hazardous (Adverse Event Reports or Theoretic Risk) | |
| Bitter orange (<i>Citrus aurantium</i>) Other names: green orange, kijitsu, neroli oil, Seville orange, shangzhou zhiqiao, zhi xi | Hypertension Increased arrhythmia risk Risk of cardiac or cerebrovascular events |
| Lobelia (<i>Lobelia inflata</i>) Other names: asthma weed, bladder pod, gagroot, Indian tobacco, pukeweed, vomit wort | Breathing difficulty Tachycardia Hypotension Diarrhea Dizziness and tremor |
| Pennyroyal oil (<i>Hedeoma pulegioides</i>) Other names: lurk-in-the-ditch, mosquito plant, piliolerial, pussing grass, squawmint, stinking balm, tickweed | Renal and hepatic failure Nerve damage and convulsions Abdominal and throat pain |
| Skullcap (<i>Scutellaria</i> spp.) Other names: blue pimpernel, helmet flower, hoodwort, mad weed, mad-dog herb, quaker bonnet | Liver damage |
| Yohimbe (<i>Pausinystalia yohimbe</i>) Other names: johimbi, yohimbehe, often in "herbal Viagra" formulations | Altered blood pressure Arrhythmias, risk of MI Respiratory depression |

Box 52-3 Effects of Common Herbs on Coagulation***Increased Potential for Hemorrhage****Decreased Prothrombin**

Baikal skullcap root
Pau d'arco bark
Sweet clover

Increased Heparin or Warfarin Effect

Black currant seed oil, Evening primrose seed oil

| | |
|-----------------|-----------------|
| Borage seed oil | Garlic |
| Danshen root | Ginkgo leaves |
| Devil's claw | Papain (papaya) |
| Dong quai | |

Inhibition of Platelet Aggregation

| | | |
|------------------------|---------------------------|------------------------|
| Baikal skullcap | Danshen | Goldenseal |
| Bilberry | Dandelion | Horse chestnut bark |
| Birch bark | Dong quai | Kava |
| Black currant seed oil | Evening primrose seed oil | Licorice |
| Borage oil | | Olive oil |
| Bromelain | Fenugreek seeds | Onion |
| Cayenne | Feverfew plant | Oregon grape root bark |
| Celery plant | Flax seed | Reishi mushroom |
| Chamomile (German) | Garlic | Turmeric |
| Cloves | Ginger | Wintergreen leaf oil |
| Coleus | Ginkgo | |

Decreased Fibrin (or Increased Fibrinolysis)

Algae (e.g., Irish moss red, kelp brown, spiral wrack brown)

Astragalus
Baikal skullcap
Bladderwrack
Bromelain
Cayenne
Ginseng
Onion

Increased Potential for Clot Formation**Herbs High in Vitamin K (Warfarin Inhibition)**

| | | |

*Includes the most frequently used herbs; list is not comprehensive. Derived from expert opinion, case reports, preliminary trial evidence, and anecdote. Note that these effects can potentially have therapeutic benefit in diabetic or hypoglycemic patients.

ginseng, kava, saw palmetto, and St. John's wort (Izzo and Ernst, 2009).

Types of Supplements**Key Points**

- Supplements can be classified as herbal remedies, vitamins and minerals, nutraceuticals, or combination products.
- Primary care physicians should be familiar with the most popular products and, when necessary, be able to find additional information on indications, safety, and efficacy.
- When discussing the safety of combination products, consider each component individually.
- Marketing information frequently outpaces the information available through good-quality scientific research.
- Price does not necessarily correlate with quality for many products.

Supplements fall into four overall classes: Herbals, vitamins and minerals, nutraceuticals, and combination remedies. In 2007 the nonvitamin, nonmineral products used by adults in the 30 days prior to the survey were fish oil/omega 3 fatty

Box 52-5 Herbs that May Alter Blood Pressure***Raise Blood Pressure**

| | | |
|------------------|-----------|-------------|
| American ginseng | Broom | Ephedra |
| Arnica | Cayenne | Ginger |
| Betel nut | Cola | Licorice |
| Blue cohosh | Coltsfoot | Yerba santa |

Lower Blood Pressure

| | | |
|----------------------|--------------------------|-----------------------|
| Aconite/monkshood | Eucalyptus oil | Melatonin |
| Alpha-linolenic acid | Evening primrose oil | Mistletoe |
| Arnica | Fish oils | Night-blooming cereus |
| Baneberry | Flaxseed/flax oil | Oleander |
| Betel nut | Garlic | Omega-3 fatty acids |
| Bilberry | Ginger | Pasque flower |
| Black cohosh | Ginkgo | Periwinkle |
| Bryony | Goldenseal | Pleurisy root |
| Calendula | Green hellebore | Shepherd's purse |
| California poppy | Hawthorn | Texas milkweed |
| Coleus | Indian tobacco (lobelia) | Turmeric |
| Curcumin | Jaborandi | Wild cherry |
| Danshen | Maitake mushroom | |

Data from Basch EM, Ulbricht CE. *Natural Standard Herb and Supplement Handbook: The Clinical Bottom Line*. Boston, Elsevier-Mosby, 2005; and Brinker F. *Herb Contraindications and Drug Interactions*, 3rd ed. Sandy, Oregon, Eclectic Publications, 2001.

*Includes the most frequently used herbs; list is not comprehensive. Derived from expert opinion, case reports, preliminary trial evidence, and anecdote. Note that these effects can potentially have therapeutic benefit.

acids, glucosamine, echinacea, flax oil or pills, and ginseng (Barnes et al., 2008).

Herbal Remedies

Herbal remedies, or *botanicals*, are supplement preparations made from various plant components. Herbals typically contain numerous chemical compounds. One study found that 34% of the U.S. population used herbal remedies at least once, and 14% took at least one herbal remedy consistently from June 2002 to June 2003 (Rogers, 2005). Chinese herbs, Ayurvedic herbs, and Latin American herbs are frequently used, but the great number of available herbs from around the world is not the only issue to discuss with patients. A given remedy's potency and efficacy are influenced by where an herb was grown, the particular species used in the formulation, how the plant products were processed, which plant parts were used, and which compounds were used for chemical standardization. Table 52-3 lists common forms of herbal preparations. Table 52-4 lists some of the most common individual herbs, with indications, efficacy, and potential adverse effects and drug interactions.

Vitamins and Minerals

A 2002 *Journal of the American Medical Association* review of vitamin use in chronic disease concluded, "We recommend that all adults take one multivitamin daily. This practice is justified mainly by the known and suspected benefits of supplemental folate and vitamins B₁₂, B₆, and D in preventing

cardiovascular disease, cancer, and osteoporosis and because multivitamins at that dose are safe and inexpensive" (Fairfield and Fletcher, 2002a, 2002b). At least 84% of U.S. residents use vitamin supplements regularly, and they probably need them. Only 20% to 30% of the American population met the goal of at least five servings of fruits and vegetables daily (Flood and Schatzkin, 2000).

Table 52-5 lists several vitamins and minerals, their uses, contraindications, and efficacy information when available. Dose recommendations for vitamins and minerals are now referred to as *reference daily intakes* (RDIs) and continue to be debated, especially for certain trace minerals. (For a full list of RDIs and food sources of various nutrients, see Mahan et al., 2004.)

Nutraceuticals

A number of terms have been used to refer to supplements that cannot be classified as either herbal remedies or as vitamins or minerals. Often, they are referred to simply as "supplements," or they may be categorized as "nutritional supplements" or as "nutraceuticals," as used here.

Nutraceuticals may be synthesized to some degree by the body or may be compounds isolated from certain foods. Often, the claim is made that the body requires more of these compounds than it can synthesize itself under certain circumstances (e.g., taking certain medications, aging, depletion with a disease process). Nutraceuticals that the body can synthesize include phosphatidylserine, methylsulfonylmethane (MSM), and S-adenosylmethionine (SAMe). Digestive enzymes (e.g., trypsin) and hormones (e.g., DHEA, melatonin) are also popular products. Substances that are not necessarily synthesized by the body but nevertheless believed to play a useful physiologic role, such as citrus bioflavonoids and fructo-oligosaccharides, also fall into this category.

Data on overall sales and use of nutraceuticals are sparse. Measurement of nutraceutical consumption is complicated by their common incorporation into foods or multivitamins, which may then be referred to as "superfoods" or "megavitamins," based on these additions. Some nutraceuticals, such as lycopene and plant bioflavonoids, are natural compounds derived from fruits, vegetables, or grains.

When advising patients, it is often difficult to determine bioavailability when nutraceuticals are consumed orally. Health benefits are frequently attributed to nutraceuticals based only on in vitro data or a nutraceutical's known physiologic role, rather than based on evidence derived from randomized controlled trials (RCTs). Dosage of a given nutraceutical may be as variable among products as price. Table 52-6 lists a number of nutraceuticals, their uses, contraindications, and efficacy when available.

Combination Products

Combination herbal products are also becoming increasingly common. Although they cannot patent individual supplement compounds, manufacturers often may still patent a "proprietary blend." In a market survey for the year preceding January 2005, "multi-herbs," products containing multiple herbal ingredients, showed the largest increase in market sales of all herbal products, up 29% from the previous year (Information Resources, 2005). Among the 10 most

Table 52-3 Types of Herbal Formulations*

| Form | Processing Method | Comments | Examples |
|----------------------|---|--|--|
| Crude herb | Food is used in the form in which it is harvested. | Many plant foods can be considered crude herbs. | Billberry (eye disorders) Ginger root (nausea) |
| Juice (succus) | Herb is crushed, and resultant liquid is consumed. | Relative concentrations of various compounds in the juice will vary. | Cranberry (urinary infection prevention) |
| Dry herb | Herb is air-dried after picking. | Dried form may be powdered and packaged into capsules or pressed together in tablets. | Dried feverfew (migraine prevention) |
| Freeze-dried extract | Ice is sublimated away at low pressures. | May contain chemical components not found in other extracts. | Stinging nettles (allergy symptoms) |
| Infusion | Water extract in which the herb parts are put in boiling water, i.e., a tea. | Typical recipe is 8 oz of water poured over 2-3 tsp of herb, steeped for 10-15 minutes. Most toxic alkaloids are water insoluble, making teas relatively safe. | Chamomile tea (relaxation) Green tea (antioxidant) |
| Decoction | Water extract in which herb and water are boiled together. | Usually more concentrated than infusions. Used to dissolve fibrous materials (roots or bark). | Coffee (stimulant) Ginseng root (overall tonic) |
| Tincture | Solvent extract that is made using an organic solvent, usually alcohol or glycerol. | Longer shelf life. Not recommended for alcoholics. A 1:5 extract means that 1 g of dried herb is contained in 5 mL of tincture. | Horse chestnut (venous insufficiency) |
| Fluid extract | More concentrated version of a tincture. | Usually a 1:1 or 1:2 ratio, i.e., 1 g of dried herb is contained in 1 or 2 mL of the extract. | Saw palmetto (prostatic hypertrophy) |
| Solid extract | Solvent in a tincture or fluid extract is boiled off to concentrate solids. | More potent extracts; a 5:1 extract has 5 g of original herb concentrated into just 1 g of solid extract. | Ginkgo (cerebral insufficiency); often studied in dry-extract form |
| Essential oil | Steam is passed through the herb to remove volatile oils. | Quite concentrated; should not be applied directly to skin. | Aromatherapy often uses essential oils. |

Data from Blumenthal M. American Botanical Council. The ABC Clinical Guide to Herbs. New York, Thieme, 2003; and Rotblatt M, Ziment I. Evidence-Based Herbal Medicine. Philadelphia, Hanley & Belfus, 2002.

*Different herbal formulations made from the same plant can contain different chemicals and have different therapeutic and adverse effects. Many herbs are sold in a variety of different forms, and dosing recommendations differ for each. Herbs can also be applied topically in various forms not described here.

Table 52-4 Popular Herbal Remedies*

| Herb | Common Uses | Cautions and Contraindications | Drug Interactions |
|---|---|--|--|
| Aloe (21) <i>Aloe vera</i> | Burns and abrasions (topical) Diabetes (oral) Laxative (A) Male genital herpes (A) Psoriasis (A) Radiation dermatitis Seborrheic dermatitis (A) | Slows wound healing by secondary intention Gel is not to be confused with aloe leaf, which is used as a laxative but has many side effects. <i>May</i> decrease potassium when used orally | Speeds healing with topical polyethylene oxide Improves skin healing rate with topical hydrocortisone in mice Follow glucose levels when used PO Improves effect of glyburide <i>May</i> increase AZT levels when taken PO |
| Barley <i>Hordeum vulgare</i> | Bronchitis Constipation Inflammatory bowel disease Lipid disorders (A) | Avoid excessive quantities of barley sprouts in pregnancy <i>May</i> lower blood glucose <i>May</i> increase pulse, wakefulness | <i>May</i> enhance effects of glucose-lowering drugs Fiber content may reduce absorption of some drugs <i>May</i> synergize with cholesterol-lowering drugs |
| Billberry (15) <i>Vaccinium myrtillus</i> | Night vision Retinopathy Peripheral vascular disorders; venous insufficiency | <i>May</i> lower blood pressure <i>May</i> lower blood sugar level (animal research) | In rats, inhibits formation of gastric ulcers caused by indomethacin, reserpine, and ethanol <i>May</i> increase warfarin and antiplatelet drug effects |

Table 52-4 Popular Herbal Remedies*—cont'd

| Herb | Common Uses | Cautions and Contraindications | Drug Interactions |
|---|---|--|---|
| Black cohosh (7) <i>Actaea racemosa</i> ; formerly <i>Cimicifuga racemosa</i> | Dysmenorrhea Menopausal symptoms PMS | Avoid in first trimester and lactation <i>May</i> increase growth of estrogen-dependent tumors (speculative) High doses can cause headache, vision change, dizziness, and sweating | <i>May</i> lead to estrogen excess with hormone replacement Unclear whether beneficial for tamoxifen hot flashes <i>May</i> augment antihypertensives |
| Cat's claw <i>Uncaria</i> spp. | Anti-inflammatory GI inflammation Osteoarthritis (A) Rheumatoid arthritis (A) | Avoid in transplants, skin grafts; <i>may</i> enhance immune function (speculative) Used as contraceptive; caution in pregnancy or lactation | Reduces intestinal damage caused by indomethacin <i>May</i> sensitize to injections, blood products, hormones, and vaccines <i>May</i> inhibit CYP3A4 (increase fexofenadine, lovastatin, azoles, etc.) <i>May</i> interfere with immunosuppressants |
| Cayenne <i>Capsicum frutescens</i> , <i>C. annuum</i> , and other spp. | Topical use for pain control (A) Fibromyalgia (A) Gastric ulcer prevention Neuralgia Osteoarthritis Rheumatoid arthritis (A) | <i>May</i> cause bronchospasm on first exposure; caution with asthma Not for topical use on damaged skin Caution in irritable bowel, stomach ulcers (with excess use), acid reflux | Topical use increased ACE inhibitor cough in one case. Reduces aspirin-induced and alcohol-induced gastric mucosal damage Antagonizes antacids when frequently used Increased theophylline levels in rabbits Enhances barbiturate effects and acetaminophen absorption in rats |
| Cranberry (2) <i>Vaccinium macrocarpon</i> | Urinary tract infections: prevention (A) and treatment | None documented | Acidity <i>may</i> counteract antacids. <i>May</i> enhance vitamin B ₁₂ absorption in patients taking PPIs |
| Dandelion <i>Taraxacum officinale</i> | Above-ground parts: anorexia, decreased appetite, flatulence, fluid retention Total plant: gallstones, muscle aches | Caution in stomach inflammation and irritable bowel; increases gastric acidity Avoid with bile duct obstruction; is a cholagogue Caution in jaundice or hyperbilirubinemia Avoid in intestinal obstruction (laxative effect) Avoid in liver cancer | <i>May</i> worsen lithium toxicity because of enhanced sodium excretion <i>May</i> enhance anticoagulant effects <i>May</i> synergize with diuretics (but no evidence of diuretic effect) |
| Dong quai <i>Angelica sinensis</i> | Amenorrhea Irregular menses Menopause PMS | Avoid in pregnancy (speculative) Caution with easy bleeding or menorrhagia Avoid in diarrhea (used as laxative) | Increases warfarin effect Effect on drugs with estrogenic effects unclear <i>May</i> enhance sun sensitivity effects of drugs <i>May</i> augment drug-induced arrhythmias |
| Echinacea (6) <i>Echinacea purpurea</i> , <i>E. pallida</i> , <i>E. angustifolia</i> | HSV infection Immune support URI prevention URI treatment (A) | Avoid in systemic autoimmune disorders (speculative) and tuberculosis | Reduces recurrent candidiasis when used with econazole cream <i>May</i> decrease immunosuppressive drug effects |
| Elder (elderberry) (22) <i>Sambucus nigra</i> | Athletic performance Influenza Upper respiratory tract illness | Stems, roots, <i>unripe</i> berries, and seeds contain cyanide (only ripe berries should be used). <i>May</i> lower glucose | None known; berries eaten as food Theoretical diuretic and laxative effects <i>May</i> alter theophylline levels |
| Eleuthero <i>Eleuthero-coccus senticosus</i> Farm Bill 2002 mandated that the name "Siberian ginseng" no longer be used. | Adaptogen High and low blood pressure HSV-2 infection (A) Does not contain ginsenosides, which are thought to be the active components in American and Chinese ginseng | Caution in cardiovascular disease (especially rheumatic heart disease) Can cause drowsiness, anxiety, irritability, mastalgia at high doses Nerve inflammation (sciatic) possible with long-term use Follow glucose levels in diabetics | Increased anticoagulant and antiplatelet effects <i>May</i> synergize with sedatives <i>May</i> inhibit CYP1A2 (increase levels of antipsychotics, SSRIs, propranolol, theophylline) <i>May</i> inhibit CYP2C9 (increasing amitriptyline, diazepam, verapamil, warfarin, tacrine, and other drug levels) |

Continued

Table 52-4 Popular Herbal Remedies*—cont'd

| Herb | Common Uses | Cautions and Contraindications | Drug Interactions |
|---|---|---|---|
| Evening primrose (12) <i>Oenothera biennis</i> | ADHD Asthma Atopic dermatitis (A) Cyclic mastalgia Diabetic neuropathy Menopause; PMS Psoriasis Schizophrenia | May cause seizures or mania (speculative) May alter blood pressure | Can cause seizures in patients taking phenothiazines Increases response to tamoxifen Reduces cyclosporine-induced kidney damage (rats) May decrease efficacy of seizure medications |
| Eyebright <i>Euphrasia officinales</i> , <i>E. rostkoviana</i> | Used topically Earaches Inflammatory eye disorders Mucosal membrane inflammation | Hygienic concerns with ophthalmic solutions High doses of eyedrops may cause confusion, photophobia, GI symptoms, headache, increased eye pressure | None known |
| Feverfew <i>Tanacetum parthenium</i> | Migraine prevention Migraine-related nausea and vomiting | Avoid in early pregnancy, with bleeding disorders or before surgery May cause withdrawal if stopped suddenly after long-term use | May enhance warfarin or aspirin effects May enhance sun sensitivity effects of drugs |
| Garlic (3) <i>Allium sativum</i> | Atherosclerosis Cancer prevention Diabetes <i>H. pylori</i> infection Hyperlipidemia (A) Hypertension Peripheral vascular disease Tinea infections (topically) | Can cause mucosal surface (stomach) irritation and acid reflux Avoid excess in early pregnancy Caution in hypothyroidism (may affect iodine uptake) Avoid before surgery | Potentiates warfarin (human studies), indomethacin, and dipyridamole (in vitro) Prevented mouse liver toxicity caused by acetaminophen May reduce insulin needs May enhance cholesterol-lowering medication effects Lowers saquinavir levels |
| Ginger (20) <i>Zingiber officinale</i> | Chemotherapy-induced nausea and vomiting Hyperemesis gravidarum (A) Inflammation Motion sickness Vertigo | Avoid more than 1 g daily in pregnancy Avoid with gallstones; may be a cholagogue Avoid in weeks before surgery | Reduced nausea from anesthetics, cyclophosphamide Increases absorption of some oral drugs (limited studies) May augment anticoagulants May antagonize antacids, reflux drugs May lower blood sugar, interfere with inotropes, increase sedative effects |
| Ginkgo (4) <i>Ginkgo biloba</i> | Depression Memory loss, dementia (A) Peripheral vascular disease and claudication (A) PMS Tinnitus Vertigo | Enhances bleeding risk; discontinue before surgery May lower serum glucose May lower blood pressure | Increases bleeding with aspirin and warfarin Decreases antidepressant sexual side effects; caused a coma with trazodone in one case May augment MAOIs Potentiates papaverine May increase seizures and antipsychotic side effects |
| Ginseng, American <i>Panax quinquefolius</i> | Mental performance enhancer (A) Type 2 diabetes (A) | Limited case reports, although has many compounds in common with Asian (Chinese) ginseng | Worked synergistically in vitro for breast cancer with tamoxifen, cytoxan, doxorubicin, taxol, and methotrexate See Chinese ginseng |
| Ginseng, Chinese (9) <i>Panax ginseng</i> | Bronchitis Erectile dysfunction General tonic Immune system modulation Libido enhancer | Can raise blood pressure (taken in high doses or for prolonged periods) May worsen asthma Caution in menorrhagia or nosebleeds Estrogen-like effects May increase QT interval | Increases alcohol metabolism May cause hypertension taken with caffeine Can cause mania with MAOIs May decrease diabetes medication requirements May reduce warfarin activity (case study) |
| Gotu kola <i>Centella asiatica</i> | Performance enhancer Schistosomiasis Venous disorders (A) Wound healing | Avoid excessive use in pregnancy May raise glucose and cholesterol levels | May enhance effects of sedatives |

Table 52-4 Popular Herbal Remedies*—cont'd

| Herb | Common Uses | Cautions and Contraindications | Drug Interactions |
|---|--|--|---|
| Grape seed (16) <i>Vitis vinifera</i> or <i>V. coignetiae</i> | Venous insufficiency (A) Other vascular and circulatory disorders Night vision | None greater than placebo in most studies May have laxative effects | May increase warfarin effects May inhibit <i>Lactobacillus</i> May induce CYP1A2, decreasing tricyclic, various antipsychotics, cyclobenzaprine, diazepam, estradiol, naproxen, etc. |
| Green tea (11) <i>Camellia sinensis</i> | Antioxidant Cancer prevention (especially bladder, breast, esophageal, gastric, pancreatic) CAD prevention Hypertension Hypotension Increased alertness (A) Oral leukoplakia Parkinson's disease prevention | Decreases estrogen levels May augment kidney, duodenal, heart, and psychiatric disorders (speculative) Caffeine-related side effects | Reduced iron absorption in children Reduced warfarin effect (case report) Sympathetic symptoms worsened with ephedrine Decreases effects of adenosine, clozapine, pentobarbital, benzodiazepines, beta blockers, lithium Fluvoxamine, quinolones, others augment caffeine effects |
| Guarana <i>Paullinia cupana</i> or <i>P. sorbilis</i> | Weight loss Performance enhancer Stimulant | See Green tea; similar side effects because of caffeine content | See Green tea |
| Hawthorn (24) <i>Crataegus</i> spp. | Stage I or II heart failure (A) Other cardiovascular disorders | Rare mild adverse effects | Enhances digoxin effects (is a positive inotrope, vasodilator) Reduces digoxin toxicity May enhance effects of antihypertensive drugs |
| Horny goat weed (14) <i>Epimedium grandiflorum</i> | Often a component of "herbal Viagra"; used for impotence and involuntary ejaculation Joint pain Weakness | Limited safety evidence; possible respiratory distress at high doses | May augment hypotensive effects May potentiate anticoagulant and antiplatelet drugs |
| Horse chestnut (19) <i>Aesculus hippocastanum</i> | Chronic venous insufficiency (A) Hemorrhoids | Tends to be safe in products with esculin removed Crude herb should not be used by children If poisoning: fasciculations, poor coordination, vomiting, diarrhea, depression, paralysis | Esculin has antithrombotic effects. Use caution with all products and anticoagulant or antiplatelet drugs. May augment glucose-lowering drug effects |
| Kava (25) <i>Piper methysticum</i> | Anxiety (A), but note concerns about adverse effects Benzodiazepine withdrawal Menopausal anxiety symptoms Many government agencies discourage use. | Avoid in liver disease (banned in Germany after several cases of hepatitis) Caution in pregnancy and lactation Avoid in depression Possibly habit-forming after 3 months Can cause bleeding, spasms, pulmonary hypertension, skin discoloration, and eye problems with chronic use | Reduces levodopa effect May enhance effects of benzodiazepines, MAOIs May increase alcohol, barbiturate effects Avoid with drugs that may harm the liver, e.g., steroids, amiodarone, acetaminophen, oral antifungals, methotrexate |
| Licorice <i>Glycyrrhiza glabra</i> | Aphthous ulcers Asthma Dyspepsia Hepatitis (intravenous use in Europe) Deglycyrrhizinated licorice (DGL) does not cause most contraindications or adverse effects listed here. | Avoid in renal insufficiency or hypertension (can cause pseudo-hyperaldosteronism) Avoid in diabetes Avoid in pregnancy Caution in liver disease bile stasis, alcoholism Decreases male libido May worsen respiratory congestion | Potentiates digoxin Potentiates corticosteroids (including topicals) Reduces testosterone Decreases aspirin and alcohol-related GI bleeding Enhances cimetidine GI protection May decrease estrogen effects May augment potassium loss via laxative use, thiazides, furosemide Antagonizes spironolactone, amiloride Increases acetaminophen metabolism |
| Milk thistle (8) <i>Silybum marianum</i> | Cirrhosis (A) Dyspepsia Other liver disorders: alcoholic/infectious hepatitis, drug-induced hepatitis | Rare GI adverse effects, one case of elevated liver enzymes | Protects from liver damage caused by alcohol, phenytoin, acetaminophen, halothane Protects kidneys from cisplatin May alter some aspects of CYP metabolism |

Table 52-4 Popular Herbal Remedies*—cont'd

| Herb | Common Uses | Cautions and Contraindications | Drug Interactions |
|---|---|--|---|
| Olive leaf (23) <i>Olea europaea</i> | Breast cancer Cardiovascular disease Constipation (A) Gallstones, gallbladder disease Infections (viral, protozoal) Rheumatoid arthritis | Olive oil seems to lower breast cancer risk. | May lower blood pressure and decrease serum glucose |
| Pau d'arco <i>Tabebuia</i> <i>impetiginosa</i> | <i>Candida</i> infection Diarrhea Parasitic infections Respiratory and urinary infections | Increased risk of bleeding in large doses | May decrease anticoagulant effects May decrease effects of immunosuppressive drugs |
| Pycnogenol <i>Pinus pinaster</i> subsp. <i>atlantica</i> | Asthma Athletic performance Dysmenorrhea Hypertension Immune support Pain control Venous insufficiency (A) | None reported | May interfere with immunosuppressants |
| Red clover (18) <i>Trifolium pratense</i> | Cyclic breast pain Dyslipidemia Menopause (hot flushes); PMS Osteoporosis | Estrogenic activity; avoid use in pregnancy and hormone-sensitive cancers | May increase anticoagulant effects of drugs such as warfarin |
| St. John's wort (10) <i>Hypericum</i> <i>perforatum</i> | Anxiety Depression, mild to moderate (A) HIV (–) Menopausal symptoms Obsessive-compulsive disorder Seasonal affective disorder | Caution in pregnancy Can cause photosensitivity (high doses) Psychosis or bipolar disorder may be worsened FDA recommends people with HIV avoid | Serotonin syndrome with SSRIs, trazodone Lowers theophylline levels Decreased metabolism of indinavir, digoxin, estrogens, cyclosporin, and general anesthetics Decreased warfarin effect May interact with calcium channel and beta blockers, tricyclics, tamoxifen, triptans, MAOIs, others |
| Saw palmetto (5) <i>Serenoa repens</i> | Benign prostatic hypertrophy (mild to moderate) (A); some recent studies have called previous positive studies into question. Prostatitis (–) | None, although not recommended in pregnancy or lactation May lower prostate-specific antigen levels Two case reports of bleeding May alter body's response to sex hormones and estrogen | Inhibition of binding of alpha-1 agonists Potentiates uterine relaxant effect with propranolol |
| Soy (1) <i>Glycine max</i> (or <i>Soja</i> spp.) | Cancer prevention or treatment Gallstones Hypertension Infant diarrhea (added to formula) (A) Kidney disease Lipid control (A) Menopausal symptoms (A) Neuropathy Obesity Osteoporosis | Occasionally causes GI effects and migraines May increase risk of endometrial hyperplasia and cancer Effects on breast cancer controversial Avoid with cystic fibrosis Avoid in hypothyroidism (speculative) | Effects may be decreased by antibiotics May inhibit estrogen May antagonize tamoxifen Decreased warfarin effect in one patient |
| Spirulina , blue-green algae <i>Microcystis</i> or <i>Spirulina</i> spp. | Infant malnutrition (–) Diabetes Nutrient source Oral leukoplakia Weight loss | Microcystin contamination of products (rare) can cause GI distress, shock Contains phenylalanine (avoid, phenylketonuria) | None known |
| Valerian (13) <i>Valeriana officinalis</i> | Anxiety Insomnia (A) Sedation (–) | None Possibility of withdrawal symptoms after long-term use | Helpful in benzodiazepine withdrawal Augments barbiturate effects May increase sedation caused by antidepressants, beta blockers, antiepileptics, anesthetics, analgesics, etc. |

Table 52-4 Popular Herbal Remedies*—cont'd

| Herb | Common Uses | Cautions and Contraindications | Drug Interactions |
|---|--|--|--|
| Yohimbe (17) <i>Pausinystalia yohimbe</i> | Erectile dysfunction Xerostomia Note: Use not generally recommended | Can worsen schizophrenia, depression, anxiety hypertension, and kidney disease <i>May</i> be harmful in pregnancy Caution in liver disease | Multiple drug interactions (most based on <i>yohimbine</i> , not <i>yohimbe</i> bark extract): tricyclics, antipsychotics, clonidine, sympathomimetics Increases naloxone side effects <i>May</i> alter CYP metabolism |
| Yucca <i>Yucca</i> spp. | Inflammation | Occasional GI effects | None known |

Data from Basch EM, Ulbricht CE. Natural Standard Herb and Supplement Handbook: The Clinical Bottom Line. Boston, Elsevier-Mosby, 2005; Blumenthal M. American Botanical Council. The ABC Clinical Guide to Herbs. New York, Thieme, 2003; Brinker F. Herb Contraindications and Drug Interactions, 3rd ed. Sandy, Oregon, Eclectic Publications, 2001; Natural Medicines Comprehensive Database (accessed November 2009); and Rotblatt M, Ziment I. Evidence-Based Herbal Medicine. Philadelphia, Hanley & Belfus, 2002.

*Numbers after herbs indicate their rank in terms of the 25 best-selling herbs in the United States in 2007, as obtained from Information Resources. These data only cover about 5.6% of the total market volume but are among the best data available for commercial herb sales. Does not include sales for Wal-Mart, Costco, and Sam's Club, some of the major supplement sellers. Other herbs in this list were featured in the top-34 best-selling herbs before October 2002 based on an earlier survey by the same marketing research group and continue to be widely used.

Not all monographs reach the same conclusions regarding the evidence base for particular supplements. Lack of randomized controlled trial (RCT) research is not equivalent to lack of efficacy. Inclusion of herbs in this table does not imply an endorsement of their use. See Web Resources or online references for detailed prescribing guidelines. Many of the herbs listed are used for dozens of different indications; only the most common (and when possible, most researched) indications are listed.

An "A" in parentheses after a supplement name denotes an A rating according to the Strength of Recommendation Taxonomy (SORT). The rating is based on systematic review data summarized primarily in the references by Basch and/or Natural Medicines Comprehensive Database (NMCD). A classification of "A" is assigned if the supplement was rated as one of the following: (1) evidence grade A or B in Basch (indicating strong or good evidence of effect) or (2) a rating of "Effective" or "Likely effective" in NMCD. Indications followed by a "(–)" have been rated category D by Basch (indicating "Fair negative scientific evidence") or as "Likely ineffective" by NMCD.

Allergic reactions (usually rash) are possible with most plant compounds. GI side effects are common (frequently equivalent to placebo) in many studies as well. Drug interactions preceded by "*May*" are speculative. No case reports or trials have verified their existence.

ACE, Angiotensin-converting enzyme; ADHD, attention-deficit hyperactivity disorder; CAD, coronary artery disease; CYP, cytochrome P-450; FDA, Food and Drug Administration; GI, gastrointestinal; HIV, human immunodeficiency virus; HSV, herpes simplex virus; MAOIs, monoamine oxidase inhibitors; PMS, premenstrual syndrome; PO, orally; PPIs, proton pump inhibitors; SSRIs, selective serotonin reuptake inhibitors; URI, upper respiratory infection.

Table 52-5 Vitamin and Mineral Supplements*

| Name | Indications/Evidence | Effects/Interactions/Comments |
|--|---|---|
| Vitamins | | |
| Biotin Considered a vitamin Stored in mitochondria Carboxylation reactions | Brittle nails Deficiency (A) Depression Diabetes Hair loss Malnutrition Peripheral neuropathy Seborrheic dermatitis of infancy | No intake levels set No adverse effects known Absorption decreased with carbamazepine, phenobarbital, phenytoin, primidone |
| Folic acid (sometimes called vitamin B ₉) "Folate" takes multiple forms (pteroylmonoglutamic acid is used in most products) Part of coenzymes involved with DNA synthesis; reduces DNA damage, cell death rate Conversion of homocysteine to methionine <i>May</i> improve endothelial function in atherosclerosis Deficiency common in depression | Alzheimer's disease Anti-aging Cancer prevention (breast, colorectal) CAD Chronic fatigue (parenteral) Deficiency (A) Depression Fragile X syndrome (–) Gingival hyperplasia High homocysteine (A) Insomnia Megaloblastic anemia (A) Methotrexate toxicity Neural tube defect prevention (A) Neuropathy Osteoporosis Vitiligo | Supplementation in breakfast cereal only raises intake by 100 µg Consider supplementation in alcoholics Well tolerated at <1000 µg/day Doses over 5 mg daily can cause GI distress and rash; over 15 mg/day can lead to altered sleep, overactivity, confusion, psychotic behavior, seizures, zinc depletion Large doses increase neuropathy in vitamin B ₁ deficiency <i>May</i> reduce toxicity of methotrexate (caution with chemotherapy) <i>May</i> reduce effectiveness of anticonvulsants; folate levels are decreased by phenytoin and phenobarbital Levels decreased by antacids, PPIs, H ₂ blockers, antibiotics, aspirin, carbamazepine, bile acid sequestrants, pancreatic enzymes, sulfasalazine, trimethoprim, and perhaps diuretics |

Table 52-5 Vitamin and Mineral Supplements*—cont'd

| Name | Indications/Evidence | Effects/Interactions/Comments |
|--|---|--|
| <p>Vitamin A (retinol) Name refers to family of molecules known as <i>retinoids</i>. <i>Retinol</i> is the most potent form; <i>carotenoids</i> are its precursors. Retinol seems to speed wound healing. Retinoic acid regulates structural protein gene expression and immune activities. <i>May</i> induce retinoic acid genes, leading to tumor suppression</p> | <p>Cancer prevention and treatment Deficiency states (A) Eye problems: decreased vision, glaucoma, cataracts GI ulcers HIV-related diarrhea IBD Infections: HIV, malaria, measles, pneumonia (–) (taken to decrease morbidity, not to cure infection) Menorrhagia PMS Skin conditions Vaginitis</p> | <p>Safe in adults in doses of <10,000 U/day; <2000 up to age 3; <3000 age 4-8; <5700 age 9-13; 9300 U ages 14-18 Acute toxicity (from a large, single doses): GI effects, headache, increased CSF pressure, vertigo, blurred vision Chronic toxicity: hepatotoxicity (caution with hepatotoxic drugs), fatigue, emotional and psychiatric changes, anorexia, abdominal discomfort, mild fever, hyperhidrosis, changes in skin, nails, and gums. Alcohol <i>may</i> augment toxicity. Increased pneumonia and diarrhea with high doses; liver damage possible with low to moderate doses (usually reversible) Vitamin E seems to augment activity and absorption while decreasing toxicity <i>May</i> antagonize vitamins D and K at high doses; <i>do not use with retinoids</i> Taken with tetracyclines, may cause pseudotumor cerebri; liver storage may be decreased by estrogens. Beta-carotene (pro-vitamin A compound) increased mortality in smokers with CAD in two trials; avoid use in smokers; seems to increase cancer risk. Alpha-carotene reduced lung cancer risk in cohort studies.</p> |
| <p>Vitamin B₁ (thiamine) Forms coenzyme used in carbohydrate metabolism <i>May</i> be involved in neuromuscular transmission Levels decreased in Crohn's disease</p> | <p>Beriberi (A) Alcoholism (Wernicke's) Appetite stimulant Colitis Diarrhea (chronic) Memory and mood Stress Motion sickness Vision problems, cataracts</p> | <p>Hypersensitivity rare orally IM use: warmth, pain, sweating, respiratory distress, cyanosis Chronic diuretics may lead to depletion (consider in heart failure) Fluorouracil, phenytoin decrease levels Metformin may reduce activity</p> |
| <p>Vitamin B₂ (riboflavin) Used in redox reactions after conversion to flavin adenine dinucleotide (FAD) Maintains erythrocyte integrity</p> | <p>Acne Alcoholism Aphthous ulcers Carpal tunnel syndrome Cataracts Deficiency (A) Energy Hair, skin, nail health Immune support Liver disease Memory Migraine prophylaxis</p> | <p>Deficiency in people with chronic infection, liver disease, malignancy, alcoholism Makes urine yellow-orange Levels decreased by anticholinergics, oral contraceptives, phenobarbital, psyllium Antibiotics may reduce synthesis</p> |
| <p>Vitamin B₃ (niacin, niacinamide) Synthesized from dietary tryptophan Part of nicotinamide adenine dinucleotide (NAD) and NAD phosphate, hydrogen-carrying molecules Inhibits free fatty acid release from adipose tissue Decreases liver synthesis of low-density lipoprotein (LDL) and very-low-density lipoprotein (VLDL); increases triglyceride removal from plasma</p> | <p>ADHD Cataracts Cholera Cognitive decline Deficiency (A) Depression Edema Hyperlipidemia (A) Meniere's disease Migraines and premenstrual headache Peripheral vascular disease Recurrent MI prevention (A) Schizophrenia Skin conditions Vertigo</p> | <p>Can cause flushing, pruritus, burning, tingling, GI distress (caution in peptic ulcer disease), increased sebum, dizziness, arrhythmias, syncope, headache, blurred vision, dental pain Chronic use at high doses causes skin effects, gout, peptic ulcer, eye and vision changes, hyperglycemia, panic Caution in liver disease and with hepatotoxic drugs Can increase risk of myopathy when given with statins Increased flushing and dizziness with nicotine patches Depleted with poor diet, isoniazid therapy, antibiotic use, carcinoid, Hartnup's disease. Increased requirements in hyperthyroidism, diabetes, cirrhosis, pregnancy, lactation Can increase blood glucose levels Can cause histamine release <i>May</i> exacerbate gallbladder disease <i>May</i> accumulate in renal disease</p> |

Table 52-5 Vitamin and Mineral Supplements*—cont'd

| Name | Indications/Evidence | Effects/Interactions/Comments |
|---|--|---|
| Vitamin B₅ (pantothenic acid) Metabolism of lipids, carbohydrates, and proteins as coenzyme A precursor Deficiency rare; seems to be related to fatigue, paresthesias, and other neurologic findings as well as GI symptoms | ADHD Allergies Arthritis Burning feet syndrome Candidiasis Carpal tunnel syndrome Celiac disease Colitis Deficiency (A) Heart failure Insomnia Infection prevention Parkinson's disease PMS Skin conditions Stress Vertigo Wound healing | Diarrhea in large doses Antibiotics may decrease levels |
| Vitamin B₆ (pyridoxine) Required for amino acid metabolism Part of coenzymes for tryptophan conversion to niacin, GABA synthesis, and metabolism of serotonin norepinephrine, dopamine, phospholipids, and homocysteine Antioxidant <i>May decrease urinary oxalate excretion</i> | ADHD Allergies Arthritis Cancer prevention Carpal tunnel syndrome Cramps Deficiency (and related seizures) (A) Depression Dizziness, motion sickness Immune support Homocysteine elevation (A) Kidney stone prevention Migraines Morning sickness PMS Sideroblastic anemia (A) Skin conditions Tardive dyskinesia | Most side effects are with taking >1000 mg daily, but neuropathy can occur with lower doses. Can cause GI distress, paresthesias, headache, somnolence, decreased folic acid, allergies, breast soreness or enlargement, sensory neuropathy (usually reversible) RDA for pregnant women: 1.9 mg/day Deficiency more likely with uremia, alcoholism, cirrhosis, hyperthyroidism, malabsorption, CHF Levels reduced with oral contraceptive use, hydralazine, isoniazid, penicillamine, theophylline Lower concentrations linked to increased C-reactive protein levels Decreases levodopa levels if carbidopa is not used <i>May reduce phenytoin and phenobarbital levels</i> |
| Vitamin B₁₂ (cyanocobalamin) Used in nucleoprotein and myelin synthesis, cell reproduction, erythropoiesis Involved in homocysteine synthesis, folate metabolism Body has large stores <i>May be a link with deficiency and chronic fatigue syndrome</i> | AIDS Allergies Anti-aging Asthma Cancer Deficiency (A) Diabetes Energy Heart disease High homocysteine IBD Male infertility Memory Pernicious anemia (A) Skin conditions Sleep disorders Tinnitus | Vegetarians (especially vegans) are at risk for deficiency Rarely causes diarrhea, itching, thrombosis, urticaria Can unmask polycythemia vera <i>May cause rosacea fulminans taken with pyridoxine</i> Folate masks deficiency Potassium may reduce absorption May have decreased levels with colchicine, antibiotics, bile acid sequestrants, H ₂ blockers, metformin, phenytoin, PPIs |

Continued

Table 52-5 Vitamin and Mineral Supplements*—cont'd

| Name | Indications/Evidence | Effects/Interactions/Comments |
|---|---|---|
| <p>Vitamin C (ascorbic acid)</p> <p>Used in tyrosine metabolism</p> <p>Cofactor in synthesis of carnitine, norepinephrine, and dopamine, and thyroxin</p> <p>Involved in metabolism of folate, bile acids, iron</p> <p>Antioxidant</p> <p>Seems to increase T-lymphocyte activity, white blood cell function, interferon production</p> <p>Frozen orange juice has higher absorbable concentrations than other forms</p> | <p>ADHD</p> <p>Allergies, asthma</p> <p>Anemia</p> <p>Anti-aging</p> <p>Arthritis</p> <p>Autism</p> <p>Cancer prevention and treatment</p> <p>Collagen disorders</p> <p>Deficiency (scurvy) (A)</p> <p>Dementia</p> <p>Depression</p> <p>Erythema</p> <p>Eye problems</p> <p>Gallbladder disease</p> <p><i>H. pylori</i> infection</p> <p>Hyperlipidemia</p> <p>Hypertension</p> <p>Lead toxicity</p> <p>Microalbuminuria</p> <p>Osteoarthritis</p> <p>Preeclampsia</p> <p>Skin conditions, wrinkles, sunburn</p> <p>Tuberculosis</p> <p>Tyrosinemia (A)</p> <p>URI prevention or treatment</p> <p>Vascular disease</p> | <p><i>Upper limits:</i> 1-3 yr, 15 mg; 4-8 yr, 25 mg; 9-13 yr, 45 mg; 14-18 yr, 75 mg boys, 65 mg girls; >19 yr, 90 mg men, 75 mg women.</p> <p><i>Pregnancy/lactation:</i> <18 yr, 115 mg; >18 yr, 120 mg; add 35 mg daily, tobacco users</p> <p>>2000 mg daily can lead to nausea and diarrhea. Absorption decreases with larger doses. 80% of 100-mg dose is absorbed, but 50% of 1250 mg</p> <p>Increases GI iron absorption</p> <p>May precipitate kidney stones</p> <p>Metabolism may increase with long-term use, leading to scurvy risk when intake is lowered</p> <p>No data regarding antioxidants reducing chemotherapeutic efficacy</p> <p>Plasma levels of estrogens may increase in deficient women</p> <p>Levels decreased by calcium channel blockers, aspirin, PPIs, and (in chronic renal failure) furosemide</p> <p>Seems to reduce protease inhibitor levels at 1 g daily for 1 week</p> <p>Cancer cells accumulate vitamin C (significance unclear)</p> <p>Tobacco users have lower levels</p> |
| <p>Vitamin D D₂, ergocalciferol</p> <p>D₃, cholecalciferol</p> <p>Seems to affect genetic expression</p> <p>Influences body calcium and phosphorus levels</p> <p>Stored in body fat</p> <p>Receptors decrease with age</p> <p>10 μg = 400 units</p> | <p>Autoimmune disease prevention</p> <p>Cancer treatment and prevention</p> <p>Diabetes prevention</p> <p>Fanconi's syndrome (A)</p> <p>Fall prevention (A)</p> <p>Familial hypophosphatemia (A)</p> <p>Hypoparathyroidism (A)</p> <p>Immune booster</p> <p>Multiple sclerosis</p> <p>Osteomalacia (A)</p> <p>Osteoporosis prevention (A)</p> <p>PMS</p> <p>Psoriasis (topicals) (A)</p> <p>Rickets (A)</p> <p>Scleroderma</p> <p>Seasonal affective disorder</p> <p>Vitiligo</p> | <p><i>Upper intake level:</i> adults, 2000 U, >1 yr; 1000 U <1 yr</p> <p>Full-body sun exposure can provide up to 10000 U daily, but vitamin D breakdown occurs with excess exposure (limits toxicity)</p> <p>Half of North American women receiving osteoporosis treatments have inadequate vitamin D stores</p> <p>Toxicity can lead to hypercalcemia, anemia, azotemia</p> <p>May increase magnesium absorption</p> <p>Cimetidine lowers conversion in liver, but minimal except with liver, kidney disease</p> <p>Levels decreased by heparins, carbamazepine, bile acid sequestrants, corticosteroids, orlistat, phenobarbital, phenytoin, stimulant laxatives, sunscreens</p> <p>May increase calcium level in lymphoma, sarcoid, renal failure, histoplasmosis, TB</p> |

Table 52-5 Vitamin and Mineral Supplements*—cont'd

| Name | Indications/Evidence | Effects/Interactions/Comments |
|---|---|--|
| <p>Vitamin E Tocopherols, tocotrienols Usually supplemented as alpha-tocopherol, but eight different forms. Gamma is most common in foods. Effects and toxicity may vary with type consumed (particularly in heart disease); however, beta, gamma, and delta may have limited bioavailability. Tocotrienols also play physiologic roles Antioxidant May increase immune cell function, especially in elderly persons</p> | <p>Allergies/asthma Anemia Angina Anti-aging Cancer prevention and treatment; (–) for lung Cardiovascular disease prevention (–) Cataract prevention Claudication Deficiency (A) Dementia Diabetes Dysmenorrhea Energy enhancer Epilepsy Huntington's chorea Hypertension Infertility and impotence Macular degeneration Menopausal symptoms PMS Preeclampsia prevention Restless legs Tardive dyskinesia Uveitis</p> | <p><i>Upper limit:</i> 1000 mg/day (1100 IU synthetic or 1500 IU natural) Adverse effects in healthy individuals rare: GI distress, headache, vision changes, fatigue, creatinuria, gonadal dysfunction May worsen outcomes/mortality for people with various chronic illnesses (diabetes, cardiovascular disease) May antagonize vitamin K–dependent clotting factors (especially at doses >1000 IU), augmenting anticoagulant effects No data on effects on chemotherapy May increase cyclosporine absorption Enhances inhibitory effect of statins on cancer growth (vitamin E succinate) Tocotrienols may inhibit HMG-CoA reductase differently from statins and decrease platelet aggregation Levels decrease with bile acid sequestrants, carbamazepine, chemotherapy, orlistat, phenytoin, phenobarbital Avoid in people with head and neck cancer, at or above 400 IU</p> |
| <p>Vitamin K Group of related compounds: K₁, phytonadione K₂, menaquinone K₃, menadiol acetate K₄, menadiol sodium acetate Coenzyme for synthesis of coagulation factors II, VII, IX, and X, proteins C and S Involved in binding of coagulation factors to platelets Low levels connected to fractures and low bone density; cofactor in osteocalcin synthesis</p> | <p>Anticoagulant overdose (A) Low prothrombin (A) Hemorrhagic disease of newborn (A) Vitamin K₂ used for osteoporosis, to lower cholesterol in dialysis patients K₃ used for treating prostate and breast cancer with vitamin C K₄ for low prothrombin caused by low K absorption or synthesis Topical use for varicose veins and other skin vascular problems</p> | <p>K₁ only K vitamin used in United States K₃ linked to hepatotoxicity Dose is individualized; no “typical” dose Coenzyme Q10 can have K-like effects; do not use concurrently Levels low in atherosclerosis Caution with supplements and drugs with coagulation effects Vitamins A and E can antagonize Should be supplemented in pregnant women taking anticonvulsants Levels decreased in patients taking bile acid sequestrants, antibiotics, mineral oil, orlistat, rifampin Can cause soft tissue calcification in dialysis patients</p> |
| Minerals | | |
| <p>Boron (B) Component of boric acid Biologic role not fully established</p> | <p>Anticoagulation Cognitive function Menopausal symptoms (–) Osteoarthritis Osteoporosis Testosterone level increase (–) Psoriasis (boric acid ointment) (–) Vaginitis (boric acid)</p> | <p>Adverse reactions unlikely except at high doses: testicular toxicity, hair loss, reduced fertility, hypotension, vomiting, lethargy, GI distress May increase estrogen, testosterone levels May lower calcitonin, insulin, phosphorus May increase vitamin D₂, thyroxine, other minerals Magnesium may interfere with effects</p> |

Continued

Table 52-5 Vitamin and Mineral Supplements*—cont'd

| Name | Indications/Evidence | Effects/Interactions/Comments |
|---|--|--|
| <p>Calcium (Ca) Component of bone as hydroxyapatite Involved in nerve transmission, muscle contraction, vasodilation, gland secretion, enzyme reactions, coagulation, renal function, amino acid uptake and binding, B₁₂ absorption, gastrin secretion Absorption varies with age <i>May</i> form insoluble complexes with saturated fatty acids, leading to their excretion Seems to repartition dietary energy from adipose to lean body tissue</p> | <p>Antacid (A) Fluorosis Hyperkalemia (Ca gluconate) (A) Hyperlipidemia Hypocalcemia (A) Hypoparathyroidism (A) Latent tetany Lead poisoning Leg cramps Osteomalacia Osteoporosis (A) Phosphate binder in renal failure (A) PIH prevention PMS (A) Preeclampsia prevention Rickets Stroke prevention Tooth retention Weight loss</p> | <p><i>Upper intake level:</i> 2.5 g daily No scientific studies showing constipation 4 g daily can cause hypercalcemia and milk-alkali syndrome Ca carbonate taken with food; other forms can be taken at any time Absorption is dose dependent. Only 500 mg absorbed at a time. Absorption is decreased by vitamin D deficiency. Can interfere with iron and zinc absorption; decreases magnesium absorption only at >2600 mg/day Decreases absorption of bisphosphonates (take 30 min before Ca or at different time of day), thyroid supplements (take 4 hr apart), quinolones, sotalol, tetracyclines <i>May</i> decrease effects of calcium channel blockers Increases risk of fatal arrhythmias with digoxin Levels increased with thiazide diuretics</p> |
| <p>Chromium (Cr) Chromium III is the form used in supplements Part of glucose tolerance factor and <i>chromodulin</i>, an enzyme that potentiates insulin receptors</p> | <p>Athletic performance Depression Diabetes (types 1 and 2) Lipid alterations in patients taking beta blockers Reactive hypoglycemia Increased muscle mass Obesity</p> | <p><i>May</i> only be helpful in patients with low Cr levels Hair, urine levels do not reflect body levels Cr picolinate, form with best evidence for its use, <i>may</i> enter cells, create free radicals Can cause cognitive, sensory, motor problems at low doses; anemia, hemolysis, thrombocytopenia, liver dysfunction, other disorders at high doses <i>May</i> cause weight gain in women Risk of increased hypoglycemia Levels increased by NSAIDs; decreased by corticosteroids, H₂ blockers, PPIs</p> |
| <p>Copper (Cu) Oxide salt most often used as supplement In bones and muscles Needed for oxidase enzymes that catalyze ATP, dopa, and melatonin formation</p> | <p>Copper deficiency and related anemia (A) Osteoarthritis Osteoporosis Wound healing</p> | <p>Copper toxicity rare: GI effects and risk of liver failure with several years of use Levels decreased by vitamin C, zinc, iron Chelates penicillamine and should be avoided in patients taking it Zidovudine decreases copper levels, but this <i>may</i> confer survival benefit</p> |
| <p>Iron (Fe) (Given as carbonate, fumarate, gluconate, pyrophosphate, sulfate) Component of hemoglobin, cofactor in neurotransmitter synthesis Low levels found in ADHD 1 g of ferrous sulfate = 200 mg elemental Fe 1 g of gluconate = 120 mg elemental Fe 1 g of fumarate = 33 mg elemental Fe</p> | <p>ACE inhibitor cough ADHD Anemia of chronic disease (taken with erythropoietin) (A) Athletic performance Canker sores Crohn's disease Depression Fatigue Female infertility Iron deficiency anemia (A) Menorrhagia</p> | <p><i>Upper level:</i> 45 mg elemental iron daily (40 mg for infants, children); higher doses lead to GI side effects. RDAs much lower. Hemosiderosis and organ damage at higher doses Supplementation may be necessary in children and menstruating or pregnant women. Also watch for deficiency in endurance athletes, vegetarians, and those with a history of hemorrhage. Levels decreased by whole grains, tannins in teas, zinc, antacids, cholestyramine, colestipol, H₂ blockers, pancreatic enzymes, penicillamine, PPIs, quinolones, tetracyclines, calcium, bisphosphonates Can decrease levels of levodopa, methyl dopa, levothyroxine, penicillamine, mycophenolate mofetil, quinolones, tetracyclines</p> |

Table 52-5 Vitamin and Mineral Supplements*—cont'd

| Name | Indications/Evidence | Effects/Interactions/Comments |
|---|---|--|
| <p>Magnesium (Mg) Given as aspartate, carbonate, chloride, citrate, gluconate, hydroxide, lactate, oxide, sulfate, others Involved with >300 enzymatic reactions One third of supply is on bone surfaces Involved in cyclic adenomonophosphate formation, nerve transmission, neuromuscular junction transmission Serum level poorly correlated with body stores Regulated by parathyroid hormone No research supporting claims of optimal calcium/magnesium ratio</p> | <p>ADHD Altitude sickness Allergies, asthma Cardiovascular disease Cerebral edema CHF Chronic fatigue Constipation (A) COPD Diabetes, insulin resistance Dyslipidemia Fibromyalgia GERD (A) Hearing protection Hypomagnesemia (A) Incontinence Leg cramps in pregnancy Lipid abnormalities Migraines Multiple sclerosis Osteoporosis PMS Preeclampsia (A) Renal calculi Restless legs Skin disorders (topical) Stroke Tetanus Torsades de pointes (A) Vasospastic angina</p> | <p><i>Upper intake level:</i> 350 mg/day (often used at higher doses). Diarrhea, thirst, hypotension, fatigue, reflex loss. Two case reports of death. Can cause weakness, arrhythmias, and coma at high doses Deficiency linked to increase substance P and osteoclast activity Levels lower in women with PMS, diabetics, elderly, alcoholics, patients with malabsorption and renal disease Levels decreased by boron, calcium, zinc, amphotericin, beta-2 agonists, cisplatin, cholestyramine, corticosteroids, cyclosporine, digoxin, loop diuretics, quinolones, foscarnet, penicillamine, pentamidine, phosphates (Fleet enemas), tetracyclines Used with aminoglycosides can lead to neuromuscular weakness and paralysis Decreases absorption of quinolones, tetracyclines Levels increased by vitamin D, potassium-sparing diuretics, estrogens Decreases bisphosphonate absorption <i>May</i> have additive effects with calcium channel blockers at high doses <i>May</i> enhance effects of muscle relaxants Mg glycinate results in less diarrhea Caution with supplementation in patients with renal failure</p> |
| <p>Manganese (Mn) Cofactor in several enzymatic reactions</p> | <p>Deficiency states (A) Microcytic anemia Osteoarthritis (usually in combination products) Osteoporosis PMS</p> | <p>Neurotoxicity possible in patients with liver disease Calcium and iron can decrease absorption Zinc can increase levels <i>May</i> decrease quinolone and tetracycline levels</p> |
| <p>Selenium (Se) Antioxidant: activates glutathione peroxidase Promotes T-helper cell growth, development Selenomethionine incorporated into proteins and serves as storage mechanism Food levels depend on food-soil content</p> | <p>Abnormal Pap smears Atherosclerosis Allergic rhinitis Cancer prevention Gray hair HIV/AIDS Heart disease Infertility Low thyroid Miscarriage prevention Mood disorders Osteoarthritis Rheumatoid arthritis</p> | <p><i>Upper intake level:</i> 400 µg daily Toxicity if >910 µg daily: nausea, vomiting, nail changes, fatigue, irritability, weight loss, thrombocytopenia, hepatorenal dysfunction Can inhibit vitamin C absorption. Pregnancy: iron decreases Se accumulation Taken with other supplements, seems to decrease statin and niacin effectiveness <i>May</i> decrease male fertility and increase skin cancer risk at high doses</p> |
| <p>Silver (colloidal) No known physiological function, despite marketing claims</p> | <p>Cancer prevention Chronic fatigue Chronic lung disease Improve digestion Infections (everything from ears and sinuses to TB and plague)</p> | <p>Argyria (blue-gray skin discoloration) possible with long-term use <i>May</i> decrease absorption of thyroid medications, penicillamine, quinolones, tetracyclines</p> |

Continued

Table 52-5 Vitamin and Mineral Supplements*—cont'd

| Name | Indications/Evidence | Effects/Interactions/Comments |
|---|--|--|
| Vanadium (V) Used in bone growth, inhibits ATPases and other phosphorus transfer enzymes May mimic insulin actions on receptors | Athletic performance Diabetes (esp. type 2) Edema Cardiovascular disease Hypoglycemia Hyperlipidemia TB, syphilis | Pentoxide form highly toxic Significant GI effects Can augment effects of hypoglycemic drugs May increase anticoagulant effects Avoid in patients with renal disorders |
| Zinc (Zn) Cofactor in DNA, RNA, protein synthesis Part of >300 enzymes, catalyst for ~100 others Tied to neutrophil, T-lymphocyte, and natural killer cell function May influence cellular glucose transport | ADHD Alzheimer's disease Anorexia nervosa Aphthous ulcers Athletic performance BPH Burns (zinc oxide) Deficiency (A) Eye disorders Hypogeusia IBD Immune booster Infections: treatment, prevention Male impotence, infertility Osteoporosis Skin problems Rheumatoid arthritis Tinnitus URI prevention Wilson's disease (A) | <i>Upper intake level:</i> 40 mg/day Can cause GI effects and metallic taste Can lead to copper deficiency Overdose: nervous system symptoms, severe GI distress, decreased immune function, renal tubular necrosis, interstitial nephritis Too much may reduce magnesium levels Case reports of anosmia with zinc gluconate nasal gel Levels increase with amiloride Levels decreased in malabsorption syndromes, rheumatoid arthritis, and patients taking penicillamine, thiazide and other diuretics, and ACE inhibitors May increase toxicity of cisplatin Decreases absorption of quinolones, tetracyclines May be a link to higher zinc intake and lowered survival time in patients with HIV infection |

Data from Basch EM, Ulbricht CE. Natural Standard Herb and Supplement Handbook: The Clinical Bottom Line. Boston, Elsevier-Mosby, 2005; Mahan LK, Escott-Stump S (eds). Krause's Food Nutrition and Diet Therapy, 11th ed. Philadelphia, Saunders-Elsevier, 2004; and Natural Medicines Comprehensive Database (accessed November 2009).

*Many of the vitamins and minerals listed are used for dozens of different indications; only the most common (and when possible, most researched) indications are listed. Lack of randomized controlled trial (RCT) research is not equivalent to lack of efficacy.

An "A" in parentheses after a supplement name denotes an A rating according to the Strength of Recommendation Taxonomy (SORT). The rating is based on systematic review data summarized primarily in the references by Basch and/or Natural Medicines Comprehensive Database (NMCD). A classification of "A" is assigned if the supplement was rated as one of the following: (1) evidence grade A or B in Basch (indicating strong or good evidence of effect) or (2) rating of "Effective" or "Likely effective" in NMCD, suggesting the same. Not all supplement monographs reach the same conclusions regarding the evidence base for particular supplements. Indications followed by a "(–)" have been rated category D by Basch (indicating "Fair negative scientific evidence") or as "Likely ineffective" by NMCD.

Adverse effects or interactions preceded by "May" are speculative. No case reports or trials have verified their existence.

ACE, Angiotensin-converting enzyme; AIDS, acquired immunodeficiency syndrome; ADHD, attention-deficit hyperactivity disorder; ATP, adenosine triphosphate; BPH, benign prostatic hypertrophy; CAD, coronary artery disease; CHF, congestive heart failure; COPD, chronic obstructive pulmonary disease; CSF, cerebrospinal fluid; DNA, deoxyribonucleic acid; GABA, γ -aminobutyric acid; GERD, gastroesophageal reflux disease; GI, gastrointestinal; H₂, histamine 2, H. pylori, *Helicobacter pylori*; HIV, human immunodeficiency virus; IBD, inflammatory bowel disease; IM, intramuscular; IU, international units; MI, myocardial infarction; NSAIDs, nonsteroidal anti-inflammatory drugs; PIH, pregnancy-induced hypertension; PMS, premenstrual syndrome; PPIs, proton pump inhibitors; RDA, recommended daily allowance; RNA, ribonucleic acid; TB, tuberculosis; URI, upper respiratory infection.

Table 52-6 Common Nutraceuticals*

| Name and Description | Uses/Efficacy | Effects/ Drug Interactions |
|---|---|--|
| Alpha-lipoic acid Coenzyme involved in the production of adenosine triphosphate Antioxidant | Diabetes (type 2) HIV dementia Liver disease Neuroprotective Peripheral neuropathy | Inhibits HIV reverse transcriptase in vitro Temporary worsening of paresthesias at beginning of therapy Most adverse effects are when given IV <i>May</i> lower blood sugars when used with diabetes drugs <i>May</i> be more toxic in thiamine deficiency |
| Acetyl-L-carnitine Exists in the body as part of “carnitine pool” Involved in mitochondrial function Involved in transport of long-chain fatty acids | Cognitive impairment Dementias Male infertility Peripheral neuropathies Peyronie’s disease Testosterone deficiency | <i>May</i> cause GI irritation or agitation Increases sperm motility Increases effects of anticoagulants <i>May</i> reverse zidovudine inhibition of carnitine transport into muscle Deficiency may be caused by taking carbamazepine, phenobarbital, phenytoin, or valproic acid <i>May</i> increase seizures, as reported with L-carnitine <i>May</i> inhibit activity of thyroid hormone; caution in hypothyroidism |
| Antioxidants Compounds that scavenge for free radical electrons in body or prevent formation Vitamins A, C, E; green tea components; selenium; grape seed extract | Cancer prevention and treatment Chronic disease prevention Heart disease prevention | <i>May</i> counteract the effects of various chemotherapeutic and immune-suppression agents (no data for this) Unclear whether or not antioxidant supplements as effective as combinations found in foods |
| Arginine “Semi-essential” amino acid Nitric oxide precursor (vasodilation) | Burn recovery Claudication CAD (–) Erectile dysfunction (benefit in one trial) Ibuprofen arginate for pain control Infertility Interstitial cystitis | Worsens inflammation in asthma Follow potassium levels with diuretic and ACE inhibitor use <i>May</i> raise blood sugar <i>May</i> increase bleeding risk with anticoagulant/antiplatelet drugs |
| Bioflavonoids Plant pigments (provide yellow, red, and orange coloration) Antioxidants Iron chelators See also Quercetin | <i>Diosmin</i> : hemorrhoids <i>Hesperidin</i> : hemorrhoids and venous stasis ulcers <i>Methoxylated bioflavones</i> : cancer prevention <i>Rutin</i> : vascular disorders (e.g., venous stasis, insufficiency); osteoarthritis; stroke prevention | Few known drug interactions or adverse effects Methoxylated bioflavones may induce CYP1A2, decreasing levels of fluvoxamine, beta blockers, olanzapine, zolmitriptan, imipramine, cyclobenzaprine, other medications |
| Choline Often classed as a “B vitamin,” but synthesized by body Precursor of acetylcholine (ACh), but no evidence choline affects brain levels of ACh when supplemented Component of phosphatidylcholine, a component of lecithin | Asthma Age-related cognitive impairment (–) Cerebellar ataxia Depression Huntington’s chorea Liver disease (A for TPN hepatic steatosis) Neural tube defect prevention Performance enhancement Schizophrenia (–) Tourette’s syndrome | Can cause GI distress, diaphoresis, and fishy body odor No drug interactions known |
| Chondroitin Component of cartilage, synthesized or extracted from bovine or shark cartilage | Osteoarthritis (A) | Well tolerated Caution in bleeding disorders or with anticoagulants Structurally similar to heparin; avoid in pregnancy |
| Coenzyme Q10 Essential for cellular function, part of electron transport chain in mitochondria Levels decrease with age | Alzheimer’s disease Angina Athlete performance (–) Cardiomyopathy CHF Gum disease (–) Hypertension (A) Medication-induced cardiac damage Mitochondrial encephalomyelopathy (A) Muscular dystrophy Parkinson’s disease Post-MI | Few side effects <i>May</i> decrease blood sugar levels <i>May</i> affect platelet levels (one case report) Rare liver function test and thyroid hormone elevations <i>May</i> reduce effects of anticoagulants (theoretic) Many drugs seem to lower natural levels in the body, including some antipsychotics, beta blockers, sulfonylureas, metformin, some statins, some TCAs |

Table 52-6 Common Nutraceuticals*—cont'd

| Name and Description | Uses/Efficacy | Effects/ Drug Interactions |
|---|---|--|
| Creatine Synthesized in liver and kidney and liver from amino acids Most adults receive 1-2 g daily in diet | Athlete conditioning (–) CHF Muscular dystrophy Exercise in short bursts made easier Lipid disorders | Used heavily by adolescents above recommended doses Can trigger allergic symptoms May cause muscle cramping, breakdown Link to dehydration, heat intolerance Avoid in renal and liver disease Case report of increased risk of compartment syndrome Probenecid may increase levels May alter blood glucose levels Caution with diuretic use (electrolyte abnormalities) May augment effects of anti-inflammatory drugs |
| Dehydroepiandrosterone (DHEA) Endogenous adrenal hormone Levels decrease after age 30 Levels decrease with anorexia, type 2 diabetes, and other chronic illnesses | Adrenal insufficiency Atherosclerosis Athletic performance Cervical dysplasia Chronic fatigue Crohn's disease Dementia (–) Depression Heart failure HIV Immune booster (–) Lupus Menopause symptoms Mental performance (–) Osteoporosis Ovulation disorders Schizophrenia Sexual performance | May be depleted by insulin, steroids, opiates, danazol Can raise androgen and estrogen levels, possibly increasing risk of hormone-sensitive cancers Adverse events such as palpitations rare Risk of masculinization, increased blood pressure, aggression Monitor thyroid, cholesterol, glucose May alter CYP metabolism May increase coagulation Levels may be increased by calcium channel blockers and alprazolam May contribute to tamoxifen resistance in breast cancer May decrease methadone's effects |
| Ethylenediamine-tetraacetic acid (EDTA) Clawlike molecular structure; binds divalent and trivalent ions | Atherosclerosis Cardiac glycoside heart toxicities (A) Chelating agent (used IV to reduce oxidation; no evidence of benefit) Heavy metal poisoning (A) Hypercalcemia (A) Metal-induced skin rash | Nephrotoxicity in excessive oral doses IV: GI distress, hypotension, dermatitis, pain at infusion site, flulike symptoms, arrhythmias, anemia, urinary urgency May decrease anticoagulant effects Severely decreases serum glucose when taken by insulin users Can decrease potassium levels (caution with diuretics) |
| Fructo-oligosaccharides Plant sugars that occur in plant-based foods (e.g., inulin) | Colon cancer prevention Constipation Inulin used for elevated triglycerides Prebiotic: used to promote growth of healthy intestinal flora | May cause GI discomfort Maintaining healthy gut flora may decrease symptoms of irritable and inflammatory bowel disorders |
| γ-Hydroxybutyrate (GHB) Occurs naturally in brain, especially basal ganglia, as well as kidneys, liver, muscle, and brown fat Metabolite of GABA Induces REM sleep FDA removed from market in 1990, but still widely available Schedule III substance | Alcohol dependence and withdrawal Fibromyalgia sleep disturbance Muscle growth Narcolepsy (FDA approved) Posthypoxic cerebral edema Sexual performance Weight loss | GHB and related compounds linked to 122 reports of serious adverse reactions, including bradypnea and death High doses can cause amnesia and decreased muscle tone Two reports of death, taken with alcohol Can cause dependence Potentiated by benzodiazepines May be antagonized by antipsychotics Near-fatal reactions with ritonavir and saquinavir reported "Date rape" substance |
| Glucosamine Normal constituent of cartilage matrix | Inflammatory bowel disease TMJ disorders Osteoarthritis (A) Venous insufficiency | Well tolerated; rare palpitations May increase cataract risk Proteinuria in several patients (unclear significance) May worsen asthma symptoms May alter drug effects on glucose levels May have more side effects when taken with diuretics |

Table 52-6 Common Nutraceuticals*—cont'd

| Name and Description | Uses/Efficacy | Effects/ Drug Interactions |
|---|--|--|
| Glutamine Most abundant free amino acid in body, made in skeletal muscle Can enhance immune cell function Levels reduced in some cancer patients | Crohn's disease HIV-related wasting Mood disorders Mucositis from chemotherapy Other chemotherapy side effects Posttrauma nutrition | Minimal side effects Theoretic increases in tumor growth have not been found to occur May antagonize some antiepileptics May antagonize antiammonia effects of lactulose Avoid if sensitive to monosodium glutamate (MSG) |
| 5-Hydroxytryptophan (5-HTP) Created from L-tryptophan and converted into serotonin in body | ADHD Anxiety Depression Fibromyalgia Headache Premenstrual syndrome Sleep disorders | Safety controversial May be link to eosinophilia-myalgia syndrome for some products May increase serotonergic and adverse effects of SSRIs and carbidopa, dextromethorphan, meperidine, tramadol |
| Inositol hexaphosphate (IP-6) Major phosphorus storage compound in plants; 1%-7% of weight of most cereals, nuts, and legumes Reduces formation of calcium, oxalate crystals | Antioxidant CAD prevention Cancer treatment and prevention Immune system enhancement Renal calculi | May increase anticoagulant effects (not demonstrated in humans) May decrease mineral absorption (e.g., calcium, iron, zinc) No adverse reactions reported |
| Lutein Accounts for 11% of carotenoids in serum and 22% in adipose tissue Antioxidant Thought to filter harmful blue-spectrum light | Cataracts Cancer prevention (colon) Macular degeneration | Most benefits found in epidemiologic studies; benefits of supplementation unclear Beta-carotene may reduce lutein bioavailability Dose is 6-10 mg/day for eye benefit in studies; many products contain much less |
| Lycopene Carotenoid found in serum, liver, adrenals, prostate, colon, skin, lungs at relatively high levels Derived from tomatoes | Antioxidant Asthma Atherosclerosis Cancer prevention Macular degeneration | Unclear if benefits found for diets high in fruits and vegetables apply for supplementation Limited studies of adverse effects May contribute to increased gastric acidity |
| Melatonin Neurohormone produced in pineal gland from tryptophan Has antioxidant activity | ADHD Benzodiazepine tapering Cancer, HIV, other chronic illnesses Cluster headache Delayed sleep phase syndrome (A) Depression (–) Glaucoma Insomnia in elderly (A) Jet lag (A) Mood disorders Seizures Sleep enhancement in healthy people (A) Stroke | Generally safe; seizures, disorientation, clotting problems with overdose May cause sleepiness, headache, mood changes, blood pressure drop, and hyperglycemia in type 1 diabetics May alter other hormone levels Levels may increase with CYP1A2 inhibitors: amiodarone, cimetidine, ciprofloxacin, SSRIs, TCAs, clarithromycin, erythromycin, ethinyl estradiol, isoniazid May augment effects of sedatives Avoid with antiseizure medications, especially in children May augment methamphetamine side effects May enhance isoniazid as TB treatment |
| Methylsulfonylmethane (MSM) Metabolite of dimethylsulfoxide Source of sulfur for amino acids Found in horsetail, algae, fruits, grains | Arthritis Chronic pain Gum disease Rhinitis Scars, stretch marks Scleroderma Snoring (nose drops) | No adverse effects or drug interactions reported Limited research into efficacy |

Continued

Table 52-6 Common Nutraceuticals*—cont'd

| Name and Description | Uses/Efficacy | Effects/ Drug Interactions |
|---|--|---|
| <p>N-acetylcysteine (NAC) Derivative of the amino acid L-cysteine Precursor of antioxidant, glutathione Decreases inflammatory mediators</p> | <p>Acetaminophen, carbon monoxide, and other poisonings (A) Alzheimer's (–) Angina Atelectasis (A) Cancer treatment (–) for head, neck, lung cancer Cardioprotection Cystic fibrosis (A) Mucolytic (A) Pulmonary disease</p> | <p>Significant GI distress for some patients when taken orally Can decrease effectiveness of charcoal Severe headache and hypotensive effect taken with nitroglycerine</p> |
| <p>NADH (reduced nicotinamide adenine dinucleotide) Involved in the production of ATP from glucose</p> | <p>Cardioprotection Chronic fatigue Dementia Depression Jet lag Mental performance</p> | <p>No evidence of adverse effects or drug interactions</p> |
| <p>Omega-3 fatty acids Contain docosahexaenoic and eicosapentaenoic acids, essential fatty acids Tend to be metabolized into anti-inflammatory compounds Alpha-linolenic acid also considered omega-3 acid (see entry)</p> | <p>Bipolar disorder CAD prevention (A) Cancer anorexia (–) Colon cancer Cyclosporine toxicity in transplant patients (A) Diabetes (–) Hypercholesterolemia (–) Hypertension (A) Hypertriglyceridemia (A) IBD Lupus Preeclampsia Rheumatoid arthritis (A)</p> | <p>Greater than 3 g/day may increase bleeding risk Tend not to contain heavy metals GI upset common (5%); may help to change brands No significant long-term glucose effects Increased LDL levels by 5%-10% Rare reports of increase liver enzymes</p> |
| <p>Phosphatidylserine Most abundant fat-soluble phospholipid in brain, used for signal transduction, membrane stability Most is obtained from foods</p> | <p>ADHD Age-related cognitive impairment Athletic performance Dementias Depression</p> | <p>No adverse effects or drug side effects noted Lowers ALT level</p> |
| <p>Probiotics Bacterial compounds ingested to fortify or replenish populations of healthy gut flora Most species used are lactobacilli, bifidobacteria, and the yeast <i>S. boulardii</i> (related to baker's yeast)</p> | <p>Bacterial vaginosis (A) Diarrhea prevention (A): <i>Clostridium difficile</i>, irritable bowel syndrome; IBD "Leaky gut" prevention and treatment (absorption of large, allergenic molecules through GI tract) Lipid disorders Rotavirus treatment</p> | <p>Caution in severely immunocompromised patients Take 2-3 hours after antibiotic to avoid killing organisms May reduce effectiveness of sulfasalazine May prolong effects of benzodiazepines or oral contraceptives (theoretic) Products are variable regarding number of live organisms</p> |
| <p>Quercetin Bioflavonoid (rutin is a derivative) Antioxidant, anti-inflammatory, and antihistamine properties In vitro decreases of T-cell and cancer cell growth</p> | <p>Allergies Atherosclerosis Cancer prevention Lipid disorders Prostatitis</p> | <p>Orally: can cause headache, tingling of extremities IV: can cause flushing</p> |
| <p>Ribose Pentose sugar supplied by pentose phosphate pathway Precursor for adenine nucleotide synthesis</p> | <p>Athletic performance Enhance energy Heart failure Myocardial ischemia Stiffness after exercise</p> | <p>Can decrease blood glucose levels and may enhance glucose-lowering effects of drugs</p> |

Table 52-6 Common Nutraceuticals*—cont'd

| Name and Description | Uses/Efficacy | Effects/ Drug Interactions |
|---|---|---|
| SAMe (SAM-e) (S-adenosyl-L-methionine) Often called "sammy" Found in all body tissues and fluids, used in >100 transmethylation reactions May stimulate cartilage growth | Alcoholic liver disease Dementia Depression ("A" for major depression treated IV) Fibromyalgia Low back pain Osteoarthritis (A) Premenstrual syndrome | Can precipitate manic episodes in bipolar patients Metabolized to homocysteine, but not shown to elevate serum homocysteine levels May augment serotonergic effects of SSRIs, meperidine Caution with MAOIs May counteract effects of levodopa in Parkinson's disease |
| Shark cartilage | Arthritis Cancer (–) Macular degeneration Pain | Generally safe May contain high levels of calcium May block formation of collateral vessels Frequent GI side effects |

Data from Basch EM, Ulbricht CE. Natural Standard Herb and Supplement Handbook: The Clinical Bottom Line. Boston, Elsevier-Mosby, 2005; Mahan LK, Escott-Stump S (eds). Krause's Food Nutrition and Diet Therapy, 11th ed. Philadelphia, Saunders-Elsevier, 2004; and Natural Medicines Comprehensive Database (accessed November 2009).

*Many of the nutraceuticals listed are used for dozens of different indications; only the most common (and when possible, most researched) indications are listed. Lack of randomized controlled trial (RCT) research is not equivalent to lack of efficacy.

An "A" in parentheses after a supplement name denotes an A rating according to the Strength of Recommendation Taxonomy (SORT). The rating is based on systematic review data summarized primarily in the references by Basch and/or Natural Medicines Comprehensive Database (NMCD). A classification of "A" is assigned if the supplement was rated as one of the following: (1) evidence grade A or B in Basch (indicating strong or good evidence of effect) or (2) rating of "Effective" or "Likely effective" in NMCD, suggesting the same. Not all supplement monographs reach the same conclusions regarding the evidence base for particular supplements. Indications followed by a "(–)" have been rated category D by Basch (indicating "Fair negative scientific evidence") or as "Likely ineffective" by NMCD.

Adverse effects or interactions preceded by "May" are speculative. No case reports or trials have verified their existence.

ACE, Angiotensin-converting enzyme; ADHD, attention-deficit hyperactivity disorder; ALT, alanine transaminase; ATP, adenosine triphosphate; CAD, coronary artery disease; CHF, congestive heart failure; CYP, cytochrome P-450; FDA, Food and Drug Administration; GABA, γ -aminobutyric acid; GI, gastrointestinal; HIV, human immunodeficiency virus; IBD, inflammatory bowel disease; IV, intravenously; LDL, low-density lipoprotein; MAOIs, monoamine oxidase inhibitors; MI, myocardial infarction; REM, rapid eye movement; SSRIs, selective serotonin reuptake inhibitors; TB, tuberculosis; TCAs, tricyclic antidepressants; TMJ, temporomandibular joint; TPN, total parenteral nutrition.

frequently used supplements in 2007, combination supplements were ranked sixth (Kennedy et al., 2008). In Chinese herbal formulations, at least eight different compounds may be mixed together, and the same may be true for Ayurvedic and other remedies. Many products contain a mix of botanicals, vitamins and minerals, and nutraceuticals.

In addressing questions or safety issues related to mixed supplements, it is important to consider each ingredient separately, based on the guidelines listed in Box 52-1. It should be remembered that there are often instances where products used in combination may have a synergistic—or occasionally an antagonistic—effect on one another. Table 52-7 lists a number of supplements that have particularly strong research supporting their use.

EVIDENCE-BASED SUMMARY

- Dietary supplements, including those that are nonvitamin and nonmineral, are widely used (Strength of Recommendation Taxonomy [SORT] Grade A).
- Many people do not inform their physicians about their supplement use (SORT A).
- It is beneficial for family physicians to be well versed in advising patients regarding dietary supplements (SORT C).
- The body of good-quality research related to dietary supplements is increasing, with studies showing variable levels of efficacy depending on the supplements evaluated (SORT A).

Table 52-7 Supplements with Particularly Strong Research Supporting Their Use*

| Supplement | Indication | Citation(s) |
|----------------------|--|---|
| Cat's claw | Joint pain | Erowele and Kalejaiye, 2009; Piscocoy et al., 2001 |
| Coenzyme Q10 | Hypertension (~17 mm Hg systolic, 10 mm Hg diastolic) | Rosenfeldt et al., 2007 |
| Cranberry | Urinary tract infection prophylaxis | Jepson and Craig, 2008 |
| Ginger | Nausea and vomiting in pregnancy | Smith et al., 2004; White, 2007 |
| Glucosamine sulfate† | Delay of arthritis progression (especially in knee) | Black et al., 2009; Towheed et al., 2005 |
| Hawthorn | Stage I or II heart failure | Pittler et al., 2008 |
| Horse chestnut | Chronic venous insufficiency | Pittler and Ernst, 2006 |
| Melatonin | Jet lag; sleep in individuals with intellectual disability | Bram et al., 2009; Herxheimer and Petrie, 2005 |
| Milk thistle | Cirrhosis | Saller et al., 2001 |
| Omega-3 fatty acids‡ | Hypertriglyceridemia | Laidlaw and Holub, 2003 |
| Peppermint oil | Irritable bowel syndrome | Merat et al., 2009 |
| Probiotics | Irritable bowel syndrome (especially <i>Bifidum infantis</i>); antibiotic-associated diarrhea; traveler's diarrhea) | Brenner et al., 2009; Doron et al., 2008; McFarland, 2007 |
| St. John's wort | Mild to moderate depression | Linde et al., 2009 |
| Valerian | Insomnia (some studies show only modest overall benefit) | Bent et al., 2006; Hadley and Petry, 2004 |

*All herbs listed have Strength of Recommendation (SOR) classification of A.

†In many cases, although much favorable evidence exists for various supplements, including those listed, meta-analyses often reveal discrepancies among trial findings. With glucosamine, for example, an overall benefit was seen using *some* osteoarthritis symptom scales with and using *some* products (the sulfate form seems to be more effective than glucosamine hydrochloride). For many of the supplements mentioned in this chapter, it is difficult to say with absolute certainty that efficacy has consistently been proven. Of course, the same often holds true for pharmaceuticals. It is important that family physicians also note the potential risk to the patient when using a given supplement. For example, glucosamine was found to be equivalent to placebo in terms of adverse effects, and St. John's wort tends to have fewer side effects than antidepressants.

‡Although omega-3 fatty acids are now recommended by the American Heart Association for the treatment of lipid abnormalities, "It is not clear that dietary or supplemental omega 3 fats alter total mortality, combined cardiovascular events, or cancers in people with or at high risk of cardiovascular disease in the general population" (Hooper et al., 2006). Again, the question becomes how to interpret the available data in a clinically meaningful way. Harms from omega-3 fatty acids appear to be minimal.

Web Resources

<http://nccam.nih.gov/health/herbsatagance.htm>

National Center for Complementary and Alternative Medicine site on herbs.

www.cfsan.fda.gov/~dms/ds-savvy.html

Good overall patient handout regarding safe use of supplements.

www.naturaldatabase.com

Subscription site offering up-to-date monographs on most popular supplements; lists ingredients for different commercial products and allows search by indication as well. Evidence for efficacy rated when available.

www.consumerlab.com

Charges small subscription fee, which is used to support research evaluating whether or not supplements contain the components their labels claim. Findings can often be a concern from a product quality standpoint.

www.naturalstandard.com

Subscription site with excellent bibliographic data for various supplements.

www.drugdigest.org

Free site, searchable by supplement or drug names and indications. The user can create a list of medications and supplements and check for any interactions between/among products in that list. Useful site to recommend to patients.

www.phytotherapies.org

Free site with registration, geared toward herbalists and professionals who prescribe botanicals; numerous monographs on different herbal supplements, as well as current news stories.

www.mdanderson.org/departments/CIMER

Well-designed free site by the University of Texas M.D. Anderson Cancer Center. Searchable for evidence related to supplements as well as research relating to other complementary and alternative/integrative medicine modalities. Supplement information is primarily for botanicals.

<http://ods.od.nih.gov/index.aspx>

National Institutes of Health Office of Dietary Supplements; has a series of well-done monographs, a number of which focus on vitamins and other nonherb supplements.

www.herbs.org

Herb Research Foundation; site is free but funded by registration fees; has useful news updates.

<http://www.americanherbalistsguild.com/>

American Herbalist Guild; click on "Find an Herbalist" to look for guild members to whom referrals could be made.

www.naturopathic.org.

American Association of Naturopathic Physicians; click on "Find" at the top of homepage to find "naturopaths" in a particular city or state.

www.InteractionReport.org/

Website for submitting case reports of supplement-related interactions.

All websites accessed November 2009.

Refer also to texts and articles cited in online references for this chapter.

Note that supplement information, particularly for herbs, vitamins, and minerals, is offered now in "mainstream" medical resources and databases, such as UpToDate, MDConsult, Epocrates, MedLine, and the Family Practice Inquiries Network (FPIN).
