Notice

Knowledge and best practice in this field are constantly changing. As new research and experience broaden our understanding, changes in research methods, professional practices, or medical treatment may become necessary.

Practitioners and researchers must always rely on their own experience and knowledge in evaluating and using any information, methods, compounds, or experiments described herein. In using such information or methods they should be mindful of their own safety and the safety of others, including parties for whom they have a professional responsibility.

With respect to any drug or pharmaceutical products identified, readers are advised to check the most current information provided (i) on procedures featured or (ii) by the manufacturer of each product to be administered, to verify the recommended dose or formula, the method and duration of administration, and contraindications. It is the responsibility of practitioners, relying on their own experience and knowledge of their patients, to make diagnoses, to determine dosages and the best treatment for each individual patient, and to take all appropriate safety precautions. To the fullest extent of the law, neither the Publisher nor the authors, contributors, or editors, assume any liability for any injury and/or damage to persons or property as a matter of products liability, negligence or otherwise, or from any use or operation of any methods, products, instructions, or ideas contained in the material herein.

*To our wives, **Peggy and Denise***

*To all primary care health professionals:
Our common goal is to achieve the very best outcome for our patients.*

Preface

The *Textbook of Family Practice* was first published in 1973, just as the new specialty of Family Practice was being established. In 2005 the American Board of Family Practice changed its name to the American Board of Family Medicine, and this eighth edition reflects that name change.

For the first time this entire edition is available as an electronic version that can be accessed online. Additional material is available online, including 30 procedural videos from Elsevier's Procedures Consult.

In this edition, David Rakel, Associate Professor of Family Medicine at the University of Wisconsin, joins his father as co-editor.

This text is designed to be a resource for family physicians to help them remain current with recent advances in medicine. It will be especially valuable to the family physician preparing for certification or recertification by the American Board of Family Medicine.

Our goal is to serve as a resource for all health professionals responsible for providing primary care to patients, especially those professionals who may not have been adequately trained in the large variety of areas that make up comprehensive primary care.

Almost all authors are family physicians. For the clinical chapters we have continued the policy established in the

first edition of having an authority in the field co-author the chapter with an experienced family physician to ensure that the information is current and relevant to the needs of the family physician.

The use of color in this edition enhances the rapid retrieval of essential information by highlighting Key Points and other essential information. Also included are more than 1000 tables and illustrations. The strength of recommendation taxonomy (SORT) in the Key Treatment boxes is used to indicate the strength of the evidence, focusing primarily on Grade A recommendations.

Although this text focuses on problems most frequently encountered by the family physician, significant attention is also paid to the diagnosis of potentially serious problems that would be dangerous if missed. Diagnosing a problem in its early, undifferentiated stage is much more difficult than after symptoms have progressed to the point that the diagnosis is evident. Early diagnosis and treatment decreases morbidity and is much more cost effective.

Our thanks to the staff at Elsevier and for their high standards and insistence on quality.

Key Points

- The rewards in family medicine come from knowing patients intimately over time and sharing their trust, respect, and friendship, as well as from the variety of problems encountered in practice that keep the family physician professionally stimulated and challenged.
- The American Board of Family Practice was established in 1969 and changed its name to the American Board of Family Medicine in 2004. It was the first specialty board to require recertification every 7 years to ensure ongoing competence of its diplomates.
- The American Academy of Family Physicians (AAFP) began as the American Academy of General Practice in 1947 and was renamed in 1971.
- Primary care is the provision of continuing, comprehensive care to a population undifferentiated by gender, disease, or organ system.
- The most challenging diagnoses are those for diseases or disorders in their early, undifferentiated stage, when there are often only subtle differences between serious disease and minor ailments.
- The family physician is the conductor, orchestrating the skills of a variety of health professionals that may be involved in the care of a seriously ill patient.
- The most cost-effective health care systems depend on a strong primary care base. The United States has the most expensive health care system in the world but ranks among the worst in overall quality of care because of its weak primary care base.
- The greater the number of primary care physicians in a country, the lower is the mortality rate and the lower the cost.

The family physician provides continuing, comprehensive care in a personalized manner to patients of all ages, regardless of the presence of disease or the nature of the presenting complaint. Family physicians accept responsibility for managing an individual's total health needs while maintaining an intimate, confidential relationship with the patient.

Family medicine emphasizes continuing responsibility for total health care—from the first contact and initial assessment through the ongoing care of chronic problems. Prevention and early recognition of disease are essential features of the discipline. Coordination and integration of all necessary health services (minimizing fragmentation) and the skills to manage most medical problems allow family physicians to provide cost-effective health care.

Family medicine is a specialty that shares many areas of content with other clinical disciplines, incorporating this shared knowledge and using it uniquely to deliver primary medical care. In addition to sharing content with other medical specialties, family medicine emphasizes knowledge from areas such as family dynamics, interpersonal relations, counseling, and psychotherapy. The specialty's foundation remains clinical, with the primary focus on the medical care of people who are ill.

The curriculum for training family physicians is designed to represent realistically the skills and body of knowledge that the physicians will require in practice. This curriculum is based on an analysis of the problems seen and the skills used by family physicians in their practice. The randomly educated primary physician has been replaced by one specifically prepared to address the types of problems likely to be encountered in practice. For this reason, the "model office" is an essential component of all family practice residency programs.

The Joy of Family Practice

If you cannot work with love but only with distaste, it is better that you should leave your work and sit at the gate of the temple and take alms from those who work with joy.

Kahlil Gibran (1883–1931)

The rewards in family medicine come largely from knowing patients intimately over time and sharing their trust, respect, and friendship. The thrill is the close bond (friendship) that develops with patients. This bond is strengthened with each physical or emotional crisis in a person's life, when he or she turns to the family physician for help. It is a pleasure going to the office every day and a privilege to work closely with people who value and respect our efforts.

The practice of family medicine involves the joy of greeting old friends in every examining room, and the variety of problems encountered keeps the physician professionally stimulated and perpetually challenged. In contrast, physicians practicing in narrow specialties often lose their enthusiasm for medicine after seeing the same problems every day. The variety in family practice sustains the excitement and precludes boredom. Our greatest days in practice are when we are fully focused on our patients, enjoying to the fullest the experience of working with others.

Patient Satisfaction

Attributes considered most important for patient satisfaction are listed in Table 1-1 (Stock Keister et al., 2004a). Overall, people want their primary care doctor to meet five basic criteria: "to be in their insurance plan, to be in a location that is convenient, to be able to schedule an appointment within a reasonable period of time, to have good communication skills, and to have a reasonable amount of experience in practice." They especially want "a physician who listens to them, who takes the time to explain things to them, and who is able to effectively integrate their care" (Stock Keister et al., 2004b, p. 2312).

Patient satisfaction correlates strongly with physician satisfaction, and physicians satisfied with their careers are more likely to provide better health care than dissatisfied physicians. If physicians do not enjoy their jobs, their patients are not likely to be happy with these physicians' job performance.

Physician Satisfaction

Physician satisfaction is associated with quality of care, particularly as measured by patient satisfaction. The strongest factors associated with physician satisfaction are not personal income, but rather the ability to provide high-quality care to patients. Physicians are most satisfied with their practice when they can have an ongoing relationship with their patients, the freedom to make clinical decisions without financial conflicts of interest, adequate time with patients, and sufficient communication with specialists (DeVoe et al., 2002). Landon and colleagues (2003) found that rather than declining income, the strongest predictor of decreasing satisfaction

Table 1-1 What Patients Want in a Physician

- Does not judge.
- Understands and supports me.
- Is always honest and direct.
- Acts as a partner in maintaining my health.
- Treats serious and nonserious conditions.
- Attends to my emotional as well as physical health.
- Truly listens to me.
- Encourages me to lead a healthier lifestyle.
- Tries to get to know me.
- Can help with any problem.
- Is someone I can stay with as I grow older.

Modified from Stock Keister MC, Green LA, Kahn NB, et al. What people want from their family physician. *Am Fam Physician* 2004;69:2310.

in practice is loss of clinical autonomy. This includes the inability to obtain services for their patients, control their time with patients, and the freedom to provide high-quality care.

In an analysis of 33 specialties, Leigh and associates (2002) found that physicians in high-income "procedural" specialties, such as obstetrics-gynecology, otolaryngology, ophthalmology, and orthopedics, were the most dissatisfied. Physicians in these specialties and those in internal medicine were more likely than family physicians to be dissatisfied with their careers. Among the specialty areas most satisfying was geriatrics. Because the population older than 65 years in the United States has doubled since 1960 and will double again by 2030, it is important that we have sufficient primary care physicians to care for them. The need for and the rewards of this type of practice must be communicated to students before they decide how to spend the rest of their professional lives. Overall, 70% of U.S. physicians are satisfied with their career, with 40% being very satisfied and only 20% dissatisfied (Leigh et al., 2002).

Development of the Specialty

As long ago as 1923, Francis Peabody commented that the swing of the pendulum toward specialization had reached its apex, and that modern medicine had fragmented the health care delivery system too greatly. He called for a rapid return of the generalist physician who would give comprehensive, personalized care.

Dr. Peabody's declaration proved to be premature; neither the medical establishment nor society was ready for such a proclamation. The trend toward specialization gained momentum through the 1950s, and fewer physicians entered general practice. In the early 1960s, leaders in the field of general practice began advocating a seemingly paradoxical solution to reverse the trend and correct the scarcity of general practitioners—the creation of still another specialty. These physicians envisioned a specialty that embodied the knowledge, skills, and ideals they knew as primary care. In 1966 the concept of a new specialty in primary care received official recognition in two separate reports published 1 month apart. The first was the report of the Citizens' Commission on Medical Education of the American Medical Association, also known as the Millis Commission Report.

The second report came from the Ad Hoc Committee on Education for Family Practice of the Council of Medical Education of the American Medical Association, also called the Willard Committee (1966). Three years later, in 1969, the American Board of Family Practice (ABFP) became the 20th medical specialty board. The name of the specialty board was changed in 2004 to the *American Board of Family Medicine* (ABFM).

Much of the impetus for the Millis and Willard reports came from the American Academy of General Practice, which was renamed the *American Academy of Family Physicians* (AAFP) in 1971. The name change reflected a desire to increase emphasis on family-oriented health care and to gain academic acceptance for the new specialty of family practice.

Specialty Certification

The ABFM has distinguished itself by being the first specialty board to require recertification, now called *maintenance of certification*, every 7 years, to ensure the ongoing competence of its members.

In the basic requirements for certification and recertification, the ABFM has included *continuing education* (CE), the foundation on which the American Academy of General Practice had been built when organized in 1947. A *diplomat* of the ABFM must complete 300 hours of acceptable CE activity every 6 years and one self-assessment module per year over the Internet to be eligible for recertification. Once eligible, a candidate's competence is examined by cognitive testing and a performance in practice evaluation. The ABFM's emphasis on quality of education, knowledge, and performance has facilitated the rapid increase in prestige for the family physician in the U.S. health care system.

The logic of the ABFM's emphasis on continuing education to maintain required knowledge and skills has been adopted by other specialties and state medical societies. All specialty boards are now committed to the concept of recertification to ensure that their diplomates remain current with advances in medicine.

The four components of "maintenance of certification" by the ABFM are professional standing, lifelong learning and self-assessment, cognitive expertise, and practice performance assessment. The ABFM also offers subspecialty certificates called *certificates of added qualifications* in five areas: adolescent medicine, geriatric medicine, hospice and palliative medicine, sleep medicine, and sports medicine. Combined residency programs are available at some institutions combining family medicine and emergency medicine or psychiatry. The combined residency makes candidates available for certification by both specialty boards with 1 year less of training than that required for two separate residencies, through appropriate overlap of training requirements.

Definitions

Family Medicine

Family medicine is the medical specialty that provides continuing and comprehensive health care for the individual and the family. It is the specialty in breadth that integrates the biologic, clinical, and behavioral sciences. The scope of

family medicine encompasses all ages, both genders, each organ system, and every disease entity (AAFP, 2009).

In many countries, the term *general practice* is synonymous with *family medicine*. The Royal New Zealand College of General Practitioners emphasizes that a general practitioner provides care that is "anticipatory as well as responsive and is not limited by the age, sex, race, religion, or social circumstances of patients, nor by their physical or mental states." The general practitioner must be the patient's advocate; must be competent, caring, and compassionate; must be able to live with uncertainty; and must be willing to recognize limitations and refer when necessary (Richards, 1997).

Family Physician

The family physician is a physician who is educated and trained in the discipline of family medicine. Family physicians possess distinct attitudes, skills, and knowledge that qualify them to provide continuing and comprehensive medical care, health maintenance, and preventive services to each member of a family regardless of gender, age, or type of problem (i.e., biologic, behavioral, or social). These specialists, because of their background and interactions with the family, are best qualified to serve as each patient's advocate in all health-related matters, including the appropriate use of consultants, health services, and community resources (AAFP, 2009).

The World Organization of Family Doctors (World Organization of National Colleges, Academies and Academic Associations of General Practitioners/Family Physicians [WONCA]) defines the "family doctor" in part as the physician who is primarily responsible for providing comprehensive health care to every individual seeking medical care, arranging for other health personnel to provide services when necessary. The family physician functions as a generalist who accepts everyone seeking care, whereas other health providers limit access to their services on the basis of age, gender, or diagnosis (WONCA, 1991, p. 2).

Primary Care

Primary care is health care that is accessible, comprehensive, coordinated, and continuing. It is provided by physicians specifically trained for and skilled in comprehensive first-contact and continuing care for ill persons or those with an undiagnosed sign, symptom, or health concern (i.e., the "undifferentiated" patient) and is not limited by problem origin (i.e., biologic, behavioral, or social), organ system, or gender.

In addition to diagnosis and treatment of acute and chronic illnesses, primary care includes health promotion, disease prevention, health maintenance, counseling, and patient education in a variety of health care settings (e.g., office, inpatient, critical care, long-term care, home care). Primary care is performed and managed by a personal physician, using other health professionals for consultation or referral as appropriate.

Primary care is the backbone of the health care system and encompasses the following functions:

1. It is *first-contact care*, serving as a point of entry for the patient into the health care system.
2. It includes *continuity* by virtue of caring for patients in sickness and in health over some period.

3. It is *comprehensive care*, drawing from all the traditional major disciplines for its functional content.
4. It serves a *coordinative function* for all the health care needs of the patient.
5. It assumes *continuing responsibility* for individual patient follow-up and community health problems.
6. It is a highly personalized type of care.

In a 2008 report, *Primary Health Care—Now More than Ever*, the World Health Organization (WHO) emphasizes that primary care is the best way of coping with the illnesses of the 21st century, and that better use of existing preventive measures could reduce the global burden of disease by as much as 70%. Rather than drifting from one short-term priority to another, countries should make prevention equally important as cure and focus on the rise in chronic diseases that require long-term care and strong community support. Furthermore, at the 62nd World Health Assembly in 2009, WHO strongly reaffirmed the values and principles of primary health care as the basis for strengthening health care systems worldwide.

Primary Care Physician

A primary care physician is a generalist physician who provides definitive care to the undifferentiated patient at the point of first contact and takes continuing responsibility for providing the patient's care. Primary care physicians devote most of their practice to providing primary care services to a defined population of patients. The style of primary care practice is such that the personal primary care physician serves as the entry point for substantially all the patient's medical and health care needs. Primary care physicians are advocates for the patient in coordinating the use of the entire health care system to benefit the patient (AAFP, 2009).

Patients want a physician who is attentive to their needs and skilled at addressing them, and with whom they can establish a lifelong relationship. They want a physician who can guide them through the evolving, complex U.S. health care system.

The ABFM and the American Board of Internal Medicine have agreed on a definition of the generalist physician, and they believe that "providing optimal generalist care requires broad and comprehensive training that cannot be gained in brief and uncoordinated educational experiences" (Kimball and Young, 1994, p. 316).

The Council on Graduate Medical Education (COGME) and the Association of American Medical Colleges (AAMC) define generalist physicians as those who have completed 3-year training programs in family medicine, internal medicine, or pediatrics and who do not subspecialize. COGME emphasizes that this definition should be "based on an objective analysis of training requirements in disciplines that provide graduates with broad capabilities for primary care practice."

Unfortunately, the number of students entering primary care continues to decline. "In 2009, for the 12th straight year, the number of graduating U.S. medical students choosing primary care residencies reached dismally low levels" (Bodenheimer et al., 2009).

Physicians who provide primary care should be trained specifically to manage the problems encountered in a pri-

mary care practice. Rivo and associates (1994) identified the common conditions and diagnoses that generalist physicians should be competent to manage in a primary care practice and compared these with the training of the various "generalist" specialties. They recommended that the training of generalist physicians include at least 90% of the key diagnoses. By comparing the content of residency programs, they found that this goal was met by family practice (95%), internal medicine (91%), and pediatrics (91%), but that obstetrics-gynecology (47%) and emergency medicine (42%) fell far short of this goal.

Personalized Care

It is much more important to know what sort of patient has a disease than what sort of disease a patient has.

Sir William Osler (1904)

In the 12th century, Maimonides said, "May I never see in the patient anything but a fellow creature in pain. May I never consider him merely a vessel of disease" (Friedenwald, 1917). If an intimate relationship with patients remains the primary concern of physicians, high-quality medical care will persist, regardless of the way it is organized and financed. For this reason, family medicine emphasizes consideration of the individual patient in the full context of her or his life, rather than the episodic care of a presenting complaint.

Family physicians assess the illnesses and complaints presented to them, dealing personally with most and arranging special assistance for a few. The family physician serves as the patients' advocate, explaining the causes and implications of illness to patients and families, and serves as an advisor and confidant to the family. The family physician receives great intellectual satisfaction from this practice, but the greatest reward arises from the depth of human understanding and personal satisfaction inherent in family practice.

Patients have adjusted somewhat to a more impersonal form of health care delivery and frequently look to institutions rather than to individuals for their health care; however, their need for personalized concern and compassion remains. Tumulty (1970) found that patients believe a good physician is one who shows genuine interest in them; who thoroughly evaluates their problem; who demonstrates compassion, understanding, and warmth; and who provides clear insight into what is wrong and what must be done to correct it.

Ludmerer (1999a) focused on the problems facing medical education in this environment:

Some managed care organizations have even urged that physicians be taught to act in part as advocates of the insurance payer rather than the patients for whom they care (p. 881). . . . Medical educators would do well to ponder the potential long-term consequences of educating the nation's physicians in today's commercial atmosphere in which the good visit is a short visit, patients are "consumers," and institutional officials speak more often of the financial balance sheet than of service and the relief of patients' suffering (p. 882).

Cranshaw and colleagues (1995) discussed the ethics of the medical profession:

Our first obligation must be to serve the good of those persons who seek our help and trust us to provide it. Physicians, as physicians, are not, and must never be, commercial entrepreneurs, gate closers, or agents of fiscal policy that runs counter to our trust. Any defection from primacy of the patient's well-being places the patient at risk by treatment that may compromise quality of or access to medical care. . . . Only by caring and advocating for the patient can the integrity of our profession be affirmed (p. 1553).

Caring

Caring without science is well-intentioned kindness, but not medicine. On the other hand, science without caring empties medicine of healing and negates the great potential of an ancient profession. The two complement and are essential to the art of doctoring.

(Lown, 1996, p. 223)

Family physicians do not just treat patients; they care for people. This caring function of family medicine emphasizes the personalized approach to understanding the patient as a person, respecting the person as an individual, and showing compassion for his or her discomfort. The best illustration of a caring and compassionate physician is "The Doctor" by Sir Luke Fildes (Figure 1-1). The painting shows a physician at the bedside of an ill child in the preantibiotic era. The physician in the painting is Dr. Murray, who cared for Sir Luke Fildes's son, who died Christmas morning 1877. The painting has become the symbol for medicine as a caring profession.

Compassion

The treatment of a disease may be entirely impersonal; the care of a patient must be completely personal.

Francis Peabody (1930)

Compassion means co-suffering and reflects the physician's willingness somehow to share the patient's anguish and understand what the sickness means to that person. Compassion is an attempt to feel along with the patient. Pellegrino (1979, p. 161) said, "We can never feel with another person when we pass judgment as a superior, only when we see our own frailties as well as his." A compassionate authority figure is effective only when others can receive the "orders" without being humiliated. The physician must not "put down" the patients, but must be ever ready, in Galileo's words, "to pronounce that wise, ingenuous, and modest statement—'I don't know.'" Compassion, practiced in these terms in each patient encounter, obtunds the inherent dehumanizing tendencies of the current highly institutionalized and technologically oriented patterns of patient care.

Figure 1-1 "The Doctor" by Sir Luke Fildes, 1891. © Tate, London, 2005.

The family physician's relationship with each patient should reflect compassion, understanding, and patience, combined with a high degree of intellectual honesty. The physician must be thorough in approaching problems but also possess a sense of humor. He or she must be capable of encouraging in each patient the optimism, courage, insight, and the self-discipline necessary for recovery.

Bulger (1998) addressed the threats to scientific compassionate care in the managed-care environment:

With health care time inordinately rationed today in the interest of economy, Americans could organize themselves right out of compassion. . . . It would be a tragedy, just when we have so many scientific therapies at hand, for scientists to negotiate away the element of compassion, leaving this crucial dimension of healing to nonscientific healers.

Time for patient care is becoming increasingly threatened. Bulger (1998, p. 106) described a study involving a "good Samaritan" principle, showing that the decision of whether or not to stop and care for a person in distress is predominantly a function of having the time to do so. Even those with the best intentions require time to be of help to a suffering person.

Characteristics and Functions of the Family Physician

The ideal family physician is an explorer, driven by a persistent curiosity and the desire to know more (Table 1-2).

Continuing Responsibility

One of the essential functions of the family physician is the willingness to accept ongoing responsibility for managing a patient's medical care. After a patient or a family has been accepted into the physician's practice, the responsibility for

Table 1-2 Attributes of the Family Physician*

- A strong sense of responsibility for the total, ongoing care of the individual and the family during health, illness, and rehabilitation.
- Compassion and empathy, with a sincere interest in the patient and the family.
- A curious and constantly inquisitive attitude.
- Enthusiasm for the undifferentiated medical problem and its resolution.
- Interest in the broad spectrum of clinical medicine.
- The ability to deal comfortably with multiple problems occurring simultaneously in a patient.
- Desire for frequent and varied intellectual and technical challenges.
- The ability to support children during growth and development and in their adjustment to family and society.
- Assists patients in coping with everyday problems and in maintaining stability in the family and community.
- The capacity to act as coordinator of all health resources needed in the care of a patient.
- Enthusiasm for learning and for the satisfaction that comes from maintaining current medical knowledge through continuing medical education.
- The ability to maintain composure in times of stress and to respond quickly with logic, effectiveness, and compassion.
- A desire to identify problems at the earliest possible stage or to prevent disease entirely.
- A strong wish to maintain maximum patient satisfaction, recognizing the need for continuing patient rapport.
- The skills necessary to manage chronic illness and to ensure maximal rehabilitation after acute illness.
- Appreciation for the complex mix of physical, emotional, and social elements in personalized patient care.
- A feeling of personal satisfaction derived from intimate relationships with patients that naturally develop over long periods of continuous care, as opposed to the short-term pleasures gained from treating episodic illnesses.
- Skills for and a commitment to educating patients and families about disease processes and the principles of good health.
- A commitment to place the interests of the patient above those of self.

*These characteristics are desirable for all physicians, but are of greatest importance for the family physician.

care is total and continuing. The Millis Commission chose the term “primary physician” to emphasize the concept of primary responsibility for the patient’s welfare; however, the term *primary care physician* is more popular and refers to any physician who provides first-contact care.

The family physician’s commitment to patients does not cease at the end of illness but is a continuing responsibility, regardless of the patient’s state of health or the disease process. There is no need to identify the beginning or end point of treatment, because care of a problem can be reopened at any time—even though a later visit may be primarily for another problem. This prevents the family physician from focusing too narrowly on one problem and helps maintain a perspective on the total patient in her or his environment. Peabody (1930) believed that much patient dissatisfaction resulted from the physician’s neglecting to assume personal responsibility for supervision of the patient’s care: “For some reason or other, no one physician has seen the case through from beginning to end, and the patient may be suffering from the very multitude of his counselors” (p. 8).

Continuity of care is a core attribute of family medicine, transcending multiple illness episodes, and it includes

responsibility for preventive care and care coordination. “This longitudinal relationship evolves into a strong bond between physician and patient characterized by trust, loyalty, and a sense of responsibility” (Saultz, 2003). Trust grows stronger as the physician-patient relationship continues and provides the patient a sense of confidence that care will always be in his or her best interest. It also facilitates improved quality of care the longer the relationship continues.

The greater the degree of continuing involvement with a patient, the more capable the physician is in detecting early signs and symptoms of organic disease and differentiating it from a functional problem. Patients with problems arising from emotional and social conflicts can be managed most effectively by a physician who has intimate knowledge of the individual and his or her family and community background. This knowledge comes only from insight gained by observing the patient’s long-term patterns of behavior and responses to changing stressful situations. This longitudinal view is particularly useful in the care of children and allows the physician to be more effective in assisting children to reach their full potential. The closeness that develops between physicians and young patients increases a physician’s ability to aid the patients with problems later in life, such as adjustment to puberty, problems with employment, or marriage and changing social pressures. As the family physician maintains this continuing involvement with successive generations within a family, the ability to manage intercurrent problems increases with knowledge of the total family background.

By virtue of this ongoing involvement and intimate association with the family, the family physician develops a perceptive awareness of a family’s nature and style of operation. This ability to observe families over time allows valuable insight that improves the quality of medical care provided to an individual patient. A major challenge in family medicine is the need to be alert to the changing stresses, transitions, and expectations of family members over time, as well as the effect that these and other family interactions have on the health of individual patients.

Although the family is the family physician’s primary concern, his or her skills are equally applicable to the individual living alone or to people in other varieties of family living. Individuals with alternative forms of family living interact with others who have a significant effect on their lives. The principles of group dynamics and interpersonal relationships that affect health are equally applicable to everyone.

The family physician must assess an individual’s personality so that presenting symptoms can be appropriately evaluated and given the proper degree of attention and emphasis. A complaint of abdominal pain may be treated lightly in one patient who frequently presents with minor problems, but the same complaint would be investigated immediately and in depth in another patient who has a more stoic personality. The decision regarding which studies to perform and when is influenced by knowledge of the patient’s lifestyle, personality, and previous response pattern. The greater the degree of knowledge and insight into the patient’s background, as gained through years of ongoing contact, the more capable is the physician in making an appropriate early and rapid assessment of the presenting complaint. The less background information the physician has to rely on, the greater is the need to depend on costly laboratory studies, and the more likely is overreaction to the presenting symptom.

Families receiving continuing comprehensive care have a decreased incidence of hospitalization, fewer operations, and less physician visits for illnesses compared with those having no regular physician. This results from the physician's knowledge of the patients, seeing them earlier for acute problems and therefore preventing complications that would require hospitalization, being available by telephone or by e-mail, and seeing them more frequently in the office for health supervision. Care is also less expensive because there is less need to rely on radiographic and laboratory procedures and visits to emergency departments.

Continuity of care improves quality of care, especially for those with chronic conditions such as asthma and diabetes (Cabana and Jee, 2004). Because about 90% of diabetic patients in the United States receive care from a primary care physician, continuity of care can be especially important. Parchman and associates (2002) found that for adults with type 2 diabetes, continuing care from the same primary care provider was associated with lower Hb_{A1c} values, regardless of how long the patient had suffered from diabetes. Having a regular source of primary care helped these adults manage their diet and improve glucose control.

Collusion of Anonymity

The need for a primary physician who accepts continuing responsibility for patient care was emphasized by Michael Balint (1965) in his concept of *collusion of anonymity*. In this situation the patient is seen by a variety of physicians, not one of whom is willing to accept total management of the problem. Important decisions are made—some good, some poor—but without anyone feeling fully responsible for them.

Francis Peabody (1930) examined the futility of a patient's making the rounds from one specialist to another without finding relief because the patient:

. . . lacked the guidance of a sound general practitioner who understood his physical condition, his nervous temperament and knew the details of his daily life. And many a patient who on his own initiative has sought out specialists, has had minor defects accentuated so that they assume a needless importance, and has even undergone operations that might well have been avoided. Those who are particularly blessed with this world's goods, who want the best regardless of the cost and imagine that they are getting it because they can afford to consult as many renowned specialists as they wish, are often pathetically tragic figures as they veer from one course of treatment to another. Like ships that lack a guiding hand upon the helm, they swing from tack to tack with each new gust of wind but get no nearer to the Port of Health because there is no pilot to set the general direction of their course (pp. 21-22).

Chronic Illness

The family physician must also be committed to managing the common chronic illnesses that have no known cure, but for which continuing management by a personal physician is all the more necessary to maintain an optimal state of health for the patient. It is a difficult and often trying job to manage

these unresolvable and progressively crippling problems, control of which requires a remodeling of the lifestyle of the entire family.

About 45% of Americans have a chronic condition. The costs to individuals and to the health care system are enormous. In 2000, care of chronic illness consumed 75 cents of every health care dollar spent in the United States (Robert Wood Johnson Foundation Annual Report, 2002).

Comorbidity, the coincident occurrence of coexisting and apparently unrelated disorders, is increasing as the population ages. Those age 60 years or older have an average of 2.2 chronic conditions, and physicians in primary care provide most of this care (Bayliss et al., 2003).

Diabetes is one of the most rapidly increasing chronic conditions (Figure 1-2). Quality of life is enhanced when care of diabetic patients is provided in a primary care setting without compromising quality of care (Collins et al., 2009).

Quality of Care

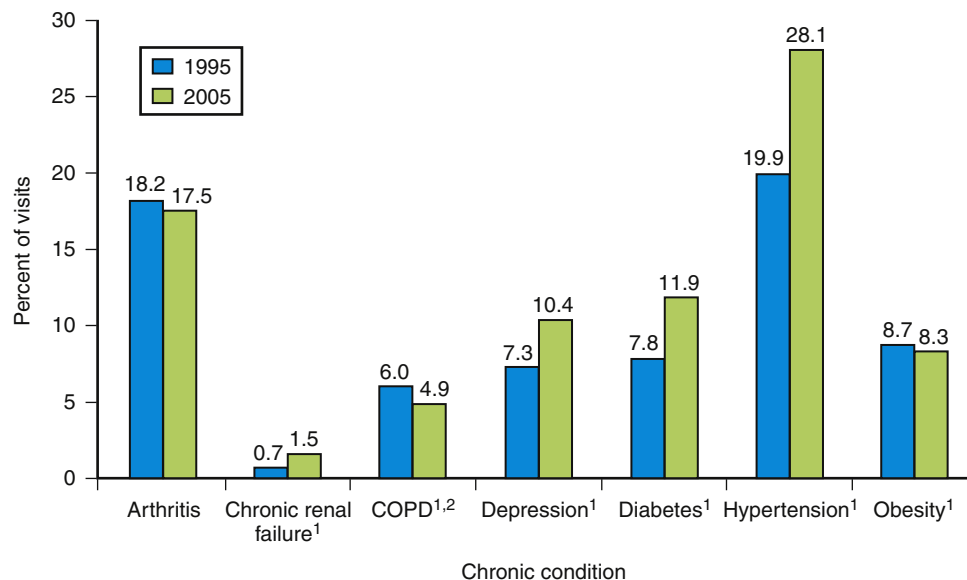

Primary care provided by physicians specifically trained to care for the problems presenting to personal physicians, who know their patients over time, is of higher quality than care provided by other physicians. This has been confirmed by a variety of studies comparing the care given by physicians in different specialties. When hospitalized patients with pneumonia are cared for by family physicians or full-time specialist hospitalists, the quality of care is comparable, but the hospitalists incur higher hospital charges, longer lengths of stay, and use more resources (Smith et al., 2002).

In the United States, a 20% increase in the number of primary care physicians is associated with a 5% decrease in mortality (40 fewer deaths per 100,000 population), but the benefit is even greater if the primary care physician is a family physician. Adding one more family physician per 10,000 people is associated with 70 fewer deaths per 100,000 population, which is a 9% reduction in mortality. Specialists practicing outside their area have increased mortality rates for patients with acquired pneumonia, acute myocardial infarction, congestive heart failure, and upper gastrointestinal hemorrhage. Specialists are trained to look for zebras instead of horses, and specialty care usually means more tests, which lead to a cascade effect and a greater likelihood of adverse effects, including death. A study of the major determinants of health outcomes in all 50 U.S. states found that when the number of specialty physicians increases, outcomes are worse, whereas mortality rates are lower where there are more primary care physicians (Starfield et al., 2005).

McGann and Bowman (1990) compared the morbidity and mortality of patients hospitalized by family physicians and by internists. Even though the family physicians' patients were older and more severely ill, there was no significant difference in morbidity and mortality. The total charges for their hospital care also were lower.

A comparison of family physicians and obstetrician-gynecologists in the management of low-risk pregnancies showed no difference with respect to neonatal outcomes. However, women cared for by family physicians had fewer cesarean sections and episiotomies and were less likely to receive epidural anesthesia (Hueston et al., 1995).

Patients of subspecialists practicing outside their specialty have longer lengths of hospital stay and higher mortality

¹Significant difference in percentages between 1995 and 2005 ($p < 0.05$).

²COPD, Chronic obstructive pulmonary disease.

Figure 1-2 Percentage of office visits by adults 18 years and older with selected chronic conditions: United States, 1995 and 2005. (From Cherry DK, Woodwell DA, Rechtsteiner EA. National Ambulatory Medical Care Survey: 2005 summary. Advance data from vital and health statistics. No 387. rates than patients of subspecialists practicing within their specialty or of general internists (Weingarten et al., 2002). The quality of the U.S. health care system is being eroded by physicians being extensively trained, at great expense, to practice in one area and, instead, practicing in another area, such as anesthesiologists practicing in emergency departments or surgeons practicing as generalists. Primary care, to be done well, requires extensive training specifically tailored to problems frequently seen in primary care.

As much-needed changes in the American medical system are implemented, it would be wise to keep some perspective on the situation regarding physician distribution. Beeson (1974) commented:

I have no doubt at all that a good family doctor can deal with the great majority of medical episodes quickly and competently. A specialist, on the other hand, feels that he must be thorough, not only because of his training but also because he has a reputation to protect. He, therefore, spends more time with each patient and orders more laboratory work. The result is a waste of doctors' time and patients' money. This not only inflates the national health bill, but also creates an illusion of doctor shortage when the only real need is to have the existing doctors doing the right things (p. 48).

Cost-Effective Care

The physician who is well acquainted with the patient provides more personal and humane medical care, and does so more economically, than the physician involved in only episodic care. The physician who knows his or her patients well can assess the nature of their problems more rapidly and accurately. Because of the intimate, ongoing relationship, the family physician is under less pressure to exclude diagnostic

possibilities using expensive laboratory and radiologic procedures than the physician unfamiliar with the patient.

The United States has the most expensive health care system in the world. In 1965 the cost of health care in the United States was just under 6% of the gross domestic product (GDP). It shot up to 16% of GDP in 2008 and continues to increase, with predictions it will reach 20% by 2015. Despite the most expensive health care, however, the United States ranks 29th in infant mortality, 48th in life expectancy, and 19th (of 19) in preventable deaths among industrialized nations.*

Although the rhetoric suggests it is worth this cost to have the best health care system in the world, the truth is that we are far from that goal. WHO ranks the quality of health care in the United States at 37th in the world, well behind Morocco and Colombia. (For the standing of all countries see www.photius.com/rankings/health_ranks.html.) In a comparison of the quality of health care in 13 developed countries using 16 different health indicators, the United States ranked 12th, second from the bottom. Evidence indicates that quality of health care is associated with primary care performance. Of the seven countries at the top of the average health ranking, five have strong primary care infrastructures. As Starfield (2000) states, "The higher the primary care physician-to-population ratio, the better most health outcomes are" (p. 485).

Similarly, the greater the number of primary care physicians practicing in a country, the lower is the cost of health care. Figure 1-3 shows that in the United Kingdom, Canada, and the United States, the cost of health care is inversely proportional to the percentage of generalists practicing in that country. Great Britain has twice the percentage of family physicians but half the cost. Administrative overhead accounts

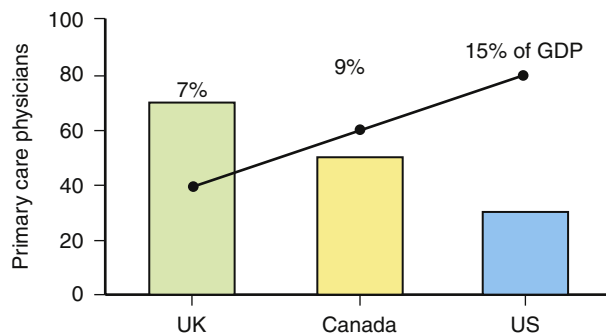

Figure 1-3 Inverse relationship between number of generalists and cost of health care in the United Kingdom, Canada, and the United States. (From Organisation for Economic Cooperation and Development. *OECD Health Data*, June 2005. http://www.oecd.org/document/56/0,2340,en_2649_34631_12968734_1_1_1_1,00.html/ Accessed April 2006.)

for a major part of the high overhead cost (31%) of U.S. health care (Woolhandler et al., 2003). For the same number of physicians, Canada has one “billing clerk” for every 17 in the United States (Lundberg, 2002).

Countries with strong primary care have lower overall health care costs, improved health outcomes, and healthier populations (Starfield, 2001; Phillips and Starfield, 2004). In comparing 11 features of primary care in 11 Western countries, the United States ranked lowest in terms of primary care ranking and highest in per-capita health care expenditures. The United States also performed poorly on public satisfaction, health indicators, and the use of medication (Starfield, 1994).

In the United States, the greater the number of primary care physicians, the lower is the mortality, and conversely, the higher the specialist/population ratio, the greater is the mortality. Adding one family physician per 10,000 people would result in 35 fewer deaths. Increasing the number of specialists, a process that continues in the United States, is associated with higher mortality and increasing cost. One third of the excessive cost is attributed to performance of unnecessary procedures (Starfield et al., 2005).

Uninsured Persons

The number of Americans without health insurance has been increasing by 1 million per year. In 2008 the number of uninsured persons was 46 million, or 16% of the U.S. population. The number of people who are *underinsured* (another 50 million) is growing even more rapidly. Contrary to widespread belief, the problem is not confined simply to unemployed or poor persons. More than one half of uninsured persons have annual incomes greater than \$75,000, and 8 of 10 are in working families.

The United States is the only developed country that does not have universal health care coverage for all its citizens. According to Geyman, “Today’s nonsystem is in chaos. A large part of health care has been taken over by for-profit corporations whose interests are motivated more by return on investment to shareholders than by quality of care for patients” (2002, p. 407).

The Institute of Medicine (IOM) report on the uninsured population, *Insuring America’s Health: Principles and Recommendations*, called for “health care coverage by 2010

that is universal, continuous, affordable, sustainable, and enhancing of high-quality care that is effective, efficient, safe, timely, patient centered, and equitable. . . . While stopping short of advocating a specific approach, the IOM’s Committee on the Consequences of Uninsurance acknowledges that the single payer model is the most effective in ensuring continuous universal coverage that would remain affordable for individuals and for society” (Geyman, 2004, p. 635).

Family physicians account for a larger proportion of office visits to U.S. physicians than any other specialty. However, Geyman (2004) observed problems:

The country’s health care (non) system has undergone a major transformation to a market-based system largely dominated by corporate interests and a business ethic. The goal envisioned in the 1960s of rebuilding the U.S. health care system on a generalist base, with all Americans having ready access to comprehensive health care through a personal physician, has not been achieved. Overspecialization was a problem as long as 4000 years ago, when Herodotus in 2000 BC noted that “The art of medicine is thus divided: each physician applies himself to one disease only and not more.”

Comprehensive Care

The term *comprehensive medical care* spans the entire spectrum of medicine. The effectiveness with which a physician delivers primary care depends on the degree of involvement attained during training and practice. The family physician must be trained comprehensively to acquire all the medical skills necessary to care for most problems. The greater the number of skills omitted from the family physician’s training and practice, the more frequent is the need to refer minor problems to another physician. A truly comprehensive primary care physician adequately manages acute infections, biopsies skin and other lesions, repairs lacerations, treats musculoskeletal sprains and minor fractures, removes foreign bodies, treats vaginitis, provides obstetric care and care for the newborn infant, gives supportive psychotherapy, and supervises diagnostic procedures. The needs of a family physician’s patient range from a routine physical examination, when the patient feels well and wants to identify potential risk factors, to a problem that calls for referral to one or more narrowly specialized physicians with highly developed technical skills. The family physician must be aware of the variety and complexity of skills and facilities available to help manage patients and must match these to the individual’s specific needs, giving full consideration to the patient’s personality and expectations.

Management of an illness involves much more than a diagnosis and an outline for treatment. It requires an awareness of all the factors that may aid or hinder an individual’s recovery from illness. This approach requires consideration of religious beliefs; social, economic, or cultural problems; personal expectations; and heredity. The outstanding clinician recognizes the effects that spiritual, intellectual, emotional, social, and economic factors have on a patient’s illness.

The family physician’s ability to confront relatively large numbers of unselected patients with undifferentiated conditions and carry on a therapeutic relationship over time is a unique primary care skill. The skilled family physician has

a higher level of tolerance for the uncertain than her or his consultant colleague.

Society benefits more from a surgeon who has a sufficient volume of surgery to maintain proficiency through frequent use of well-honed skills than from one who has a low volume of surgery and serves also as a primary care physician. The early identification of disease while it is in its undifferentiated stage requires specific training; it is not a skill that can be automatically assumed by someone whose training has been mostly in hospital intensive care units.

Interpersonal Skills

One of the foremost skills of the family physician is the ability to use effectively the knowledge of interpersonal relations in the management of patients. This powerful element of clinical medicine may be the specialty's most useful tool. Physicians too often are seen as lacking personal concern and as being unskilled in understanding personal anxiety and feelings. There is a need to nourish the seed of compassion and concern for sick people that motivates students as they enter medical school.

Family medicine emphasizes the integration of compassion, empathy, and personalized concern. Some of the earnest solicitude of the "old country doctor" and his or her untiring compassion for people must be incorporated as effective but impersonal modern medical procedures are applied. The patient should be viewed compassionately as a person in distress who needs to be treated with concern, dignity, and personal consideration. The patient has a right to be given some insight into his or her problems, a reasonable appraisal of the potential outcome, and a realistic picture of the emotional, financial, and occupational expenses involved in his or her care. The greatest deterrents to filing malpractice claims are patient satisfaction, good patient rapport, and active patient participation in the health care process.

To relate well to patients, a physician must develop compassion and courtesy, the ability to establish rapport and to communicate effectively, the ability to gather information rapidly and to organize it logically, the skills required to identify all significant patient problems and to manage these problems appropriately, the ability to listen, the skills necessary to motivate people, and the ability to observe and detect nonverbal clues (see Chapter 12).

Accessibility

The mere availability of the physician is therapeutic. The feeling of security that the patient gains just by knowing he or she can "touch" the physician, in person or by phone, is therapeutic and has a comforting and calming influence. Accessibility is an essential feature of primary care. Services must be available when needed and should be within geographic proximity. When primary care is not available, many individuals turn to hospital emergency departments. Emergency department care is fine for emergencies, but it is no substitute for the personalized, long-term, comprehensive care a family physician can provide.

Many practices are instituting open-access scheduling, in which patients can be seen the day they call. This tells the patient that they are the highest priority and that the problem will be handled immediately. It also is more efficient for

the physician who cares for a problem early, before it progresses in severity and becomes complicated, requiring more physician time and greater patient disability.

Diagnostic Skills: Undifferentiated Problems

The family physician must be an outstanding diagnostician. Skills in this area must be honed to perfection, because problems are usually seen in their early, undifferentiated state and without the degree of resolution that is usually present by the time patients are referred to consulting specialists. This is a unique feature of family medicine, because symptoms seen at this stage are often vague and nondescript, with signs being minimal or absent. Unlike the consulting specialist, the family physician does not evaluate the case after it has been preselected by another physician, and the diagnostic procedures used by the family physician must be selected from the entire spectrum of medicine.

At this stage of disease, there are often only subtle differences between the early symptoms of serious disease and those of self-limiting, minor ailments. To the inexperienced person, the clinical pictures may appear identical, but to the astute and experienced family physician, one symptom is more suspicious than another because of the greater probability that it signals a potentially serious illness. Diagnoses are frequently made on the basis of probability, and the likelihood that a specific disease is present frequently depends on the incidence of the disease relative to the symptom seen in the physician's community during a given time of year. Many patients will never be assigned a final, definitive diagnosis, because a presenting symptom or a complaint will resolve before a specific diagnosis can be made. Pragmatically, this is an efficient method that is less costly and achieves high patient satisfaction, even though it may be disquieting to the purist physician who believes a thorough workup and specific diagnosis always should be obtained. Similarly, family physicians are more likely to use a therapeutic trial to confirm the diagnosis.

The family physician is an expert in the rapid assessment of a problem presented for the first time. He or she evaluates its potential significance, often making a diagnosis by exclusion rather than by inclusion, after making certain the symptoms are not those of a serious problem. Once assured, some time is allowed to elapse. Time is used as an efficient diagnostic aid. Follow-up visits are scheduled at appropriate intervals to watch for subtle changes in the presenting symptoms. The physician usually identifies the symptom that has the greatest discriminatory value and watches it more closely than the others. The most significant clue to the true nature of the illness may depend on subtle changes in this key symptom. The family physician's effectiveness is often determined by his or her knack for perceiving the hidden or subtle dimensions of illness and following them closely.

The maxim that "an accurate history is the most important factor in arriving at an accurate diagnosis" is especially appropriate to family medicine, because symptoms may be the only obvious feature of an illness at the time it is presented to the family physician. Further inquiry into the nature of the symptoms, time of onset, extenuating factors, and other unique subjective features may provide the only diagnostic clues available at such an early stage.

The family physician must be a perceptive humanist, alert to early identification of new problems. Arriving at an early

diagnosis may be of less importance than determining the real reason the patient came to the physician. The symptoms may be the result of a self-limiting or acute problem, but anxiety or fear may be the true precipitating factor. Although the symptom may be hoarseness that has resulted from postnasal drainage accompanying an upper respiratory tract infection, the patient may fear it is caused by a laryngeal carcinoma similar to that recently found in a friend. Clinical evaluation must rule out the possibility of laryngeal carcinoma, but the patient's fears and apprehension regarding this possibility must also be allayed.

Every physical problem has an emotional component, and although this factor is usually minimal, it can be significant. A patient's personality, fears, and anxieties play a role in every illness and are important factors in primary care.

The Family Physician as Coordinator

Francis Peabody (1930), Professor of Medicine at Harvard Medical School from 1921 to 1927, was ahead of his time. His comments remain appropriate today:

Never was the public in need of wise, broadly trained advisors so much as it needs them today to guide them through the complicated maze of modern medicine. The extraordinary development of medical science, with its consequent diversity of medical specialism and the increasing limitations in the extent of special fields—the very factors that are creating specialists—in themselves create a new demand, not for men who are experts along narrow lines, but for men who are in touch with many lines (p. 20).

The family physician, by virtue of her or his breadth of training in a wide variety of medical disciplines, has unique insights into the skills possessed by physicians in the more limited specialties. The family physician is best prepared to select specialists whose skills can be applied most appropriately to a given case, as well as to coordinate the activities of each, so that they are not counterproductive.

As medicine becomes more specialized and complex, the family physician's role as the integrator of health services becomes increasingly important. The family physician facilitates the patient's access to the whole health care system and interprets the activities of this system to the patient, explaining the nature of the illness, the implication of the treatment, and the effect of both on the patient's way of life. The following statement from the Millis Commission Report (Citizens' Commission, 1966) concerning expectations of the patient is especially appropriate:

The patient wants, and should have, someone of high competence and good judgment to take charge of the total situation, someone who can serve as coordinator of all the medical resources that can help solve his problem. He wants a company president who will make proper use of his skills and knowledge of more specialized members of the firm. He wants a quarterback who will diagnose the constantly changing situation, coordinate the whole team, and call on each member for the particular contributions that he is best able to make to the team effort (p. 39).

Such breadth of vision is important for a coordinating physician. She or he must have a realistic overview of the problem and an awareness of the many alternative routes to select the one that is most appropriate. As Pellegrino (1966) stated:

It should be clear, too, that no simple addition of specialties can equal the generalist function. To build a wall, one needs more than the aimless piling up of bricks, one needs an architect. Every operation which analyzes some part of the human mechanism requires it to be balanced by another which synthesizes and coordinates (p. 542).

The complexity of modern medicine frequently involves a variety of health professionals, each with highly developed skills in a particular area. In planning the patient's care, the family physician, having established rapport with a patient and family and having knowledge of the patient's background, personality, fears, and expectations, is best able to select and coordinate the activities of appropriate individuals from the large variety of medical disciplines. He or she can maintain effective communication among those involved, as well as function as the patient's advocate and interpret to the patient and family the many unfamiliar and complicated procedures being used. This prevents any one consulting physician, unfamiliar with the concepts or actions of all others involved, from ordering a test or medication that would conflict with other treatment. Dunphy (1964) described the value of the surgeon and the family physician working closely as a team:

It is impossible to provide high quality surgical care without that knowledge of the whole patient, which only a family physician can supply. When their mutual decisions . . . bring hope, comfort and ultimately, health to a gravely ill human being, the total experience is the essence and the joy of medicine (p. 12).

The ability to orchestrate the knowledge and skills of diverse professionals is a skill to be learned during training and cultivated in practice. It is not an automatic attribute of all physicians or merely the result of exposure to a large number of professionals. These coordinator skills extend beyond the traditional medical disciplines into the many community agencies and allied health professions as well. Because of his or her close involvement with the community, the family physician is ideally suited to be the integrator of the patient's care, coordinating the skills of consultants when appropriate and involving community nurses, social agencies, the clergy, or other family members when needed. Knowledge of community health resources and a personal involvement with the community can be used to maximum benefit for diagnostic and therapeutic purposes and to achieve the best possible level of rehabilitation.

Only 5% of visits to family physicians lead to a referral, and more than 50% are for consultation rather than direct intervention. Surgical specialists are sent the largest share of referrals at 45.4%, followed by medical specialists at 31% and obstetrician-gynecologists at 4.6%. Physicians consulted most frequently are orthopedic surgeons, followed by general surgeons, otolaryngologists, and gastroenterologists. Psychiatrists are consulted the least (Forrest et al., 2002; Starfield et al., 2002).

Figure 1-4 Number of persons experiencing an illness during an average month per 1000 people. (From Green LA, Fryer GE Jr, Yawn BP, et al. *The ecology of medical care revisited*. *N Engl J Med* 2001;344:2021-2025.)

The Family Physician in Practice

The advent of family medicine has led to a renaissance in medical education involving a reassessment of the traditional medical education environment in a teaching hospital. It is now considered more realistic to train a physician in a community atmosphere, providing exposure to the diseases and problems most closely approximating those she or he will encounter during practice. The ambulatory care skills and knowledge that most medical graduates will need cannot be taught totally within the tertiary medical center. The specialty of family practice emphasizes training in ambulatory care skills in an appropriately realistic environment, using patients representing a cross section of a community and incorporating those problems most frequently encountered by physicians practicing primary care.

The lack of relevance in the referral medical center also applies to the hospitalized patient. Figure 1-4 places the health problems of an average community in perspective. In any given month, 800 people experience at least one symptom. Most of these people are managed by self-treatment, but 217 consult a physician. Of these, eight are hospitalized, but only one goes to an academic medical center. Patients seen in the medical center (with most cases used for teaching) represent atypical samples of illness occurring within the community. Students exposed to patients in only this manner develop an unrealistic concept of the types of medical problems prevalent in society and particularly those composing primary care. It focuses their training on knowledge and skills of limited usefulness in later practice. Medical schools should accept the responsibility of providing health

care for a defined population, and the dean's office should ensure that the curriculum is congruent with the health needs of that population.

Practice Content

Since 1975, the National Ambulatory Medical Care Survey conducted by the National Center for Health Statistics (NCHS) of the U.S. Department of Health and Human Services has annually reported the problems seen by office-based physicians (in all specialties) in the United States. More than 53% of all office visits in the United States were to primary care physicians (Figure 1-5). The 20 most common diagnoses seen by physicians in their office are shown in Table 1-3. Note that arthritis is fourth and diabetes mellitus sixth, reflecting the prominence of chronic diseases in practice. For those who think primary care is little more than caring for acute pharyngitis, note that it is 19th. When only chronic conditions are listed (Table 1-4), arthritis is second and diabetes fourth.

Primary care physicians manage an average of 1.65 problems per visit. Of visits to primary care physicians, 61% were for a medical examination, compared with 23% for surgical specialists. Although hypertension is the most common problem encountered in offices (see Table 1-3), primary care physicians checked the blood pressure at 60% of the visits, compared with only 20% of surgical specialists and 40% of visits to medical specialists (National Center for Health Statistics, 2002).

Available data concerning primary care indicate that more people use this type of medical service than any other and that, contrary to popular opinion, sophisticated medical technology is not normally either required or overused in basic primary care encounters. Most primary care visits arise

from patients requesting care for relatively uncomplicated problems, many of which are self-limiting but cause the patients concern or discomfort. Treatment is often symptomatic, consisting of pain relief or anxiety reduction rather than a "cure." The greatest cost-efficiency results when these patients' needs are satisfied while the self-limiting course of the disease is recognized, without incurring unnecessary costs for additional tests.

Patient-Centered Medical Home

The patient-centered medical home ((PCMH; see Chapter 2) has been proposed as an enhanced model of primary care by four medical organizations (family medicine, pediatrics,

Table 1-4 Rank Order of Chronic Conditions, All Ages

14. Chronic renal failure

internal medicine, osteopathy) and is focused on reducing fragmentation of care and overcoming the reliance on specialty rather than primary care (Berenson et al., 2008; Rogers, 2008).

Primary care was encouraged to expand beyond its restrictive role as a provider of care to one that analyzes the needs of a community and focuses on those at risk of disease. This process was first described in the 1950s by Sydney Karf, who looked at the needs of his community in South Africa, whether or not they were his patients (Kark and Cassel, 1952). The process involves identifying the health problems of a community, such as diabetes or obesity, and developing a program to prevent the disease and care for people in the early stage, then evaluating the effectiveness of the program (Longlett et al., 2001).

Looking toward the Future

The pace of medical progress may result in tomorrow's innovations exceeding today's fantasies. Family medicine in the future will be different as a result of technology. Every patient and physician will be computer literate, with patients having access to the same sources of information as the physician. Patients are likely to have their own home page that contains their medical information and gives them access to whatever services they need (Scherger, 2005). Although the Internet is an excellent tool for consumers to access information about their health and for disseminating health care information, it will never be a substitute for a face-to-face discussion and physical examination. It cannot convey the worry in a voice or the subtle nonverbal clues to the real reason for the patient's distress. However, the Internet does allow the individual patient to be more active and involved in his or her own care.

The advent of the electronic medical record may be as significant as the discovery of penicillin (see Chapter 9). It will allow the family physician to incorporate the latest evidence-based recommendations into an individual's care, write electronic prescriptions, and be alerted to drug interactions while seeing a patient. Internet-based textbooks such as this one will provide immediate access to information during the patient visit.

The intuitive mind is a sacred gift, and the rational mind is a faithful servant. We have created a society in which we honor the servant and have forgotten the gift.

Albert Einstein

Key Points

- Continuous, health-oriented relationships are the foundation on which the medical home, or “health home,” is built. This is the interpersonal environment.
- The patient-centered medical home brings together health professionals to work collectively toward the health needs of the community through the creation of health teams.
- A continuous self-reflective process is required for the physician leader to maintain joy in her or his work, which will translate into the quality of the health home.
- The health home can have the greatest impact on community health by working toward the incorporation of positive lifestyle behaviors. This is the behavioral environment.
- Patient empowerment is a way of interacting in which accurate information is provided in a manner that is understandable to the individual and that both respects and promotes the patient’s ability to make decisions. A patient’s decision making is the inner, personal environment, influenced by external issues such as culture, family, peer group, work, and payment for care.
- Creating an optimal healing environment (including inner, inter, behavioral, and external) within the medical home will encourage empowerment toward positive change.

History

The concept of the “medical home” was first described in *Standards of Child Care* by the American Academy of Pediatrics (AAP) Council on Pediatrics Practice in 1967. It defined

“ideal care” for children with disabilities as a practice that provided care that was accessible, coordinated, family centered, and culturally effective.

The American Academy of Family Physicians (AAFP) used this concept to expand the characteristics based on discussions defining the future of family medicine. These characteristics described the “personal” medical home, which focused on bringing attention to the importance of continuous, relationship-centered, whole-system, comprehensive care for communities (Martin et al., 2004). In 2007 the AAP, AAFP, American College of Physicians (ACP), and American Osteopathic Association (AOA) collaborated to define further the foundational principles of the patient-centered medical home (PCMH; Table 2-1). The goal of the medical home is to emphasize the importance of primary care in improving quality of care, health outcomes, and patient experience, with improved cost-efficiency.

However, the ingredients of the medical home (or “health home”) continue to be defined and modified based on the needs of the clinicians and communities who implement them. These ingredients and how they are delivered are key to the achievement of the lofty goals of the medical home and family medicine in general. This chapter discusses the most important ingredients for the medical home and the actions that the family physician must take to create one.

Healing, Curing, and the Goals of the Medical Home

Medicine in general and primary care in particular involve constant tension between diagnosis and elimination of the disease (cure) on one hand and alleviation of suffering in the context of disease and treatment (healing) on the other. In this context, *healing* means helping patients cope

Table 2-1 Principles of a Patient-Centered Medical Home

1. Access to care based on an ongoing relationship with a personal physician who is able to provide first-contact, continuous, and comprehensive care.
2. Care provided by a physician-led team of individuals within the practice who collectively take responsibility for the ongoing needs of patients.
3. Care based on a whole-person (holistic) orientation in which the practice team takes responsibility for either providing care that encompasses all patient needs or arranges for the care to be done by other qualified professionals.
4. Care coordinated and integrated across all elements of the complex health care system and the patient's community.
5. Care facilitated by the use of office practice systems (e.g., registries, information technology, health information exchange) to ensure that patients receive the indicated care when and where they need and want it in a culturally and linguistically appropriate manner.
6. Reimbursement structure that supports and encourages this model of care.

Modified from American College of Physicians. Joint principles of the patient-centered medical home, March 2007.
http://www.acponline.org/advocacy/where_we_stand/medical_home/approve_jp.pdf.

emotionally and practically with whatever condition they face, even when cure is not possible.

In *The Nature of Suffering and the Goals of Medicine*, Casell (2004) elegantly describes this tension and the continual erosion of healing practices under the pressure to apply more specific, technologic cures. In *A Time to Heal*, Ludmerer (1999) documents how, despite decades of efforts in curriculum change, these core values of healing in medical education have failed to gain significant traction under the forces driving the payment for cure-seeking behaviors.

Thus, the physician seeking to create a medical home that balances cure and healing faces considerable challenges, especially in the delivery of healing. What are the essential components of such a health care home? How can they be delivered in the current medical context? What actions must the family physician take to create not only a practice that treats disease, but an optimal healing environment as well?

Balancing Treatment of Disease and Promotion of Health

Health is largely a result of positive lifestyle behaviors that are often challenging to change. Addressing issues such as smoking, obesity, substance abuse, and inactivity can reduce premature death by 40% (McGinnis et al., 2002; Schroeder, 2007). Positive lifestyle behaviors not only prevent premature death but also extend the average life expectancy by 14 years (Khaw et al., 2008). Currently, approximately 4 cents of every dollar spent for health care goes toward prevention and public health, with 96% spent on treating established disease (Lambrew, 2007). Two thirds of chronic disease is behavior related and could be mitigated by working interprofessionally to help guide patients toward healthy choices (McGinnis et al., 2002).

Behaviors that have the greatest impact on preventing chronic disease and its progression are (1) reducing exposure to toxic substances (tobacco, alcohol, drugs, pollution), (2) movement and exercise, (3) healthy diet, (4) psychosocial integration and stress management, and (5) early disease

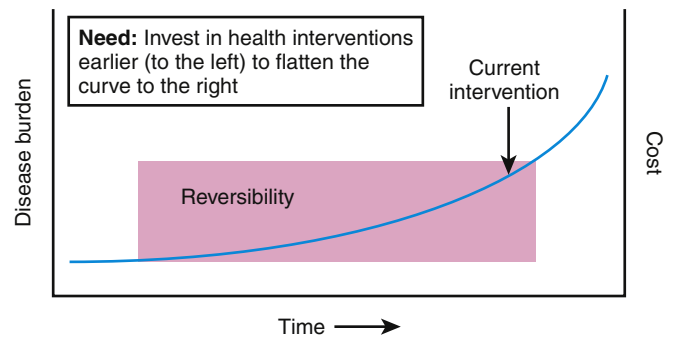

Figure 2-1 Profit in the current U.S. health care system is obtained focusing on the right of the curve. Investment toward the left of the curve will reduce disease burden and cost over time.

detection and intervention (Jonas, 2009; McGinnis, 2003). For these behaviors to have an impact, the health home will need to be financially supported and have the goal of health as its primary focus. This will require new forms of funding that go beyond the disease-focused throughput model of payment. A primary care clinic that only works from this model will encourage shorter office visits while promoting reliance on expensive technology that often suppresses symptoms without addressing its cause. The health home will push the curve in Figure 2-1 to the left and will involve professionals who specialize in health promotion (or creation) to flatten the curve and reduce the need for the “disease care” teams currently well established in the tertiary care setting.

Establishing an Optimal Healing Environment

An *optimal healing environment* (OHE) involves the delivery and context of medical treatment rather than the specific treatment itself. It focuses on creating healing in the process of disease treatment. This means optimizing the “meaning and context” effects of the care process rather than ignoring or dismissing them as “placebo” effects. An OHE involves attending to three primary domains of care delivery: (1) the “inner,” personal environment of the team and patient; (2) the “inter,” personal or relationship environment of care delivery; and (3) the “external” behavioral and physical environment of the medical home (Jonas et al., 2003).

Often, a “medicine” itself is given the most credit in medicine. A prescribed medication is valued for its “specific” medical influence, as deemed beneficial by randomized (placebo-)controlled trials (RCTs). This research focuses on the effects of the drug and attempts to control the context in order to reduce “nonspecific” (placebo) effects that may compromise the results. This helps physicians understand the specific effects of the drugs they prescribe, but it does not value those nonspecific effects that surround the prescribing of a medication. It is impossible, even undesirable, to remove all nonspecific effects from the patient encounter.

“Meaning” and “context” effects are rooted in relationship-centered care, including empathy, trust, empowerment, and hope. Research on one of the most frequently prescribed drugs in primary care, selective serotonin reuptake inhibitors (SSRIs), shows that these work only about 6% to 9% better than placebo (Kirsch et al., 2002; Turner et al., 2008). Both placebo and drug work well and are often almost 60%

Table 2-2 Optimal Healing Environments

| Inner Environment to the Outer Environment | | | | | | |

Modified from Jonas WB, Chez RA. Toward optimal healing environments in health care. *J Altern Complement Med* 2004;10 Suppl 1:S1-S6.

effective. Therefore, if the drug only accounts for 9% of this effect, which factor accounts for the majority of the healing influence? Maybe researchers are not giving enough credit to the clinician and the nonspecific variables that surround the prescribing of the pill. Maybe it is simply the act of listening to people who are suffering and giving them a sense of understanding that there is something they can do to overcome the suffering. Maybe it is the interaction between two people before the medicine is prescribed that has the greatest healing effect. Psychiatrists gifted at developing a trusting relationship were found to have better effects with placebo in treating depression than their colleagues less talented at developing relationships who used active drug (McKay et al., 2006). Acupuncture delivered with a greater ritual produces better effects than the same points treated with less ritual (Kaptchuk et al., 2008; Kelley et al., 2009). Maybe it is the cost. Drugs that cost more (up to a certain point) work better in pain treatment than the same drugs that cost less (Waber et al., 2008).

Family physicians do not need to wait for further research to create an OHE for patient care. Physicians already know that the factors summarized in Table 2-2 will help encourage the healthy unfolding of complex systems. The most important part in influencing healing in others is focused on the left side of the table and starts with a self-reflective, internal process. Family physicians first need to understand the importance of continuously exploring their own health, so that they are prepared to do the same for their patients.

The Importance of Self-Care

To care deeply for others, we must know how to care for ourselves. As Cassell (2004) says, “. . . virtually all the doctor’s healing power flows from the doctor’s self-mastery.” True primary care, therefore, also includes what we do for ourselves. Up to 60% of practicing physicians report symptoms of “burnout” (Shanafelt et al., 2003; Spickard et al., 2002). This is associated with emotional exhaustion, depersonalization (seeing patients as objects), reduced empathy, and the loss of meaning in work.

The characteristics lost in burnout are important ingredients in facilitating health and healing in others. If the health team physician leader is “burning out,” the health home will

not be healthy. When physicians practice healthy lifestyle behaviors, they are more likely to educate patients on the importance of these behaviors (Lewis et al., 1991) and to become more motivating to their patients toward positive change (Frank et al., 2000; Lobelo et al., 2009). Every family physician benefits from a self-reflective inquiry about personal balance toward health. This behavior will constantly be challenged and will require attention and “mastery.”

Most primary care physicians are attracted into the field to make a difference in people’s lives through continuous healing relationships. When the demands of the working environment tax the sense of control to maintain these relationships, stress and potential burnout can ensue. One remedy for this is to use the patient encounter to allow *meaning* to flow through the work. The healing-oriented primary care approach recognizes each patient as a unique individual with specific needs in the physical, emotional, and spiritual domains and sets aside both mental space and physical time to deal with those needs. To be aware of these personal needs is a mindful practice in which the physician is fully present in the moment with the patient, where each is able to reduce suffering in the other (Epstein, 1999). This “mindfulness” approach has been found to enhance well-being and physician attitudes in patient-centered care (Krasner et al., 2009). It requires that physicians create physical time in the health home to sit and listen to patient stories (Rakel, 2008).

Investing in Relationship

The medical home is just that, a “home” where someone feels welcome, known, and part of a community. The ongoing relationship with patients provides insight into the complexity of their health care needs and honors the interaction between multiple health perspectives. It allows the clinician to use evidence-based guidelines while realizing that variability is the norm. The best care for one individual may not be best for another. Patient-centered care recognizes that care should be focused on the needs of the individual patient, not simply on a disease state. Ideally, the goal should be “relationship centered,” encouraging attention to the unique needs of the patient to be well. Thus, creating healing relationships is a core goal of an effective medical home (Chez and Jonas, 2005).

The evidence for the benefits of continuous, relationship-centered primary care is solid and growing. It has been found to improve quality of care (Starfield, 1991), reduce expenditures on diagnostic testing (Epstein et al., 2005), reduce hospital admissions (Gill and Mainous, 1998), and lower total health care costs (De Maeseneer et al., 2003). Having continuous, ongoing relationships with patients is often cited as the most rewarding aspect of being a family physician (Fairhurst and May, 2006). A systematic review of controlled trials on effective “team care,” where relationship-centered factors are formalized in the care process, has demonstrated reduced mortality and morbidity, improved morale of health care workers, and reduced costs of health care (Safran et al., 2006).

One health care system that restructured its whole organization around establishing long-term, trusting, accountable relationships is the Southcentral Foundation Alaska Native Health Care model (Eby, 2007). This was the main request of the leaders of native Alaskans when they were asked what they wanted most in their public-owned health care system. Above all else, they valued the relationship with their physician, someone who “listens to them, takes time to explain things and who is able to coordinate effectively their overall care” (Gottlieb, 2007). The system made this its primary objective. After transforming their health model in 1999, urgent care and emergency department utilization decreased by 40%, specialist utilization by 50%, and hospitalization days by 30%. Customer satisfaction surveys showed that 91% rated their overall care as “favorable” (Gottlieb et al., 2008).

Empowerment

The greatest amount of suffering, disability, and cost occurs when the individual becomes more dependent on tertiary health care. The goal of the primary health team is to reduce this need. This requires that physicians empower individuals, families, and communities to understand what they can do to reduce the risk of disease and move the acuity curve in Figure 2-2 to the left. This will increase control of health by the individual, family, and community, with less dependence on the health care industry. To understand how best to work toward this goal, it is important to understand the process of empowerment.

Empowerment does not mean that patients do what is asked of them; this is *compliance*. Empowerment is the antithesis of compliance because noncompliance is two people working toward different goals. Empowerment is a way of interacting in which accurate information is provided in a manner understandable to the individual that both respects and promotes patients’ ability to make decisions for themselves. A patient’s decision making is the “inner,” personal environment, influenced by external issues such as culture, family, peer group, work, and payment for care. Anderson and Funnell (2009) describe this well in their research on empowerment and diabetes care, reporting that 98% of diabetes care is “patient directed.” When a patient is told to act a certain way, this is successful less than 5% of the time.

Empowerment is both a process and an outcome. The *process* requires that a health care partner recognizes individuals’ unique needs and helps them think critically to make informed decisions on which they choose to act. This results in an *outcome* that individuals decide is best for them

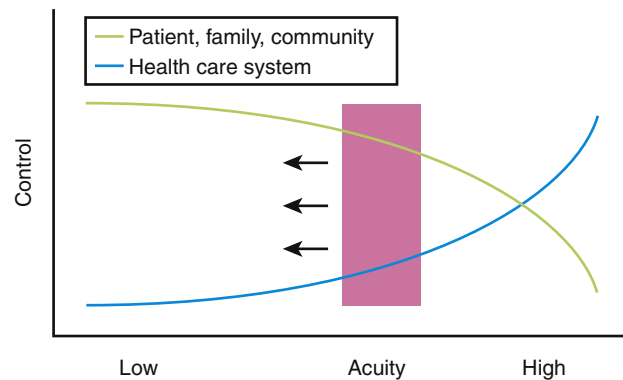

Figure 2-2 The Alaska Native Health Care model moved the slashed lines to the left, reducing dependence on the health care system and increasing control of the family. The goal is to flatten the curves to the right. The health care system should empower the family and community to maintain control of their health and make people less dependent on the “health rescue.” (Modified from Gottlieb K, Sylvester I, Eby D. *Transforming your practice: what matters most.* *Fam Pract Manag* 2008;15:32-38.)

and their current situations. Health care practitioners cannot control their patients’ decisions and thus cannot own the outcome. The clinician can recognize the psychosocial and emotional underpinnings that allow positive change to take place, then gradually and supportively work with the patient toward positive behaviors that the patient, family, and community can define with the guidance of their family physician. As the health guide of the community, the relationship-centered health home requires the development of health teams to facilitate this change.

Health Teams

Health-focused care requires that primary care physicians evolve beyond “physician-centered care” that is restricted by the dwindling access of the one-on-one physician visit. The family physician of the future can be a leader in the creation of a team of health professionals who provide multiple paths to access care (Figure 2-3) (Grumbach and Bodenheimer, 2004). This may involve group visits, phone contact, and information technology. The goal should be a proactive, collaborative team effort toward meeting patient goals, not just expecting adherence to treatment guidelines (Nutting et al., 2009).

In 2003 the Robert Wood Johnson Foundation supported research to bring behavior change initiatives into primary care to address inactivity, unhealthy eating, smoking, and risky drinking (Cifuentes et al., 2005). Lessons learned from 17 practice-based research networks showed that health behavior change resources are enthusiastically received by practices and patients (Cohen et al., 2005; Woolf et al., 2005), and that practices that use multifaceted team-based interventions are more effective in promoting healthy behaviors than those providing isolated therapy (Goldstein et al., 2004; Prada, 2006; Solberg et al., 2000; Woolf et al., 2005).

When working within teams, it is important to understand the difference among multidisciplinary, interdisciplinary, and transdisciplinary team models (Table 2-3). Traditional *multidisciplinary* teams are often focused on disease states and are limited to specific organ systems. In multidisciplinary teams, clinicians work in isolation, with limited

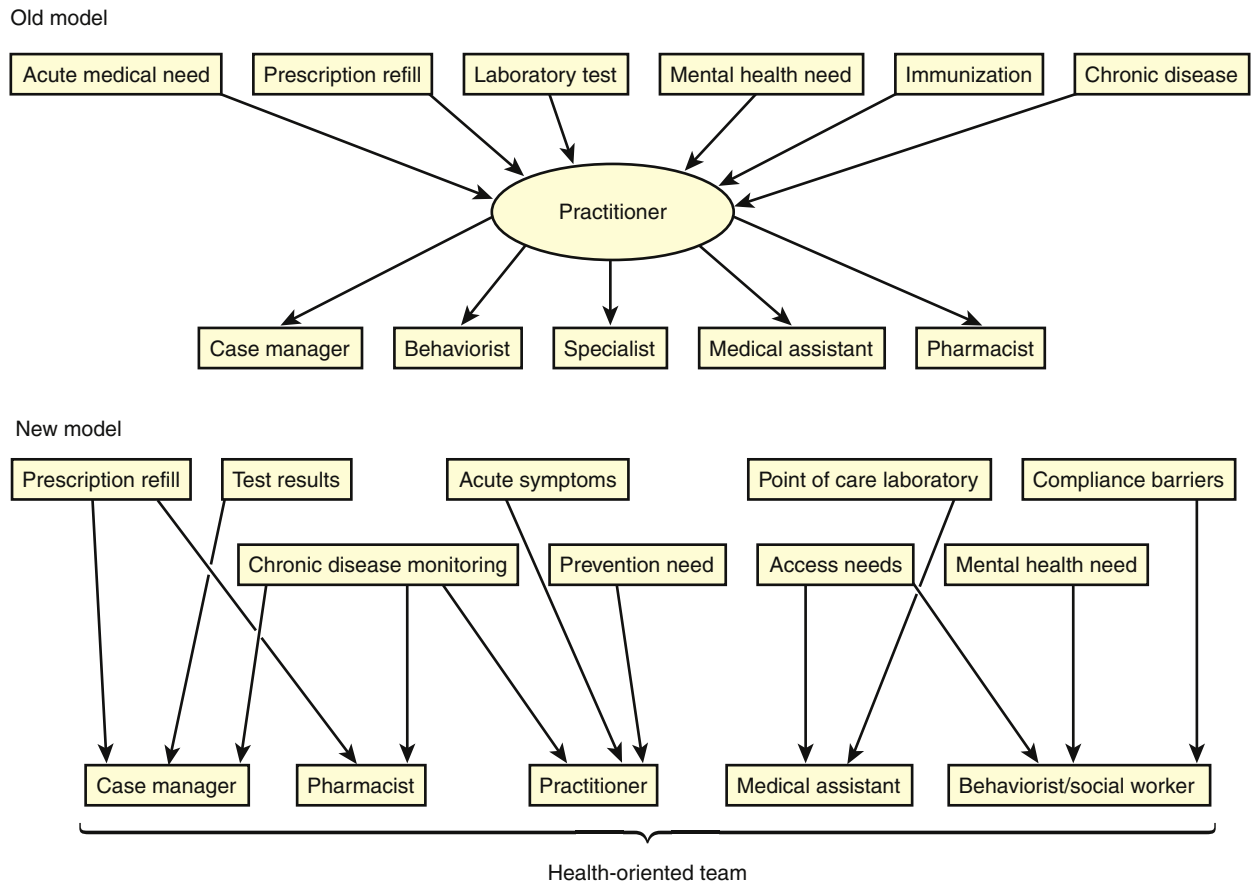

Figure 2-3 Traditional model versus new model of care showing multiple ways to access the health home (medical home).

communication and collaboration. These models tend to focus on body parts or systems in isolation, not recognizing their interdependency. Developing a common goal of health facilitation allows professionals to come together to develop *interdisciplinary* teams that encourage insight toward new ways of problem solving not previously in the group's collective consciousness. When this new insight develops, the interdisciplinary team becomes a *transdisciplinary* team as its members develop novel ways to create (or promote) health that transcend the "siloed" model of care (Choi and Pak, 2006; Soklaridis et al., 2007).

Who Should Compose the Health Team?

The family physician knows the population of the community served and their specific health care needs. This insight will define the professionals who will be of most benefit for health creation (promotion). For example, obesity is a significant health threat in many locales. A team of professionals working together toward sustained optimal weight for patients might include a registered dietician, an exercise physiologist, and a psychologist or mind-body practitioner, to understand the interplay between stress and eating. The process to develop a health-oriented team for musculoskeletal health (back pain) is summarized in Table 2-4.

The health team may look different from a disease team, but there will be obvious overlap. A health home may include a nutritionist who works with diabetic patients. This team member can also provide counseling for prediabetic

persons and overweight youths, to prevent the expression of a disease that is often the result of lifestyle choices.

Health Team Models

There are many ways to develop health-oriented teams. The approach will depend on the needs of patients, the availability of team members, the size of the clinic, strategic planning, and the support of administration and clinic staff. Teams can be initiated in all sizes of clinics, from large, complex institutions to small, rural settings, and may take many forms. For example, a team may include only the family physician and two health coaches or medical assistants. This "teamlet" model extends the office visit to include communication before the visit, after the visit, and between visits (Bodenheimer and Laing, 2007). The teamlet uses these opportunities to address patient needs and develops appropriate strategies. The health team's common mission is working toward the greatest improvement in the patient's quality of life. If the group agrees to work toward uncovering root causes of symptoms, this common goal will progress to disease resolution.

The team does not need to share the same space as long as they maintain communication and build intermember relationships. This will help clinicians learn of each other's interests and talents in relation to common goals, fostering mutual understanding, trust, and respect. Without the team concept, there will simply be separate therapies and professionals working in isolation, causing fragmentation of care.

Table 2-3 Defining Disciplinary Teams

| Term | Definition |
|------------------------|---|
| Multidisciplinary team | Additive. “Comprised of more than two professionals from different health care disciplines who work with the same patient, set of patients, or clinical condition, but provide care independently of each other” (Interdisciplinary Team Building). For example, a patient may have visits with both a primary care practitioner (PCP) and physical therapist (PT). Although the PCP may view clinical notes or a report from the PT, the two disciplines usually do not interact. |
| Interdisciplinary team | Interactive. An ongoing and integrated care team of one patient, set of patients, or clinical condition. Team members develop collegial relationships with shared goals and joint decision making. They interact, supporting as well as questioning each other’s opinions, and negotiate to develop health strategies based on the needs of the individual. |
| Transdisciplinary team | Holistic. Professionals learn from each other and in the process transcend traditional disciplinary boundaries, which may result in new knowledge. Often, the greater the difference between professions (epistemologic distance; e.g., engineering and humanities), the more likely insight will develop toward the creation of a new way to solve a problem. |

Data from Choi BC, Pak AW. Multidisciplinarity, interdisciplinarity and transdisciplinarity in health research, services, education and policy. 1. Definitions, objectives, and evidence of effectiveness. 3. Discipline, inter-discipline distance, and selection of discipline. Clin Invest Med 2006;29:351-64; 2008;31:E41-E48.

The most important ingredient in effective teams is trust—trust that each team member will play his or her particular part in care delivery and process improvement (Sargeant et al., 2008). Changing to an effective team approach takes humility and time and requires constant fine-tuning and quality improvement. However, the physician can begin in any domain that fits the readiness of the practice (see Table 2-4), and the effects will often spread to other domains. The following checklist provides some places to start in a practice assessment format.

The Health Home Checklist

- Create a “home” where those who enter feel known and welcome. Patients will remember how they *felt* in a health home longer than what they are told.
- Create a common mission supported by all health home members; for example, “To invest in a continuous healing relationship with the well-being of the community we serve.”
- Provide multiple ways to access care from the most appropriate health professional (see Figure 2-3).
- Provide a variety of encounter visits that complement the one-on-one office visit. These may include group visits, e-mail, support groups, and health promotion or disease-focused programs.
- Create relationships through open communication with a team of health professionals who can positively influence lifestyle behaviors or address specific disease states.

Table 2-4 Health-Oriented Team Creation Worksheet (Example: Achieving Optimal Back Health)

| Task | Action |
|--|--|
| Health need of my community | Achieving optimal back health |
| Identify professionals to address health need. | 1. Manual practitioner 2. Physical therapist 3. Psychologist/“mindfulness” instructor 4. Health coach |
| Delineate the team-focused goal/mission. | To empower patients to learn how to achieve their ideal back function and health. |
| Name the health-oriented program. | “Back to Health” program |
| Create relationships between team members. | Team members to meet initially to develop program goal/mission and methods of interacting. Periodic meetings as needed for team building and interactions around patient issues. |
| Agree on team communication method. | Fax or e-mail will be sent to the team for referrals, findings, and discussion. |
| Follow up and promote sustainability. | Patient will meet periodically with health coach/nurse at the medical home to sustain lifestyle behaviors. |

- Provide a way for the consumers (patients) to have input into what health-related programs or services are implemented based on their perceived needs.
- Provide an opportunity to understand the most important areas that patients believe need to be addressed for their long-term health. (See the Health Agreement document online at www.expertconsult.com.)
- Learn to provide rapid and evidence-based information on lifestyle and complementary medicine in each team encounter.
- Review the space of the practice, and develop a plan to make it less stress inducing and more comfortable to the patient and team members.
- Make sure the health home that is created matches that which gives family physicians meaning and purpose in their work. This will translate across the medical home, encouraging team acceptance while reducing the risk of burnout.

Conclusion

Creating optimal healing environments with health-oriented teams honors the concepts of the medical home as primary care physicians transition to health as a critical focus (see Table 2-2). This is an exciting opportunity for professionals from varied disciplines to come together to work toward a common goal and honors specific expertise. The family physician’s expertise in understanding the

multiple, complex systems working toward the patient's unique goal of health leads the implementation of these model health homes.

The gift of primary care is the human connection that occurs within continuous healing relationships. Family physicians will succeed in providing efficient, cost-effective quality care if they invest in aspects of care that are the most valuable yet most difficult to measure. The most important area is the nonquantifiable process occurring between the practitioner and patient in which both are transformed (Scott et al., 2008).

EVIDENCE-BASED SUMMARY

- Positive lifestyle behaviors have the largest effect on reducing morbidity and mortality (Khaw et al., 2008; McGinnis et al., 2002; Schroeder, 2007) (SOR: A).
- Team-based interventions are more effective in promoting healthy behaviors than are those that provide isolated therapy (Woolf et al., 2005, Safran et al., 2006) (SOR: B).
- Relationship-centered care improves quality of care (Starfield, 1991) (SOR: B).
- Relationship-centered care reduces health care costs (De Maese-neer et al., 2003; Epstein et al., 2005) (SOR: B).

Key Points

- Factors that influence health include age, gender, and sexual orientation.
 - Religious, ethnic, and cultural groups affect individual functioning.
 - Individuals are affected by family composition, structure, and functioning.
 - The health of an individual is influenced by work and school status.
 - Individuals are affected by their social support network and significant others.
 - Financial resources, including health insurance status, affect health status.
 - Personal and family history of major loss, trauma, or illness should be integrated into the assessment of a patient's health status.
 - Psychological functioning, including personality, defensive style, and current mental status, warrant evaluation.
 - Data about the patient's physical environment, including home, neighborhood, and environmental hazards, are essential.
 - The physician should elicit an account of recent stressors and changes in the patient's life.
 - Collaborative physician-patient relationships that emphasize physician listening form the context for sensitive psychosocial care.
-
- An overweight 11-year-old boy with abnormal lipids tells his family physician that his favorite activity is playing online video games.
 - A middle-aged woman emphatically asserts that her blood pressure is elevated only when she has it taken in a medical setting.
 - A single mother with a part-time job but no health insurance tells her doctor that she can only take medications that have a co-pay of a few dollars.

Psychosocial factors influence health. Assessing and treating patients in a manner that integrates psychosocial and biologic aspects of care are the essence of excellent family medicine and its greatest challenges. The following example is illustrative.

Mr. Ramirez is a 52-year-old man who lost his well-paying job as a software engineer several years ago. After 8 months of unemployment, he took a less satisfying job for less money. Mr. Ramirez has type 2I diabetes, diagnosed when he was 45 years old and well-controlled before he lost his job. He has taken diabetes education classes and can accurately describe what he must do to maintain good glucose control. Reluctantly, Mr. Ramirez acknowledges to his physician that he doesn't follow his diet as closely as he once did and more frequently eats fast food. He also misses the exercise facility at his former workplace and struggles with motivation to exercise. His marriage "isn't as good as it used to be," and he reports decreased interest in sex. When the physician asks him about feelings of depression, Mr. Ramirez says that he never thought he was a weak person, but he just doesn't enjoy things as he once did. His physician emphasizes the changes Mr. Ramirez has experienced in the past few years and the emotional toll of such stress. She briefly describes how stress and depression make diabetes more difficult to control, and how she and Mr. Ramirez can collaboratively work on strategies to improve his health and quality of life.

This case highlights the following three imperatives for providing care that is appropriately responsive to psychosocial issues:

1. The physician *sees the person first*, conceptualizing symptoms and behaviors in their social and psychological context and responding with sensitivity to the patient's experience and priorities.
2. The physician *understands the interactive nature of multiple biopsychosocial variables* and communicates this effectively to the patient.

3. The physician *fosters a supportive and empathic physician-patient relationship* to provide the foundation for gathering information and intervening effectively.

As the case illustrates, biomedical factors may be only a small part of what patients bring to their physicians. The *biomedical model*, based on the assumptions of mind-body dualism, biologic reductionism, and linear causality, has resulted in miraculous achievements of high-technology medicine, but primary care physicians who restrict their attention to purely medical considerations are of limited use to their patients. Nevertheless, the shift from a biomedical to a biopsychosocial paradigm has been a major challenge to modern medicine.

In 1977, psychiatrist George Engel proposed a *biopsychosocial model* that included social and psychological variables as crucial determinants of disease and illness. According to his new framework, the subsystems of the body interact to produce successively more complex biologic systems, which are simultaneously affected by social and psychological factors. The organism is thus conceptualized in terms of complex interacting systems of biologic, psychological, and social forces, and neither disease nor illness is seen as understandable only in terms of smaller and smaller biologic components. Engel (1980) believed that systemic interactions of biopsychosocial factors were relevant to all disease processes and to the individual's experience of illness. Accordingly, understanding a person's response to a disease requires consideration of such interacting factors as the social and cultural environment, the individual's psychological resources, and the biochemistry and genetics of the disorder in the population (Brody, 1999).

In the following section, we present a number of conceptual models and perspectives that emphasize different but overlapping psychosocial dimensions that influence health (Table 3-1). These models can aid practicing physicians in thinking about their patients in a psychosocial context and conceptualizing potentially helpful interventions. Subsequently, we elaborate on practical strategies for gathering and using psychosocial information in clinical practice and discuss a pragmatic approach to addressing psychosocial considerations in primary care. We conclude with brief discussions of evidence-based practice and how current challenges and trends in the health care system may affect the practice of family medicine.

Conceptual Models

The Biopsychosocial Model

As previously noted, the biopsychosocial model was proposed as a scientific paradigm by Engel (1977), who encouraged the clinician to observe biochemical and morphologic

Table 3-1 Psychosocial Influences: Conceptual Models

Biopsychosocial model
Systems approach
Stress and coping model
Life span perspective
Ethnomedical cultural model

changes in relation to a patient's emotional patterns, life goals, attitudes toward illness, and social environment. Engel proposed that the brain and peripheral organs were linked in complex, mutually adjusting relationships, affected by changes in social as well as physical stimuli. Within this model, environmental and psychological stress is seen as potentially pathogenic for the individual. Emotions may serve as the organism's bridge between the meaning (or significance) of stressful events and the changes in physiologic function (Zegans, 1983). Engel urged physicians to evaluate the patient on biologic, psychological, and social factors in order to understand and manage clinical problems effectively (Wise, 1997). For example, a workplace accident could be seen as resulting from poorly designed equipment (social) and inattentiveness (psychological) brought about by low blood sugar (biologic). Similarly, the accident could result in damage to internal organs (biologic), distress (psychological), and lost income (social), any or all of which may become the focus of physician intervention.

Comprehensive evaluation of biopsychosocial dimensions would assess the following:

- *Biologic factors*, including genetics, medical history, and environmental factors that affect physiologic functioning (e.g., those causing cancer).
- *Psychological factors*, including affective, cognitive, and behavioral components, such as feelings, beliefs, expectations, personality, coping style, and health behaviors (e.g., exercise, diet, smoking), which are contributors to patients' experience of health and illness.
- *Social factors*, including access to health care, quality of available health care, social systems (e.g., family, school, work, church, government), social values, customs, and social support.

Further discussion of biologic influences on health is beyond the scope of this chapter. Psychological and social factors known to affect health are discussed next.

Psychological Factors

The numerous theories about personality in human history reflect a variety of cultural, religious, philosophic, and scientific perspectives. Two of these, "hardiness" and the five-factor model, are discussed here. We also review key features of the literature on the relationship between emotions and health.

Hardiness is one personality construct that has received considerable research support in explaining who does and who does not become sick under stress (Kobasa, 1979). Hardiness includes three characteristics (Table 3-2): (1) a strong sense of *personal control*; (2) *commitment*, a sense of purpose or involvement in events or activities; and (3) *challenge*, the ability to see change as an opportunity for growth. Kobasa and her colleagues (1982) demonstrated that people with high levels of the "three Cs" of control, commitment, and challenge tended to remain healthier than their less hardy

Table 3-2 The Three "C"s of Hardiness

Control: having a sense of personal control of the future.
Commitment: sense of commitment and purpose in life.
Challenge: seeing change as a challenge or opportunity.

Table 3-3 Five-Factor Model of Personality

1. Openness to experience: tendency to be curious and appreciative of a variety of experience.
2. Conscientiousness: proclivity to be self-disciplined, to plan, and to direct behavior toward achieving goals.
3. Extraversion: reference for being around other people, to be enthusiastic and socially energetic.
4. Agreeableness: inclination to be cooperative with others, strongly preferring harmony over disagreement.
5. Neuroticism: propensity to experience negative emotions on an ongoing and regular basis.

counterparts. Studies show that illness increased with stress and decreased with greater hardiness and exercise. A physician's knowledge of a patient's degree of hardiness may help in assessing the patient's response to stressors.

The most prominent approach to personality at present is the *five-factor model* (Goldberg, 1993). The five broad personality domains in this model, for which OCEAN can be an acronym, are *openness to experience*, *conscientiousness*, *extraversion*, *agreeableness*, and *neuroticism* (Table 3-3). Research on the relationship of these factors to health variables has generated several findings. *Conscientiousness* has been associated with longevity among healthy individuals and better functional status in those with physical illnesses or impairments, whereas *neuroticism* is consistently found to be negatively correlated with health (Goodwin and Friedman, 2006; Smith and Mackenzie, 2006). *Agreeableness*, *extraversion*, and *openness to experience* generally tend to have weaker associations with health and therefore are considered less relevant to understanding links between personality and health.

Because personality style is regarded as stable across the life span, physician focus on changing personality for health reasons is not a sensible pursuit. However, viewing personality from a broader perspective, with specific regard to how individuals experience and manage emotion, does offer the physician more latitude in intervention.

The experience of *chronic negative emotions* (depression, anxiety, and anger) tends to be associated with poorer health. There is an extensive research literature linking negative affectivity and pessimism to adverse health outcomes (Peterson et al., 1988; Salovey et al., 2000). Although the experience of negative emotions is a natural part of the human experience, effective management of such emotions through cognitive strategies, active coping, and social support can be learned, and medications can be a helpful adjunct when negative emotional states are prolonged or severe.

Likewise, a large body of research indicates that *positive* emotional states are associated with better health and longevity. Happiness, optimism, and positive attitudes toward aging have been associated with 7 more years of life (Daner et al., 2001; Levy et al., 2002). Almost three decades of research have shown that an optimistic outlook has a positive effect on coping and on mental and physical health outcomes (Peterson and Steen, 2002). Family physicians have long recognized the importance of mobilizing and maintaining patient hopefulness through encouraging words that foster positive expectations of medical treatment. Additionally, the demonstrated efficacy of placebos affirms the importance of this approach (Sobel, 1991).

Social Factors

A gradient between socioeconomic status (SES) and health is consistently found in epidemiologic studies (Marmot, 2004). Persons with less education and income tend to have poorer health than their better-educated and richer counterparts. Interestingly, subjective SES (i.e., individuals' perceptions of where they view themselves on the social ladder) has an even stronger relationship to health than objective SES (Singh-Manoux et al., 2005). Negative affect, stress, pessimism, and a decreased sense of control are among the factors thought to contribute to the relationship between lower subjective SES and poorer health (Operario et al., 2004).

In general, social support reduces stress and contributes to more positive health outcomes. *Social support* refers to the process by which a social network provides psychological and material resources to enhance an individual's ability to cope with stress (Cohen, 2004). Both quantity and quality of support are important, and sources of support include spouse, lover, friends, family, co-workers, and health care professionals. A person who has many friends but no confidant may have inadequate social support in a time of need. Some people report high levels of satisfaction with just a few close friends, whereas others require larger social networks.

There are several varieties of social support (Cohen, 2004). *Emotional support* involves the expression of caring, concern, and empathy toward the person and typically involves opportunities for the recipient to express emotions and vent. *Instrumental support* involves providing some type of direct assistance, which might include financial resources, transportation, or help with daily tasks. *Informational support* involves giving advice or providing relevant information to an individual.

Social support appears to undergird health by buffering the person against negative effects of stress, perhaps by affecting the cognitive appraisal of stress. When people encounter a strong stressor, such as a major financial crisis, individuals with high levels of social support may appraise the situation as less stressful than will those with low levels of support. Social support may further buffer the stress by modifying people's response to a stressor as they turn to friends for advice, reassurance, or material aid. Social integration, or participating in a broad range of social relationships, benefits health and well-being by enhancing self-esteem and fostering positive health behaviors in people who believe that others count on them. Social integration is beneficial, whether or not an individual is experiencing stress (Cohen, 2004).

Relationships also can involve significant negative social exchange and be harmful to health. For example, negative interactions in troubled marriages have adverse effects on cardiovascular, endocrine, and immune system function (Robles and Kiecolt-Glaser, 2003).

Misconceptions

Polan (1993) identified and addressed two common misconceptions about the biopsychosocial model. First, contrary to popular belief, the physician who is "humanistic" is not necessarily practicing biopsychosocial medicine. A physician can be ethical and caring but still neglect scientific knowledge from psychology, sociology, anthropology, and relevant data from the patient's life. For example, compassion by itself

is of limited usefulness to a physician who needs an effective treatment plan for an asthmatic patient who smokes. Knowledge of the social environment and of the individual psychology of the patient is crucial.

The second common misconception is that people can be reduced to distinct biologic, psychological, and social categories, or that problems can then be expressed as a set of scientific principles from which diagnosis and treatment can be neatly derived. In fact, use of the biopsychosocial model *increases* rather than decreases the level of complexity required to understand patient status, introducing multiple avenues for intervention. Interpreting the biopsychosocial model as a new opportunity for reductionist thinking diminishes the power to inform more holistic treatment. Borrell-Carrio and colleagues (2004) proposed a biopsychosocially oriented clinical practice, based on self-awareness, active cultivation of trust, an emotional style characterized by empathic curiosity, self-calibration to reduce bias, cultivation of emotional sensitivity to assist with diagnosis and therapeutic relationships, use of informed intuition, and communication of clinical evidence to foster dialogue.

The Systems Approach

Humans are infinitely complex. Adequately conceptualizing a person in health or illness requires a systems approach that encompasses this complexity. The concept of *systems* was first developed by von Bertalanffy (1968) to refer to the dynamic interrelationships of various components. A systems approach rejects the notion of linear causality in favor of multidimensional and multidirectional models.

The systems approach has strongly influenced conceptualizations of family functioning. Smilkstein (1978) developed one of the first applications of “family systems” thinking for family medicine. Physician attention is important to the systemic interactions of family members and the impact of crisis, coping styles, and resources on family functioning. He incorporated these components into the “family APGAR”

(*adaptation, partnership, growth, affection, and resolve*), a simple instrument and mnemonic device for assessing the functioning of a family system in health and illness (not to be confused with the newborn Apgar score).

The Stress and Coping Model

General relationships among life stresses, coping resources, and health outcomes are presented schematically in Figure 3-1. This approach represents another example of the application of a systems model. As this model illustrates, health outcomes are impacted by how life stresses affect the individual. The effect of stress is moderated by the individual’s appraisal and coping responses, personality, and the person’s available social resources. Although the complex synergistic interactions that characterize these relationships are beyond the scope of this chapter, the major variables provide a basis for considering physician interventions.

Definitions of Stress

Stress has been variously defined as an environmental event, a response to an event or circumstances, and a process. One approach defines stress in terms of life events—as a stimulus—circumstances or events that require the person to adapt produce feelings of tension. These *stressors* may be major catastrophic events (e.g., natural disaster), major life events (e.g., death of a loved one), or recurrent daily hassles (e.g., need to manage a chronic medical condition).

Stress can also be seen as a response. For example, a person with a social phobia feels stressed in a social setting such as a party, experiencing a psychological state of nervousness with associated physical symptoms of dry mouth, palpitations, and sweating. This physiologic and psychological response to a stressor is often called *strain*.

A third approach emphasizes stress as a process in which “environmental demands tax or exceed the adaptive capacity of an organism, resulting in psychological and biologic

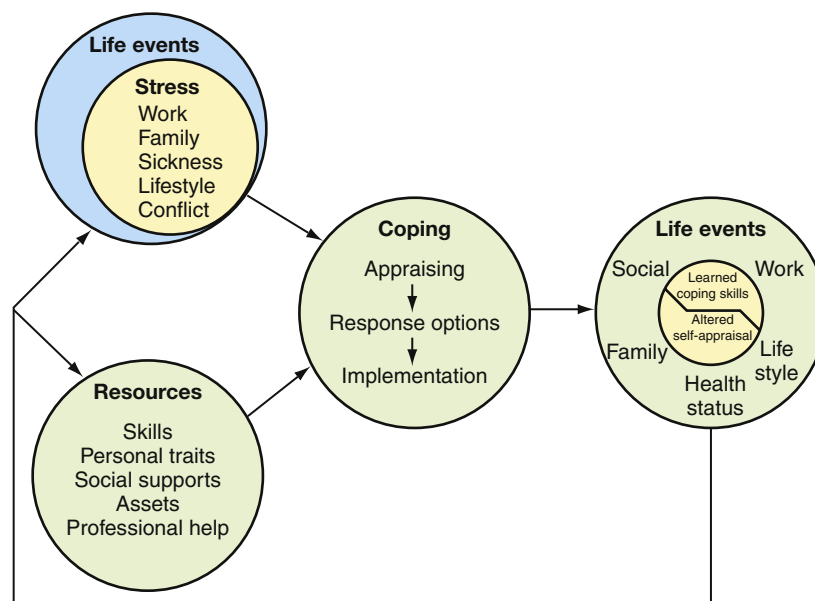

Figure 3-1 Stress, life events, and coping. (From Tunks E, Bellissimo A. *Behavioral medicine: concepts and procedures*. Boston, Allyn & Bacon. Copyright © 1991 Person Education.)

changes that may place persons at risk for disease” (Cohen et al., 1995). Within this approach, stress includes stressors and strains, along with the relationship between the person and the environment. The process involves transactions between the person and the environment, with each affecting and being affected by the other (Sarafino, 1990). “Adaptive capacity” is operationalized in terms of resilience and vulnerability; the physician considers aspects of a person’s psychological makeup and social world that may render the patient more susceptible or more resilient (Steptoe, 1998).

Stress Appraisal and Coping

Every family physician sees patients under stress who present with a wide spectrum of stress-related symptoms and coping responses. How the individual interprets and copes with stress is as significant as the stressor itself. Cognitive appraisal of a stressor, rather than severity or duration alone, determines physiologic and behavioral responses (Epel et al., 1998).

Coping refers to how individuals manage the real or imagined discrepancy between environmental demands and their resources for addressing the stressful situation. According to Lazarus and Folkman (1984), adaptation to stress is mediated by appraisal (i.e., personal meaning of a stressor and one’s sense of resources for dealing with it) and coping (i.e., thoughts and behaviors used to manage stress). With emotion-focused coping, a person directs energy to regulating internal feeling states, whereas with problem-focused coping, a person directs attention to reducing the stressor or expanding resources for dealing with it (Sarafino, 1990). The effect of stressful life events on health is determined by many factors related to coping, such as cognitive style, personality characteristics, and social and behavioral tendencies.

Personal Control

An individual’s perception of the extent of his or her control in a stressful circumstance is a critical component of the appraisal process in coping. This includes control over the stressor or circumstances as well as control over one’s responses, whether problem focused or emotion focused. How a person deals with the loss of control precipitated by stressful life events can affect health outcomes.

Personal control can be defined as the feeling that one can make decisions and take effective action to produce desirable outcomes and avoid undesirable ones (Rodin, 1986). Mobilizing a strong sense of personal control can significantly reduce the impact of stressors on the individual, particularly when the response is appropriate to the circumstance. Sarafino (1990) classified personal control into the following five types:

1. *Behavioral control* involves the ability to take concrete action to reduce the impact of a stressor; for example, using a special breathing technique to reduce pain.
2. *Cognitive control* involves the ability to use thought processes or strategies to modify the impact of a stressor. For example, focusing on a pleasant thought during suturing of a laceration may decrease the pain sensation.

3. *Decisional control* involves the opportunity to choose between alternative procedures or courses of action. For example, a victim of domestic violence may benefit from considering various options when and how she will leave her abuser.
4. *Informational control* involves the opportunity to obtain knowledge about a stressful event, what will happen, why, and what consequences are likely. For example, a patient may decrease anxiety regarding upcoming surgery when he learns more about managing discomfort from the procedure.
5. *Retrospective control* involves beliefs about causation of a stressful event after it has occurred. The attribution that the person makes about the adversity can affect future perspective and behavior. For example, attributing misfortune for factors that are temporary and specific leaves an individual feeling more optimistic than when misfortune is attributed to stable and global factors (Seligman, 1990).

Life stresses affect health outcomes. These effects are moderated not only by individual differences in genetics and pathophysiology, but also by psychosocial factors. Psychosocial influences include appraisal and coping, personality traits, cognitive styles, and resources (including social support).

The Life Span Perspective

The life span perspective emphasizes the importance of an individual’s place on his or her personal developmental trajectory. Past development, current status, and anticipated developmental changes and challenges are taken into account. On the biologic level, changes in cellular functions occur from infancy through old age; decline in physical stamina is one manifestation of this dynamic change. On the psychological level, personality interacts with ongoing changes that occur across the life span (e.g., becoming a parent), and each developmental stage brings its own psychosocial challenges. Erikson’s eight stages of development highlight the importance of trust issues in infancy, autonomy issues in early childhood, and issues of generativity and meaning in old age (Erickson, 1959). On the social level, family and peer relationships change throughout life, with significant implications for health, which may be either positive or negative. For example, the typical adolescent’s shift toward greater reliance on peer relationships may lead to behaviors that endanger health, such as smoking or substance abuse. The death of a husband who has been physically abusive may lead to improved well-being for the surviving wife. The primary care physician needs to keep the life span model in mind and assist patients in addressing psychosocial factors that facilitate or block health and development.

The Ethnomedical Cultural Model

Every encounter between a patient and a physician is a cross-cultural transaction. Each person brings to the physician-patient relationship a unique mix of culturally embedded attitudes, knowledge, and beliefs. Ethnicity, gender, religion, language, education, and personal history shape expectations and behavior on both sides of the relationship. A physician’s cultural proficiency is instrumental in establishing rapport

and gathering information for accurate and comprehensive diagnosis and treatment (Carrillo et al., 1999). The patient's acculturation status and cultural background are important to understand, and physicians should become familiar with the dominant cultural groups they serve.

The ethnomedical cultural model emphasizes cultural concepts relevant to health and illness (Kleinman et al., 1978), including patient beliefs and expectations about the body, illness, and treatment. Berlin and Fowkes (1983) operationalize this model in clinical encounters with their LEARN acronym, exhorting physicians to do the following:

- Listen with empathy and understanding to a patient's perception of the problem by eliciting the patient's explanatory model for the illness.
- Explain your perceptions or explanatory model in language the patient can understand.
- Acknowledge the differences and similarities between your explanatory model and that of the patient, and discuss any significant discrepancies.
- Recommend treatment that you decide is optimal within your explanatory model.
- Negotiate treatment with the patient, seeking a compromise that is acceptable to the patient, is consistent with your ethical standards, and uses the patient's social network when necessary.

The ethnomedical cultural model highlights cross-cultural elements in all physician-patient interactions.

Integration of Psychosocial Issues in Clinical Practice

Wynne (2003) states, "In the 'real' world of health care, systems thinking is more needed than ever before, but its increased complexity challenges both clinicians and researchers to the depths of their resources." Knowledge, attitudes, beliefs, emotions, behaviors, relationships, and social environmental interact to affect the experience of illness or well-being. Accordingly, physicians' ability to promote health and relieve suffering depends on their ability to engage effectively in this complex web of interrelationships. This is a daunting task that depends on fostering a quality relationship over time, gathering sufficient biopsychosocial data about a particular patient, and integrating data with theoretic understanding to inform interventions.

The challenge for even the most astute physician is to assess and address psychosocially important issues within the limited time available for each patient. In a 10- to 15-minute period, a detailed evaluation of all relevant psychosocial factors is an impractical goal. Using a pragmatic approach that balances this goal with time constraints, a physician can maintain awareness of psychosocial cues and information in all patient encounters while restricting direct inquiry, depending on the specific situation. A physician may not need to elicit a detailed psychosocial assessment with every patient who presents with an upper respiratory infection, but knowing if the patient smokes would be useful, leading to further inquiry and potential smoking intervention.

Following pragmatic considerations, a physician should work collaboratively with patients to identify problems of highest priority and to address different issues in different encounters. For example, in the case of domestic vio-

lence, immediate needs for patient safety must be addressed. Addressing long-standing issues, such as dysfunctional means of coping with stress, must be a secondary concern in the face of the primary need to achieve safety. Similarly, every physician learns to place high priority on patient complaints of chest pain, adjusting questioning depending on the patient's age, gender, family history of coronary heart disease, and patient medical history. Nevertheless, the physician must look for psychosocial clues, evaluate stressors, and be aware of factors that suggest an anxiety or somatization disorder. These secondary factors can be addressed in more depth when the physician is assured that a cardiac crisis is not imminent.

Collection of Psychosocial Data

In family practice settings, the most common and natural approach to gathering psychosocial data is interviewing the patient over time. Freud suggested that the major achievements of healthy development were the abilities "to work and to love," and this is often a good place to start, even in the first contact with a physician. Where does this patient work, and how does he or she feel about the job, school, or household responsibilities? Who is "family" for this patient, and what is the nature of the support system? Detailed inquiries about work and love made in the context of the ongoing physician-patient relationship result in significant accretion of knowledge over time and make it easy to flag stressful changes in these important arenas.

Other important areas of inquiry include the patient's physical and social environment. Factors such as the quality of housing, neighborhood, food, and financial resources all affect patient safety, health care use, family stress, and physical health. Understanding the ethnic, religious, and political culture of a patient and family is important for guiding culturally appropriate care. Personal and family history, usually gathered gradually over time, can alert the physician to important family coping patterns, strengths, and liabilities. Of special importance is information on major personal family "dislocations," including losses, illness, and trauma. Knowledge of traumatic patient encounters with previous medical care may alert the physician to anticipate and manage potential crisis situations.

Information from patient dialogue can be supplemented by standard measures such as health questionnaires (e.g., SF 36), screening inventories (e.g., Beck Depression Inventory), and stress, coping, and social support tools. Other areas include interviews with family members, including structured assessments (e.g., family APGAR); review of existing records (e.g., school records); consultation with multidisciplinary colleagues (e.g., psychologist, occupational therapist); observation of the patient's environment through home visits; and consultation with cultural informants and translators when needed.

Interventions Using Psychosocial Data

A comprehensive review of interventions addressing psychosocial influences in health is beyond the scope of this chapter and would require discussions of clinical psychology, social work, nursing, occupational therapy, and public health. Even in optimal circumstances, competency can be achieved only within a limited range. Realistically, family physicians should

achieve basic proficiency in selected interventional strategies and pursue additional training in areas of interest relevant to their specific practice needs. Here we discuss pragmatic interventions for practicing physicians based on the general model of stress, life events, coping, and health discussed earlier.

Because health outcomes are affected by stressful life events, coping (e.g., stress appraisal), and resources (e.g., personality, social support), addressing any dimension can have a positive effect on functioning. As stress increases relative to available support and coping capacities, disequilibrium results. Increases in stress or decreases in social support tend to destabilize functioning, and various factors can contribute to exacerbating or mitigating stress. For example, a new medical diagnosis is stressful, whereas a loving partnership is a source of support and will tend to ease stress. Some life events, such as the death of a supportive partner, affect several elements in the model, as the bereaved partner confronts a major loss (stress) without the person who had previously offered comfort in such times (decreased support). Accordingly, persons who are grieving are at higher risk for experiencing health problems (Rogers and Reich, 1988).

Interventions that should be part of the standard repertoire for family physicians are those that do no harm, usually help, and employ traditional skills. Specifically, physicians can work with patients directly to reduce stress, to enhance or mobilize social support resources, and to reinforce or model positive stress appraisal and coping. *Direct approaches* to stress reduction may include intervening in the patient's environment (e.g., arranging respite care for an older patient to relieve stress on his middle-aged daughter) and allaying a patient's unrealistic fears about an illness. *Social support* can be enhanced directly through the provision of more contact with the physician or indirectly through mobilizing the patient to increase contact with family or friends. Physicians can support *positive coping* through instilling hope, modeling optimism, and encouraging patients who adapt. Reminding patients of personal strengths previously used to confront crises is also helpful. The physician often can implement these strategies through the process of asking questions that allow the patient to respond in a broader perspective (e.g., "What do you remember doing to help you cope with the death of your good friend several years ago?"). Especially when behavior change is indicated, collaborating rather than giving advice is more likely to be effective. One collaborative approach that has demonstrated efficacy is motivational interviewing (Rollnick et al., 2008; Rubac et al., 2005).

In the provision of care within a biopsychosocial model, interdisciplinary teams, rather than solo practitioners, have the advantage, and physicians can have more positive impact on their patients' lives when they harness the wisdom of colleagues from other fields through referral or consultation. Depending on physician training, interest, and time, these basic categories of intervention can be supplemented by a wide range of psychosocial interventions, from family therapy to behavior modification.

Important Times for Psychosocial Interventions

Interventions that attend to psychosocial issues are especially important at specific times in the provision of family medical care. *Natural transitions in the family life cycle*, such as the

birth of a child or the death of a spouse, call on the physician to provide empathic support, assess the patient's support system, normalize emotional reactions, and provide anticipatory guidance as patients confront changing family roles and functioning.

When adherence or lifestyle issues impinge on health, interventions that focus on biologic mechanisms alone are likely to be ineffective. The health effects of substance abuse, domestic violence, poverty, or inactivity are often best addressed through attention to social environment and psychological concerns.

A dramatic change in patient symptoms also indicates consideration of psychosocial factors. A psychosocial crisis can provoke an exacerbation of a chronic condition (e.g., rheumatoid arthritis), a new manifestation of illness (e.g., myocardial infarction), or emotional-psychiatric symptoms (e.g., anxiety, trouble sleeping) best treated through stress reduction and symptomatic care.

A significant medical diagnosis may precipitate emotional distress or psychosocial upheaval and requires physician attention to the context of the patient's life. Effective physician intervention may involve anticipating the nature of the potential family crisis, including family members in discussions with the patient, and addressing family needs for support. Timely provision of accurate information can enhance a patient's sense of control. Direct support by the physician during the initial adjustment phase can minimize more serious emotional disruption.

Patients living with chronic illness require sensitive psychosocial care. Managing a chronic health problem challenges a person's ability to adhere to a myriad of medical recommendations, making it more difficult to cope with other life stressors. Patients often deal with the predictable set of issues in highly idiosyncratic ways. Adequate attention to these issues can make medical management easier and more successful. These issues can often be effectively addressed within the physician-patient relationship and through judicious referral to support groups for chronically ill patients. Pollin (1995) identified eight emotionally charged issues that patients with chronic illnesses inevitably confront: control, self-image, dependency, stigma, abandonment, anger, isolation, and death. The professional stance useful in assisting the patient with each issue is important. In response to control issues, for example, professionals should help patients express their feelings of loss of control and to identify areas where they may feel powerless. Normalizing the patient's feelings and fears is the first step in helping address control issues. The goal of intervening in this issue is to reinforce the patient's confidence in being able to cope with the demands of the medical condition.

Evidence-Based Practice

Increasingly, high-quality data are available that support the therapeutic efficiency of a variety of general and specific behavioral interventions relevant to primary care practice (Trask et al., 2002). A systematic review by Di Blasi and colleagues (2002) on the consequences of nonspecific effects of the physician-patient relationship found that providing information and emotional support contributed to recovery or improvement from physical illness. Because coping with

stress and managing chronic illness often involve behavior change, physicians may use “motivational interviewing” approaches to assist these patients (Rollnick et al., 2008).

Much research demonstrates the efficacy of psychosocial interventions in diseases historically viewed as purely medical, including cancer (Anderson et al., 2007; Edwards et al., 2008; Rehse and Pukrop, 2003; Spiegel et al., 1989) and diabetes (Bogner et al., 2007), as well as behavioral interventions such as exercise for cardiovascular disease (Taylor et al., 2004). Online resources are available to search for study results (see Web Resources at end of chapter).

Given the time constraints typically encountered by primary care physicians and the expertise required to use behavioral interventions effectively, the physician should be aware of behavioral health providers in the community in order to make effective and timely referrals. The evidence base for effective behavioral interventions in numerous psychiatric and psychosocial problems, as well as medical problems, continues to expand (e.g., mood and anxiety disorders, trauma victims). Highly effective treatments are underused when physicians underrefer to mental health professionals with specialized training and overrely on the use of psychotropic medicines alone. Unfortunately, even when guidelines are available that physicians could follow themselves, resistance to change impedes their implementation (Torrey et al., 2001).

EVIDENCE-BASED SUMMARY

- Providing information and emotional support contributes to the recovery and improvement from physical illness (SOR: A; Di Blasi et al., 2002).
- Negative emotions such as anger, anxiety, and depression are associated with poor health (SOR: B; Salovey et al., 2000).
- Positive emotions such as happiness, optimism, and a positive attitude have been shown to add 7 years to life (SOR: B; Danner et al., 2001; Levy et al., 2002).
- “Motivational interviewing” outperforms traditional advice-giving in addressing a broad range of behavioral problems (SOR: A; Rubac et al., 2000).
- Exercise-based rehabilitation for patients with cardiovascular disease is associated with reduced cardiovascular-related and all-caused mortality (SOR: A; Taylor et al., 2004).
- Treating depression in older patients with diabetes reduces mortality (SOR: A; Bogner et al., 2007).

The Patient-Centered Medical Home and Psychosocial Issues

The passage of federal health care reform in 2010 has made this issue even more controversial in the United States. Health care spending currently represents approximately 18% of the U.S. gross domestic product (GDP) and is projected to surpass 20% within a decade (Sisko et al., 2009). Concern about uninsured and underinsured persons remains, although new legislation to mandate insurance coverage is scheduled to take effect in 2014.

Numerous perspectives exist on how the health care system needs to change, but a consensus is emerging that focuses on the importance of primary care and on managing chronic

disease in the context of a high-quality physician-patient relationship (Bein, 2009). This consensus reflects the accumulating evidence that higher-quality health care at lower cost is achieved when primary care is emphasized (Starfield et al., 2005).

The concept of the patient-centered medical home (PCMH) embodies this emerging emphasis. As discussed in Chapter 2, the numerous components of a PCMH (or “health home”) include the use of an electronic health record, better access and scheduling processes, use of evidence-based medicine, more point-of-care services (e.g., multidisciplinary teams, group visits), and an ongoing emphasis on quality improvement. Some argue that incremental change in this regard is insufficient, and that transformation of practices is necessary (Nutting et al., 2009). Such transformation would include a broad, population-based approach to preventive services and chronic care, beyond a “single patient at a time” approach. However, services are individualized to each patient based on the patient’s goals and unique needs, which includes attention to the psychosocial factors that affect chronic disease prevention and management.

These trends represent an opportunity for family medicine to take a leadership role in health care reform, with an emphasis on psychosocial aspects. The PCMH philosophy is consistent with family medicine’s long-standing emphasis on whole-person care in the context of a high-quality physician-patient relationship. Ideally, the family physician in a health home setting will address the psychosocial needs of patients in collaboration with ancillary providers, as needed.

Conclusion

To practice in a way that sensitively integrates psychosocial concerns, a physician needs to have a solid knowledge base in the social and behavioral sciences (Cuff and Vanselow, 2004). This general knowledge base complements specific knowledge of self, patients, practice, and community. Self-knowledge entails an honest assessment of the physician’s knowledge base, skills, and attitudes relevant to comprehensive care. Acknowledging limitations in dealing with psychosocial issues in primary care is vital and can serve as an impetus to pursue further training and to develop appropriate collaborative relationships with other professionals. The responsible physician feigns neither knowledge nor empathy, but relies on an interdisciplinary network of professional and community resources to complement personal limitations.

Knowledge of each patient is also requisite to the provision of sensitive psychosocial care, with attention to life stresses, coping, personality, and social resources. As Osler (1904) emphasized, knowing what kind of person has a disease is as important as knowing the disease. Also, the physician needs to know the population, including demographic, socioeconomic, cultural, and epidemiologic dimensions. Addressing psychosocial issues in a practice that serves an ethnically diverse, indigent population presents different challenges than addressing the needs of an affluent population from a familiar ethnic and cultural background. Understanding the practice also entails knowing the health care economics and current systems of care, which inevitably introduce challenges to comprehensive care.

Family physicians are responsible for the care of increasing numbers of elderly patients and their unique and complex primary care needs. Older patients often have comorbidities, “polypharmacy,” and psychological, social, and functional impairments. These can lead to variability in presentation of health problems and make diagnosis and treatment challenging for the family physician.

This chapter discusses common geriatric syndromes and outlines a process by which the family physician can effectively and efficiently care for the elderly patient. The main goal is to assist elderly persons to maintain function and quality of life with self-respect, preserving their lifestyle as much as possible. The chapter addresses functional assessment, falls, elder abuse, pressure ulcers, rational drug prescribing, and incontinence; geriatric conditions such as dementia, delirium, and depression are discussed in other chapters.

Geriatric Assessment

Key Points

- A comprehensive geriatric assessment includes a systematic approach assessing medical, functional, psychological, and social domains.

- A medication review is an essential component of a geriatric assessment.
- A multidisciplinary approach is used to identify intervention and management strategies.
- A questionnaire targeted to the geriatric assessment domains will expedite the patient visit.
- The goals of the geriatric assessment are to maintain function and preserve quality of life.

Longer life spans and aging “baby boomers” will double the population of Americans age 65 years and older over the next 25 years. The dramatic increase in life expectancy in the United States is the result of improved medical care and prevention efforts. In 2006, persons 65 years or older numbered 37.3 million and represented 12.4% of the U.S. population, about one in every eight Americans. The population 65 and over increased from 35 million in 2000 to about 40 million in 2010, a 15% increase, and then will increase to 55 million in 2020, a 36% increase for that decade. According to the Centers for Disease Control and Prevention (CDC, 2007), by 2030 there will be about 71.5 million older persons, more than twice their number in 2000 and about 20% of the U.S. population (Table 4-1).

There has been a significant shift in the leading causes of death for all groups from infectious disease and acute illnesses to chronic diseases and degenerative illnesses. Of the

Table 4-1 Population by Age and Gender: 2008*

*Numbers in thousands; civilian noninstitutionalized population.

elderly population, approximately 8% experience severe cognitive impairment, 20% have chronic disabilities and vision problems, and 33% have restrictions in mobility and hearing loss (Freedman et al., 2002). There are also the predictable age-related structural and physiologic changes that occur with aging. External factors such as diet, occupation, social support, and access to health care can significantly influence the extent and speed of the physiologic decline (Arif et al., 2005; Sarma and Peddigrew, 2008; Tourlouki et al., 2009).

America's aging population is also marked by a more racially and ethnically diverse group of individuals. Simultaneously, the health status of racial and ethnic minorities lags far behind that of nonminority populations. The burden of many chronic diseases and conditions, such as hypertension, diabetes, and cancer, varies widely by race and ethnicity. Data from the 2004 National Health Interview Survey (NHIS) indicated that 39% of non-Hispanic white adults aged 65 years or older reported very good or excellent health, compared with 24% of non-Hispanic blacks and 29% of Hispanics.

There is a strong economic incentive for action. The cost of providing health care for an older American is three to five times greater than the cost for someone younger than 65. As a result, by 2030, the nation's health care spending is projected to increase by 25% because of these demographic shifts (CDC, 2006).

A comprehensive geriatric assessment is a systematic approach to the collection of patient data. The approach varies greatly, from single-physician evaluation with referral as needed, to full teams of professionals evaluating all patients. The geriatric assessment can assist in developing an individualized approach to each patient (Table 4-2). It is imperative to recognize the unique "blueprint" of what characterizes each elderly patient, including age, ethnicity, education, religious or spiritual beliefs, traditions, diet, interests/hobbies, daily routines, medical illness and disabilities, language barriers, functional status, marital status, sexual orientation,

Table 4-2 Goals of Geriatric Assessment

1. Focus on preventive medicine rather than acute medicine.
2. Focus on improving or maintaining functional ability and not necessarily on a "cure."
3. Provide a long-term solution for "difficult to manage" patients with multiple physicians, recurrent emergency department visits, and hospital admissions with poor follow-up.
4. Aid in the diagnosis of health-related problems.
5. Develop plans for treatment and follow-up care.
6. Establish plans for coordination of care.
7. Determine the need and site of long-term care as appropriate.
8. Determine optimal use of health care resources.
9. Prevent readmission into the hospital.

family and social support, occupation, life experiences, and socioeconomic position.

The geriatric assessment can be divided into four categories: medical, functional, psychological, and social. Within each of these categories are a number of approaches, including use of office-based instruments that can aid in collection of information and streamline the plan of care.

Medical Assessment

The medical assessment includes a review of the patient's medical record, medication history (past and present), and a nutritional evaluation. On average, elderly patients have four to six diagnosable disorders, which may require the use of several medications. One disorder can affect another, and in turn a collective deterioration of both can lead to overall poor outcomes. Review of the patient's medical record should focus on conditions that are more common in the elderly (geriatric syndromes) and in particular their risk factors.

Four shared risk factors—older age, baseline cognitive impairment, baseline functional impairment, and impaired mobility—have been identified within the five most common

geriatric syndromes: pressure ulcers, incontinence, falls, functional decline, and delirium (Inouye et al., 2007). It is important that health care providers familiarize themselves with the common geriatric body area or system disorders that can directly influence these risk factors. Understanding the basic mechanisms involved in geriatric syndromes is essential to targeting therapeutic options.

During the medical assessment, the review of systems should be completed with special emphasis on sensory impairment, dentition, mood, memory, urinary symptoms, falls, nutrition, and pain. The U.S. Preventive Services Task Force (1996) recommends routine screening for visual and hearing impairment.

Hearing loss is the third most prevalent chronic condition in elderly people, after hypertension and arthritis, and its prevalence and severity increase with age. In persons age 65 to 75 years, the prevalence of hearing loss ranges from 20% to 40% (Cruikshanks et al., 1998; Rahko et al., 1985; Reuben et al., 1998), whereas in those over age 75, it ranges from 40% to 66% (Ciurlia-Guy et al., 1993; Parving et al., 1997).

Screening for hearing loss can be accomplished using two office-based methods: the audioscope (objective) and a validated short questionnaire (subjective). The audioscope is a handheld instrument that functions as an otoscope and audiometer and can be used to visualize the ear canal and eardrum and remove cerumen if necessary. The audioscope is easy to use, with 87% to 96% sensitivity and 70% to 90% specificity (Abyad, 1997; Mulrow, 1991). The Hearing Handicap Inventory for the Elderly–Short Version (HHIE-S) is a subjective, 10-item, 5-minute questionnaire with an overall accuracy of 75% in identifying hearing loss (Mulrow et al., 1990).

A formal audiologic evaluation should be offered to any patient who fails a hearing screening. The evaluation can assist in determining the need for further testing or management, including hearing aid, medical treatment, or surgical intervention.

Review of the patient's current medication list, including over-the-counter (OTC) medications, as well as any drug allergies or previous adverse drug reactions, is a necessary component of the geriatric assessment. *Adverse drug reactions* (ADRs; also adverse drug events) are a significant public health issue, especially in the elderly population (Thomsen et al., 2007). *Polypharmacy* is defined as taking more than four medications and is an independent risk factor for both delirium and falls (Inouye et al., 2000; Molyan and Binder, 2007).

Patients or family members should be asked to bring in all the patient's prescription medications and supplements at the initial visit and periodically thereafter. Clinicians can make sure patients have the prescribed drugs, but possession of these drugs does not guarantee adherence. Patients should be asked to demonstrate their ability to read labels (often printed in small type), open containers (especially the child-resistant type), and recognize their medications. Pillboxes may be helpful in organizing the patient's medications by the week or month.

Nutritional evaluation is an integral part of the geriatric assessment. The type, quantity, and frequency of food eaten should be determined. Malnutrition and undernutrition can lead to health problems that include delayed healing and longer hospital stays. A reliable marker of nutritional problems is weight loss, specifically, more than 5% in the past month and 10% or greater weight loss in the last 6 months

(Huffman, 2002). Clinicians should ask about any special diets (e.g., low carbohydrate, vegetarian, low salt) or self-prescribed "fad" diets. A nutritional screen can aid in further assessment of the patient's nutritional health and help guide interventions (Figure 4-1). Additional questioning should include weight loss and change of fit in clothing; amount of money spent on food; and accessibility of grocers with a variety of fresh foods.

The ability to chew and swallow should also be evaluated. It may be impaired by xerostomia (dryness of mouth), which is common in elderly persons. Decreased taste or smell may reduce the pleasure of eating, so patients may eat less. Patients with decreased vision, arthritis, immobility, or tremors may have difficulty preparing meals and may injure or burn themselves when cooking. Patients worried about urinary incontinence may reduce their fluid intake and thus may eat less food.

Functional Assessment

A primary goal of the geriatric assessment is to identify interventions to help patients maintain function and stay at home in independent living situations. The functional assessment focuses on *activities of daily living* (ADLs) and risk screening for falls. The basic ADLs include eating, dressing, bathing, transferring, and toileting. The instrumental ADLs (IADLs) consist of shopping, managing money, driving, using the telephone, housekeeping, laundry, meal preparation, and managing medications (Katz, 1983). Home health and social services referral should be considered for patients who have difficulty with the ADLs. A simple method of screening patients for gait and mobility problems is to ask, "Have you fallen all the way to the ground in the past 12 months?" A positive screen should lead to a more thorough evaluation and consideration of a physical therapy referral (Ganz et al., 2007) (see Falls Assessment).

Psychological Assessment

The psychological assessment screens for cognitive impairment and depression, two conditions that significantly impact both the patient and the family. The most studied test to screen for cognition is the Mini-Mental State Examination, which is best for identifying patients with moderate or severe dementia. Depression can be readily screened with shorter versions of the original 30-item Yesavage Geriatric Depression Scale (GDS) (Yesavage et al., 1983). The five-item version of the GDS asks the following:

1. Are you basically satisfied with your life?
2. Do you often feel bored?
3. Do you often feel helpless?
4. Do you prefer to stay home rather than going out and doing new things?
5. Do you feel pretty worthless the way you are now?

A score of greater than two positive answers is positive (97% sensitivity, 85% specificity) (Rinalde et al., 2003). The Yale Depression Screen ("Do you often feel sad or depressed?") is a validated one-item GDS screening tool (Mahoney et al., 1994).

Social Assessment

It is important to assess the patient's living situation and social support when performing a geriatric assessment. The living situation should be evaluated for potential hazards,

Directions: Read the statements below. Circle the number in the YES column if it applies to you or the person you are completing the questionnaire for. Add the circled numbers for the total.

| | YES |
|--|-----|
| I have an illness or condition that made me change the kind and/or amount of food I eat. | 2 |
| I eat fewer than two meals per day. | 3 |
| I eat few fruits or vegetables or milk products. | 2 |
| I have three or more drinks of beer, liquor, or wine almost every day. | 2 |
| I have tooth or mouth problems that make it hard for me to eat. | 2 |
| I don't always have enough money to buy the food I need. | 4 |
| I eat alone most of the time. | 1 |
| I take three or more different prescribed or over-the-counter drugs a day. | 1 |
| Without wanting to, I have lost or gained 10 pounds in the last six months. | 2 |
| I am not always physically able to shop, cook, and/or feed myself. | 2 |

Total

| | |
|-----------|---|
| 0–2 | Good! Recheck your nutritional score in six months. |
| 3–5 | You are at moderate nutritional risk. See what can be done to improve your eating habits and lifestyle. Your office on aging, senior nutrition program, senior citizens center or health department can help. Recheck your nutritional score in three months. |
| 6 or more | You are at high nutritional risk. Bring this checklist next time you see your doctor, dietitian or other qualified health or service professional. Talk with them about any problems you may have. Ask for help to improve your nutritional health. |

Figure 4-1 Nutrition questionnaires such as this (Determine Your Nutritional Health) can help in the assessment of the elderly patient's nutritional health. (Courtesy Nutrition Screening Initiative, Washington, DC, 2007.)

especially if the patient is identified as being at risk of falling. The social assessment also includes questions about financial stressors and caregiver concerns. Advance planning is a key component of the assessment and includes clarifying the patient's values and setting goals for care in case of future incapacity, including identifying the patient's "power of attorney" for health care.

Summary

A geriatric assessment can identify frequent problems, thus leading to earlier interventions for the common medical and social concerns of the elderly population. It is important to remember, however, that patients may underreport medical problems because they worry about losing their independence. Patients may also be reluctant to repeat their health concerns to their primary care physician because they fear being perceived as having an emotional or psychiatric illness. Often, older patients will rationalize their symptoms as being a "normal" component of aging.

The key to a successful geriatric assessment is to establish trust and effective communication between the patient and the physician. Allotting for adequate time during appointments and, if needed, scheduling frequent office visits are essential to the gathering of information. Inquiring about recent socioeconomic changes, functional losses, or life transitions is also important. The physician should obtain the patient's medical records before the first visit. A questionnaire targeted to the geriatric assessment domains should be completed by the patient, with family assistance if needed

(Figure 4-2). Language, education, social support, economic status, and cultural/ethnic factors play a vital role in the patient's health care outcome. A multidisciplinary approach is used to interventions and management. Preserving function and maintaining quality of life are the primary goals of the geriatric assessment (Miller et al., 2000).

Falls

Key Points

- Falls result in significant morbidity, mortality, and functional decline.
- Patients should be asked about history of falls and balance issues.
- Medication review is a key component of falls assessment.
- Multifactorial interventions can reduce the rate of falls.
- Exercise programs that focus on strength and balance training are most effective in preventing falls.

Epidemiology

Falls result in significant morbidity and mortality as well as an increased rate of nursing home placement. Each year, approximately 30% of persons over age 65 fall at least once, and the incidence increases with age. Up to 10% of falls result in serious injury. Falls are the leading cause of injury-related deaths in people over 65 years (CDC, 2005). In the United States, hip fractures currently account for more than 300,000

GERIATRIC HEALTH QUESTIONNAIRE

Date: _____ Birthdate: _____ Hosp #: _____
 Name: _____ Address: _____

INSTRUCTIONS: PLEASE CIRCLE ANSWERS.

1. **General health:** In general, would you say your health is:
 Excellent / Very good / Good / Fair / Poor

 How much bodily pain have you had during the past 4 weeks?
 None / Very mild / Mild / Moderate / Severe / Very severe
2. **Activities of daily living:** Are you (I) independent (can do by myself); (A) require assistance (need help from another person); or (D) dependent (cannot do at all) with each of the following tasks?

| | | | | | | | |
|-----------|---|---|---|--------------------|---|---|---|
| Walking | I | A | D | Using telephone | I | A | D |
| Dressing | I | A | D | Shopping | I | A | D |
| Bathing | I | A | D | Preparing meals | I | A | D |
| Eating | I | A | D | Housework | I | A | D |
| Toileting | I | A | D | Taking medications | I | A | D |
| Driving | I | A | D | Managing finances | I | A | D |
3. **Geriatric review of systems:**
 - a. Do you have difficulty driving, watching TV, or reading because of poor eyesight? Yes / No
 - b. Can you hear normal conversational voice? Yes / No
 Do you use hearing aids? Yes / No
 - c. Do you have problems with your memory? Yes / No
 - d. Do you often feel sad or depressed? Yes / No
 - e. Have you unintentionally lost weight in the last 6 months? Yes / No
 - f. Do you have trouble with control of your bladder? Yes / No
 Do you have trouble with control of your bowels? Yes / No
 - g. How many falls have you had in the past year? _____
 - h. Do you drink alcohol? Yes / No
 If yes, how many drinks per week? _____
4. Do you live with anyone? Yes / No
 If yes, who? Spouse / Child / Other / Relative / Friend
 Who would help you in an emergency? _____
 Who would help you with health care decisions if you were not able to communicate your wishes?

5. How many medicines do you take, including prescribed, over the counter, and vitamins? _____
 What is your system for taking your medications? Pill box / Family help / List or chart / None
6. Are you sexually active? Yes / No
7. Has anyone intentionally tried to harm you? Yes / No
8. Have you had a shot to prevent pneumonia? Yes / No
9. Please draw the face of a clock with all the numbers and the hands set to indicate 10 minutes after 11 o'clock.

Figure 4-2 Geriatric health questionnaires assist in gathering pertinent information regarding the functioning of the elderly patient.

hospitalizations, with a 1-year mortality rate of up to 33% (Sattin, 1992; Tinetti et al., 1998). By 2050, it is estimated that the worldwide number of hip fractures will rise to 6.26 million. Direct medical costs related to falls in adults age 65 or older exceeded \$19 billion in 2000 (Stevens et al., 2006).

Falls also cause functional limitations by both direct injury and indirect psychological consequences. Postfall anxiety leads to loss of self-confidence in ambulation and self-imposed limitations in activity. Postfall anxiety syndrome can also result in depression, social isolation, and increased risk of falls from deconditioning. Because the cause of falls is often multifactorial, the assessment and interventions target several areas (Nevitt et al., 1989).

Risk Factors

The multiple risk factors for falling can be categorized as intrinsic or extrinsic. *Intrinsic* risk factors include age-related physiologic changes and diseases that affect the risk of falling (Table 4-3). *Extrinsic* risk factors include medications and environmental obstacles. The risk of falling increases significantly in people with multiple risk factors. A prospective study found that 19% of older patients with one risk factor have a fall in a given year, compared with 60% of older patients with three risk factors (Tinetti et al., 1998).

Taking four or more prescription drugs is itself a risk factor for falling. Also, several medication classes have a higher potential to cause falls, including tricyclic antidepressants, neuroleptic agents, serotonin reuptake inhibitors, benzodiazepines, and class 1A antiarrhythmic medications. Narcotic analgesics, antihistamines, and anticonvulsants are also associated with increased risk for falls (Ensrud et al., 2002; Rubenstein and Josephson, 2002).

Physical restraints have been used in an attempt to reduce falling. Although the focus here is on community-dwelling elderly persons, it is worth noting that use of physical restraint in the nursing home and hospital setting does *not* reduce the risk of falling and is instead associated with an increased risk of injury (Neufeld et al., 1999). Since the 1980s, the use of physical restraints has been appropriately and dramatically reduced.

Table 4-3 Intrinsic Risk Factors for Falls

| Cognitive impairment |
| Depression |
| Functional impairment |
| History of falls |
| Visual impairment |
| Gait or balance impairment |
| Use of assistive device |
| Arthritis |
| Leg weakness |

Screening

At present, no one screening test can be recommended to identify potential fallers (Gates et al., 2008). The two best predictors of falls are a history of falls and a reported abnormality in gait or balance (Ganz et al., 2007). "Have you had any falls in the past year?" is a simple screening question that can be answered by the patient or caregiver in a previsit questionnaire. For patients who have not fallen, the pretest probability of a fall in the upcoming year ranges from 19% to 36%. Also, asking the patient, "Have you noticed any problems with gait, balance, or mobility?" is another simple screening question. Answering "yes" to either screening question warrants further assessment (Tinetti, 2003).

Falls Assessment

Falls assessment should include a multifactorial evaluation beginning with the circumstances surrounding the fall(s), associated symptoms, risk factor assessment, and medication history (Table 4-4). The physician should ask about the environment (e.g., indoors or outdoors, dark or well lighted, time of day), environmental obstacles (e.g., throw rugs, door thresholds, stairs), and footwear worn at the time. The history should also include questions about prodromal symptoms (e.g., lightheadedness, dizziness), if there was a loss of consciousness or other symptoms of arrhythmias (i.e., palpitations). If available, obtain information from a witness. The evaluation should also include questions about risk factors, functional abilities and medication history (AGS et al., 2001).

Postural blood pressure and pulse are important assessments in the examination. Up to 30% of older persons have orthostatic hypotension, and although some may be asymptomatic, others become lightheaded and dizzy (Luukinen et al., 1999). The musculoskeletal examination should focus on range of motion in the legs, inflammatory or degenerative conditions of the leg joints, kyphosis, and abnormalities of the feet. The neurologic examination should include proprioception, coordination, muscle strength, and cognition. The cardiovascular examination should focus on detecting

potential causes of falls (e.g., arrhythmias, aortic stenosis). Visual acuity and hearing should be assessed. Disturbances in gait and balance can be identified through the patient or caregiver's direct report or a simple office-based assessment, such as the "get up and go" test (Podsiadlo and Richardson, 1991). This test may be scored, timed, or used as an overall assessment of the patient's gait, stability, balance, and strength. The patient is asked to stand from a seated position, walk about 10 feet (3 meters), turn around, walk back, and sit down again. If the patient needs to push off the chair or rock back-and-forth several times to arise, leg strength is diminished. The task should be completed within 10 seconds. Gait abnormalities, such as poor step height, decreased stride length, and shuffling, may be observed. A wide-based stance and slow, multiple-point turning may reveal poor balance.

Laboratory evaluation and imaging are based on the history and clinical findings. If an underlying metabolic abnormality is suspected (e.g., diabetes, anemia, dehydration), appropriate blood tests may assist in the diagnosis. If a patient is suspected of having syncope, cardiac rhythm monitoring (e.g., Holter or event monitor) is appropriate. An echocardiogram may be necessary for evaluation of a murmur. Neuroimaging with magnetic resonance imaging (MRI) or computed tomography (CT) is indicated for the evaluation of focal findings on neurologic examination.

Management

Evidence has demonstrated that a multifactorial approach and intervention strategy is needed to reduce the rate of falling in older patients (Figure 4-3). Because one of the most modifiable risk factors is medication use, medication review is a key component of management (Hanlon et al., 1997). The review should focus on decreasing the dose or discontinuing sedating medications. If orthostasis is present, adjustment of diuretics and antihypertensive medications should be considered. The role of vitamin D in fall prevention is questionable. Although, it probably does not decrease the risk of falls, except in patients with low levels of vitamin D, supplementation should be started in patients with osteopenia or osteoporosis (Gillespie et al., 2009).

Supervised exercise programs should be considered for patients at high risk for falls; exercise can reduce the physical risk factors (Rose, 2008). Specifically, programs that focus on two of three exercise components (strengthening, balance training, and aerobic/endurance training) for a minimum of 12 weeks have shown the most benefit (Costello and Edelstein, 2008). Finally, home hazard evaluation and intervention is an essential component in the assessment of falls in elderly

persons, particularly those with visual impairment and multiple risk factors (Gillespie et al., 2001; Stevens et al., 2001).

Elder Abuse

Key Points

- Elder abuse is underreported.
- Direct questioning for elder abuse is recommended.
- Physicians should recognize the physical and behavioral signs of abuse.
- A positive screen for elder abuse should be followed by a safety assessment.
- Physician reporting requirements regarding elder abuse vary by state.

Elder abuse is a significant public health issue that physicians need to identify and address in both outpatient and inpatient settings. The prevalence of elder abuse is difficult to determine because its definition varies across U.S. states and other countries and research is still limited in this area (Erlingsson, 2007). In a systematic review of international literature, estimates ranged from 3.2% to 27.5% based on population studies. More than 6% of the general population had reported abuse in the prior month (Cooper et al., 2008).

In the United States, the number of people age 65 and older who have been victims of elder abuse ranges between 1 and 2 million. In 2000, adult protective services (APS) departments received approximately 470,000 reports. Of the types of abuse, elder "self-neglect" is most often reported. A prospective, population-based cohort study found that elder self-neglect was associated with a 5.82 times increased risk for mortality in the year after a report of self-neglect (Dong et al., 2009). From incidence studies, it is estimated that for every case reported, about five go underreported (National Elder Abuse Incidence Study, 1998). Underreporting stems from both patient issues (familial secrecy, denial, fear, shame) and provider issues (lack of awareness) (Kahan and Paris, 2003). Primary care physicians have the opportunity to detect early signs of elder abuse in patients with whom they have well-established relationships (Stiles et al., 2002).

Definition

The National Center on Elder Abuse (2009) defines elder abuse as "a term referring to any knowing, intentional, or negligent act by a caregiver or any other person that causes harm or a serious risk of harm to a vulnerable adult." Although terms vary across states, elder abuse can be generally categorized into several types: physical abuse, emotional abuse, sexual abuse, exploitation, neglect, self-neglect, and abandonment (Table 4-5). Elder abuse is also classified by its setting. *Domestic* abuse occurs in the home of the victim. *Institutional* abuse occurs in a nursing home, hospital, assisted-living center, or group home.

Risk Factors

Awareness of risk factors for abuse can increase the chance of identification and early intervention. Although research is ongoing, several characteristics of both the victim and the

KEY TREATMENT

Risk factor assessment and multifactorial intervention reduces rate of falls (Gillespie et al., 2009) (SOR: A).

Exercise programs that target more than two components reduce rate of falls (Gillespie et al., 2009) (SOR: A).

Community-living elderly patients who have fallen or who have risk factors for falling should have their homes assessed for safety (Gillespie et al., 2001) (SOR: A).

All older individuals should be asked at least once yearly about falls (Tinetti, 2003, AGS et al., 2001) (SOR: C).

PREVENTION OF FALLS IN OLDER PERSONS LIVING IN THE COMMUNITY

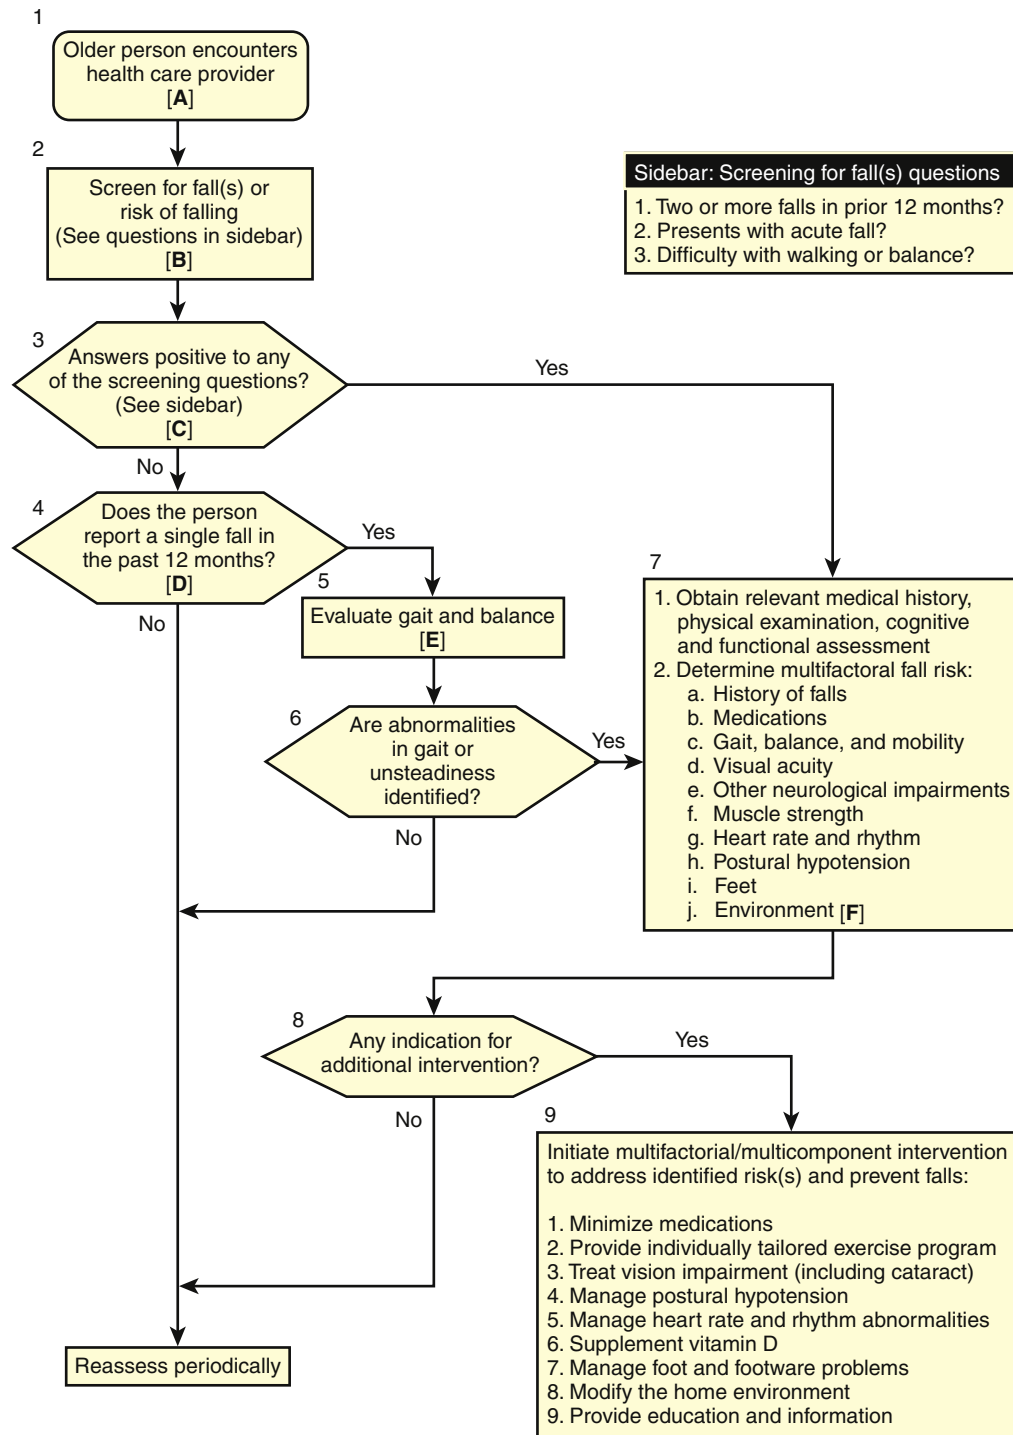

Figure 4-3 Practice guideline for the prevention of falls in older persons.

(From American Geriatrics Society (AGS), British Geriatrics Society, and American Academy of Orthopedic Surgeons Panel on Falls Prevention: Guideline for the prevention of falls in older persons. *J Am Geriatr Soc* 2001;49:664-672.)

abuser should trigger further screening questions. Risk factors associated with the *victim* include shared living situations, history of dementia, and social isolation. *Perpetrator* risk factors include a history of mental illness (specifically depression), alcohol abuse, and financial dependency (Lachs and Pillemer, 2004).

Screening

There is no consensus that asymptomatic patients should be screened for elder abuse. The American Medical Association (AMA, 1992) suggests that all outpatients be screened for family violence, but the U.S. Preventive Services Task

Table 4-5 Elder Abuse: Definitions

Physical abuse: Inflicting, or threatening to inflict, physical pain or injury on a vulnerable elderly person, or depriving the person of a basic need.

Emotional abuse: Inflicting mental pain, anguish, or distress on an elderly person through verbal or nonverbal acts.

Sexual abuse: Nonconsensual sexual contact of any kind.

Exploitation: Illegal taking, misuse, or concealment of funds, property, or assets of a vulnerable elder.

Neglect: Refusal or failure by those responsible to provide food, shelter, health care or protection for a vulnerable elder.

Abandonment: The desertion of a vulnerable elder by anyone who has assumed the responsibility for care or custody of that person.

Self-neglect: Characterized as the behavior of an elderly person that threatens his or her own health or safety.

Modified from National Center on Elder Abuse.
http://www.ncea.aoa.gov/NCEARoot/Main_Site/Index.aspx. October 2009.

Force (2009) concluded that there was insufficient evidence for or against screening for older adults or their caregivers for elder abuse. Patients should be screened if there is a suspicion of elder abuse. The questions should be open-ended, nonthreatening, and asked in a variety of ways to assess for the different forms of elder abuse (Table 4-6). A positive response should be followed by more direct questions as to the nature of the abuse. Direct questioning by physicians has been shown to increase reporting (Oswald et al., 2004).

Clinical Manifestations

Certain behavioral and physical signs should raise suspicion for elder abuse. Behavioral signs in the caregiver include answering for the patient, insisting on being present for the entire visit, failing to offer assistance, and displaying indifference or anger. Behavioral signs in the elderly patient include poor eye contact, hesitation to talk openly, or fearfulness toward the caregiver. Other indicators of possible abuse include confusion, paranoia, anxiety, anger, and low self-esteem. Physical signs that may signal neglect include poor hygiene, malnutrition, dehydration, pressure ulcers, and injuries (Table 4-7). Medication nonadherence may also be a warning sign for abuse.

Assessment

In suspected cases of abuse, the assessment includes a thorough history, physical examination, and functional, cognitive, and mental health assessments. The patient and the caregiver should be interviewed alone and separately (Abbey, 2009). Documentation begins with the description of the abusive or neglectful event, using the patient's words whenever possible. The duration, frequency, and severity of the abuse should be recorded. If injuries are present, a detailed description of the injuries and photographs, if available, should be documented. Assessment of functional dependence can be helpful in recommending resources, whereas evaluation of cognitive impairment is important in assessing both risk and capacity. The assessment should also include a mental health screening, with particular attention to depression, anxiety, insomnia, and alcohol abuse.

Table 4-6 Screening Questions for Elder Abuse

Are you afraid of anyone at home?
 Are you alone a lot?
 Has anyone at home ever hurt you?
 Has anyone taken anything that was yours without asking?
 Does anyone at home make you uncomfortable or afraid?
 Has anyone ever forced you to sign a document that you did not understand?
 Are you kept isolated from friends or relatives?

The elderly patient's caregiver should be assessed for caregiver stress and for risk factors for elder abuse, including alcohol abuse, depression, and financial dependency.

Management

Because the cause of elder abuse is often multifactorial, management involves a multidisciplinary approach with social workers and legal, financial, and APS representatives. The immediate management is determined by the safety and capacity assessments. Is the patient in any immediate danger? If so, acute hospitalization, safe home placement, and a protective court order may be indicated. If the patient lacks capacity, the physician should work with APS on options, including guardianship, financial management resources, and order of protection if indicated. In other cases, management should focus on utilizing community resources to maintain the patient in the least restrictive environment. The

emphasis is to decrease social isolation and caregiver stress. Interventions can include respite care, home health or custodial services, counseling, and drug or alcohol rehabilitation.

Reporting Requirement

All 50 states have laws authorizing APS departments to intervene in cases of elder abuse. It is important for primary care physicians to know their state's requirements on mandatory reporting for elder abuse and which type of abuse (e.g., physical, emotional, sexual, financial) requires reporting. Higher rates of abuse have been documented in states that require public education regarding elder abuse and states that require mandatory reporting (Jogerst et al., 2003). Mandatory reporting laws in 42 states are controversial because they conflict with a competent elder's autonomy and with the physician-patient relationship. In such cases, physicians should explain their legal obligation to report and emphasize that the goal of reporting is to develop a care plan to assist the patient.

KEY TREATMENT

Direct questioning by physicians for elder abuse increases the rate of reporting (Oswald et al., 2004) (SOR: B).
Older individuals should be screened for elder abuse (AMA, 1992) (SOR: C).

Pressure Ulcers

Key Points

- Preventive measures can reduce the incidence of pressure ulcers in elderly patients.
- Classification is only one aspect of wound assessment.
- Assessment of pressure ulcers includes identification of risk factors.
- Pain assessment is an essential component of management.
- Risk factor modification is the key to management of pressure ulcers.

Pressure ulcers are a common and serious public health issue, especially in the elderly population. The reported incidence is as high as 22% in the nursing home population and range from 4.7% to 9% up to 32% in the hospitalized population (Allman, 1995, 1997; Coleman et al., 2002; Kaltenthaler et al., 2001). The treatment costs related to pressure ulcers exceed an estimated \$5 billion annually in the United States (Xakellis et al., 1995). Prevention is paramount and can reduce the incidence of pressure ulcers by 50%. A thorough assessment of the wound and potential risk factors is the key to management.

Classification

Wound assessment begins with classification, as initially proposed in 1989 by the National Pressure Ulcer Advisory Panel (NPUAP) and then adopted for the Agency for Health Care Policy and Research (AHCPR) Pressure Ulcer Clinical

Practice Guidelines (1992 and 1994). The NPUAP revised the stage I classification in 1998 and added two stages in 2007: suspected deep tissue injury and unstageable. The six classifications are as follows:

Suspected deep tissue injury: Purple or maroon, localized area of discolored skin or blood-filled blister caused by damage to underlying soft tissue from pressure and shear. The area may be preceded by tissue that is painful, firm, mushy, boggy, and warmer or cooler compared with adjacent tissue.

Stage I: Intact skin with nonblanchable redness of a localized area, usually over a bony prominence. Darkly pigmented skin may not have visible blanching; its color may differ from the surrounding area. The area may be painful, firm, soft, and warmer or cooler compared with adjacent tissue. Stage I may be difficult to detect in individuals with dark skin tones.

Stage II: Partial-thickness skin loss involving the epidermis, the dermis, or both. The ulcer is superficial and presents clinically as an abrasion, blister, or shallow crater, without slough.

Stage III: Full-thickness skin loss involving damage or necrosis of subcutaneous tissue that may extend down to, but not through, underlying fascia. The ulcer presents clinically as a deep crater with or without undermining of adjacent tissue.

Stage IV: Full-thickness skin loss with extensive destruction, tissue necrosis, or damage to muscle, bone, or supporting structures (e.g., tendons, joint capsules). Slough or eschar may be present on some parts of the wound bed, often with undermining and tunneling.

Unstageable: Full-thickness tissue loss in which the base of the ulcer is covered with slough (yellow, tan, gray, green, or brown) and/or eschar in the wound bed.

A wound cannot be accurately staged if eschar or slough is present. The staging system is useful only for initial classification because wounds do not heal predictably (Ferrell, 1997). Thus, it is important to include other factors when describing the wound, to help assess treatment over time. These factors include size, type of exudate, and a description of the predominant tissue type. Size can be assessed by measuring the two largest diameters at right angles. The type and amount of exudate should be recorded. Exudate types include serous (clear or amber), sanguineous (bloody), or purulent (thick, yellow, and/or odiferous). The predominant tissue types are epithelial, granulation, necrotic, and eschar (AHCPR, 1992; Ferrell, 1997; Makelbust, 1997; NPUAP, 2007).

Risk Factors

An understanding of risk factors for pressure sore development is the key to prevention and management. Risk factors can be divided into extrinsic and intrinsic categories (Table 4-8).

Extrinsic Risk Factors

Extrinsic factors include direct pressure, shearing forces, friction, and moisture. Direct pressure results in hypoperfusion of the affected tissue, which can lead to hypoxia, acidosis, and if prolonged, tissue death and necrosis. Pressure sores most frequently occur over bony prominences below the

Table 4-8 Risk Factors for Pressure Sore Development

| Extrinsic Factors |
|--------------------|
| Pressure |
| Shear |
| Friction |
| Moisture |
| Intrinsic Factors |
| Age |
| Impaired mobility |
| Malnutrition |
| Sensory impairment |

waist: the sacrum, greater trochanter, malleolus, heel, ischial tuberosity, and fibular head. Of note, heels are the second most common site for pressure ulcer development. As the prevalence of pressure ulcers at other sites has decreased or remained the same, prevalence of heel pressure ulcers has increased.

Shear forces result from traction on the skin, which causes a relative displacement of the underlying structures. This usually occurs when patients are positioned in bed more than 30 degrees, or seated, and then slide down. In these patients the underlying sacrum is at risk for pressure sore development. *Friction* between the skin and a stationary source such as bedclothes or sheets is another factor. Care must be taken to avoid friction, especially during transfers in and out of bed. Excessive *moisture* can lead to skin maceration and subsequent skin breakdown. Common causes include incontinence, diarrhea, and excessive perspiration (AHCPR, 1994; Patterson and Bennett, 1995).

Intrinsic Risk Factors

Intrinsic risk factors for pressure ulcer development include age, conditions that impair mobility, malnutrition, and sensory impairment. Skin changes associated with aging (e.g., epidermal thinning, diminished vascularity) increase the susceptibility of older persons to shearing forces, pressure, and friction. Immobility can cause infrequent position changes, thus exposing an older person to prolonged pressure. Malnutrition, specifically an inadequate intake of calories or protein, has been associated with the development of pressure sores (Thomas, 2001). AHCPR (1994) defines clinically significant malnutrition as a serum albumin level of less than 3.5 mg/dL, a total lymphocyte count of less than 1800 cells/mm³, or body weight less than 80% of ideal weight. Supplementation of micronutrients involved in skin healing, such as ascorbic acid and zinc, has not been shown to prevent pressure sores or improve rates of healing. Sensory impairment, such as in diabetic neuropathy, can prevent an individual from responding appropriately to pressure-related discomfort (Patterson and Bennett, 1995; Reddy et al., 2006; Thomas, 1997, 2001).

Risk Factor Assessment Tools

The AHCPR's guidelines recommend that individuals with limited mobility be assessed on admission to hospitals, nursing homes, and home care programs for risk factors for

Table 4-9 Risk Factor Modification

| Implement | Avoid |
|-------------------------------------|---------------------------------------|
| Support devices to reduce pressure | Donut-type devices |
| Frequent repositioning | Massage over bony prominences |
| Positioning devices such as pillows | Raising head of bed above 30 degrees |
| Lifting devices such as a trapeze | Dragging the patient during transfers |

pressure sore development. The most common assessment tool is the Braden scale (Pancorbo-Hidalgo et al., 2006). Risk factor identification and subsequent intervention are integral components of pressure sore prevention and management.

Management

The principles of pressure sore management include modification of risk factors, nutritional support, maintaining a wound environment optimal for healing, and pain control.

Risk Factor Modification

The primary goal is to reduce pressure, shear, and friction over high-risk bony prominences (Table 4-9). This can be accomplished by frequent turning and repositioning while in bed (every 2 hours), frequent repositioning while sitting (every hour), and use of a support device to lower surface pressure, such as foam, static air, alternating air, gel, or water mattress. Positioning devices such as pillows or foam wedges should be used to keep bony prominences (e.g., knees, ankles) from touching each other or high-risk areas from contacting the bed (e.g., heels). Donut-type devices should be avoided because the tissue within the ring can become necrotic from increased venous congestion.

Massage should be avoided over bony prominences because it can lead to deep tissue trauma. When positioning on the side, avoid pressure directly on the trochanter. To decrease the effect of shear forces, maintain the head of the bed at the lowest degree of elevation. To decrease the effect of friction lubricants, use protective films, dressings, or padding. Also, lifting devices such as a trapeze can be used to assist patients with limited mobility in transfers and repositioning (AHCPR, 1994; Bergstrom, 1997; Bluestein and Javaher, 2008; Reddy et al., 2006; Remsburg and Bennett, 1997).

Nutritional Support

Nutritional support emphasizing adequate protein and calorie intake is another key component of pressure sore management. Protein intake should be 1.0 to 1.5 g/kg/day. Caloric intake should be 30 to 35 kcal/kg/day. Some experts recommend supplementation with vitamin C and zinc, although evidence that either enhances wound healing is limited (AHCPR, 1994; Langer et al., 2003; Reddy et al., 2006; Thomas, 2001).

Debridement

Wound healing requires a moist environment, free of necrotic tissue and infection, which allow for granulation and reepithelialization. Debridement is often needed to remove necrotic tissue, slough, and eschar, which can be accomplished by sharp, mechanical, enzymatic, and/or autolytic techniques. The technique used depends on the patient's condition, location, clinical urgency and overall goals for patient care. Debridement is not recommended for heel ulcers that have stable, dry eschar without edema or signs of infection (AH CPR, 1994; NPUAP, 2007).

Sharp debridement is appropriate for removing areas of thick eschar and necrotic tissue in extensive ulcers. Care must be taken to control pain when using this technique. Also, surgical debridement may cause transient bacteremia, and prophylactic antibiotics may be needed for high-risk patients.

Mechanical debridement includes wet-to-dry dressings, hydrotherapy, wound irrigation, and dextranomers, which are small beads of highly hydrophilic dextran polymers (e.g., Debrisan). Wet-to-dry dressings may be painful when changed and need be discontinued when the wound bed is clean to avoid desiccation (Ovington, 2001). *Hydrotherapy* is appropriate for pressure sores with thick exudate or necrotic tissue. Care must be taken not to place the wound too close to the jets. Irrigation pressures need to be high enough to adequately cleanse the wound, but not too high to potentially cause tissue trauma. Safe and effective pressures are between 4-15 pounds per square inch (psi). Examples of safe irrigation devices include 35-mL syringe with 19-gauge needle or angiocatheter, water-jet device at the lowest setting, and saline squeeze bottle (250 mL) with irrigation cap.

Enzymatic debridement is accomplished by products that have proteolytic enzymes such as papain and urea (e.g., Accuzyme, Panafil) and collagenase. Typically used once daily, these products may damage healthy tissue and should not be used if infection is present. Thus, special care is needed in application, and use should be limited to short periods (<2 weeks).

Autolytic debridement involves the use of occlusive synthetic dressings that allow enzymes normally present within wounds to self-digest necrotic tissue. Occlusive dressings should not be used if the wound is infected or if there is a moderate amount of exudate (AH CPR, 1994; Cervo et al., 2000; Goode and Thomas, 1997).

Infection Control

In the majority of cases, infection can be prevented by adequate debridement and cleansing. Wounds should be cleansed daily and with dressing changes. Normal saline is the most appropriate solution for cleansing. Avoid skin cleansers or antiseptics that are cytotoxic, such as povidone-iodine, hydrogen peroxide, and acetic acid. Signs of a wound infection include delayed healing, increasing wound size, purulent exudate, pain, and foul odor. Initially, consider a trial of topical antibiotics, such as silver sulfadiazine cream (Silvadene), for 2 weeks. Superficial cultures of the wound are not helpful because they detect only the surface colonization. Ideally, bacterial tissue cultures should be performed to guide antibiotic coverage. Systemic antibiotics are reserved for patients with cellulitis, osteomyelitis, bacteremia, or sepsis (AH CPR, 1994).

Dressing Selection

Wound dressings provide a physiologically moist wound environment shown to enhance healing, reduce pain, debride necrotic tissue, and decrease infection rates in pressure sores. Dressing selection depends on the stage, amount of exudate, size, site, and condition of surrounding skin. No moist-dressing type has proved superior to the others (Bouza et al., 2005). The main categories of modern dressings are polyurethane films, hydrocolloids, amorphous hydrogels, hydrogel sheets, polyurethane foams, foamed gels, alginates, and hydrocolloid/alginate combinations (Table 4-10).

For deep, stage III and stage IV pressure sores, packing is often needed to eliminate dead space. This can be accomplished with saline-moistened gauze, calcium alginates, gels, and dextranomers. After packing, the wound is covered with an occlusive or semiocclusive dressing. If excessive exudate is present, the dressing must have absorptive properties to control exudate without drying the wound bed. Examples include saline-moistened gauze, alginates, and combination hydrocolloid/alginate dressings.

Pressure sores should be evaluated weekly by a health care professional. Reevaluation of the treatment plan should be considered if there are not signs of healing within 2 weeks of treatment (Ferrell, 1997; Goode and Thomas, 1997).

Pain Control

The overall management of a patient with a pressure sore includes pain assessment and control. Patients should be assessed for pain related to the pressure sore. Management includes the appropriate use of analgesics and eliminating or modifying the source of the pain. This can be accomplished by repositioning, using support surfaces, and using wound dressings shown to reduce pain. Pain should be anticipated before dressing changes and debridement. Appropriate analgesia should be provided as needed.

Adjunctive Therapy

Numerous modalities have been attempted to expedite the wound healing process, but their role remains unclear. Examples include electrical stimulation, hyperbaric oxygen, ultrasound, and hydrotherapy (Baba-Akbari et al., 2006; Kranke et al., 2004; Olyae Manesh et al., 2006). Negative-pressure wound therapy has shown promise in the management of stage III and IV pressure ulcer (Banwell and Teot, 2003; Mendez-Eastman, 2004). Further research is needed to establish efficacy of adjunctive therapy for wound healing.

KEY TREATMENT

- Assess all support surfaces and patient factors for increased pressure and modify appropriately (AH CPR, 1994, Reddy et al., 2006) (SOR: A).
- Assess and manage the patient's nutritional status (AH CPR, 1994; Langer et al., 2003; Thomas, 2001) (SOR: B).
- Assess all patients for pain related to the pressure ulcer treatment or its treatment (AH CPR, 1994; NPUAP, 2007) (SOR: C).

Table 4-10 Wound Dressing Properties

| Wound Dressings | Absorbent Quality* | Debriding Action | Frequency of Dressing Change | Stage |
|--|---------------------|------------------|------------------------------|-------------|
| Polyurethane films (e.g., Bioclusive, Opsite, 3M Tegaderm) | None | None | Every 7 days or less | I, II |
| Hydrogels (e.g., Dermagauze, Flexigel, 3M Tegagel) | Minimal to moderate | Autolysis | Every 7 days or less | II, III, IV |
| Hydrocolloids (e.g., Combiderm, Duoderm, 3M Tegaderm) | Minimal to large | Autolysis | Every 7 days or less | II, III, IV |
| Polyurethane foams (e.g., Alleevyn, Curafoam, Optifoam) | Minimal to moderate | None | Every 7 days or less | II, III, IV |
| Alginates (e.g., Algicell, Kalginate, Sorbsan) | Minimal to large | Autolysis | Daily to every 3 days | II, III, IV |

*None, minimal, moderate, or large.

Rational Drug Prescribing for Elderly Patients

Key Points

- Adverse drug events result in significant morbidity and a high rate of hospital admissions.
- Medications should be adjusted for the individual patient's renal function.
- Medication lists of elderly patients should be periodically reviewed, focusing on indications and side effects.
- One drug should not be used to treat the side effects of another medication.
- Pharmacists' recommendations should be incorporated in a rational drug-prescribing plan.

The primary care physician plays an important role in addressing an array of pharmaceutical issues and concerns for elderly patients, including polypharmacy, adverse drug reactions, adherence, and undertreatment of certain conditions.

Medication use is common in the elderly population and increases with age. A population-based survey showed that 44% of men and 57% of women over age 65 used five or more medications weekly (Kaufmann et al., 2002). Although persons over 65 represent only 13% of the general population, they account for more than 30% of U.S. drug expenditures, totaling over \$73 billion in 2006 (MEPS, 2006). Polypharmacy is a major risk factor for *adverse drug events* (ADEs). Up to 10% of emergency department visits and 10% to 17% of hospital admissions are the result of ADEs (Hayes et al., 2007).

Pharmacokinetics and Pharmacodynamics

Knowledge of the physiologic changes that occur with aging is essential when prescribing medications to the elderly patient. Changes in pharmacokinetics and pharmacodynamics can result in increased or decreased amounts of medication and drug-drug interactions (Table 4-11).

Pharmacokinetics refers to the body's response to the drug and includes absorption, distribution, metabolism, and elimination (excretion). Age-related gastrointestinal and skin changes have minimal effect on drug *absorption*, except for drugs that require active gastrointestinal transport (vitamins,

Table 4-11 Pharmacokinetic Changes in Older Persons

Absorption generally does not change.
 Longer half-life of lipophilic drugs.
 Increased amount of water soluble and free (active) drug.
 Decreased excretion.

minerals), which decreases with aging. The *volume of distribution* (Vd) is determined by degree of plasma protein binding and body composition. The changes in protein binding are not clinically significant, unless a condition (e.g., acute illness, malnutrition) is causing a marked decline in albumin. Water composition and lean body mass decrease with aging. Fat composition increases, resulting in a larger Vd of lipid-soluble drugs, such as benzodiazepines. Although liver function tests are unchanged, liver size and blood flow are somewhat reduced. The clinical significance is difficult to determine because there is such wide interindividual variation in hepatic metabolism. Drug *elimination* is mainly affected by a decrease in creatinine clearance. Also, decreased muscle mass causes a decrease in serum creatinine. Because serum creatinine may appear normal even when significant renal impairment exists, it is important to calculate clearance and adjust medication dosages accordingly (Cusak, 2004). The Cockcroft-Gault (1976) formula can be used to estimate creatinine (Cr) clearance:

$$\text{Cr clearance} = (140 - \text{Age}[\text{yr}]) \times (\text{Actual body weight}[\text{kg}] / (72 \times \text{Serum Cr}[\text{mg/dL}]])$$

For women, multiply the result by 0.85. Of note, this formula is less accurate in extremely ill patients and those with moderate to severe renal insufficiency.

Pharmacodynamics refers to the end-organ response to a drug. Although not as well understood as pharmacokinetic changes, pharmacodynamic changes can lead to changes in receptor binding, a decrease in receptor number, and altered translation of response to a receptor. One clinical example involves beta-adrenergic blockers and beta-adrenergic agonists. With aging, there is a reduction in beta-adrenergic activity in the cardiovascular and respiratory systems that can result in less responsiveness to beta blockers and beta agonists (Cooney and Pascuzzi, 2009).

Common Prescribing Issues

Prescribing problems that can lead to ADEs include a failure to monitor medications appropriately, to prescribe clinically indicated medications, to educate patients, or to maintain continuity (Higashi et al., 2004). One well-researched problem is the use of inappropriate medications in elderly patients. In 1991, based on ADEs in the nursing home, an

expert panel developed a list of drugs that should generally be avoided in the elderly population (Beers et al., 1991). These Beers Criteria were updated in 2002 to include ambulatory and nursing facility populations (Fick et al., 2003/04). Medications on the list are generally ineffective in elderly patients, have a higher risk for ADEs, or have safer alternatives (Table 4-12). The list also includes recommendations regarding medication dosages that generally should not be

Table 4-12 Drugs to Avoid or Limit in the General Elderly Population

| Pharmacologic Agents | Comments |
|---|---|
| Drug Classes to Avoid | |
| Antihistamines | Nonsedating antihistamines (e.g., fexofenadine, loratadine) are considered safer. |
| Antispasmodics | May result in anticholinergic side effects, sedation, and generalized weakness. |
| Barbiturates | Highly addictive with many side effects; numerous other agents for sedation are preferred. |
| Gastrointestinal antispasmodic drugs (e.g., dicyclomine, hyoscyamine) | Highly anticholinergic |
| Long-acting benzodiazepines (e.g., chlordiazepoxide, diazepam) | Short-acting or medium-acting agents are preferred; start with smaller doses. |
| Muscle relaxants | May result in anticholinergic side effects, sedation, and generalized weakness. |
| Specific Drugs to Avoid | |
| Amitriptyline | Highly anticholinergic; use newer antidepressants or less anticholinergic tricyclics. |
| Chlorpropamide | Long half-life leads to increased risk of hypoglycemia; newer insulin secretagogues are preferred. |
| Dipyridamole | May cause dizziness and hypotension. |
| Disopyramide | Anticholinergic and negative inotropic properties. |
| Doxepin | Highly anticholinergic; use newer antidepressants or less anticholinergic tricyclics. |
| Indomethacin | Compared with other NSAIDs, risk of CNS, gastrointestinal, and renal side effects is greater. |
| Meperidine | Active metabolite normeperidine may accumulate and cause CNS stimulation and seizures. |
| Meprobamate | Highly addictive, may worsen depression; other anxiolytics preferred. |
| Methyldopa | Common side effects include depression, sedation, and edema; multiple antihypertensive options are available. |
| Pentazocine | Mixed narcotic agonist/antagonist with potent CNS effects. |
| Phenylbutazone | May cause severe bone marrow suppression; other NSAIDs are preferred. |
| Propoxyphene | Weak narcotic pain reliever (probably no better than acetaminophen alone) but has same side profile as other narcotics. |
| Reserpine | CNS side effects include sedation and depression; multiple antihypertensive options are available. |
| Ticlopidine | More toxic effects than aspirin or clopidogrel. |
| Trimethobenzamide | May cause extrapyramidal side effects; numerous alternative antiemetics are available. |
| Drugs to Limit | |
| Digoxin | Limit to 0.125 mg/day or less in most elderly patients. |
| Ferrous sulfate | Limit to 325 mg/day or less in most elderly patients. |

CNS, Central nervous system; NSAIDs, nonsteroidal anti-inflammatory drugs.

Data from Beers MH: Explicit criteria for determining potentially inappropriate medication use by the elderly: an update. *Arch Intern Med* 157:1531-536, 1997; Fick DM, Cooper JW, Wade WE, et al: Updating the Beers criteria for potentially inappropriate medication use in older adults. *Arch Intern Med* 163:2716-2724, 2003.

exceeded and medications to avoid in certain comorbid conditions. It is important to note that this list is only a *guideline*; if a patient has been taking one of the medications without adverse effects, it may not need to be discontinued.

On the other end of the spectrum is failure to prescribe clinically appropriate medications. Common oversights include a failure to prescribe a beta blocker for a patient with congestive heart failure or with a history of a myocardial infarction, aspirin in a patient with known coronary heart disease, or ACE inhibitors for a patient with diabetes and proteinuria (Rosen et al., 2004; Sloane et al., 2004).

Principles of Prescribing

With patients seeing multiple providers across different clinical settings, it is essential that the medication list remain updated. In one prospective observational study, 74% of patients were taking at least one medication of which their primary physician was unaware (Bikowski et al., 2001).

At least once yearly, ask your older patients to bring in all their medications, including OTC medications. Use a checklist to review each medication (Table 4-13). With each medication, first and foremost, review the indication. Educating the patient about the indication can decrease ADEs and increase adherence (Garcia, 2006). Is the medication effective? Medications are often started for good clinical reasons but never revisited as to their efficacy. Are there side effects? Medications should be discontinued if there are intolerable side effects, and always consider an ADE as a cause of any new patient symptom. Avoid the “prescribing cascade,” in which medications are started to treat an ADE. Does the medication require any laboratory monitoring? This may include direct drug levels (e.g., digoxin) or monitoring for side effects (e.g., electrolytes in patient taking hydrochlorothiazide).

Is the patient taking the medication? Medication nonadherence is a common and complex issue with both physician and patient factors. Depending on the definition, “nonadherence” ranges from 14% to 70% (DeSmet et al., 2007). Adherence is associated with the number of medications, cost, frequency of dosing, and patient’s knowledge of the condition. It is important to obtain the patient’s perspective and concerns about medications in a nonjudgmental manner (Eric Group, 2009). Methods to increase adherence have focused on educational interventions and external cognitive aids. For short-term therapies, written information, counseling about the medication’s indication and potential side effects, and personal phone calls increased adherence. The same effect was not seen for patients taking long-term medications (Haynes et al., 2008; McDonald et al., 2002).

Finally, the checklist should include asking if the medication is still needed. Has the patient’s condition changed to

where you can stop unnecessary drugs, such as preventive medications in a hospice patient?

Continuity of pharmacists is as important as continuity of physicians in decreasing medication errors. Encourage patients to use one pharmacy, and inform the pharmacist of any medication changes. Seeking input from the pharmacist can reduce inappropriate prescribing (Garcia, 2006). With inpatient settings, pharmacists obtain more accurate medication histories from patients, reducing the rate and severity of ADEs (Carter et al., 2006; Reeder and Mutnick, 2008). Simplify the medication regimen by using once-daily dosing and generic drugs, if possible. Discontinue medications that have no indication or benefit (Carlson, 1996). When initiating medications, start one at a time at the lowest dose possible (Table 4-14).

The decision to prescribe a drug depends on many factors besides age, including the patient’s functional status, comorbidities, other medications, and personal preferences and values. Physicians must be extremely vigilant in prescribing, especially for the frail elderly patient, carefully weighing the risks and benefits of any new medication. Periodic review of patients’ medication list is essential to monitor for adverse effects, potentially inappropriate drugs, drug-drug interactions, and drug-disease interactions.

KEY TREATMENT

Current methods of improving medication adherence for chronic health problems are not predictably effective (Haynes et al., 2008; McDonald et al., 2002) (SOR: B).

Certain drugs should be avoided or limited in the elderly patient (Fick et al., 2003/04) (SOR: C).

Obtain local pharmacists’ recommendations to reduce inappropriate prescribing and adverse drug events (Garcia, 2006) (SOR: B).

Reviewing a medication list regularly can reduce polypharmacy and inappropriate prescribing (SOR: B).

Urinary Incontinence

Key Points

- Incontinence is a common medical problem in the elderly population, affecting up to 30% of women and 15% of men.
- Older women are more likely to have urge and stress incontinence, and older men are more likely to experience overflow and urge incontinence.
- Acute episodes of incontinence are more likely the result of underlying medical conditions (e.g., infection, hyperglycemia) or new medications (e.g., diuretics).

Table 4-14 Principles of Rational Drug Prescribing for Elderly Patients

1. Periodically update and review the medication list.
2. Work with the community pharmacist.
3. Educate the patient about the medication.
4. Consider an adverse drug event (ADE) as a cause of any new patient symptom.
5. Simplify the medication regimen.
6. Start one medication at a time, at lowest possible dose.

Table 4-13 Medication Question Checklist

1. Is there a clear indication for this medication?
2. Is it working?
3. Are there side effects?
4. Is the patient taking the medication routinely?
5. Does the medication need lab monitoring?
6. Is it still needed?

- Specific health risks, including depression and falls, have been linked to urinary incontinence in the elderly patient.
- History, physical examination, urinalysis, and postvoid residual assessment are the key elements in categorization of incontinence.
- In the majority of patients, incontinence can be diagnosed and treated by the primary care provider.
- Treatment options for incontinence include behavior modification, pelvic floor exercises, pharmacologic agents, vaginal pessaries, periurethral bulking agents, and surgical procedures.
- Systemic hormone replacement therapy may exacerbate incontinence.

Urinary incontinence, defined as involuntary leakage of urine, affects 25% to 30% of all adults in their lifetime. The estimated prevalence of urinary incontinence in people over 65 years of age ranges from 35% in community-dwelling individuals to more than 60% for those who reside in long-term care facilities (Goode et al., 2008; Song and Bae, 2007; Tennstedt et al., 2008). Incontinence not only increases in prevalence with age, but also is considered part of a geriatric syndrome. Within the younger population a specific condition of the lower urinary tract or its neurologic control is often the cause of urinary incontinence. In older persons, however, incontinence is often secondary to physiologic age-related changes, comorbidities, medications, and functional impairments.

In 2000 the estimated total cost of urinary incontinence in the United States was \$16.3 billion, with \$12.4 billion spent on incontinence care for women alone. Routine incontinence care represented the largest expenditure (Hu et al., 2004). Women spend almost \$750 annually out of pocket for incontinence management, have significantly decreased quality of life, and are willing to pay almost \$1400 per year for a cure. The annual costs of incontinence care are greater than annual direct costs for breast, ovarian, cervical, and uterine cancer treatments combined (Subak et al., 2006, 2008; Wilson et al., 2001).

Urinary incontinence is associated with increased morbidity and mortality. Studies have demonstrated an association between urinary incontinence and worsening in overall function. Health-related quality-of-life measurements have been found to decline in individuals with urinary incontinence (DuBeau et al., 2009; Ko et al., 2005; Teunissen et al., 2006). This decline has been seen in those living independently, in assisted-living facilities, and in long-term care environments (DuBeau et al., 2006).

Specific health risks linked to urinary incontinence include depression, social isolation, urinary tract infections, pressure ulcers, falls and fractures, decreased sexual activity, sleep deprivation, and increased caregiver stress (Brown et al., 2000; Griebing, 2006; Ory et al., 1986; Spector, 1994). Urinary incontinence is also found to be a common reason for institutionalization of the elderly patient (Holroyd-Leduc et al., 2004).

Age-Related Changes in Urinary System

Specific age-related changes in the urinary system can directly influence urinary continence. The pelvic floor muscles can lose tone and predispose women to uterine, bladder, and rectal prolapse, causing secondary urge incontinence. Overall

Table 4-15 Medications Associated with Urinary Incontinence in Elderly Patients

| |
|--|
| Diuretics: polyuria, frequency, urgency |
| Angiotensin-converting enzyme (ACE) inhibitors: cough precipitating stress incontinence |
| Anticholinergics: urinary retention, overflow incontinence, stool impaction |
| Psychotropics: anticholinergic actions, sedation, immobility, delirium |
| Narcotic analgesics: urinary retention, fecal impaction, sedation, delirium |
| Alpha-adrenergic agonists: contraction of smooth muscle of urethra and prostatic capsule |
| Alpha-adrenergic blockers: urethral relaxation |
| Alcohol: polyuria, frequency, urgency, sedation, delirium, immobility |
| Caffeine: polyuria, bladder irritation |

bladder capacity also tends to decrease, limiting total volume and therefore increasing urge to urinate. Prostatic hypertrophy predisposes older men to increases in postvoid residual volumes. Older incontinent persons may also experience increased involuntary bladder contractions, exacerbating the problem.

Presentation

Urinary incontinence presentations can be divided into acute (“transient”) or chronic. Sudden onset of incontinence by potentially reversible and treatable conditions is referred to as *acute* urinary incontinence. Conditions contributing to acute incontinence include lower urinary tract conditions, stool impaction, delirium, fluid imbalance, impaired mobility, and medications (Table 4-15). These conditions not only precipitate acute urinary incontinence, but can also contribute to chronic incontinence.

Chronic incontinence can be divided into five types: urge, stress, overflow, functional, and mixed (Table 4-16).

Urge Incontinence

Urge incontinence is the most common type of incontinence identified in the older ambulatory patient. It is defined as an abrupt, urgent sensation to urinate and results in loss of urine, with both large and small amounts. Urinary frequency and nocturia are often associated with urge incontinence. *Detrusor overactivity* is also associated, caused by age-related smooth muscle changes, central inhibitory pathway lesions, history of pelvic irradiation, and bladder sensory or motor innervation deficits. Urge incontinence with an elevated postvoid residual volume can occur when detrusor overactivity and impaired detrusor contractility occur simultaneously. Urinary frequency and retention are common in these patients, particularly those receiving anticholinergic medications.

Stress Incontinence

Stress incontinence is the unintentional loss of urine. It is most often associated with weakening of the pelvic floor muscles and subsequent hypermobility of the bladder outlet and urethra. Stress incontinence occurs with physical movement or activity, such as coughing, sneezing, laughing, or heavy lifting. Stress incontinence is often seen in older women with previous vaginal deliveries or pelvic surgery. It

Table 4-16 Persistent Urinary Incontinence: Types, Causes, and Treatments

| Types | Symptoms | Common Causes | Primary Treatment |
|------------|--|--|---|
| Stress | Involuntary loss of urine with increases in intra-abdominal pressure (e.g., cough, laugh, exercise) | Urethral hypermobility Sphincteric dysfunction Radical prostatectomy | Scheduled voiding Pelvic muscle exercises Alpha-adrenergic agonist* Estrogen (topical)* Periurethral injection Surgical bladder neck suspension or sling |
| Urge | Leakage of urine because of inability to delay voiding after sensation of bladder fullness is perceived | Detrusor overactivity Neurologic disorders Spinal cord injury | Antimuscarinic drugs Topical estrogen (for severe vaginal atrophy or atrophic vaginitis) Bladder training (including pelvic muscle exercises) |
| Mixed | Combination of urge and stress symptoms | Combination of above causes | One or combination of above, targeting most bothersome symptom(s) first |
| Overflow | Leakage of urine resulting from mechanical forces on overdistended bladder, or from other effects of urinary retention on bladder and sphincter function | Detrusor failure Neurologic disorders Spinal cord injury Diabetes Anatomic obstruction | Bladder retraining Surgical removal of obstruction Intermittent catheterization Indwelling catheterization |
| Functional | Urinary accidents associated with inability to toilet, caused by impairment of cognitive or physical functioning, psychological unwillingness, or environmental barriers | Mobility impairment Cognitive impairment | Behavioral interventions with toileting assistance Environmental adaptations Undergarments and pads |

*Controversial.

is also associated with lack of estrogen in the menopausal woman. Obesity can exacerbate the symptoms of stress incontinence.

Overflow Incontinence

Symptoms of overflow incontinence include weak urine stream, dribbling, urinary hesitancy, frequency, and nocturia. These symptoms may overlap with other types of incontinence, influencing the diagnosis. The etiology of overflow incontinence includes detrusor muscle weakness, bladder outlet obstruction, or both. Medications such as narcotics, anticholinergics, and alpha-adrenergic blockers can contribute to overflow incontinence.

Functional Incontinence

Functional incontinence refers to leakage of urine caused by factors not directly associated with the bladder. Cognitive impairment (e.g., dementia), mobility disorders (e.g., Parkinson's disease), and inaccessible bathrooms are the most common contributing factors in functional incontinence. Factors may be temporary, as in the patient with a lower extremity fracture who is not able to transfer independently on and off the toilet.

Mixed Incontinence

Mixed urinary incontinence is the combination of two types of incontinence simultaneously, typically stress and urge incontinence. Mixed incontinence is the most common type in women, and the causes of the two forms may or may not

be related. *Detrusor hyperactivity with impaired contractility* (DHIC) is a form of mixed incontinence specific to older adults. Symptoms include urinary frequency and urgency caused by uninhibited contractions of the detrusor smooth muscle. When patients try to void, the bladder does not contract sufficiently, and emptying is incomplete, leading to overflow incontinence.

Evaluation

The initial step in the clinical evaluation is the identification of patients with urinary incontinence. Many older patients do not complain about incontinence to their health care provider because they are embarrassed or believe their symptoms are just part of normal aging. Direct questioning during the review of systems can help identify urinary incontinence: Do you have trouble with your bladder? Do you lose urine when you do not want to? Do you find that you have to wear pads or adult diapers for protection? (Fantl et al., 1996; Kane et al., 2004).

A thorough history and physical examination are important in the clinical evaluation of older patients with urinary incontinence. The main objectives of the workup are to diagnose and treat reversible causes, establish the principal type of urinary incontinence to help guide treatment, identify patients who may need subspecialty referral, and improve overall quality of life for the patient. Once urinary incontinence has been identified, the evaluation should continue with a detailed incontinence history, including the type of leakage, frequency, duration, inciting factors, previous treatments, and overall treatment goals. The physical exam should include abdominal, genitopelvic, rectal, and neurologic

evaluation. Health care providers need to be aware of the specific “red flags” to refer a patient for further urologic, gynecologic, or urodynamic evaluation (Table 4-17).

A urinalysis should be obtained in all patients to assess for urinary tract infections, hematuria, or other medical conditions that may be associated with urinary incontinence. Persistent hematuria should prompt additional evaluation, including upper urinary tract imaging and cystoscopy. A postvoid residual volume (with ultrasound or catheterization) helps to exclude overflow incontinence. In clinical practice, a postvoid volume of less than 50 mL is regarded as normal, and in general, residual volumes greater than 200 mL are considered abnormal (Fantl et al., 1996).

Voiding (bladder) diaries can provide valuable information for the clinician and patient. The diary includes documentation of each urination episode and any associated symptoms of incontinence for three 24-hour periods. If possible, the patient can also record the amount of fluid intake and output (Abrams and Klevmark, 1996). Several patterns of abnormality can emerge from the voiding diary. For example, frequent small volumes can occur in patients with overactive bladder syndrome, detrusor overactivity, and some painful bladder conditions (e.g., cancer). Frequent large-volume voids are associated with polyuria, as seen in patients with excessive fluid intake and conditions causing polyuria (e.g., diabetes, hypercalcemia). Obstructive sleep apnea, physiologic aging, congestive heart failure, and medications can all cause nocturnal polyuria (Bryan et al., 2004). A simple office tool that can help detect stress incontinence is the cough test. The patient is asked to produce a forceful cough with a comfortably full bladder to determine any urine leakage and potential stress incontinence.

Treatment

Several therapeutic options exist to help manage the different types of urinary incontinence. Many older adults prefer to start with conservative therapies such as behavioral modification techniques before considering medications or surgery. In many cases, several small behavioral changes together may lead to significant improvement in symptoms.

Behavioral Interventions

Particular beverages can aggravate the lower urinary tract symptoms in older adults. Alcohol, caffeine, and highly acidic citrus fruits and drinks are considered direct

bladder-irritants and may worsen incontinence symptoms. Alcohol has diuretic properties, causing increased urinary frequency. Weight loss may be beneficial for some patients, in particular women with stress incontinence. *Nocturia* is a common complaint for many elderly patients with multifactorial causes (Sugaya et al., 2008). Minimizing late-afternoon and evening fluid intake may decrease nocturnal episodes for some patients. Reduced production of antidiuretic hormone has been seen in patients with obstructive sleep apnea. Treatment of the sleep apnea may help reduce nocturia symptoms (Kujuba and Aboseif, 2008).

In older patients with symptoms of urinary urgency, *timed voiding* is often suggested. Many patients experience symptoms only when the bladder is full, so voiding more frequently will reduce the amount of bladder distention and the sense of urinary urgency. Older patients with cognitive or mobility impairments will often need assisted-toileting programs. Providing physical assistance in going to the toilet on a regular basis can reduce incontinence episodes (van Houten et al., 2007). Some patients benefit from *bladder retraining*, in which they are taught to delay voiding at progressively longer intervals (Wallace et al., 2004). Bladder retraining can take months and has the most benefit for patients with urge incontinence and those with mixed incontinence when combined with pelvic floor exercises (Tuenissen et al., 2004). The patient is encouraged to focus on the sensations in the pelvis, complete pelvic floor contractions and wait until the urgency sensation subsides before proceeding to the toilet.

Pelvic floor muscle (Kegel) exercises remain one of the mainstays of behavioral therapy in the treatment of urinary incontinence. The exercises involve repetitive contractions and relaxations of the pelvic floor muscles. They have been found effective in stress, urge, and mixed incontinence (Hay-Smith and Dumoulin, 2006). A simple way to teach women to identify and isolate the pelvic floor muscles is by having the patient squeeze the examiner’s finger during vaginal examination. Squeezing the examiner’s finger by contracting the anal sphincter during a rectal exam can help both men and women isolate the pelvic floor muscles.

Pessaries in many different forms have been used for hundreds of years for the treatment of pelvic organ prolapse and urinary incontinence in women. The support offered by the pessary helps in correcting the angles and contacts between adjacent organs, thus minimizing bladder irritation and spontaneous contractions that lead to incontinence. Pessaries come in a variety of shapes and sizes and must be individually fitted for each patient by their health provider. Routine cleaning and care by either the patient or, in many cases, their provider is required. In many women, pessaries offer the advantage of avoiding surgery while providing functional support.

Many older adults with urinary incontinence use some type of pad or undergarment to help with their urinary incontinence. Although these products play an important role in the management of incontinence symptoms, patients should be encouraged to seek other types of treatment if appropriate. The cost of these products can be significant and is not covered by Medicare or most other insurance plans. However, it is important to realize that these absorbent products can help older adults maintain their functional independence and participate in their preferred activities.

Table 4-17 “Red Flag” Criteria for Referral of Older Patient with Incontinence to Subspecialist

| |
|--|
| Significant uterine, bladder, or rectal prolapse |
| Surgery or radiation involving lower urinary tract within past 6 months |
| Two or more symptomatic urinary infections in past 6 months |
| More than five red blood cells per high-power field (>5 RBCs/hpf) on repeated urinalysis in the absence of infection |
| Postvoid residual volume greater than 200 mL |
| Marked prostatic enlargement, prominent asymmetry, or induration of bladder lobes |
| Persistent symptoms after appropriate trials of behavioral or drug therapy |

Pharmacologic Therapies

Various medications have been used to treat the different forms of urinary incontinence. However, most current medications are used for urge or mixed incontinence, because there is little evidence that adrenergic agonists help stress incontinence (Alhasso et al., 2005) (Table 4-18). The anticholinergic, antimuscarinic medications prescribed for urge incontinence work by blocking cholinergic receptors in the bladder, which in turn diminishes bladder contractility. This class of medications is effective but has adverse side effects (e.g., dry mouth, constipation) related to the cross-reactivity with muscarinic receptors in the salivary glands and colon (Alhasso et al., 2006). Additional side effects include dry eyes, blurry vision, and risk of urinary retention. Anticholin-

ergics in the elderly patient can also worsen cognitive function or cause drug-induced delirium, mimicking dementia. Newer medications that are theoretically more uroselective and preferentially bind to the muscarinic receptors in the bladder may be associated with fewer adverse side effects. Incontinence medications should not be prescribed to those patients with untreated closed-angle glaucoma and in memory-impaired patients already taking cholinesterase inhibitors, to prevent further deterioration of memory function. The anticholinergic agents and cholinesterase inhibitors work in direct opposition and, if taken together, can lead to rapid loss of cognitive function (Sink et al., 2008).

Alpha-adrenergic antagonists are helpful in treating urge incontinence in men with benign prostatic hypertrophy (BPH). Hypotension is a common side effect with traditional

Table 4-18 Drug Treatment for Urinary Incontinence

| Generic Drugs (Trade Name) | Dosages | Mechanisms of Action | Type of Incontinence |
|---|--|---|--|
| Antimuscarinic | | | |
| Darifenacin (Enblex) | 7.5-15 mg qd | Lessen involuntary bladder contractions and increase bladder capacity | Urge or mixed |
| Oxybutynin (Ditropan) (Ditropan XL) (Oxytrol transdermal) | 2.5-5 mg tid 5-30 mg qd (extended release) 3.9-mg patch every 4 days | Lessen involuntary bladder contractions and increase bladder capacity | Urge or mixed |
| Solifenacin (Vesicare) | 5-10 mg qd | Lessen involuntary bladder contractions and increase bladder capacity | Urge or mixed |
| Tolterodine (Detrol) (Detrol XL) | 1-2 mg bid 2-4 mg qd (extended-release) | Lessen involuntary bladder contractions and increase bladder capacity | Urge or mixed |
| Trospium (Sanctura) (Santura XR) | 20 mg bid 60 mg qd (extended release) | Lessen involuntary bladder contractions and increase bladder capacity | Urge or mixed |
| Estrogen | | | |
| Topical estrogen Topical cream | 0.5-1.0 g qd for 2 weeks, then twice weekly | Strengthen periurethral tissues Increase periurethral blood flow | Urge, associated with severe vaginal atrophy or atrophic vaginitis Stress |
| Vaginal ring | One ring every 3 months | | |
| Vaginal tablets | One 25- μ g tablet qd for 2 weeks, then twice weekly | | |
| Cholinergic Agonist | | | |
| Bethanechol (Urecholine) | 10-30 mg tid | Stimulate bladder contraction | Overflow, with atonic bladder |
| Alpha-Adrenergic Antagonists | | | |
| Alfuzosin (UroXatral) | 10 mg qd | Relax smooth muscle of urethra and prostate capsule | Urge, and symptoms associated with BPH |
| Tamsulosin (Flomax) | 0.4 mg qd | | |
| Terazosin (Hytrin) | 1-10 mg qhs | | |

qd, Every day; tid, three times daily; bid, twice daily, qhs, every night at bedtime; BPH, benign prostatic hypertrophy.

alpha agents. The newer agents have less adverse side effects and should be used in older men who have low blood pressure or episodes of dizziness. The addition of an antimuscarinic drug can be considered in those men who are still symptomatic on alpha-antagonist therapy. For long-term treatment of overflow incontinence in men, 5 α -reductase inhibitors alone or in combination have been shown to reduce the voiding symptoms from BPH as well as the incidence of urinary retention (McConnell et al., 2003).

The role of *estrogen* in the treatment of incontinence in the elderly patient remains uncertain. Topical estrogen is often prescribed for older women with urge incontinence related to atrophic vaginitis or severe vaginal atrophy. Conversely, combination estrogen/progestin oral hormone therapy has been associated with increased frequency of incontinence (Cody et al., 2009; Grady et al., 2001; Rossouw et al., 2002).

Surgical Treatment

The *slings procedure* is the primary form of open surgical treatment in women with stress incontinence. Several variations of the procedure exist with relation to the exact location of the sling and the nature of the graft material used to make the sling. The principal function of the sling is to increase the outlet resistance and thus prevent urine leakage during periods of increased intra-abdominal pressure. Initial success rates for the sling procedure range from 80% to 90% but

decrease with time. Some women respond to other forms of therapy or elect to undergo another sling procedure (Anger et al., 2007).

Periurethral injection of bulking agents can be an effective treatment in some elderly women with stress incontinence. The procedure is minimally invasive and can be performed in the outpatient setting with rapid recovery and immediate results. To date, there is limited evidence that this can relieve stress incontinence in women (Keegan et al., 2007). One disadvantage is that treatment usually needs to be repeated with time. Injection therapy may be particularly useful in elderly women who are unable to undergo the more invasive sling procedure or who are symptomatic after a previous sling procedure. Older men with mild postprostatectomy stress incontinence may benefit from periurethral injection of bulking agents (Fantl et al., 1996).

KEY TREATMENT

Pelvic floor exercises help with all types of urinary incontinence in women (Hay-Smith and Dumoulin, 2006) (SOR: A).
 Anticholinergic drugs are effective for overactive bladder syndrome, but are associated with common side effects (Alhasso et al., 2006) (SOR: A).
 There is limited evidence that periurethral injection helps women with stress incontinence (Keegan et al., 2007) (SOR: A).

Medical education and our professional attitude regarding patient care are oriented primarily toward sustaining life and curing disease. This is reasonable, because not long ago the major causes of death were the infectious diseases, which usually attacked young people, who died before experiencing life. With the advent of antibiotics, it was possible to triumph over these diseases and prevent untimely death. Patients had a high probability of complete recovery. It is no surprise, therefore, that the medical profession emphasized preserving life at all costs and became preoccupied with the advancing technology that made such triumphs possible. Today, people no longer die of acute illness, but rather from chronic disease for which there is no cure. This calls for medicine to focus on improving the *quality* rather than the quantity of life and to recognize that the relief of suffering is superior to attempts to cure when there is limited likelihood of success. Patients with chronic diseases and those who are terminally ill will benefit most from supportive therapy.

In previous centuries, it was assumed that life should be lived so that one would be able to "die well," but contemporary American culture has refused to accept death as a normal occurrence. Children and young adults have been conditioned to consider death from the viewpoint of the observer or disinterested third party. An individual's attitude toward his or her own death depends largely on experiences in dealing with the deaths of relatives or friends. Rather than

a time of despair, sickness may be used as an opportunity for reflection. For some patients, it may be the first time they have faced their own mortality. Too often, however, this natural personal encounter has been depersonalized by removing the dying patient to an institutional setting.

Care of a terminally ill patient typically focuses on the disease, neglecting the patient as a whole person. The value of treatment must be interpreted on the basis of its net value to the individual. When additional treatments no longer provide benefits, the patient needs someone who provides personalized care with attention to the patient's emotional as well as physical comfort. The dying person often is isolated physically and emotionally from familiar surroundings and placed in a social setting that gives very low priority to an individual's personality, fears, and past experiences. Informed physicians, family, and friends can do much to help the terminal patient die with integrity and with dignity. However, if dying is really to be accepted as a normal component of the life cycle, reintegration of the dying patient into the routine course of living is necessary.

The concept of quality care does not always demand that death be regarded as an enemy to be fought with every weapon at a physician's disposal. An obsession with quantity of life can adversely affect its quality; at times, a graceful death with dignity is preferable to lingering torment (LORAN Commission, 1989, p. 27). Many people consider

quality of life more important than quantity and want to leave while they still have something to say about it. Today, it is possible to keep people alive indefinitely, often without consideration for the quality of life.

The Physician's Attitude

Less than 10% of people die suddenly, whereas more than 90% experience a protracted life-threatening illness (Emanuel et al., 2003). Terminal illness is more taxing on the physician than sudden and unexpected death. Not surprisingly, an empathic family physician with a long patient relationship may be uncomfortable in dealing with the patient's impending death. Physicians are most uncomfortable when they feel helpless. Unfortunately, this leads to withdrawal from the patient who is terminally ill, because the physician inappropriately feels helpless and impotent, when in fact a great deal of comfort and help can be provided.

While expressing concern and compassion for a terminal patient, the family physician still must maintain composure and objectivity to remain effective. Osler (1904) referred to this as "calm equanimity" and added, "Our equanimity is chiefly exercised in enabling us to bear with composure the misfortunes of our neighbors" (p. 8). Medicine long has emphasized the need for physicians to remain objective and deal with problems factually; if a physician is unable to do so effectively, attempts to hide emotion may lead the physician to adopt a facade that appears unsympathetic and insensitive to the patient's needs. A son reported that "with the worsening of my father's condition, the physician stopped being friendly and warm; his visits became rare and brief; his manner became quite detached, almost angry" (Seravalli, 1988, p. 1729).

Physicians sometimes lose enthusiasm for care once an illness has been recognized as incurable. If this occurs, interaction with the patient diminishes at the very time emotional support is needed most. Time-motion studies indicate that nurses and other ward personnel also spend less time with the terminally ill patient when giving baths and providing routine care. Using videotape surveillance of terminally ill patients' rooms in a university hospital, Sulmasy and Rahn (2001) found that the average patient spent more than 10 hours alone while awake per day. Since abandonment is a major fear of terminally ill patients, we must remain aware of the need to reduce the time patients spend without human interaction by physicians, nurses, or family.

Compassion fatigue is a form of emotional exhaustion and diminished empathy more common in health professionals caring for dying patients. Symptoms parallel those of post-traumatic stress disorder (PTSD), that is, hyperarousal, in the form of disturbed sleep and irritability, avoidance of the patient, and intrusive thoughts or dreams relating to the provider's work with dying patients (Kearney et al., 2009).

During the terminal stages of a fatal illness, it is vital to the dying patient that the family physician maintain a warm and caring relationship and, through the strength of the doctor-patient bond, provide support for the patient.

The physician who is uncomfortable discussing impending death can discourage conversation in many subtle ways. Hospital rounds are made rapidly, perhaps in a superficial, lighthearted manner, never pausing long enough to give the

patient an opportunity to express fears and concerns. Comments such as "everything will be all right" effectively close lines of communication with an intelligent patient who is fully aware of the seriousness of the situation. When the physician tells a patient, "Don't worry," the patient interprets this as, "Don't bother me." Patients are unlikely to initiate discussions regarding their fears of death or feelings of helplessness under such circumstances and will remain silent or will avoid these issues unless they think the physician is interested and will listen. The physician easily can squelch such conversation, but a slight indication of willingness to discuss the problems disturbing the patient often results in frank conversations, which relieve much of the patient's anxiety and reveal concerns that can be shared only with the physician.

The "Right Time" to Die

Simpson (1976) described the "how dare you die on me" syndrome, in which the patient has the "effrontery" to die before medical and nursing staff have used all the treatments in their repertoire. The patient is supposed to die "at the right time"—neither before all potential effective therapies have been tried nor too long after all palliative procedures have been utilized. Health professionals often need to feel that everything possible was done for the patient before death. These attitudes have developed because the health care process too often focuses more on professional expectations than patient needs.

We might consider what we have done to the patient who dies in the isolation of a laminar flow room, without having been able to touch another person's hand during his last few weeks of life. Such treatment is a *false-positive*, a treatment inappropriate to the real needs of the patient (Saunders, 1976).

However, it is impossible for physicians to provide adequate support during this difficult time unless they have come to grips with their own mortality. Studies by the Group for the Advancement of Psychiatry have revealed that physicians are afraid of death in greater proportion than patient controls (Aring, 1971). What better defense against death than to make one's full-time vocation fighting it?

Patients are often more willing to accept death than the physicians who treat them, and many fear that they will receive more aggressive treatment than they want. Based on interviews with seriously ill patients, 60% preferred that treatment focus on comfort, even if it meant shortening their lives. The other 40% wanted life-extending care. Of those preferring comfort care, only 41% reported that treatment matched their wishes (Teno et al., 2002). In another study, more than half of physicians interviewed admitted they had provided overly aggressive care to patients (Solomon et al., 1993).

Many if not most patients will choose toxic chemotherapy, even if there is only a slight chance of cure, or even if it would prolong their life by only a few months. The concern is that they may choose this route on the advice of their physician, even though they will be miserable for those remaining months. It is important to have a straightforward discussion with the patient about the quality and quantity of life with and without chemotherapy. More than 20% of Medicare patients with metastatic cancer had a new chemotherapy

treatment regimen started in the 2 weeks before death (Earle et al., 2004).

Unfortunately, chemotherapy is better compensated than are discussions as to its need and potential side effects. It is no surprise that oncologists prefer third- or fourth-line chemotherapy to discussing hospice care. One patient received intrathecal chemotherapy 6 days before his death at a cost of \$3400 (Harrington and Smith, 2008).

Communication

Key Points

- Abandonment is a major fear of dying patients, who spend an average of 10 awake hours alone per day.
- Listening and allowing patients to express their fears and concerns is of great therapeutic benefit.
- Touch and sitting with the patient convey support and compassion.
- Frequent assessment of the patient and family's desire for information must be accompanied by honest answers.
- Patients should be allowed as much control as possible to avoid fear of the unknown.
- When cure is not possible, much benefit can be derived from attention to daily symptom control.
- Avoid giving false hope, but remember that hope and humor can be therapeutic.

When to Tell the Patient

The issue today is not so much whether to tell patients they have a terminal illness, but rather how to share this information with them—because most patients know the nature of their disease process to some degree. Because they know their patients well, family physicians should be able to gauge patients' desire to be told and their capacity to withstand the shock of disclosure. When a terminal state of cancer is inevitable, most patients prefer to discuss such issues with their family physician rather than with their oncologist.

Patients who have end-of-life conversations with their family physician have lower health care costs during the final week of life. Better communication results in better quality of life and quality of death as well as lower cost (Zhang et al., 2009). End-of-life care is often fragmented among providers, leading to a lack of continuity of care and impeding the ability to provide high-quality, interdisciplinary care. Enhanced communication among patients, families, and providers is crucial to high-quality end-of-life care (National Institutes of Health, 2004).

A frank discussion of death or how long the patient is expected to live may not be necessary or even indicated. A good understanding between physician and patient may make open disclosure unnecessary. The physician's role may be primarily one of supporting patients during the progressive, terminal course of their illness. However, the physician who is uncomfortable with the subject of death should not use such a situation as an excuse to avoid discussing the issue. The family physician's primary responsibility is to take the time to evaluate the situation, make sure the patient's

true desires have been assessed correctly, and provide whatever support is needed, based on the patient's concepts and needs rather than those of the physician (Table 5-1).

The physician who can deal with death honestly is able to focus more attention on the patient and can determine the patient's level of awareness by listening and observing nonverbal cues. Clues to the patient's wish to discuss the condition may simply be a deep sigh, a tear, or a shaky voice. The physician must be alert during busy hospital rounds for these or similar signs. The physician can pause to sit and encourage conversation if time permits, or return later when more time is available. Whenever possible, however, the response should be at that moment, because the patient is more likely to communicate freely in a spontaneous situation. Physicians who are uncomfortable in this situation may insulate themselves from the issue during hospital rounds by checking the bedside monitoring equipment, or otherwise directing attention away from the patient, effectively ignoring overt as well as subtle clues to the patient's needs.

Talking with patients about their death can be difficult, but end-of-life discussions with patients do not result in greater emotional or psychological stress. On the contrary, worse outcomes are found in those who do not have these conversations. Such discussions result in less aggressive medical care near death and earlier hospice referrals. Wright and colleagues (2008) showed that quality of life deteriorates with a greater number of aggressive end-of-life interventions and improves with longer hospice care. Patients who spend less than a week in hospice have the same quality of life as those who receive no hospice care.

When the patient is ready to discuss her or his impending death, physician and patient are probably past the most difficult stage, and the physician needs merely to listen, accept the patient's feelings, and respond to questions honestly. Most patients will raise questions that indicate how much they wish to know, provided the physician gives them the opportunity. The most supportive and facilitative act the physician can provide is to sit and ask the patient, "Do you have any questions?" When asked in a sincere manner, patients who are ready to talk about their death will take advantage of the opportunity, but they may be reluctant under other, more hurried circumstances.

Patients usually will indicate their desire to discuss their prognosis, as well as when they want to avoid the subject and focus on other topics. Even patients who fully accept their terminal process cannot remain constantly focused on that

Table 5-1 Useful Questions in Determining a Terminally Ill Patient's Needs and Wishes

| |
|---|
| • What do you fear most? |
| • What would you like to accomplish in the time left? |
| • Which is your highest priority? |
| • How can I help you achieve this? |
| • What has been most difficult about this illness for you? |
| • How is your family (wife, husband, daughter, etc.) dealing with your illness? |
| • Is religion important to you? |

subject and must attend to more satisfying issues. Physicians should honor and respond to this need, just as they would respond to a desire to discuss pain or other problems.

What physicians say to dying patients is not nearly as important as their willingness to listen. One of the most comforting steps physicians can take in caring for the dying is to allow them to talk about their fears, frustrations, hopes, needs, and desires. *Talking about problems can be very therapeutic.* Patients who are permitted to examine and discuss their feelings about death and dying are grateful for the opportunity and usually become less anxious, experience less pain, and accept their situation more easily. If they are denied this opportunity, especially when the terminal process is obvious, they may be convinced that the time remaining is too terrible to be discussed, and their anxiety will be significantly increased. Often, terminally ill patients are more fearful of the manner in which death will occur (e.g., painful, alone and abandoned, weak and helpless) than they are of death itself.

Do all patients want to be told of their fatal illness, however? Surveys indicate that 80% to 90% of patients say they wish to be told, whereas many physicians prefer not to tell a patient that he or she is dying. Ward (1974) found that family physicians are more likely to discuss a fatal diagnosis with women than with men (22% vs. 7.5%) and more often with patients in the upper social class than the lower social class (24% vs. 5% for men; 30% vs. 26% for women). Many physicians who state that they theoretically believe in telling the patient of the terminal nature of the illness employ evasion in their actual practice as often as most other physicians. Because of this reluctance, which may be based on discomfort with the issue emanating from intensive conditioning to preserve health and maintain life, future medical students must be trained more adequately in assisting patients with the process of living just before death.

Most physicians will tell a patient that he or she has terminal cancer if the patient asks a direct question, but otherwise will evade the issue and discuss it openly only with the family. In many cases this is the most appropriate course of action; some patients clearly indicate that they cannot and do not wish to face the fact that they have an incurable disease. It is essential, however, that the physician evaluate the true nature of the patient's desire in the matter and neither avoid the issue when the patient wishes to discuss it nor force a discussion on an unwilling individual. "When the task of telling a patient about an onerous diagnosis is too easy, the doctor has become callous. When it is too difficult, he needs to examine his own guilt or anxiety" (Weisman and Brettell, 1978, p. 251).

Patients should be given adequate time to absorb the knowledge of the terminal nature of their illness and the opportunity to react appropriately before death intervenes. This is not possible if the physician procrastinates or rationalizes that it is better not to inform the patient. The process should not be allowed to advance to such a final a stage that inadequate time remains for individuals to react appropriately and put their affairs in order.

How to Tell the Patient

There is no need to answer questions the patient has not yet asked. One way to approach the subject is to ask patients what they think the problem is, or how sick they think they really are. The response may be straightforward ("I think I have

cancer"), or the patient may indicate a wish to avoid the issue by saying, "I hope it's nothing serious." The patient's condition can be revealed gradually or in stages, such as telling the patient after surgery that there is a suspicion of cancer, but that further information will have to wait for the pathology report. The physician should observe the patient's response to this initial suspicion and, based on that reaction, choose a method for presenting subsequent information. Tumulty (1973) supported the concept of *gradualism* in informing a patient and the family of the terminal nature of the illness: "The total truth is revealed in small doses as the illness unfolds, affording the family the opportunity to get its feet under itself before another blow falls.... The patient and the family need to be eased into the truth... not slugged with it" (pp. 180-181).

Such a gradual disclosure is likely to lead to acceptance, whereas a harsh, sudden, or abrupt disclosure is likely to result in denial or severe depression. If the patient appears reluctant to accept the information, do not push the issue; merely make sure that openings for discussion are made available periodically and further information is provided when the patient is ready.

One statement is never appropriate: "There is nothing more that we can do." Such statements tell patients they are being abandoned and increase their feelings of isolation and vulnerability. There is *always* something the family physician can do to provide compassionate, comforting care to the patient and family, even if it is only sitting at the bedside so the patient does not feel abandoned. *Distress* can take many forms: physical, emotional, and spiritual, as well as anticipating symptoms that may arise, such as pain, constipation, anxiety, depression, and nausea. Family physicians also can help by stopping or avoiding treatments and diagnostic procedures that hold little promise of improving the patient's quality of life, such as taking vital signs or turning patients in bed when they are trying to sleep. If a test will not lead to a change in treatment, the test is not indicated.

Delivering "Bad News"

When giving "bad news" to a patient, do so privately and without interruption (see eTable 5-1 online). Use language the patient can understand; allow the patient to be emotional; offer to help break the news to family and employer; and be sure that care providers know what the patient has been told (Field and Cassel, 1997).

Health care professionals caring for patients at the end of life should assess the patient's readiness to engage in the discussion and appreciate their level of understanding about the situation and how much they want to know. Once physicians know the patient's preferences, they can tailor the discussion appropriately, checking periodically for the patient's level of comprehension and desire for more. It is best to provide small amounts of information at a time, frequently assessing the patient's desire to continue. Also, besides comprehension, what are the patient's expectations?

When sharing information regarding a fatal diagnosis with a patient, eye contact, touch, and personal closeness are important. If possible, sit with the patient and hold her or his hand or touch the forearm. Such gestures convey a sense of support, closeness, and compassion, reinforcing verbal assurance that the patient will not be abandoned during the difficult time remaining. Be positive whenever possible (Table 5-2).

Table 5-2 Positive Language to Use with Dying Patients

- I will keep you as comfortable as possible.
- I will focus on maintaining your quality of life.
- I want to help you live meaningfully in the time you have left.
- I will do everything I can to help you maintain your independence.
- Maintaining your independence and dignity will be my top priority.
- I will do my best to fulfill your wish to remain at home.

Modified from Stone MJ. Goals of care at the end of life. *Baylor University Med Center Proc* 2001;14:134-137.

Sitting with the patient on the bed or at the bedside rather than standing puts the physician on the same level and conveys in a clear, nonverbal manner a willingness to talk and listen. In one study, physicians visited with hospitalized patients for exactly 3 minutes. Half the visits they sat down, and the other half they remained standing, a little removed from the bed. "Every one of the patients [with whom] the physician had sat down thought the physician had stayed at least 10 minutes. None of the ones [with whom] the physician remained standing estimated that it was as long" (Kübler-Ross, 1975, p. 20).

Prognosticating

One of the most difficult tasks in medicine is predicting how long someone with a terminal illness will live. People enjoy repeating stories of patients who survived long after the date their doctor predicted. In most cases, however, physicians tend to be overly optimistic, and short estimates are more accurate than longer ones (Evans and McCarthy, 1985).

Physicians overestimate survival more than 60% of the time and underestimate it only 17% of the time (Christakis and Lamont, 2000). In addition to physicians overestimating prognosis, many patients believe their treatment at the end of their life (e.g., radiation) is intended to be curative, when in reality it is palliative. The better that physicians know their patients, the more they overestimate survival, probably hoping the best for patients they know well. The longer the physician has been in practice, the more accurate the prognosis. Most patients want optimistic physicians, but at some point, this optimism may delay palliative treatment.

Attempts have been made to develop indexes (e.g., Karnofsky score) to assist the physician in making objective estimates that correlate with actual survival. However, no accurate method is currently available, largely because of the multiple variables that influence when a patient dies. A good policy is to provide a conservative estimate. It is better to have the patient and family proud that they "beat the odds" or exceeded the physician's prediction than to have the patient die earlier than anticipated.

Conspiracy of Silence

Honesty with the terminal patient will provide the greatest benefits. However, the physician frequently is torn between patient and family, with the patient saying, "Don't tell my

wife because she can't handle it," while the wife is saying, "Don't tell my husband because he can't handle it." Although the wishes and desires of the family must be considered when deciding how to care for a dying patient, the physician's primary obligation is to the patient. The method of management must be based on the physician's knowledge of the patient and insight into the patient's desires, feelings, and approach to life. Despite all efforts at deception, the patient knows or will soon learn about his or her condition.

By cooperating with the family in a conspiracy of silence, information that really belongs to the patient is withheld. Only if the physician believes that the patient is not yet ready to cope with the information, or sincerely wishes not to be told, should the information be withheld; however, this is more often the exception than the rule. One patient said, "I knew it was cancer from the moment they started lying to me" (Lamerton, 1976, p. 28). Simpson (1976) described a 63-year-old woman whose family insisted she knew nothing of her inoperable gastric carcinoma. When visited by the physician, "She gave a dry chuckle: 'Only a little ulcer... and my relatives down from Wales to see me for the first time in 15 years, and the priest here at 6 in the morning?'" (p. 193). When such a charade continues, terminally ill patients become more and more isolated because they are unable to communicate their concerns and fears honestly and openly with those closest to them. The elaborate schemes some families and physicians develop to "protect" the patient lead to great tension within the family, as everyone attempts to perpetuate the lie while continuing to interact with the patient.

Similarly, failure to provide the information to the patient's family can lead to a decrease in the quality of their relationship in the time remaining, because the patient's tensions and fears are not understood by family members and friends. Dunphy (1976) described a patient with terminal cancer who asked that his wife not be told. He then quickly planned a world cruise, which they had wanted to take for some time. The wife, unaware of the reason for the hasty departure, was unhappy and complaining throughout the trip, while the husband saw himself as a silent martyr, trying to provide a final measure of happiness for his wife. Only after returning home and reminiscing on this miserable cruise did he tell his wife the truth and the reason for the precipitous departure. Had she been told earlier, their final days together could have been a pleasant and memorable experience. At a time when the terminally ill patient most needs closeness, a lie may serve to push them apart.

Denial

Most patients tend to deny the reality of their situation after being made aware of the terminal nature of their illness. Denial is one way of coping with or protecting oneself against overwhelming anxiety, which otherwise could be incapacitating. This reaction is more marked in the patient who is told abruptly without adequate preparation. Although denial is noted primarily when the patient first learns of impending death, it can appear in different degrees at different times. Even patients who have accepted the terminal nature of their illness will need to employ denial periodically to avoid feelings of hopelessness. The mental burden of impending death is too heavy to carry all the time, and periodic relief

is necessary to carry on customary activities and enjoy the limited time left. As Aring (1971) noted, La Rochefoucauld said, "Neither the sun nor death can be looked at steadily."

Patients who avoid asking about their illness or prognosis when the physician offers every opportunity usually are experiencing denial. Excessive denial usually means that the patient subconsciously knows the truth but wants to avoid facing it consciously. Even when repeatedly given the accurate diagnosis, some patients deny ever having been told. This denial provides constant emotional protection until the patient is ready to face the truth.

"Watch with Me"

The greatest fear of the dying patient is that of suffering alone and being deserted. There is less fear of a painful death than of the loneliness and alienation that may accompany it. A patient particularly dreads being abandoned by the physician in the face of death and may need increasing levels of professional support as the illness progresses. This is particularly true if family and friends are not able to cope with the deteriorating condition and begin to avoid contact, thus contributing further to the patient's feelings of loneliness and abandonment. If the patient feels that no one is available to discuss the situation openly and honestly, despair is likely to ensue. The patient's fear of the unknown is easier to cope with if his or her apprehension can be shared with a caring physician who provides comfort, support, encouragement, and even a modicum of hope.

Each new problem of the dying patient should be viewed as a nuisance requiring relief or removal and approached with the vigor that one would devote to an acute, short-term illness. When a fresh complaint arises, the patient should be reexamined and attempts made to relieve the symptom so the patient will not feel unworthy of further attention. If everyday nuisances can be controlled or lessened, the patient will feel that there is sincere concern for making her or his remaining life pleasant. The physician should give attention to details such as improving the taste of food by fixing or replacing dentures or stimulating the patient's appetite; eliminating foul odors; and suggesting occupational therapy to avoid boredom.

The physician should take advantage of every opportunity to touch and examine the patient rather than standing apart. Gentle palpation of areas of pain or merely taking a pulse can convey a sense of concern and warmth and provide comfort for an apprehensive and lonely patient. The physician and other health professionals can provide much support merely through conversation. The tendency to withdraw and reduce conversation contributes to the patient's sense of loneliness. Silence is an enemy of dying patients and increases their separation from society. Conversation is a social bond that affirms life and reduces anxiety by providing a means of catharsis. Saunders (1976) summed up the needs of a dying patient with the words of one patient: "Watch with me," asking that he not be abandoned in his final days. The readiness to listen and personal, caring contact are comforts that cannot be matched by modern "wonder drugs" and procedures.

When dying patients notice that people are avoiding them, they may interpret it as rejection, because their condition has not improved, or as the loss of love from family and friends,

which is particularly traumatic because it tends to negate long-cherished relationships; the joys of a rewarding life can suddenly lose their value. The dying patient's contentment depends on maintaining warm relationships with loved ones as well as continuing other satisfying interpersonal relationships, including with the physician. If physicians and others withdraw from interaction with the terminally ill patient, much of the motivation for living disappears and is replaced by despair or terminal depression. The following plea to fellow health professionals is from a young student nurse who was terminally ill (Kübler-Ross, 1975):

I know you feel insecure, don't know what to say, don't know what to do. But please believe me, if you care, you can't go wrong. Just admit that you care.... All I want to know is that there will be someone to hold my hand when I need it. I am afraid. Death may get to be a routine to you, but it is new to me. You may not see me as unique!... If only we could be honest, both admit of our fears, touch one another. If you really care, would you lose so much of your valuable professionalism if you even cried with me? Just person to person? Then, it might not be so hard to die—in a hospital—with friends close by (p. 26).

Patient Control

We need to provide options to patients so they can actively participate in their care and feel a sense of control.

Terminally ill patients have a need to believe that they are still in control of their affairs as much as possible, even though they have lost control of their bodies. They should be given the freedom to make choices and assume responsibility over as many aspects of their existence as possible. For many individuals, this is an essential part of living, and its loss may destroy their motivation to live. A terminally ill patient should be helped to focus on and cope with the realities of daily living, because these problems remain very real and can serve as a diversion from constant preoccupation with the prospect of death. When patients have understanding and insight into the treatment and feel they still have some control over the decision-making process regarding their lives, they are more likely to cooperate with prescribed treatment regimens.

It is often fear of the unknown that makes a patient suspicious and resistant to therapy. Patients also should be given the opportunity to settle their affairs. Studies have shown that 40% of terminally ill patients are most concerned about being a burden to their family and friends, and that 40% of the families of cancer patients become impoverished as a result of providing care for a family member (Emanuel et al., 2003). Concentration on financial business and putting the house in order is a pragmatic approach to active participation in the decision-making process. Some patients may have a burning desire to complete a cherished project, reconcile an estranged relationship, or visit particular places before they die. Positive motivation can be maintained by assisting them to focus on and deal with these issues.

A sense of control is more possible for the patient if pain is controlled and the patient is made comfortable. Sleep should not be forced with medication, because some patients resist

going to sleep, fearing they may never awaken, while others frequently have terrifying dreams.

The Importance of Hope

Hope is one of the essential ingredients of human existence, without which life is dark and cold and frustrating. It maintains strength and gives substance to courage. In the presence of hope, suffering of all sorts still has some positive qualities. In its absence, suffering is a completely negative experience (Tumulty, 1973, p. 171).

Hope allows patients to face the shortness of their lives constructively. Twycross (1986) defined hope as having “an expectation greater than zero of achieving a desired goal.” Hope can also be defined as the patient believing in what is still possible. Anything that contributes to a sense of meaning or purpose in life fosters hope. Thus, belief in God or a higher being provides hope and may give a sense of meaning to suffering for some patients.

The physician should not raise false hopes or be overaggressive in treating a terminal illness to help the patient maintain hope. Some patients find it best to plan for a little time and hope for more. A false sense of hope may deflect the patient and family from finding final meaning and value in their remaining lives together.

Even advanced cancer patients can maintain a positive outlook on life. The physician can help direct a patient toward an achievable goal, such as pain relief, support for the family from a hospice service, or making a trip to visit relatives.

Even laughter can contribute to hope. One patient said, “I may not have much control over the nearness of death, but I do have the power to joke about it.” Also, recalling uplifting moments such as vacations or looking at old photograph albums can support hope. Memories of the past can serve to enrich the present (Herth, 1990).

Having one’s individuality accepted, honored, and acknowledged fosters hope, whereas devaluation of personhood and a feeling of abandonment and isolation interfere with hope. Hope is also hindered by uncontrollable pain and discomfort. The continuation of pain after attempts to control it have failed contributes to the loss of hope (Herth, 1990).

Even when death is near, the patient can hope for a measure of happiness during the amount of time he or she has remaining. The physician can support the patient’s hope for a good quality of life in the remaining time, for spiritual healing, and for a final phase of life that has integrity and dignity.

Hope is a potent force for patients to deal with their illness and to have a confiding relationship with a physician, spouse, or close friend, which can also help prevent depression. Every physician-patient encounter should leave the dying patient emotionally more able to deal with end-of-life issues. Always promote the patient’s sense of hope (Ngo-Metzger et al., 2008).

Discussing Religious and Spiritual Issues

As patients approach the end of their life and grapple with their mortality, their spiritual and religious concerns may be awakened or intensified. Although some physicians may be

uncomfortable discussing a patient’s spiritual and religious concerns, they can listen respectfully without judgment or discussion of religious views. Patients who believe that the physician really understands their concerns no longer feel isolated or alone in their final days (Low et al., 2002).

One way to approach this issue is to ask the patient, “Is faith or religion important to you in this illness?” In a study of patients with advanced cancer, 88% reported that religion and spirituality were important factors in adjusting to their illness (Balboni et al., 2007). Although religious coping can offer patients a sense of meaning and comfort when facing a life-threatening illness, it is somewhat surprising that a high level of religiousness is associated with preference for aggressive end-of-life care such as mechanical ventilation. These patients may have a greater trust that God will heal them through the treatment even when near death (Phelps et al., 2009).

Prolonging Living or Prolonging Dying?

It has been a long time since pneumonia was accepted as “the old man’s friend.” As one organic system after another slowed to a halt, the aged person was released from nausea, pain, delirium, and the degradation of lingering deterioration by finally developing pneumonia and dying. The family doctor merely showed concern and support; before antibiotics, there was not much to do but stand by and “let nature take its course.” With improved medical care, however, a dying process that might have taken only a few days in previous years now may drag out for months (Veatch, 1972). Modern technology allows improved medical care to be taken to unrealistic extremes; one person was kept alive in a vegetative state for over 37 years (LORAN Commission, 1989).

Protraction of the dying process is a modern epidemic. Some physicians seem to forget that their primary responsibility is to relieve suffering, not prolong it. Greater clinical skill often is required to provide daily supportive care than to cure acute illness. Tenderness and caring must be included in the protocols of terminally ill patients so that the ravaged patient is allowed to die peacefully, without tubing and respirators. Patients should be allowed “to experience those waning moments unencumbered by high-tech devices that serve only to impede their capacity for human interaction. Here it is the patient’s comfort, not the caregiver’s need ‘to do something,’ that should prevail” (LORAN Commission, 1989, p. 29).

In some situations, therapeutic restraint is necessary to permit a patient to die with dignity. When a cure is no longer possible, care should focus on the comfort of patient and family. At St. Christopher’s Hospice in London, feeding is provided by human hands instead of nasogastric or intravenous tubes; “even if the patient does not get enough physical nourishment, he or she gets what is more important—the personal nourishment of someone who cares enough to sit by the bed several hours each day” (Nelson and Rohricht, 1984, p. 174).

Management of Symptoms

When fewer therapeutic options are available, the physician’s involvement should increase. Even when no cure is possible, much can still be done to relieve pain and suffering.

Table 5-3 Common Symptoms in Seriously Ill Hospitalized Patients

| Symptom | Percentage of Total Patients | |
|------------|------------------------------|---------------------|
| | At Any Time | Severe and Frequent |
| Pain | 51% | 23% |
| Dyspnea | 49% | 23% |
| Anxiety | 47% | 16% |
| Depression | 45% | 14% |
| Nausea | 34% | 6% |

From Expert Consult—Cecil Medicine, after Desbiens NA, Mueller-Rizner N, Connors AF Jr, et al, for the SUPPORT Investigators. The symptom burden of seriously ill hospitalized patients. *J Pain Symptom Manage* 1999;17:248-255.

The family physician can help alleviate the fear, symptoms, and family stress that often make this a distressing time, keeping the patient as comfortable as possible and avoiding any impression of abandonment. A good death means being free of pain and unpleasant symptoms yet having the ability to make clear decisions and prepare for death.

Care of the dying patient can be one of the most rewarding aspects of the family physician's practice. Too often, however, the physician's discomfort with this stage of life contributes to the isolation and discouragement of the terminally ill patient. Unwarranted fears of respiratory depression, addiction, or tolerance prevent the prescribing of adequate amounts of analgesics. The resulting uncontrolled pain makes those final weeks a nightmare for all. Families may disintegrate as a result of the sleepless nights, fears, and guilt that come from trying to cope with uncontrolled symptoms.

Table 5-3 shows symptoms most often encountered in seriously ill hospitalized patients; some are predictable, and all are manageable to some extent. Rarely is a single symptom present, and most patients have two or more. Symptom severity can be decreased if anticipated and treated early. Eliciting and addressing the patient's concerns about anticipated suffering can often be as important as managing the symptoms. Good control of pain, nausea, and dyspnea can enable patients to die in the place of their choosing with comfort and dignity.

The keys to symptom control, as in all areas of medicine, are a careful history and physical examination to determine the various causes of discomfort, as well as a broad knowledge of the therapeutic agents available.

Pain Control

Key Points

- Analgesics should be given regularly and in adequate doses. When given for severe pain, analgesics do not cause addiction or respiratory depression.
- Oral morphine is the drug of choice for severe pain.
- NSAIDs are recommended for bone or joint pain; antidepressants or anticonvulsants for burning or shooting pain; anticholinergics

for cramping abdominal pain or bladder spasms; and antihistamines for restlessness and generalized discomfort.

- Prevention and treatment of constipation is required for all patients receiving opioids.

Pain can be physical, psychological, emotional, or spiritual. It can also be a combination of chronic, somatic, visceral, and neuropathic pain. *Somatic* and *visceral* pain accounts for about two thirds of patients with pain and responds to conventional opioids. About 35% of patients have some degree of *neuropathic* pain, a shooting or stabbing, electric shock-like pain. *Chronic* pain is influenced by memories of past pain and the anticipation of future pain. The fear of worsening pain may distort the patient's perception of current discomfort. Frustration and anxiety may accentuate the pain. All these factors can lower the patient's pain threshold and greatly magnify even minor disturbances (Twycross, 1993).

Failure to treat the whole person often results in inadequate pain control for patients with terminal cancer. Fatigue, insomnia, anxiety, boredom, and anger all contribute to a lower threshold for pain. Rest, sleep, diversion, and companionship all help to increase the patient's tolerance for pain.

Analgesics should be given in adequate amounts to provide comfort. The approach of giving analgesic doses as needed should be abandoned in the treatment of dying patients, because it contributes to a lower pain threshold and a need for increasing doses to relieve the pain. When medication is given regularly in adequate doses, the anxiety and fear that accentuate pain are avoided, and lower doses of the drug are effective, because the patient no longer fears recurrent or "breakthrough" pain.

Nonpharmacologic Techniques

Nonpharmacologic pain management techniques include transcutaneous electrical nerve stimulation (TENS), exercise, heat, cold, acupuncture, cognitive therapies (relaxation, imagery, hypnosis, biofeedback), behavioral therapy, psychotherapy, music therapy, and massage. Cold works especially well for neuropathic pain; heat works well for muscle spasm.

Opioids

A symptom-oriented history and careful examination may reveal a number of different sources of pain. Oral candidiasis, decubitus ulcers, constipation, and infected wounds all have specific remedies. Most patients with pain from cancer (and many with pain from nonneoplastic illnesses) require an opioid analgesic. Opioids are often the safest analgesics available, usually causing only temporary sedation and increased need for laxatives. Opioid toxicity may manifest as myoclonus or nightmares; the patient may exhibit spontaneous jerking or pull the hand away when touched, which can be misinterpreted by others, making them reluctant to touch the patient. Morphine taken orally gives good relief for cancer pain but has some unwanted side effects, mainly constipation and nausea.

High doses of opioids may be necessary to obtain initial pain control in a patient with severe pain. Psychological dependence is rarely a problem in patients who receive appropriate opioid doses for chronic, severe cancer pain. When medication is given before the recurrence of pain,

craving for medication does not occur. Physical dependence does occur with routine use, but withdrawal symptoms can be avoided by reducing a dose no more than a 20% in any 2-day period.

In the past, physicians feared scrutiny by the U.S. Drug Enforcement Administration (DEA) for using high doses of morphine to control pain. However, failure to use adequate doses of morphine may be a greater concern now because a physician was successfully sued for undertreatment of pain in a terminally ill patient. The proper combination of pain medications can relieve pain without clouding the mind or suppressing the spirit.

Concerns about addiction, respiratory depression, and tolerance usually are unwarranted in patients with severe pain (Twycross, 1993). If the dose is titrated carefully, the patient's pain (or dyspnea) usually can be controlled completely. Patients can still be alert and mentally clear even when they receive hundreds of milligrams of oral morphine every 4 hours (Bruera et al., 1990).

A number of effective oral opioid preparations are available (Tables 5-4 and 5-5). If hydrocodone, 5 to 10 mg every 4 hours, is not adequate, oxycodone, 5 to 10 mg every 4 hours, should be used. Oral morphine beginning with 15 to 20 mg every 4 hours is usually the next step, but hydromorphone is a good alternative. The morphine dose should be titrated upward until analgesia lasts the full 4 hours, even if large doses are required.

The particular drug used is less important than the method of administration. To *prevent* pain, and end the cycle of uncontrolled pain followed by oversedation, an oral narcotic should be administered on a regular schedule around the clock. "Booster" doses equal to about half the regular 4-hour dose can be used as needed for breakthrough pain.

Long-acting drugs such as methadone (half-life, 48-72 hours) can be prescribed every 6 to 8 hours but are often unsuitable for booster doses. They will accumulate over several days and are difficult to titrate, especially in patients who have fluctuating levels of pain or deteriorating renal or hepatic function. Methadone is a synthetic that has no cross-allergenicity with morphine and is less expensive than other sustained-release opioid products. It is available in oral and injectable forms and has been successfully used via other routes. It is metabolized in the liver and has no active metabolites, making it especially useful in patients with renal insufficiency (Toombs and Kral, 2005).

Slow-release morphine preparations such as MS Contin or Oramorph SR can provide excellent analgesia for 8 to 12 hours, and Kadian and Avinza will last 12 to 24 hours. The shorter-acting, slow-release tablets may be given rectally when the patient cannot swallow (Wilkinson et al., 1992). Small, soluble tablets or concentrated solutions of morphine or hydromorphone can be given sublingually when the patient is too weak to swallow and can be used for both 4-hour and booster doses.

Fentanyl, a synthetic opioid, is available for use as a transdermal patch (Duragesic), in 25-, 50-, 75-, and 100- μ g/hr strengths, or a transmucosal lozenge on a stick (Actiq), in 200 to 1600- μ g strengths. Because these products are expensive and deliver a wide variation of plasma levels (25- μ g patch = 4 to 11 mg of oral morphine every 4 hours), they should be reserved for patients who cannot receive drugs by the oral or subcutaneous routes. However, the patches may

Table 5-4 Select Oral Opioids

| Narcotic and Dose | Oral Morphine Equivalent (mg) |
|--|-------------------------------|
| Codeine (30 mg) + acetaminophen (300 mg) (Tylenol No. 3) | 1-2 |
| Hydrocodone (5 mg) + homatropine (1.5 mg) (Hycodan) | 1-2 |
| Hydrocodone (5 mg) + acetaminophen (500 mg) (Vicodin) | 1-2 |
| Oxycodone (5 mg) + aspirin (325 mg) (Percodan) | 8 |
| Oxycodone (5 mg) + acetaminophen (325 mg) (Percocet) | 8 |
| Oxycodone (5 mg/5 mL) (Roxicodone) | 8/5 mL |
| Hydromorphone (2 mg) (Dilaudid) | 10 |
| Fentanyl patches (50 μ g/hr) (Duragesic) | 15 q4h |
| Morphine | |
| Tablets (Lilly, Roxane, Purdue-Frederick) | 10, 15, or 30 |
| Syrup (Roxane, Purdue-Frederick) | 10 or 20/5 mL |
| Solution (Roxane, Purdue-Frederick) | 20/mL |
| Slow release (MS Contin [30 mg], Oramorph SR, Kadian) | 10 q4h \times 3 |
| <i>q4h</i> , Every 4 hours. | |

not work in thin, malnourished elderly patients because they need a subcutaneous fat reservoir to work. There is no need to use injections when an adequate dose by mouth will work as well. Table 5-6 provides a checklist of items to remember when prescribing an opioid.

Two opioid agents that also are available orally are not recommended for cancer pain. Meperidine (Demerol) has a very low oral potency, a short duration of action, and a toxic metabolite that can cause tremors or even seizures (Kaiko et al., 1983). Pentazocine (Talwin, Talacen) is an agonist-antagonist agent that is no more potent than aspirin with codeine and has a high incidence of psychotomimetic effects (hallucinations, confusion) in cancer patients.

Co-Analgesics

Co-Analgesics are drugs that potentiate the analgesic effects of opioids for particular types of pain (Table 5-7)

Bone Pain

Nonsteroidal anti-inflammatory drugs (NSAIDs) are quite helpful in the alleviation of pain from lesions in bones or skeletal muscles. The nonacetylated salicylates (e.g., salsalate [Disalcid], choline magnesium trisalicylate [Trilisate]) are less toxic to the gastric mucosa and do not inhibit platelet function (Zucker and Rothwell, 1978) but are less potent analgesics. The newer nonsalicylate NSAIDs are more potent, more convenient, more expensive, and less toxic than aspirin.

Table 5-5 Dosing Data for Opioid Analgesics

Guidelines

- Evaluate pain for all patients using a 0 to 10 scale:
 - Mild pain: 1-3
 - Moderate pain: 4-7
 - Severe pain: 8-10
- For chronic moderate or severe pain, do the following:
 - Give baseline medication around the clock.
 - Order 10% of the total daily dose for PRN administration given every 1 to 2 hours for the PO route or every 30 to 60 minutes for the SC or IV route.
 - For continuous infusion, PRN administration can be the hourly rate every 15 minutes or 10% of the total daily dose every 30 to 60 minutes.
 - Adjust the baseline upward daily in an amount roughly equivalent to the total amount used for PRN.
 - Negotiate with the patient the target level of relief, usually achieving a level at least <4.
- In general, the oral route is preferable, then transcutaneous, subcutaneous, and intravenous routes.
- When converting from one opioid to another, some experts recommend reducing the equianalgesic dose by one third to one half and then titrating as in guideline 2.
- Elderly patients or those with severe renal or liver disease should start on one half of the usual initial dose.
- If parenteral medication is needed for mild to moderate pain, use one half of the usual starting dose of morphine or an equivalent.
- Refer to the Physicians' Desk Reference for additional fentanyl guidelines.
- Naloxone (Narcan) should be used only in emergencies: Dilute 0.4mg of naloxone with 9mL of normal saline; give 0.1mg (2.5mL) by slow IVP until effect; and monitor patient every 15 minutes. It may be necessary to repeat naloxone again in 30 to 60 minutes.
- Short-acting preparations should be used in the initial period and postoperatively. Switch to long-acting preparations when the pain is chronic and after the total daily dose is determined.

| Medication* | Equianalgesic Dose (for chronic dosing) | | Usual Starting Doses†(for opioid-naïve patients) | | Comments | Pain | Half- life (hr) | Duration (hr) | Relative Generic Cost |

Table 5-6 Physician's Checklist when Prescribing Opioids

| |
|--|
| 1. Has an appropriate starting dose been determined? |
| 2. Is a co-analgesic needed? |
| 3. Is an antiemetic needed? |
| 4. Has a laxative been prescribed? |
| 5. Is the drug regimen written out in sufficient detail? |
| 6. Has the patient been warned about possible side effects that might occur initially? |
| 7. Do the patient and family know what to do if the pain remains uncontrolled? |
| 8. Have arrangements been made for follow-up after 1, 3, and 7 days—either by the physician or by a trained hospice nurse? |
| 9. Does the patient know what to do if he or she needs help or advice before the next follow-up visit? |
| 10. Is the patient confident that the pain will improve considerably, probably within a few days, certainly within 1 or 2 weeks? |

Modified from Twycross RG. Symptoms Control in Far Advanced Cancer: Pain Relief, ed 2. London, Pitman, 1993.

Although no single agent has been shown to be consistently more efficacious, particular patients do seem to favor one drug over another. If swallowing large tablets becomes a problem, piroxicam (Feldene) capsules, naproxen (Naprosyn) suspension, or indomethacin (Indocin) rectal suppositories may be used. The cyclooxygenase-2 (COX-2) inhibitor celecoxib (Celebrex) offers comparable analgesia and less gastrointestinal toxicity but at a higher risk of stroke or heart attack (which may not be an issue in the final weeks of life) and a higher cost. Steroids may also be a helpful adjuvant for bone pain.

Neuropathic Pain

For the burning, stabbing, or shooting pain caused by nerve damage, an anticonvulsant such as gabapentin (Neurontin), 100 to 400 mg orally one to four times a day, or pregabalin (Lyrica) 50-100 mg orally three times a day, may be a useful addition (Rosenberg et al., 1997). Amitriptyline or nortriptyline, in doses smaller than those used to treat depression (10-50 mg at bedtime), are often effective, but newer agents such as venlafaxine (Effexor) or duloxetine (Cymbalta) may be effective for neuropathic pain and have fewer side effects. If swallowing problems arise, and a tricyclic drug is needed, doxepin (Sinequan) solution may be used. The addition of carbamazepine (200 mg three times daily) or valproate (Depakene, 250 mg three times daily) should be considered if the tricyclic agent alone is not adequate. Both doxepin and carbamazepine can be administered rectally in gelatin capsules (Storey and Trumble, 1992). A short course of steroids also has been helpful in treating difficult, opioid-resistant neuropathic pain.

Visceral Pain and Smooth Muscle Spasm

If smooth muscle spasms are not caused by a treatable condition, such as urinary tract infection from a nonessential Foley catheter, these are best treated with an anticholinergic agent

such as dicyclomine (Bentyl) or oxybutynin (Ditropan). If only small doses are needed, Transderm Scop patches may be useful. For more severe cases, 0.6 to 1.6 mg of glycopyrrolate (Robinul) subcutaneously may be used (Storey et al., 1990). The physician must be alert for side effects such as dry mouth, constipation, and delirium.

Anxiety and Depression

If anxiety is severe enough to require drug therapy, a benzodiazepine such as lorazepam (Ativan), 0.5 to 1 mg two or three times a day, may be effective. Antidepressants such as nortriptyline (Pamelor), desipramine (Norpramin), and doxepin in low doses (25-75 mg at bedtime) have analgesic properties and can help with insomnia and agitation. Selective serotonin reuptake inhibitors (SSRIs) and serotonin-norepinephrine reuptake inhibitors (SNRIs) may also be effective. Mirtazapine may provide the advantage of improved sleep and appetite. Psychostimulants such as methylphenidate (Ritalin), 2.5 to 10 mg orally at 9 AM and 12 noon, take effect quickly and can relieve depression and pain in some terminally ill patients, especially when prognosis is limited (Block, 2000).

Grief and depression may appear similarly. The key to their differentiation is whether the patient is able to function. For example, a grieving patient will still function by taking the children to school or going to work and will temporarily improve on seeing the grandchildren, whereas depressed patients will not function appropriately.

In family members, *complicated grief*, also called "unresolved grief," is grief persisting more than 6 months and occurring at least 6 months after death. Normally, grief symptoms fade over time, but those of complicated grief linger or worsen, resulting in a chronic state of mourning. Although complicated grief can lead to depression, it may be distinct and associated with long-term functional impairment (Prigerson et al., 1995). Parents who have not successfully worked through their grief are at increased risk of mental and physical problems 4 to 9 years later (Lannen et al., 2008).

Dyspnea

As with pain, dyspnea can have many causes. When anemia, bronchospasm, and heart failure have been excluded or treated, the focus should be on symptom control. Oxygen has been shown to be helpful for controlling dyspnea in patients with hypoxia, but may be less convenient and more expensive than opioids. When the dose of opioid is titrated carefully to control the pain and is administered on a regular schedule, with additional doses available for breakthrough dyspnea, the patient can obtain excellent relief without significant respiratory depression (Bruera et al., 1990).

Evidence from 13 studies shows a valuable effect of morphine for dyspnea in advanced lung disease and terminal cancer. However, using nebulized versus oral opioids showed no additional benefit. Good-quality evidence shows that long-acting beta agonists are beneficial in the treatment of dyspnea in chronic obstructive pulmonary disease (Qaseem et al., 2008).

It may also be helpful to provide cool, moving air (open window, fan) and keep an unobstructed line of sight between

Table 5-7 Dosing Data for Co-Analgesics

| Pain Source | Pain Character | Drug Class | Examples | Comments |
|-----------------------------|---|--------------------------|---|--|
| Bones or soft tissue | Tenderness over bone or joint pain on movement | NSAIDs | Ibuprofen, 400mg q4hr | Inexpensive; large pills |
| | | | Sulindac (Clinoril), 200mg q12hr | Well tolerated; preferred in renal impairment |
| | | | Naproxen (Naprosyn susp, 125mg/5mL), 15mL q8hr | Liquid preparation |
| | | | Indomethacin (Indocin, 50-mg caps or susp), q8hr | Suppository; more gastritis? |
| | | | Piroxicam (Feldene, 20-mg caps), qd | Easiest to swallow; more gastritis? |
| | | | Choline magnesium trisilicylate (Trilisate susp, 500mg/5mL), 15mL q12hr | No platelet dysfunction; less problem with gastritis; less effective |
| Nerve damage or dysesthesia | Burning or shooting pain radiating from plexus or spinal root | Tricyclic antidepressant | Amitriptyline (Elavil), 10-50mg hs | Best studied; sedating; start with low dose |
| | | | Doxepin (Sinequan), 10-50mg hs | 10mg/mL susp available |
| | | | Trazodone (Desyrel), 25-150mg hs | Less anticholinergic effect; one third as potent as amitriptyline |
| | | Anticonvulsant | Carbamazepine (Tegretol), 200mg q6-12hr | Absorbed from rectum, unlike phenytoin |
| | | | Valproic acid (Depakene), 250mg q8-12hr | Liquid available, can be absorbed rectally |
| | | | Gabapentin (Neurontin), 100-400mg qd to qid | Often effective but expensive |
| Smooth muscle spasms | Colic: cramping, abdominal pain bladder spasms | Anticholinergic | Scopolamine (Transderm-Scop), 1-2 patches q3d | Transdermal patch |
| | | | Dicyclomine (Bentyl), 10mg q4-8hr | Capsules |
| | | | Oxybutynin (Ditropan), 5-10mg q8hr | Tablets |
| | | | Hyoscyamine (Levsin), 0.125mg q4-8hr | Sublingual available |
| Anxiety | Generalized restlessness and discomfort | Antihistamine | Hydroxyzine (Atarax or Vistaril), 10-30mg q4hr | Orally or by subcutaneous infusion |

Caps, capsules; NSAID, nonsteroidal anti-inflammatory drug; susp, suspension.

the patient and the outside. Careful consideration should be given to the use of antibiotics for pneumonia in the terminally ill patient. Because dyspnea can be controlled well without antibiotics, the physician must decide whether the antibiotics will improve the quality of life or just prolong the dying.

Constipation

Constipation can be more easily prevented than treated. When mobility and oral intake decrease and opioid analgesics are required, virtually every patient will require regular doses of laxatives to avoid distressing constipation. The

laxative should be given once or twice *every* day and the amount increased until an effective dose is found. Bulk laxatives are tolerated poorly and rarely are adequate for these patients. If docusate (Colace), 100 to 200 mg twice daily, is not effective, add senna (Senokot), 1 to 4 tablets twice daily. Sorbitol 70% or lactulose should be added in doses of 15 to 45 mL two or three times per day if the tablets are inadequate or cause excessive cramping. If a patient has gone several days without a bowel movement or is having small, frequent, liquid stools, an impaction may require manual removal. Bisacodyl (Dulcolax) 10-mg suppositories or sodium phosphate (Fleet) enemas may be needed occasionally until an effective oral regimen is found. Impaction may cause delirium,

which can mimic pain. In these patients, the delirium may be improved with a simple enema.

Nausea and Vomiting

In patients with nausea and vomiting, the physician should first look for a reversible cause such as constipation or gastritis from NSAIDs. If increased intracranial pressure is the cause, the patient may require steroids. Overfeeding may be the problem if a nasogastric or gastrostomy tube is in place. Metoclopramide (Reglan) is the agent of choice when an enormous liver limits gastric emptying or slow motility is causing early satiety. Many patients whose nausea and vomiting have not responded to prochlorperazine (Compazine) or promethazine (Phenergan) will be relieved by haloperidol (Haldol), 0.5 to 2 mg orally or subcutaneously every 8 hours. Effective and expensive preparations (usually unnecessary for hospice patients) that are approved for the treatment of nausea associated with chemotherapy include ondansetron (Zofran), granisetron (Kytril), dolasetron (Anzemet), and palonosetron (Aloxi).

As with persistent pain, persistent nausea should be treated with regularly scheduled antiemetics. Combinations of antiemetics that have different modes of action may be needed. A combination of haloperidol with metoclopramide or dexamethasone may be effective. When oral antiemetics cannot be tolerated, rectal suppositories can be tried but rarely provide adequate control for persistent nausea and vomiting unless they are compounded from the potent agents just mentioned. Continuous subcutaneous infusions of metoclopramide, haloperidol, and the required opioid are more effective (Baines, 1988). Even vomiting associated with complete bowel obstruction can be controlled *without* a nasogastric tube or gastrostomy with a continuous subcutaneous infusion of narcotics, antiemetics, and anticholinergic agents (Baines et al., 1985). Octreotide (Sandostatin) has also been extremely effective.

Hiccup

Persistent hiccup can be caused by any lesion affecting the phrenic nerve and by gastric distention or systemic problems, such as uremia. Oral treatment may include baclofen (Lioresal), 10 mg every 8 hours; chlorpromazine (Thorazine), 25 to 50 mg every 4 to 6 hours; metoclopramide, 10 to 20 mg every 6 to 8 hours; or haloperidol, 1 to 2 mg every 4 to 6 hours.

Subcutaneous Route

When oral opioids or antiemetics cannot be tolerated because of nausea, vomiting, stupor, or extreme weakness, parenteral medications may be needed. Frequent intramuscular injections or frequent restarting of intravenous infusions can be painful and difficult to manage at home. In these cases medications can be administered subcutaneously, either by intermittent bolus or by continuous infusion. At least 50 mL of medication per day can be infused through a small-gauge butterfly needle under the skin of the upper chest, arms, abdomen, or thighs using a portable pump. Morphine and hydromorphone have been shown to be safe and effective when administered by this route (Bruera et al., 1988). Metoclopramide (60-90 mg/day), haloperidol

(1-10 mg/day), and glycopyrrolate (0.4-2.0 mg/day) can also be administered subcutaneously.

Nutrition

Although uncontrolled pain is the principal complaint of many patients, the family's primary concern is often the patient not eating well. The causes of cancer cachexia are still poorly understood. Because patients seem to stop eating, lose weight, and eventually die, the natural assumption has been that even if physicians cannot effectively treat the cancer, they can at least treat malnutrition and thereby delay death.

The problem is that more harm than good can come from tube feedings or pushing multiple cans of supplement each day. The family may feel responsible if the patient loses weight and may feel guilty when the person dies. Unfortunately, the patient's final weeks become a struggle with the family over how much the person has eaten. One patient said, "Tell her to stop pushing that spoon into my face; I don't want any more!" This can be carried to extremes, such as inserting nasogastric tubes in patients who "do not cooperate." If they tug on the tube, their hands may be tied to the bed rails. A study of tube feedings in elderly patients revealed that, within 2 weeks, 67% of patients with nasogastric tubes had attempted self-extubation, and 43% had aspiration pneumonia. Gastric or jejunal tubes had a lower self-extubation rate (44%), but 56% of the patients had aspiration pneumonia, 31% had a leak or infection at the insertion site, and 50% had a clogged or kinked tube (Ciocon et al., 1988). Another comprehensive analysis found evidence of many risks and no benefits from tube feeding in patients with advanced dementia (Finucane et al., 1999). Large volumes of supplemental feeding can cause painful gastric distention, nausea, diarrhea, and copious pulmonary secretions.

There is no evidence that forced feeding of cancer or dementia patients prolongs life. Careful metabolic studies on force-fed cancer patients at the National Institutes of Health showed irreversibly increased metabolic rates from forced feeding. It was speculated that tumor growth was accelerated (Terepka and Waterhouse, 1956). Animal experiments have shown that growth rates of a variety of different cancers are nutrient dependent; the growth rate slows down with fasting or protein-free diets and speeds up with total parenteral nutrition (TPN) (Buzby et al., 1980; Stragand et al., 1979). In several trials, patients who received TPN plus chemotherapy were compared with those receiving chemotherapy alone. The TPN group died faster, especially patients with lung adenocarcinoma (Jordan et al., 1981), colorectal cancer (Nixon et al., 1981), and small-cell lung cancer (Shike et al., 1984). Pooling data on TPN and cancer through 1985, Klein and associates (1986) found that infections were more common in patients receiving TPN, and that these patients were less responsive to chemotherapy and had shortened survival. After reviewing all the clinical trials of parenteral nutrition in patients receiving cancer chemotherapy, the American College of Physicians (1989) concluded, "The evidence suggests that parenteral nutritional support was associated with net harm, and no conditions could be defined in which such treatment appeared to be of benefit. Thus, the routine use of parenteral nutrition for patients undergoing chemotherapy should be strongly discouraged."

What should be done to relieve the anorexia of advanced cancer? eTable 5-2 lists a number of treatable causes of anorexia. Uncontrolled pain blunts any person's appetite and can be alleviated. Low-level nausea, oral candidiasis, and constipation can interfere with eating and can be treated effectively. Families can be taught to relieve xerostomia (dry mouth), using a small syringe filled with water or juice, and to prepare soft foods. Corticosteroids or megestrol have been beneficial to some but can cause side effects. The most important service the family physician can provide is to allay guilt. An appropriate statement would be: "I do *not* believe that how much time your husband has, or how comfortable he is, depends on how much he eats."

Where to Die

Death with dignity is easiest to accomplish when the patient dies amid the surroundings that gave meaning to his or her life and in the company of those whose companionship provided most of the rewards of living. Physicians too often deny this, however, in the medically conditioned struggle to prolong life. Medical technology has advanced to the point that too few patients are permitted to die at home, even though improved diagnostic techniques identify the irreversible nature of a terminal process at an earlier stage. A sorry commentary, reflecting the abuse of technology, is the case of a man who had built his house with his own hands and wanted to die there but was prevented from doing so while physicians exhausted their therapeutic armamentarium in an attempt to prolong his life a few days or weeks. The family physician must remain in charge as the patient's advocate when the consultants want to continue aggressive therapy, yet all the patient wants to do is go to sleep. The family physician must have the courage to discontinue aggressive therapy when the evidence points to its futility.

Charles Lindbergh is an excellent example of an individual who insisted on designing his final days in a manner that would preserve dignity and allow him to die as comfortably as possible. When dying of lymphoma, he refused to remain in a medical center on the East Coast and returned to his home in Hawaii, where he made final arrangements regarding his estate and discussed with friends and family the details of his memorial service and burial site. His death was as he preferred—quiet, dignified, private, and in the company of family and friends—a striking contrast to what it would have been had he not insisted on leaving the medical center.

Although 70% of Americans still die in institutions (39% in hospitals and 31% in nursing homes), polls show that 80% of them say they would rather die at home (Farber et al., 2002). Jacqueline Onassis is an example of a prominent person whose wish to die at home was respected. Similarly, Richard Nixon's wishes were respected when his physicians and family knew that he wanted no extraordinary means taken to keep him alive if he developed an illness that left him seriously debilitated, particularly intellectually.

Some patients do not want to be a burden to their families and pride themselves on being able to afford hospitalization or nursing home care. For some of these patients, the gradual withdrawal from family may be an emotional "letting go"

that is necessary for all concerned in their particular family and circumstances. In other cases, the spouse simply may not be equipped physically or psychologically to deal with the loved one dying in the house over time. The important aspect is a network of support for all concerned, with no arbitrary judgment about the best approach. The family physician will be sensitive to the style of living and the style of dying that seem most appropriate in a given case once the options have been explained to the patient and family.

Hospice Care

Key Points

- Hospice care is intended for patients with a prognosis of 6 months or less.
- Most patients are referred too late, with a reported median survival only 3 weeks.
- A primary goal of a hospice is to support the patient's wish to die at home.
- The hospice team gives around-the-clock support to the family, relieves them at times to prevent burnout, and provides follow-up bereavement care for up to 1 year.

"Hospice" originally meant a way station for pilgrims and travelers, where they could be replenished, refreshed, and cared for if needed. The Irish Sisters of Charity viewed death as one stage of a journey. They opened hospices for dying patients in Dublin in 1879 and in London in 1905. These were places where dying people could be cared for when such care could not be managed at home.

Cicely Saunders was trained as a nurse and social worker in London in the 1940s. She cared for a dying cancer patient who made a £500 donation to "be a window" in the special home for the dying they both knew was needed. Ms. Saunders went to medical school and then worked in St. Joseph's Hospice in London from 1958 to 1965. She discovered the effectiveness of interdisciplinary team support, scheduled doses of oral opioids, and other methods to relieve the symptoms and stresses of her patients and their families. She opened St. Christopher's Hospice in south London in 1967, and the modern hospice movement was born. In 2008 there were almost 5000 hospices in the United States alone.

The hospice concept can benefit patients and families wherever death takes place. A hospice program consists of palliative and supportive services that provide physical, psychological, social, and spiritual care for dying persons and their families. Services are provided by a medically supervised interdisciplinary team of professionals and volunteers and are available both in the home and in an inpatient setting. Home care is provided as necessary: on a part-time, intermittent, regularly scheduled, or around-the-clock on-call basis. The hospice concept is directed toward providing compassionate care for people facing a life-limiting illness or injury. Hospice and palliative care involve a team-oriented approach to expert medical care, pain management, and emotional and spiritual support expressly tailored to the patient's needs and wishes. Support is provided to the patient's loved ones as well. At the

center of hospice and palliative care is the belief that each of us has the right to die pain-free and with dignity, and that our families will receive the necessary support to allow us to do so (www.nhpco.org, 2009).

The principal requirement for hospice admission is a life-limiting illness with a prognosis of 6 months or less, should the disease run its normal course, as certified by the patient's physician and the hospice physician. **eTable 5-3** lists the standards of a hospice program as developed by the National Hospice and Palliative Care Organization (NHPCO).

The interdisciplinary hospice team consists of a patient care coordinator, a nurse, a physician, a counselor, a volunteer coordinator, and spiritual support. Medical services are on call 24 hours a day, 7 days a week. Continuity of care by the same group of team members provides a familiarity that is comforting to the patient. Volunteers are an integral part of the program and provide many helpful services. Hospice services are covered by Medicare, Medicaid, and most insurance companies to some extent. Some hospices are able to provide charity care.

To qualify for hospice under the Medicare Hospice Benefit, a patient should have a life expectancy of less than 6 months. Again, however, referrals are usually made much too late. A study of five hospice programs in Chicago showed that the median survival after referral was only 24 days (Stone, 2001). In fact, 7% of patients referred to hospice die within hours of admission. This may be because survival estimates by physicians at admission are accurate only 20% of the time, 63% being optimistic and 17% pessimistic. The longer the physician had cared for the patient, the more optimistic the prediction. In 2009 the median length of stay in a hospice was only about 26 days, with one third enrolling in the last week of life and 10% on the last day of life (www.nhpco.org). Family physicians should discuss hospice care when there are still options, not at the end of life.

Support for the Family

Families and close friends of the dying patient also suffer and should be supported. A good policy is for the physician not only to be sensitive to the needs of family members before death, but to follow up with the family after the patient dies, either with a phone call, a letter, or a home visit.

Hospice care is not focused only on the patient; the unit of care is the patient and family. The physical, psychological, and interpersonal needs of both the patient and the family are addressed. After a patient's death, family members may experience increased morbidity and mortality, emphasizing the need for greater family support from the physician. Unfortunately, most physicians do not routinely contact the family after a patient's death, so this need often goes unrecognized.

The "widower effect" is the likelihood that the surviving spouse will die shortly after the death of the partner. However, spouses of partners who received hospice care lived longer than those whose spouse died without the benefit of hospice care, probably because hospice patients impose less stress on the family (Christakis and Iwashyna, 2003).

The hospice team provides follow-up bereavement care to the family up to 1 year after the patient's death. Family members who experience grief after the death of a loved one

are more vulnerable to physical and other emotional disturbances than at any other time in their lives. They need help dealing with the grief, guilt, and symptoms associated with this emotional turmoil. The bereavement services of a hospice team can minimize these problems and can help family members cope with the pain of memories that arise from time to time, especially at holidays, birthdays, and other stressful occasions.

A man dying of cancer did not tell family or friends in order to spare them. After his death, some admired his ability to suffer in silence, but many were angry and hurt, believing he did not think they were strong enough to suffer with him. The survivors not only were angry because he did not appear to need them, but also were hurt because he did not even say good-bye (New Age, 1989).

The most remarkable contribution of the hospice movement is not that it provides a special and compassionate setting in which terminally ill persons can die without heroic measures, but that the family becomes involved and comfortable in caring for the ill member. With the rapid increase of scientific and technologic competence in the field of medicine, families feel increasingly incompetent and impotent to deal with dying. The hospice movement has reversed this trend and helps family members work with community support services to provide home care for many of these patients. When symptoms cannot be controlled at home, the hospice inpatient unit can provide medical and nursing expertise in a homelike setting.

Selecting a Hospice

Most cities now have more than one hospice. Some organizations consist of volunteers with little or no medical expertise. Others have freestanding inpatient units and their own medical staffs. The questions in **eTable 5-4** will help in the selection of a hospice.

Some patients and their families resist entering hospice for fear that their care will be taken over by a stranger and their personal physician will no longer be involved. That fear should be addressed directly by the family physician (CA, 2009). Many hospices employ a physician board-certified in hospice and palliative medicine who can help with particularly difficult symptom problems. (See www.abhpm.org for a list of certified physicians in each area.)

Social support and resources in the community are discussed online at www.expertconsult.com.

Advance Directives

Key Points

- An advance directive is a legal document expressing a person's preferences regarding care in the event the person becomes unable to make decisions regarding care.
- The most important item is the appointment of a health care surrogate as the patient's proxy.
- Advance directives vary from simple to complex, but still cannot cover every possibility.
- A variety of state-specific advance care-planning documents are available on the Internet.

An advance directive is a legal document that allows competent adults to express their intentions regarding medical treatment in the event that they lose decision-making capacity because of a terminal illness. Types of advance directives are as follows:

Living will: A form regarding the limitation of life-sustaining medical treatment in the face of a life-threatening illness.

Health care surrogate: The appointment of a person to serve as the health care proxy (or medical power of attorney) to make medical decisions according to the incapacitated patient's preference.

Durable power of attorney: Designates a person to make health, financial, and legal decisions if the patient is unable to do so.

"Do not resuscitate" order: Determined by the physician and patient or the patient's health care surrogate or power of attorney.

If a person has only one action to take, it should be to appoint a health care surrogate as the person's proxy. Family physicians should encourage every patient to name a substitute decision maker, proxy, or surrogate who can represent the patient's wishes when needed. One problem is that often the surrogates named in the advance directive are not present to make decisions or are too emotionally overwrought to offer guidance.

Each state has its own laws governing advance directives, available at www.caringinfo.org. Other sites for useful advance directive information follow:

www.familycaregiversonline.com/legal-medical.html

www.uslivingwillregistry.com/forms.shtm

The Patient Self-Determination Act of 1991 requires hospitals and other health care institutions that receive Medicare or Medicaid funds to inform patients of their right to formulate an advance directive. The purpose is to encourage greater awareness and use of advance directives so that situations of ambiguity can be avoided (Field and Cassel, 1997). The act requires hospitals to provide written information to all patients concerning their rights under state law to refuse or accept treatment and to complete advance directives.

Almost 90% of Americans say that they would not want extraordinary steps taken to prolong their lives if they were

dying, but only 20% have put that wish in writing in the form of a "living will." The version of the living will shown in Figure 5-1 has several advantages over others. It clarifies the person's preferences, and instead of locking elements arbitrarily in place, it leaves two witnesses as guardians of the individual's wishes and intentions, with discretion to use their judgment in the specific circumstances. This statement presumes goodwill on all sides and should be helpful to all concerned.

There is no one-size fits-all approach to advance care planning. Some people prefer a simple approach, and others choose a more comprehensive, step-by-step process. The simple approach prevents support measures from being undertaken that should never have been initiated. It is best to have a patient both complete a living will and designate a health care surrogate, to ensure that the person receives the desired medical care.

Although advance directives are not guarantees that the patient's wishes will be followed, without them, these wishes probably will not be followed. Since the case of Terri Schiavo, a 41-year-old woman whose feeding tube was removed in 2005 after a legal battle and political storm, patients are much more aware of the need to declare their feelings about life-sustaining treatment. The Schiavo case illustrates the importance of advance care planning to save both family and physicians considerable anguish.

Unfortunately, the legal restrictions arising out of the Schiavo case may be counterproductive. Courts in several states have now ruled that life-sustaining interventions must be continued in the absence of *clear and convincing evidence* that the patient would not want them. Despite efforts to make advance directives address a greater variety of terminal situations, it is almost impossible to state accurately the patient's wishes in every scenario. Advance directives are poorly equipped to cope with the complex clinical situations that often arise, emphasizing the need to appoint a health care surrogate.

In the past, end-of-life decisions were usually limited to deciding whether or not to use cardiopulmonary resuscitation (CPR). Now the range includes feeding tubes, hydration, hospitalization, antibiotic use, and terminal sedation. The more the family can focus on what the patient would want, instead of what makes the family members feel most comfortable, the better will be the final decision (Lang and Quill, 2004).

I wish to live a full and long life, but not at all costs. If my death is near and cannot be avoided, and if I have lost the ability to interact with others and have no reasonable chance of regaining this ability, or if my suffering is intense and irreversible, I do not want to have my life prolonged. I would then ask not to be subjected to surgery or resuscitation. Nor would I then wish to have life support from mechanical ventilators, intensive care services, or other life-prolonging procedures. I would wish, rather, to have care that gives comfort and support, that facilitates my interaction with others to the extent that this is possible, and that brings peace.

In order to carry out these instructions and to interpret them, I authorize _____ to accept, plan, and refuse treatment on my behalf in cooperation with attending physicians and health personnel. This person knows how I value the experience of living, and how I would weigh incompetence, suffering, and dying. Should it be impossible to reach this person, I authorize _____ to make such choices for me. I have discussed my desires concerning terminal care with them, and I trust their judgment on my behalf.

In addition, I have discussed with them the following specific instructions regarding my care:
[List instructions.]

Date _____ Signed _____

Witnessed by _____ and by _____

Figure 5-1 Example of a living will.

CPR can be lifesaving in some cases, but in most terminally ill patients, it is extremely unlikely to result in return of satisfactory cardiopulmonary function, survival to discharge from the hospital, or ability to live outside an institution. In a large multi-institutional study, physicians did no better than chance in identifying their seriously ill hospitalized patients' wishes to forgo CPR, and such wishes, even when known, rarely were respected when the physician believed that another course was more appropriate (Connors et al., 1995).

A relatively simple Advance Care Plan Document is available from Project GRACE (Guidelines for Resuscitation and

Care at End-of-life) at www.projectgrace.org. A document that attempts to address a variety of clinical situations that may arise is the Medical Directive site at www.medicaldirective.org. This permits patients and physicians to download a scenario-based living will that includes six different scenarios to cover a variety of situations, plus a personal statement and a Health Care Proxy. See Web Resources for additional sites and more information.

Euthanasia and assisted suicide are discussed online at www.expertconsult.com.

EVIDENCE-BASED SUMMARY

- Regularly assess patients for pain, dyspnea, and depression at end of life (SOR: B; Qaseem et al., 2008).
- Use therapies of proven effectiveness to manage pain at end of life, including NSAIDs and opioids (SOR: A; McNicol et al., 2005; Nicholson, 2007; Qaseem et al., 2008; Quigley, 2007; Wiffen and McQuay, 2007).
- Use therapies of proven effectiveness to manage dyspnea at end of life, including opioids and oxygen (SOR: B; Qaseem et al., 2008; Cranston et al., 2008; Jennings et al., 2001).
- Use therapies of proven effectiveness to manage depression at end of life, including tricyclic antidepressants, SSRIs, or SNRIs (SOR: B; Qaseem et al., 2008).
- Ensure that advance care planning, including completion of advance directives, occurs for all patients with serious illness (SOR: C; Qaseem et al., 2008).
- Use anticonvulsant drugs as adjuvants in management of pain (SOR: B; Wiffen et al., 2005a, 2005b; 2005c).
- Use antidepressants as adjuvants in management of neuropathic pain (SOR: B; Saarto and Wiffen, 2007).
- Treat anxiety at end of life (SOR: C; Jackson and Lipman, 2004).
- Treat constipation at end of life with laxatives (SOR: B; Miles et al., 2006).
- Use therapies of proven effectiveness to manage nausea and vomiting at end of life (SOR: C; Perkins and Dorman, 2009).
- For patients receiving palliative radiotherapy, if pressure symptoms occur in the beginning of treatment, or if symptoms are expected during therapy, start steroid therapy (e.g., dexamethasone, 3-10 mg × 1-3 orally or parenterally) (SOR: A; Finnish Medical Society, 2003).
- Opioids are effective in the treatment of dyspnea (SOR: A; Finnish Medical Society, 2003).
- Opioids are effective in the treatment of dyspnea; starting dose with morphine solution is 12 to 20 mg; starting dose with long-acting morphine is 10 to 30 mg; and dose is increased by 20% to 30% (up to 50%) (SOR: A; Finnish Medical Society, 2003).

Key Concepts in Evidence-Based Prevention

Key Points

- Because prevention involves intervention in a healthy, asymptomatic patient, clinicians should demand a high standard of evidence. Proposed prevention strategies must be proven to be effective in improving patient-oriented outcomes.
- The evidence-based recommendations of the U.S. Preventive Services Task Force are considered the "gold standard" for clinical preventive services, and the regularly updated recommendations can be accessed on their website or in *The Guide to Clinical Preventive Services*.
- Risk factor identification allows targeted, efficient, and cost-effective preventive service provision; patients who are more likely to develop a specific disease may preferentially benefit from preventive strategies, including screening, counseling, chemoprevention, and immunizations.
- To determine whether a screening test is a good assessment, test accuracy (i.e., sensitivity and specificity) and the prevalence of the disease in the population to be screened must be considered.
- Screening for colorectal cancer, breast cancer, and cervical cancer has proven to be effective in decreasing the morbidity and mortality rates of these cancers.
- Cardiovascular disease prevention requires treatment of modifiable risk factors, including hypertension, hyperlipidemia, and smoking, to prevent cardiovascular events and cardiovascular-related deaths.
- Smoking cessation counseling and medical treatment should be provided to all adults who smoke.
- Short, simple depression screening instruments accurately identify patients who can benefit from early identification and treatment.
- Using local health departments as a resource, a family physician's knowledge of his or her patient population is the best guide to developing a risk-based screening strategy for sexually transmitted infections (e.g., HIV, chlamydia, gonorrhea).
- Diabetes screening should be offered to adults with hypertension.
- All women age 65 years or older and women age 60 or older with risk factors should be routinely screened for osteoporosis.
- Intensive behavioral counseling about consuming a healthy diet should be offered to all adults with hyperlipidemia and other known risk factors for cardiovascular and diet-related chronic diseases.
- Prevention plays a critical role in caring for all age groups. Special concerns about children, pregnant women, and elderly persons include ethical issues, competing causes of mortality, and the role of shared decision making.
- Changing the health behaviors of Americans has the greatest potential impact of any approach for decreasing morbidity and mortality and for improving the quality of life across diverse populations.
- The health belief model, theory of reasoned action, transtheoretical model, and social cognitive theory involve behavioral change and can help family physicians counsel patients.
- Improving the quality, delivery, and effectiveness of prevention in the family physician's office practice requires changes in the office system.

Prevention and the Family Physician

Prevention is central to family medicine for several reasons. A key mission of family medicine is preserving health and maximizing function of patients throughout their lives. The most common causes of morbidity and mortality are preventable chronic diseases. Prevention is important across the life span and requires repeated and evolving messaging over time. Family physicians care for patients within a family and community context that is critical to linking preventive services in the clinic with community resources. Much of prevention involves supporting patients in making healthy lifestyle changes, and family medicine has a strong foundation of behavioral medicine.

Evidence-Based Prevention

Definitions

Prevention is often categorized as primary, secondary, and tertiary prevention. *Primary prevention* is defined as interventions that reduce the risk of disease occurrence in otherwise healthy individuals. Counseling patients to avoid smoking and prescribing fluoride to children to prevent cavities are examples of primary prevention. *Secondary prevention* includes screening to identify risk factors for disease or the early detection of a disease among asymptomatic and at-risk individuals. Evaluating and treating abnormal blood pressure in adults is an effective way to identify individuals at risk for heart disease and provides an opportunity to intervene before the disease occurs. Screening for colon cancer using colonoscopy to detect precancerous polyps and then removing the polyps is another example of secondary prevention. Individuals who receive primary or secondary prevention services have no obvious signs of illness; in clinical terms, they are asymptomatic.

In contrast, *tertiary prevention* services are provided to individuals who clearly have a disease, and the goal is to prevent them from developing further complications. For example, diabetes care, including regular retinal examinations, foot care, and management of blood sugar levels, is tertiary prevention because the care provided is focused on limiting the complications of a disease that has already been identified. Many believe tertiary prevention is outside the scope of traditional prevention and should be a part of disease management.

Because prevention involves an intervention in a patient who is asymptomatic, clinicians should demand a high standard of evidence that proposed prevention strategies, including screening, counseling, chemoprevention, and immunizations, have been proven to prevent disease. This is critical because all interventions, including preventive screenings and immunizations, have harms. Evidence-based prevention recognizes that doing something to healthy asymptomatic patients requires a good evidence base that the benefits of the intervention outweigh its harms. Benefits to patients should be improvements in patient-oriented outcomes—benefits that are meaningful to a patient's function and well-being—rather than in intermediate outcomes, such as improvements in laboratory test results.

Steps involved in systematically assessing the net benefit of a preventive service involve assessing the ability to detect a risk factor or early disease before it causes complications; understanding and quantifying the effectiveness of early

identification to modify a risk factor or condition and early intervention (compared with waiting until the condition becomes clinically apparent); understanding and quantifying the harms that result from the preventive service, including those from additional confirmatory testing and treatment of the condition; and balancing the overall benefits and harms of this preventive service.

Preventive services also involve costs of time and money to the patient and the health care system. Even services such as counseling that, on face value, appear to require minimal cost, actually involve a considerable cost in time and personnel resources, especially for counseling services that require intensive and repeated multifaceted counseling sessions to be effective. The time and personnel costs of counseling interventions must be balanced against the cost savings resulting from prevention or delay of a costly chronic illness. A well-established set of criteria from the World Health Organization (WHO) can help in evaluating whether screening is appropriate for specific diseases (Table 6-1).

In general, evidence-based prevention involves evidence derived from populations, and what “works” for a population may or may not be appropriate for an individual patient. Often, the populations who choose to be a part of randomized, controlled trials and other clinical trials are carefully selected and monitored for adherence to treatments. At the same time, it is not feasible to do an N-of-1 trial for every patient who visits the clinic. When considering applying evidence-based prevention, like evidence-based medicine in general, it is important to ask if the evidence or guideline applies to the individual patient.

Preventive Services Task Force and Evidence-Based Prevention

The U.S. Preventive Services Task Force (USPSTF) is an independent panel of 16 private-sector experts in primary care, clinical prevention, and epidemiologic methodology

Table 6-1 World Health Organization Criteria for a Screening Test

1. The condition being screened for should be an important health problem.
2. The natural history of the condition should be well understood.
3. There should be a detectable early stage.
4. Treatment at an early stage should be of more benefit than at a later stage.
5. A suitable test should be devised for the early stage.
6. The test should be acceptable.
7. Intervals for repeating the test should be determined.
8. Adequate health service provision should be made for the extra clinical workload resulting from screening.
9. The physical and psychological risks should be less than the benefits.
10. The costs should be balanced against the benefits.

From Wilson JMG, Jungner G. Principles and Practice of Screening for Disease. Geneva, World Health Organization, 1968.

(Guirguis-Blake, 2007). The USPSTF addresses a broad array of prevention topics important to primary care practice, including cancer prevention. Their recommendations address primary and secondary preventive services performed in primary care settings or recognized in primary care settings and referred to specialists. The 16 experts come from the clinical fields of family medicine, general internal medicine, pediatrics, obstetrics and gynecology, preventive medicine, behavioral medicine, and nursing. The USPSTF releases recommendations on a variety of topics relevant to family medicine that address preventive services for children, adolescents, and adults, including pregnant women.

The purpose of the USPSTF is to provide evidence-based recommendations for the provision of preventive services to apparently healthy individuals in the primary care setting. Primary and secondary preventive services addressed by the USPSTF include screening, counseling, and preventive medications. The methodology of the USPSTF is rigorous and transparent and involves the following steps:

1. Creation of an analytic framework and key questions to determine the scope of the literature review.
2. Systematic review of all relevant literature answering the key questions.
3. Quality-rating bodies of literature supporting each key question.
4. Quantification of the magnitude of benefits and harms.
5. Balancing the net benefits and harms of a specific preventive service.

The recommendation is then linked to a letter grade that reflects the magnitude of net benefit (i.e., balance of benefits and harms) and the strength of the evidence supporting the provision of a specific preventive service (see Evidence-Based Summary).

Using screening for osteoporosis as an example, the task force created a set of key questions beginning with an overarching question: Does osteoporosis screening result in decreased mortality or disability from osteoporosis? Because no evidence directly answered this question, a chain of intermediate key questions was systematically searched. What is the accuracy of screening tests (e.g., dual-energy x-ray

absorptiometry [DEXA] scans)? What is the effectiveness of treatment of these screen-detected cases in preventing osteoporosis-related fractures, fracture-specific mortality, or overall mortality? What harms are caused by screening for and treatment of osteoporosis (Figure 6-1)? For USPSTF to recommend screening, each link in the chain of evidence must be supported by evidence, and there must be fair- or good-quality evidence that the benefits outweigh the harms. Any break in the chain of evidence (e.g., single key question for which there is insufficient evidence) results in a conclusion of insufficient evidence for that preventive service.

Challenges in Evidence-Based Prevention

Evidence-based prevention faces three levels of challenges: determining which services are effective (i.e., state of the science); delivering the message to prioritize the effective services; and applying the evidence in clinical practice. Conducting systematic reviews of literature to determine which preventive services are effective is time and resource intensive. Such reviews favor a team approach rather than one clinician conducting these reviews alone. Prevention literature is limited in some areas, especially harms of preventive services, and because of these limitations, many guidelines use expert opinion as a type of evidence supporting recommendations.

Conflicting guidelines create confusing messages. For example, conflicting guidelines leave clinicians without clear direction about what to do in their practices. Clinicians may have difficulty determining the methodologies of each specific guideline (e.g., consensus opinion, evidence based, evidence informed) and deciding which guideline to use in their practices. Evidence-based guidelines with transparent methodology (e.g., USPSTF) are reproducible and more reliable for implementation. Prioritizing effective preventive services leads to decreased overuse of ineffective services and increased use of effective services.

Systems challenges, including a lack of linkages to community resources, delivery system support, and clinical information support (e.g., reminder systems, electronic health

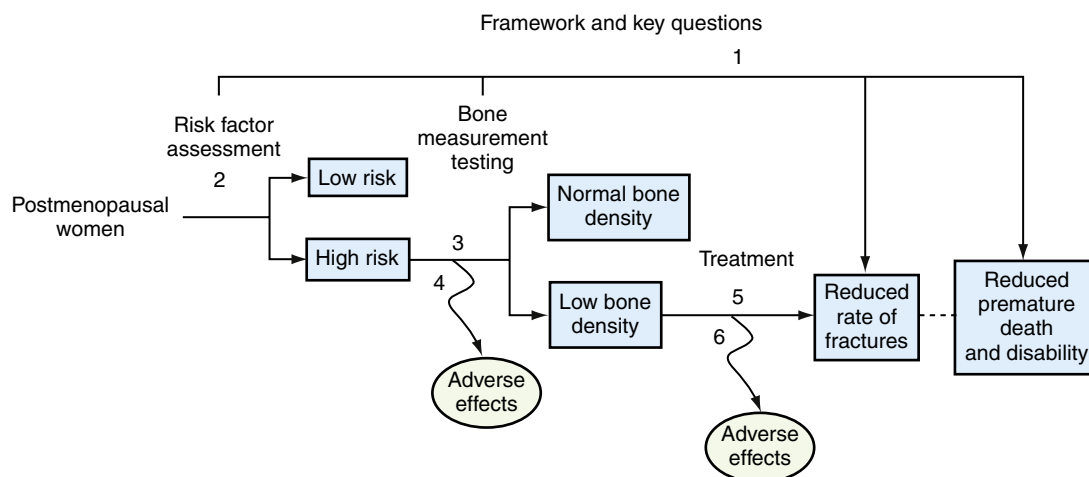

Figure 6-1 U.S. Preventive Services Task Force (USPSTF) framework for osteoporosis screening. Key questions addressed include the following: (1) Does screening using risk factor assessment or bone density testing reduce fractures? (2) Does risk factor assessment accurately identify women who may benefit from bone density testing? (3) Do bone density measurements accurately identify women who may benefit from treatment? (4) What are the harms of screening? (5) Does treatment reduce the risk of fractures in women identified by screening? (6) What are the harms of treatment?

records), make it difficult to apply evidence-based prevention in practice. A systematic approach to offering preventive services enables a busy clinician to prioritize the most effective services. A systematic team approach ensures that immunizations are administered on time, screening tests are done appropriately, and counseling services are offered to those who need them.

Statistical Concepts in Prevention

Expressing the Burden of Disease

Prevalence and Incidence

Several measures can quantify the burden of a disease in a particular community. *Prevalence* is the proportion of a defined group of people who have a condition or disease at a given point in time. Prevalence can be expressed in cases per 1000, 10,000, or 100,000 people or as a percentage. *Incidence* is the proportion of an initially disease-free group of people who develop the disease over a given period. Prevalence and incidence may describe the frequency and burden of disease in a population; however, incidence specifically communicates new cases of the disease over a specific period (e.g., new cases in a given year).

Tracking prevalence and incidence over time can help to determine health care strategies aimed at limiting the burden of a disease. For example, human immunodeficiency virus (HIV) prevalence has been rising over the past decade, partly because patients who previously would have died (from AIDS) within a few years of diagnosis now live longer. More effective treatment is prolonging life, and the rising prevalence is a sign of success of advances in therapy; health care strategies should continue to provide highly active antiretroviral therapy to treat HIV-infected patients. The incidence of HIV infection in particular communities is also increasing. This is a sign of increased transmission and means that more people are being infected; health care strategies should therefore focus on primary prevention of HIV infection.

Morbidity is the impact of the disease on health and functioning, and *mortality* is the degree to which a condition results in death. Some diseases may have a high prevalence but cause low morbidity, and other diseases may be rare but life-threatening conditions. Quantifying the burden of disease must take into account the number of people who are at risk for the disease and the consequences of the disease itself.

Expressing Screening Test Accuracy

When deciding whether an assessment is a “good screening test,” the accuracy of the test and the prevalence of the disease in the population to be screened are important factors. The *accuracy* of a test is its ability to measure the actual value of the quantity being measured. Sensitivity and specificity are two measures used to express the accuracy of a screening or diagnostic test. *Sensitivity* is defined as the proportion of people with the target disorder who have a positive test result. *Specificity* is the proportion of people without the target disorder who have a negative test result. Sensitivity and specificity do not vary in relation to the prevalence of the condition being tested.

Positive and negative *predictive values* take into account the accuracy of the screening test and the prevalence of the disease, to express the likelihood that a test result is a true result rather than a false-positive or false-negative result. The *positive predictive value* is the proportion of people with a positive test result who have the target disorder. The *negative predictive value* is the proportion of people with a negative test result who are free of the target disorder. The positive predictive value is higher and the negative predictive value lower when a test is used in a population with a higher prevalence. Clinicians need to remember that in a population with a low prevalence of a specific disease, a positive test result is likely to be a false-positive result, even for a test with a high specificity.

Expressing the Yield of a Screening Test: Number Needed to Screen

“Number needed to screen” is a concept used to express the number of individuals who would need to be screened for a disease to prevent a single complication (morbidity or mortality) of that disease. The “number needed to treat” is a corollary concept that may be used for preventive medications (e.g., aspirin therapy). The number needed to treat is the number of individuals who would need to undergo the treatment or intervention to prevent a single case of disease (e.g., heart disease). This type of statistic may be useful for clinicians and patients when prioritizing different prevention or treatment options.

Risk Factors

A risk factor is a condition that is associated with an increased likelihood of a disease. For example, obesity is a risk factor for diabetes; obesity makes it more likely that a person will develop diabetes in his or her lifetime compared with someone who is not obese. Some risk factors are *causal*; the risk factor causes the disease. For example, smoking is a risk factor for and a proven cause of lung cancer; a smoker is many times more likely than a nonsmoker to develop lung cancer in his or her lifetime. Other risk factors are *associations*; people living at northern latitudes are more likely to have multiple sclerosis (i.e., there is no known causal relationship; it is simply an association). Risk factors for having a heart attack include gender, age, hypertension, smoking, and high cholesterol levels; other risk factors include sedentary lifestyle, obesity, and diabetes. Some risk factors are modifiable (i.e., can be changed), such as smoking, level of physical activity, and cholesterol levels, and others are nonmodifiable, such as age, gender, family history, and race. Some risk factors are *behavioral* risk factors, such as alcohol use, physical activity, and diet, and some type of change in behavior is required to modify these risk factors. Modifiable behavioral risk factors are significant contributors to most of the leading causes of death in the United States (Table 6-2). Preventive services strive to identify and change modifiable risk factors to prevent or delay disease.

When considering prevention programs, it is often cost-effective to target populations who have a higher risk of disease rather than to offer the service to the general population, in whom the risk factor or disease may be uncommon overall. For example, some sexually transmitted infections

are rare in the general population but are more prevalent among certain groups of people. In some areas of the United States, gonorrhea has a prevalence of zero, whereas other areas have concentrated populations with gonorrhea. If community clinicians were asked to design a program to prevent gonorrhea, they might selectively screen those with risk factors or those living in communities with a documented high prevalence of gonorrhea. A key concept to consider is that even with a high sensitivity and specificity, screening for a risk factor or disease that is rare will result in a low positive predictive value. In other words, the yield of screening will be low, and false positives may outnumber true positives. It is therefore important to consider the burden of a risk factor or disease in a given population before deciding whether screening for that condition is worthwhile.

Preventive Services by Disease Category

Cancer

Almost one in every four deaths in the United States is caused by cancer, making it the second leading cause of death. It is estimated that approximately 1500 Americans die of cancer each day; a total of 562,340 cancer deaths were expected in 2009 (National Cancer Institute [SEER], 2009). The top causes of cancer-related deaths are presented in Table 6-3. Cancer has a significant impact on individuals, their families, and society as a whole. In 2001, there were an estimated 9.8 million people alive in United States who had received the diagnosis of cancer—some still had evidence of cancer, some were

in remission, and the remainder were cancer free. In 2009, an estimated 1,479,350 new cases of cancer were diagnosed. In the United States the lifetime risk of a cancer diagnosis is one in two for men and one in three for women (ACS, 2009). The National Institutes of Health (NIH) estimate that the direct and indirect overall cost of cancer in 2008 was \$228 billion when total health expenditures and loss of productivity from morbidity and premature death were included.

Colorectal Cancer

Burden of Disease

Colorectal cancer is the fourth most common cancer in the United States and is the second leading cause of cancer deaths. In 2009, an estimated 49,920 people died of colorectal cancer, with the disease newly diagnosed in more than 146,000 patients. Incidence is low until age 45, after which the incidence increases with each year of life. A 50-year-old person has a 5% chance of having colon cancer and a 2.5% chance of dying of the disease (Pignone et al., 2002b). The colorectal cancer mortality rate rises 10 years after the incidence rises, and the stage at diagnosis influences prognosis. The estimated 5-year survival falls from 90% for Dukes stage A (localized) cancers to 8% in Dukes stage D cancers (presence of distant metastases). Risk factors for colorectal cancer include a first-degree relative with a history of colorectal cancer, a family history of hereditary nonpolyposis colorectal cancer or familial adenomatous polyposis, and patients with ulcerative colitis. However, most cases occur in persons of average risk.

Accuracy of Screening Tests

Sensitivity of screening with fecal occult blood testing (FOBT) varies with the frequency of testing and the method used. Sensitivity and specificity have been estimated at 40% and 96% to 98%, respectively. Hydration of the specimen increases sensitivity (60%) but reduces specificity (90%), producing more false-positive results (Pignone et al., 2002b).

Sigmoidoscopy visualizes only the lower half of the colon but has been estimated to identify 80% of all patients with significant findings in the colon because abnormal findings on sigmoidoscopy trigger examination of the entire colon (Pignone et al., 2002b). A colonoscopy has a sensitivity of 90% for large polyps and 75% for small polyps. Specificity for endoscopic screening is difficult to determine because many patients have polyps removed that would never have developed cancer. Newer stool study modalities with limited data include fecal DNA and fecal immunochemical tests.

Other screening tests for colorectal cancer include double-contrast barium enema, which has not reached the level of sensitivity of other modern screening procedures, and computed tomography (CT) colonography (i.e., virtual colonoscopy), which may have similar sensitivity as direct colonoscopy in finding colorectal cancer and large adenomas. Digital rectal examination (DRE) is not a recommended screening method for colorectal cancer because less than 10% of lesions are within the reach of an examiner's finger.

Effectiveness of Early Detection and Intervention

Screening for colorectal cancer reduces the incidence of and mortality from colorectal cancer by removing premalignant adenomatous polyps (USPSTF, 2008). Potential harms arise when false-positive screens lead to unnecessary invasive

*The APC is significantly different from zero ($p < .05$).

testing or false-negative results lead to false reassurance. Invasive screening procedures have risks such as bleeding and bowel perforation, which are even higher when therapeutic procedures (e.g., polypectomy) are performed (Pignone et al., 2002b).

Recommendation

The USPSTF strongly recommends screening for colorectal cancer in men and women 50 years to 75 years using FOBT, sigmoidoscopy, or colonoscopy. Screening may be initiated earlier for those with risk factors (e.g., 10 years before earliest diagnosis of family member). Screening methods include FOBT, flexible sigmoidoscopy, and colonoscopy (USPSTF,

2008). Unless individual risk factors indicate otherwise, there is insufficient evidence to continue screening after age 75. The American Academy of Family Physicians (AAFP), American College of Obstetrics and Gynecology (ACOG), and American College of Surgeons support similar recommendations (Pignone et al., 2002b).

The American Cancer Society (ACS) recommends screening average-risk adults beginning at age 50 with yearly FOBT or fecal immunochemical test annually, a flexible sigmoidoscopy examination every 5 years, an FOBT plus flexible sigmoidoscopy every 5 years, a double-contrast barium enema every 5 years, a CT colonography every 5 years, or a colonoscopy every 10 years.

Cervical Cancer

Burden of Disease

The incidence of cervical cancer is decreasing but is still the 10th leading cause of cancer deaths. In the United States an estimated 11,000 new cases of cervical cancer were diagnosed in 2009, and 4070 of these patients will die from this preventable disease (ACS, 2009). Women who have never been screened represent a significant majority of those with diagnosed invasive cervical cancers and deaths caused by cervical cancer. The most important risk factor for this disease is infection with human papillomavirus (HPV). HPV is transmitted sexually, and 90% of squamous cell cervical cancers contain HPV DNA. Other risk factors for cervical cancer include early onset of intercourse, greater number of sexual partners, and cigarette smoking.

Accuracy of Screening Tests

The estimated sensitivity of a single conventional Papanicolaou (Pap) test ranges from 60% to 80% for high-grade lesions, and it is lower for low-grade lesions (Hartman et al., 2002). The available data on the accuracy of thin-layer cytology (e.g., ThinPrep, AutoCyte PREP), a newer screening test, indicate that it has a higher sensitivity but lower specificity compared with traditional Pap smears, but does result in fewer inadequate samples.

Effectiveness of Early Detection and Intervention

Early detection of cervical cancer is effective at decreasing morbidity and mortality because survival depends on the stage at diagnosis. More than 90% of women with local disease survive 5 years, but only 13% of women with distant disease at diagnosis survive 5 years (Hartman et al., 2002). Introduction of a screening program with Pap tests has consistently reduced morbidity and mortality across populations.

Increased detection of low-grade lesions and false positives are the primary potential sources of harm. Harms include increased evaluations, including repeated Pap tests and biopsies; psychological distress for the women with diagnosed low-grade lesions that may not be clinically important; and potential adverse effects from unnecessary treatment.

Two vaccines are designed to protect against the major strains of high-risk HPV. The quadrivalent HPV vaccine (types 6, 11, 16, 18) is currently approved by the U.S. Food and Drug Administration (FDA) for a three-injection series, which is maximally effective if given before the first sexual experience. Pap screening is still necessary even if the woman is fully vaccinated.

Recommendation

For cervical cancer in women who have been sexually active and have a cervix, USPSTF recommends screening within 3 years of onset of sexual activity or by age 21, whichever comes first, and screening at least every 3 years. They recommend against the use of routine Pap tests in low-risk women older than 65 years and in women who have had a hysterectomy for benign reasons (USPSTF, 2003). The AAFP (2008) endorses this recommendation. ACOG (2009) recommends starting at age 21 with screening every 2 years, then every 3 years for women over age 30 with three consecutive normal Pap smears. The ACS recommends initiating screening

3 years after a woman becomes sexually active or at age 21, with annual Pap tests (or biannual tests if using liquid-based preparation) until age 30 and then every 2 to 3 years thereafter (Hartman et al., 2002).

The USPSTF does not currently have recommendations regarding HPV vaccination. ACOG recommends HPV vaccination of females age 9 to 26 years against HPV. The ACS recommends beginning HPV vaccination series as early as 9 years at the discretion of the physician, with the understanding that it is still necessary to continue screening with the Pap test at the appropriate intervals even with the history of HPV vaccination.

The American Society for Colposcopy and Cervical Pathology suggests an option of using HPV screening as an adjunct to Pap smears in women age 30 and older. If HPV testing is negative, Pap smears can be spaced to every 3 years; however, if HPV screening is positive, Pap and HPV testing could be repeated in 1 year. ACOG endorses this option of using HPV testing as an adjunct in women 30 years and older.

Breast Cancer

Burden of Disease

Breast cancer is the second leading cause of cancer deaths in U.S. women; in 2008, an estimated 182,460 cases of invasive cancer and 67,770 cases of in situ breast cancer were diagnosed, with 40,480 breast cancer deaths (ACS, 2009). The risk for breast cancer increases with age: the 10-year risk for breast cancer is 1 in 69 for a woman at age 40 years, 1 in 42 at age 50, and 1 in 29 at age 60 (SEER, 2009). Several tools are available to predict risk of developing breast cancer for individual women (e.g., BRCAPRO, Gail, Claus, Tyrer-Cuzick). All these tools incorporate age and number of first-degree relatives with breast cancer into the calculations (Nelson et al., 2005). One example is found at www.cancer.gov/bcrisktool/.

Accuracy of Screening Tests

The prevalent methods of breast cancer screening are mammography, clinical breast examination (CBE), and self breast examination (SBE), or breast self-examination (BSE). The sensitivity of mammography ranges from 77% to 95% for cancers diagnosed over the following year, and specificity ranges from 94% to 97%. Sensitivity is lower in women younger than age 50 and in women taking hormone replacement because of increased breast tissue density. Specificity increases with shorter screening intervals and availability of prior mammograms. Adequate evidence suggests that teaching BSE does not reduce breast cancer mortality. The evidence for additional effects of CBE independent of mammography on breast cancer mortality is inadequate. The sensitivity of CBE ranges from 40% to 69% and specificity from 86% to 99% (Humphrey et al., 2002).

Effectiveness of Early Detection and Intervention

Trials evaluating the efficacy of mammography have limitations but have reported reductions in mortality of 15% to 32%, with a greater absolute risk reduction in older women. The number needed to invite for screening to extend one woman's life is 1904 for women age 40 to 49 years and 1339 for women age 50 to 59 years. Controversy still surrounds routine screening of average-risk women between ages 40 and 49; cancer-related mortality reduction has been observed

in this age group, although false-positive results are a concern. BSE has not been shown to reduce breast cancer mortality or significantly alter the stage at diagnosis. CBE has not been evaluated independent of mammography; screening with CBE and mammography is comparable to using mammography alone (Humphrey et al., 2002; USPSTF, 2009).

Potential harms of breast cancer screening stem from false-positive results. Harms include unnecessary follow-up testing and invasive procedures, anxiety, and additional medical expense.

Recommendation

The USPSTF recommends the decision to start regular, biennial screening mammography before the age of 50 years should be an individual one and take patient context into account, including the patient's values regarding specific benefits and harms. USPSTF recommends biennial screening mammography for women aged 50 to 74 years. They recommend against teaching BSE (USPSTF, 2009). AAFP has endorsed USPSTF recommendations in the past. The American College of Physicians (ACP) recommends breast cancer risk assessment and individualized discussions of benefits and harms of mammography in women 40 to 49 years. ACS recommends annual mammography beginning at age 40, annual CBE after age 40, and insufficient evidence to recommend BSE. ACOG recommends mammography every 1 to 2 years for women age 40 to 49 years and annually after age 50 and CBE for all women, noting that BSE can be recommended.

The USPSTF recommends genetic counseling referral for women with a family history who may be at risk for BRCA mutation (USPSTF, 2005).

- Two first-degree relatives with breast cancer, one of whom received the diagnosis at age 50 or younger.
- A combination of three or more first- or second-degree relatives with breast cancer, regardless of age at diagnosis.
- A combination of both breast and ovarian cancer among first- and second-degree relatives.
- A first-degree relative with bilateral breast cancer.
- A combination of two or more first- or second-degree relatives with ovarian cancer, regardless of age at diagnosis.
- A first- or second-degree relative with both breast cancer and ovarian cancer at any age.
- A history of breast cancer in a male relative.

Lung Cancer

Burden of Disease

Lung cancer is the leading cause of all cancer deaths in the United States. ACS estimated 219,440 new cases and more than 159,390 deaths in 2009. Cigarette smoking is the main risk factor, with 87% of lung, bronchial, and tracheal cancers attributed to smoking (Humphrey et al., 2004). Other risk factors include family history and exposure to asbestos, radon, or passive smoke.

Accuracy of Screening Tests

Chest radiography with or without sputum cytology and low-dose computed tomography (LDCT) are being evaluated as methods of screening. LDCT sensitivity for detecting lung

cancer is four times greater than the sensitivity of chest radiographs, but LDCT is associated with a greater number of false-positive results, more radiation exposure, and increased costs compared with chest radiography (Humphrey et al., 2004).

Effectiveness of Early Detection and Intervention

Chest radiography with or without sputum cytology and LDCT have not been shown to affect lung cancer mortality, even in high-risk populations. Both are associated with considerable harms because of the invasive procedures used to evaluate false-positive results (Humphrey et al., 2004).

Recommendation

The USPSTF (2004) found insufficient evidence to recommend for or against screening asymptomatic individuals for lung cancer. No other major organizations recommend any methods of screening for lung cancer (ACS, 2009).

Ovarian Cancer

Burden of Disease

Ovarian cancer is the fifth leading cause of cancer deaths in women, with an estimated 22,000 new cases and 14,600 deaths in 2009 (SEER, 2009). Most women have non-localized disease at diagnosis. Risk factors for developing ovarian cancer include having a first- or second-degree relative with ovarian cancer, being a carrier of the *BRCA1* or *BRCA2* gene mutations, and taking estrogens after menopause. Oral contraceptive use and parity have a protective effect, reducing the risk of disease (Nelson et al., 2004b).

Accuracy of Screening Tests

Determining the sensitivity and specificity of CA 125 blood level and transvaginal ultrasound as screening tests for ovarian cancer is difficult because thresholds for abnormal findings and lengths of follow-up differ among studies. Because the incidence of ovarian cancer in the general population is low, most women with positive screening test results do not have ovarian cancer.

Effectiveness of Early Detection and Intervention

No evidence indicates that any screening test reduces mortality from ovarian cancer. There is also insufficient evidence that any screening test that could detect early-stage cancer and lead to earlier diagnosis would reduce mortality. Screening for ovarian cancer is likely to result in a high false-positive rate, unnecessary surgery, and anxiety. Large, randomized controlled trials (RCTs) are underway to provide greater insight on methods of screening for ovarian cancer that may reduce morbidity and mortality.

Recommendation

The USPSTF (2004) recommends against routine screening for ovarian cancer. Routine screening is not recommended by any organization. ACS states that women with a strong family history may consider screening, and ACOG recommends that clinicians remain alert for early signs and symptoms of the disease (Nelson et al., 2004b).

Prostate Cancer

Burden of Disease

Prostate cancer is the second leading cause of cancer deaths in men. It was projected to result in 27,000 deaths and 192,280 new cases in 2009 (National Cancer Institute, SEER). Incidence increases with age, and more than 75% of cases are in men older than 65 years. Other risk factors include black race and having a first-degree relative with prostate cancer. Although a major cause of cancer death among men, many more men have a diagnosis of prostate cancer than die of it. Men in the United States have a 15% lifetime risk of diagnosis, but have only a 3% risk of dying of prostate cancer (Harris et al., 2001).

Accuracy of Screening Tests

The sensitivity and specificity of prostate-specific antigen (PSA) depend on the threshold set for a clinically significant abnormal value. Using the cutoff of 4.0 ng/mL has an estimated sensitivity of 63% to 83% and a specificity about 90% in the first screening. Sensitivity decreases with increasing age and the presence of benign prostatic hyperplasia. DRE evaluates only the posterior and lateral aspects of the prostate, has poor interoperator agreement, and detects less than 60% of prostate cancers (Harris et al., 2001). The combination of DRE with PSA increases the sensitivity but also increases the rate of false-positive results.

Effectiveness of Early Detection and Intervention

Screening with PSA and DRE can detect prostate cancer in its early stages, but it is not clear whether early detection improves health outcomes. Screening may result in several potential harms, including frequent false-positive results, biopsies, and anxiety. Treatment side effects may include erectile dysfunction, urinary incontinence, and bowel dysfunction. Treatment of all cases detected by screening is likely to result in many interventions for men who would never have experienced symptoms from their cancers (Harris et al., 2001).

Recommendation

The USPSTF concluded that the evidence is insufficient to recommend for or against routine screening for prostate cancer using PSA or DRE in men younger than age 75. ACS, AAFP, American Urological Association (AUA), and all other major organizations and societies concur with this recommendation of not recommending routine testing but consideration of shared decision making. USPSTF recommends against screening of men older than 75 (USPSTF, 2008).

Heart and Vascular Disease

Cardiovascular disease is a major public health burden and the leading cause of death in the United States; it is the underlying or contributing cause in approximately 60% of deaths (Wolff et al., 2009). Effective screening tests and early preventive interventions are available for early asymptomatic states and modifiable risk factors (Figure 6-2). An assessment of cardiovascular risk using validated prediction tools is an important first step in preventing cardiovascular events. The most studied tools are based on Framingham data and are available online* and can be incorporated into electronic medical record systems.

*<http://hp2010.nhlbi.nih.net/atpiii/calculator.asp?usertype=prof>.

Hypertension

Burden of Disease

Hypertension (HTN) is the most common cardiovascular disease and the most common reason patients visit family physicians (AAFP, 2002; AHA, 2005). Approximately 30% of adult Americans have hypertension; 7% of adults with HTN have never been told by their physician that they have high blood pressure (BP). Age is an important risk factor for hypertension: 7% of adults 18 to 39 years old have hypertension, versus 67% of adults age 60 and older (Ostchega et al., 2008).

The risk of death from coronary artery disease and stroke (cerebrovascular accident, CVA) is doubled with every 20-mm Hg systolic or 10-mm Hg diastolic increase in BP (Table 6-4). Elevated BP is also associated with heart failure and renal disease (JNC-7, 2004). Treatment and control of hypertension are less than ideal; 68% of hypertensive adults are treated with BP medications, and of those treated, 64% had their BP lowered to recommended levels (Ostchega et al., 2008).

Accuracy of Screening Tests

Office-based BP measurements are typically done with a sphygmomanometer. The accuracy depends on the examiner, patient factors, and the instrument used. Because of the resulting variability, two BP measurements at separate visits are necessary for diagnosis. Properly performed measurements are highly correlated with arterial BP and predict cardiac risk. Ambulatory monitoring may be more accurate and a better predictor of cardiac risk than office BP measurement, but it is subject to the same errors. A significant advantage of ambulatory monitoring is that it may identify patients with “white coat hypertension” (Sheridan et al., 2003).

Effectiveness of Early Detection and Intervention

No studies have examined the direct effect of screening on clinical outcomes; however, treating a patient for hypertension detected through screening appears to provide morbidity and mortality benefits. The benefits of screening and treatment depend on the degree of BP elevation and the presence of other cardiovascular risk factors, such as age, gender, lipid disorders, and diabetes. Potential harms from screening include labeling and exposure to the side effects of antihypertensive treatment.

Recommendation

The USPSTF (2007) recommends that clinicians screen all adults age 18 and older for high blood pressure. AHA and AAFP make similar recommendations.

Hyperlipidemia

Burden of Disease

Of U.S. adults, 16% have a total cholesterol level greater than 240 mg/dL. Women have a higher prevalence of elevated total cholesterol than men (Schober et al., 2007). Low HDL is much more common in men than women (AHA, 2005). Total cholesterol levels higher than 200 mg/dL account for 27% of coronary heart disease (CHD) events in men and 34% in women. Elevated total cholesterol and low-density

**Risk assessment tool for estimating 10-year risk of developing hard CHD
(myocardial infarction and coronary death)**

The **risk assessment tool** below uses recent data from the Framingham Heart Study to estimate 10-year risk for “hard” coronary heart disease outcomes (myocardial infarction and coronary death). This tool is designed to estimate risk in adults aged 20 and older who do not have heart disease or diabetes. Use the calculator below to estimate 10-year risk.

Age:
 years

Gender:

Figure 6-2 Risk factors for cardiovascular disease. (From the National Heart, Blood, and Lung Institute. <http://hin.nhlbi.nih.gov/atp/iii/calculator.asp?usertype=prof>.)

Table 6-4 Adult Blood Pressure Classification System (JNC-7)

| Blood Pressure Class | Blood Pressure (mm Hg) | | |
|----------------------|------------------------|-----|-----------|
| | Systolic | | Diastolic |
| Normal | <120 | and | <80 |
| Prehypertension | 120-139 | or | 80-89 |
| Stage 1 hypertension | 140-159 | or | 90-99 |
| Stage 2 hypertension | ≥160 | or | ≥100 |

Modified from Chobanian AV, Bakris GL, Black HR, et al. The Seventh Report of the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure: the JNC-7 Report. JAMA 2003;289:2560-2572.

lipoprotein (LDL) and low levels of high-density lipoprotein (HDL) increase the risk of CHD linearly (Pignone et al., 2001).

Accuracy of Screening Tests

Total cholesterol and HDL are the preferred screening tests and can be measured in fasting and nonfasting patients. Both values are reliable and do not vary substantially between fasting and nonfasting samples. In contrast, triglyceride levels vary 20% to 30% between fasting and nonfasting samples. Because LDL levels are calculated using the triglyceride value,

a fasting sample is needed to measure LDL accurately (Pignone et al., 2001).

Effectiveness of Early Detection and Intervention

Treating lipid abnormalities in persons with elevated cardiac risk reduces coronary events and mortality (Grundy et al., 2004). The benefits for persons with elevated lipid levels and low cardiac risk are less certain. Although typical initial interventions, lifestyle modifications such as diet and exercise appear to have minimal effect on abnormal lipid levels, and most adults will eventually require drug therapy. The harms of screening are not well defined, but a potential harm is drug treatment of persons who are unlikely to benefit because of low overall cardiac risk (USPSTF, 2008).

Recommendation

The USPSTF recommends screening all men older than 35 and men younger than 35 if they are at increased risk for CHD. Women older than 20 should be screened if they are at increased risk for CHD. The overall benefit of screening for lipid abnormalities for women not at increased risk and for younger men not at increased risk is small (USPSTF, 2008). AAFP agrees with the USPSTF recommendation. The third report of the National Heart, Lung, and Blood Institute's National Cholesterol Education Program's Expert Panel on the Detection, Evaluation, and Treatment of High Blood Cholesterol in Adults (Adult Treatment Panel III)

recommended screening adults older than age 20 every 5 years (ATP III, 2002).

Abdominal Aortic Aneurysm

Burden of Disease

Approximately 9000 people die each year of abdominal aortic aneurysm (AAA), and most of them are men older than age 65. AAAs occur in 4% to 8% of older men and 0.5% to 1.5% of older women (Fleming et al., 2005). Major risk factors include age 65 or older, smoking (≥ 100 cigarettes in a lifetime), and male gender. Family history also increases risk in men and possibly in women (USPSTF, 2005). As many as one of every three untreated AAAs may rupture, and most of these individuals will die (Fleming et al., 2005).

Accuracy of Screening Tests

Ultrasound is a noninvasive test that accurately identifies AAA. It is 95% sensitive and 100% specific when appropriately performed. Physical examination is not an acceptable screening substitute (USPSTF, 2005). Patients without AAA on their initial ultrasound are unlikely to develop clinically important AAAs in their lifetimes (Fleming et al., 2005). Among men in the target age group (65-74 years), the number needed to screen to prevent one AAA-related death in 5 years is 500 smokers or 1783 nonsmokers (USPSTF, 2005).

Effectiveness of Early Detection and Intervention

Screening for AAA and surgical repair of large AAAs (≥ 5.5 cm) in men age 65 to 75 who have ever smoked leads to decreased AAA-specific mortality (USPSTF, 2005); whether screening affects all-cause mortality is uncertain. Although ultrasound can detect AAAs in women, women are unlikely to benefit from screening because they tend to develop AAAs at an older age. Screening studies have not shown a benefit for women (Fleming et al., 2005).

Screening can cause short-term anxiety. Surgical AAA repair carries a mortality risk of up to 5%. Perioperative cardiac and pulmonary complications are common, occurring in one third of patients (Fleming et al., 2005).

Recommendation

The USPSTF recommends screening for AAA in men between the ages of 65 and 75 years who have ever smoked, with no recommendation for or against screening men who never smoked, and recommending against routine screening in women (USPSTF, 2005). The Society for Vascular Surgery recommends screening all men age 60 to 85 years, women age 60 to 85 with risk factors for CHD, and men and women age 50 or older with a family history of AAA (Fleming et al., 2005).

Screening for AAA with ultrasound is part of a package of ultrasound screening offered by for-profit companies that is being marketed directly to patients. These packages usually include screening for carotid artery stenosis (CAS), AAA, and peripheral arterial disease (PAD). Patients may ask about these during visits to a family physician. Although there is evidence that screening for AAA in some populations is beneficial, evidence indicates that screening for CAS and PAD is harmful and thus not recommended (USPSTF, 2005, 2007).

Coronary Heart Disease and Cerebrovascular Disease

Burden of Disease

The epidemiology of cerebrovascular disease events is different for men and women. Men have a higher risk for coronary heart disease (CHD) and tend to have these events at a younger age than women. Women are more likely to die as a result of a myocardial infarction (MI); 38% of women die within 1 year of their first MI, versus 25% of men (Wolff et al., 2009).

Cerebrovascular disease is the third leading cause of death in the United States and approximately 500,000 people annually experience a first stroke (CVA). The mortality rate for cerebrovascular disease has declined by almost 70% since 1950, primarily because of reduced cigarette smoking and improved control of HTN. According to the Framingham data, the 10-year risk for initial ischemic stroke at age 55 years is 1.8% for women and 2.4% for men; at age 65 the risk increases to 3.9% for women and 5.8% for men (Wolff et al., 2009).

Accuracy of Screening Tests

Several screening mechanisms exist for CHD: electrocardiogram (ECG), exercise testing, and electron beam computed tomography (EBCT) for coronary calcium. The sensitivity of resting ECG abnormalities for CHD is low. The sensitivity of an exercise test ranges from 10% to 70% and the predictive value from 2.2% to 24%. False-positive results are more likely for young persons and women (Pignone et al., 2003). Evidence is limited on the use of nontraditional risk factors in CHD assessment, including ankle-brachial index (ABI), leukocyte count, fasting glucose level, periodontal disease, carotid intimal medial thickening, EBCT, homocysteine level, lipoprotein(a) level, and high-sensitivity C-reactive protein (hs-CRP) level. Screening for cerebrovascular disease with an ultrasound of the carotid artery to detect significant stenosis has a reported sensitivity of 86% to 90% and specificity of 87% to 94% (Wolff, 2007).

Effectiveness of Early Detection and Intervention

Although ECG and exercise stress tests can detect disease, the sensitivity and specificity of these tests limits their use in evaluating asymptomatic persons. False-positive results lead to invasive testing, and false-negative results lead to inappropriate reassurance. It is unclear that these assessments provide information beyond risk scoring, even for higher-risk persons. Although hs-CRP and ABI may reclassify some individuals into a higher or lower CHD risk category, evidence is lacking regarding the effect of screening or assessment with these or other modalities on outcomes (USPSTF, 2009).

Hormone replacement therapy does not prevent CHD in postmenopausal women (Anderson et al., 2004; Rossouw et al., 2002), and evidence does not support a benefit from vitamin supplements (Lee et al., 2005). There is good evidence that screening for CAS with an ultrasound leads to important harms, including strokes from confirmatory tests or surgery. For men at increased risk for CHD, aspirin prophylaxis decreases the rate of CHD events; and for women at increased risk of strokes, aspirin decreases the rate of strokes (Berger et al., 2006; USPSTF, 2009). The ideal dose is uncertain, but low doses (75 mg) are as effective as high doses

(325 mg). Smoking cessation, BP and lipid control, a healthy diet, and exercise have also been shown to be beneficial in preventing cerebrovascular disease events.

Recommendation

The USPSTF recommends against using ECG, exercise testing, or CT scanning to screen low-risk adults for CHD. Evidence is insufficient to recommend these techniques even for adults at increased risk (USPSTF, 2004). AAFP does not recommend routine ECG in asymptomatic children or adults as part of a periodic health examination (Pignone et al., 2003). USPSTF concluded that the evidence is insufficient for the use of nontraditional risk factors to screen asymptomatic men and women. They recommend against screening for asymptomatic CAS in the general adult population. USPSTF recommends the use of aspirin for men age 45 to 79 years and women age 55 to 79 when the potential benefit from a reduction in MIs or strokes, respectively, outweighs the potential harm from an increase in gastrointestinal hemorrhage (Table 6-5). It is important to discuss both the benefits and the harms with patients. Aspirin in younger men and women is not recommended because they are likely to experience more harm than benefit. There is no evidence to use aspirin for cardiovascular disease prevention in average-risk men and women 80 years or older (USPSTF, 2009).

Substance Abuse and Mental Health

Tobacco

Burden of Disease

Tobacco use, particularly cigarette smoking, is the leading cause of preventable death in the United States, and it results in approximately 443,000 premature deaths annually (CDC, 2008a). Among adults, approximately 41% of the smoking-attributable deaths are caused by cancer, 33% by cardiovascular disease, and 26% by respiratory disease (CDC, 2008a). Smoking during pregnancy results in almost 800 ($n = 776$) fetal deaths annually. An estimated 49,400 deaths annually from lung cancer and cardiovascular causes are attributable to second-hand smoke exposure (CDC, 2008a). Despite the known health effects, in 2007, an estimated 19.8% of U.S.

adults continued to smoke (CDC, 2008b). The prevalence of smoking is higher among certain subgroups, including Native Americans and Native Alaskans, those with a lower level of education, adults age 25 to 44, and people living below the poverty level (CDC, 2008b).

Screening and Identification of Risk Group

Clinics that implement screening systems designed to identify and document a patient's tobacco use status increase the rate at which clinicians intervene with their patients who smoke. Including tobacco use as a "vital sign" increases the probability that tobacco use is routinely assessed and addressed. However, there is limited evidence that a screening system has a substantial impact on tobacco cessation rates (Fiore et al., 2008).

Effectiveness of Counseling Intervention

The optimal duration and frequency of tobacco counseling interventions is unknown, but good evidence indicates that even brief counseling interventions (<3 minutes) increase tobacco abstinence rates. Increasing the intensity of the counseling increases its efficacy (Fiore et al., 2008). The "5As" behavioral counseling framework provides a useful strategy for engaging patients in smoking cessation discussions (see later discussion). Providing problem-solving guidance and social support within and outside treatment is particularly important. Patients who are unwilling to try to quit should receive an intervention designed to motivate them to quit.

Several pharmacotherapies are safe and effective in helping adults to quit smoking. Nicotine replacement therapy—nicotine gum, transdermal patches, nicotine nasal spray, and nicotine inhalers—and sustained-release bupropion and varenicline are among the medications shown to be effective in increasing abstinence rates. There is limited evidence regarding the safety or efficacy of pharmacotherapy during pregnancy (Fiore et al., 2008).

Recommendation

The USPSTF recommends that clinicians screen all adults, including pregnant women, for tobacco use and provide tobacco cessation interventions for those who use tobacco products. The AAFP, American College of Preventive Medicine (ACPM), and the ACOG recommend a similar course of action. Brief smoking cessation interventions for adults and extended, tailored counseling for pregnant women are effective in increasing the proportion of smokers who successfully quit smoking and remain abstinent (USPSTF, 2009).

Alcohol

Burden of Disease

Alcohol abuse and *alcohol dependence* are associated with repeated negative physical, psychological, and social effects, and the effectiveness of interventions for alcohol dependence are well established. *Alcohol misuse*, such as "risky or hazardous" and "harmful" drinking, does not meet criteria for dependence but place individuals at risk for future problems. Across various primary care populations, the prevalence rates for risky drinking are 4% to 29%; for harmful drinking, 0.3% to 10%; and for alcohol dependence, 2% to 9%. Drinking alcohol influences tobacco use (and vice versa), and drinking onset during adolescence correlates with dependence as an

Table 6-5 10-Year Risk Levels* for Coronary Heart Disease (CHD, Men) and Stroke (Women)

| Men | | Women | |
|-------------|------------------|-------------|---------------------|
| Age (years) | 10-Year CHD Risk | Age (years) | 10-Year Stroke Risk |
| 45–59 | >4% | 55–59 | >3% |
| 60–69 | >9% | 60–69 | >8% |
| 70–79 | >12% | 70–79 | >11% |

*Level at which the number of cardiovascular disease events prevented is closely balanced to the number of serious bleeding events. Shared decision making is strongly encouraged with persons whose risk is close to (either above or below) these estimates of 10-year risk levels. As the potential cardiovascular disease reduction benefit increases above harms, the recommendation to take aspirin should become stronger.

adult and increases the risk of alcohol-related injuries. Alcohol misuse frequently coexists with depression or anxiety disorders (Whitlock et al., 2004).

Accuracy of Screening

Several effective screening instruments are available for use in the primary care setting. The Alcohol Use Disorders Identification Test (AUDIT) incorporates questions about consequences of drinking along with questions about quantity and frequency. Its specificity ranges from 78% to 96% and the sensitivity from 51% to 97%. The CAGE questionnaire (i.e., feeling the need to cut down, annoyed by criticism, guilty about drinking, and need for an eye-opener in the morning) is widely used in primary care. Specificity for CAGE ranges from 70% to 97% and sensitivity from 43% to 94%. The TWEAK and the T-ACE instruments are designed to screen pregnant women for alcohol misuse (Whitlock et al., 2004). The CRAFFT questionnaire has been validated for screening adolescents for substance abuse in primary care settings (Knight et al., 2003). Tools are available at <http://www.niaaa.nih.gov/Publications/AlcoholResearch/>. Biologic markers, such as carbohydrate-deficient transferrin and serum γ -glutamyltransferase, are poor indicators of alcohol misuse.

Effectiveness of Counseling Intervention

Counseling interventions can be delivered wholly or partly in the primary care setting, and their effectiveness varies in terms of duration and frequency of the sessions. Effective interventions include feedback, advice, and goal setting, and most also include follow-up and further assistance. Depending on the intensity of the counseling, reduction in alcohol consumption ranges from three to nine drinks per week after 6 to 12 months of follow-up (Whitlock et al., 2004). The benefits of behavioral intervention for preventing or reducing alcohol misuse in adolescents are not known.

Recommendation

The USPSTF recommends screening and behavioral counseling interventions to reduce alcohol misuse by adults, including pregnant women, in primary care settings. They concluded that the evidence was insufficient to recommend for or against screening and behavioral counseling to prevent or reduce alcohol misuse by adolescents in primary care settings (USPSTF, 2004). The AMA, AAFP, and Canadian Task Force on Preventive Health Care (CTFPHC) also recommend screening adults for alcohol misuse and counseling for those who screen positive. ACOG recommends counseling all women about the harmful effects of drinking to the fetus and that abstinence is the best policy (Whitlock et al., 2004).

Screening adults for alcohol misuse in primary care settings can accurately identify patients at risk for increased morbidity and mortality, and brief behavioral counseling interventions with follow-up produce small to moderate reductions in alcohol consumption that are sustained for 6 to 12 months or longer (USPSTF, 2004).

Depression

Burden of Disease

Depressive disorders are common, chronic, and costly. Depression is the fourth leading contributor to the global burden of disease and a leading cause of disability. In the

primary care setting, the point prevalence of major depression ranges from 5% to 9% for adults, and up to 50% of depressed patients are not recognized (Pignone et al., 2002a). The estimated prevalence of major depressive disorder is 2.0% in children younger than 13 years and 5.6% in adolescents age 13 to 18 (Williams et al., 2009). Risk factors for depression include female gender, family or personal history of depression, substance abuse, and chronic disease.

Accuracy of Screening

Several screening instruments are available and have a sensitivity of 80% to 90% and specificity of 70% to 85% (Pignone et al., 2002a). Instruments include the Beck Depression Inventory, the Zung Self-Assessment Depression Scale, and the General Health Questionnaire. Most instruments are easy to use and take less than 5 minutes to administer, although most depressed patients can be identified simply by asking about depressed mood and anhedonia (loss of pleasurable feelings). The Patient Health Questionnaire for Adolescents and the Beck Depression Inventory–Primary Care have demonstrated good sensitivity and specificity in primary care settings in adolescents (Williams et al., 2009). A review of these tools can be found in the article at <http://www.aafp.org/aafp/2002/0915/p1001.html>.

Effectiveness of Early Detection and Intervention

There are effective treatments for patients with depressive illnesses detected through screening. Antidepressant medications include selective serotonin reuptake inhibitors (SSRIs) and tricyclic antidepressants (TCAs). Psychosocial and psychotherapeutic interventions are also effective treatments for major depression.

Clinicians who screen for depression should have systems in place to ensure that positive screening results are followed by accurate diagnosis, proper treatment, and adequate follow-up. All positive screening tests should be followed by full diagnostic interviews using standard diagnostic criteria to determine the presence or absence of major depression, dysthymia, or other psychological problems. The potential harms of screening include false-positive screening results, the inconvenience of further workup, and the potential adverse effects of labeling an individual “depressed.”

Recommendation

The USPSTF (2002) recommends screening adults for depression in clinical settings that have systems in place to ensure accurate diagnosis, effective treatment, and follow-up. AAFP and CTFPHC endorse similar recommendations, and ACOG recommends that clinicians remain alert to symptoms of depression and ask questions about psychosocial stressors when taking a patient's history (Pignone et al., 2002a). USPSTF recommends screening adolescents (12–18 years of age) for major depressive disorder when systems are in place to ensure accurate diagnosis, psychotherapy, and follow-up. Routine screening has been recommended by Medicaid's EPSDT program and the American Academy of Pediatrics (AAP), and the American Medical Association (AMA) recommends screening for depression among adolescents who may be at increased risk for depression (USPSTF, 2009).

Screening for depression in adults and adolescents improves the accurate identification of depressed patients in primary care settings, and treatment of depressed patients identified in these settings decreases clinical morbidity. Screening should be offered to adults in clinical practices that have systems in place to ensure accurate diagnosis, effective treatment, and follow-up (USPSTF, 2002). Screening for major depressive disorder should be offered to adolescents when systems are in place to ensure accurate diagnosis, psychotherapy, and follow-up (USPSTF, 2009).

Infectious Diseases

Physicians need to consider which risk factors, both behavioral and demographic, place individual patients at increased risk of infection. Although the evidence base establishing risk factors for each sexually transmitted infection (STI) is based on the particulars of the individual studies examining each STI, clinicians may choose to consider high-risk sexual behaviors as having multiple current partners, having a new partner, using condoms inconsistently, having sex while under the influence of alcohol or drugs, and having sex in exchange for money or drugs. In addition to evaluation of a patient's modifiable behaviors, physicians should consider their patients' nonmodifiable demographics and social situation.

As noted earlier, all U.S. communities do not present the same infection risk. For example, both syphilis and gonorrhea have significantly higher prevalence rates in the South and many urban centers. Because of underlying social factors that increase STI risk, including poverty, discrimination, and social networks, black and Hispanic Americans have higher prevalence rates of most STIs. When considering screening for STIs, physicians should consult with local public health officials and use national, regional, and local epidemiologic data to tailor screening programs based on communities and populations they serve. In addition to behavioral risk factors, physicians should remember that for chlamydial infection and gonorrhea, all sexually active women age 24 years and younger are considered at increased risk (Meyers et al., 2008).

Chlamydial Infection

Burden of Disease

Chlamydia trachomatis infection is the most common sexually transmitted bacterial disease in the United States. In 2007, more than 1 million cases of chlamydial infection were reported to the Centers for Disease Control and Prevention (CDC), 370 cases per 100,000 population; an additional 2 million cases are thought to occur annually (Weinstock et al., 2004). Age is the strongest risk factor for infection in both men and women, with adolescent girls and women between ages 15 and 24 and men between 20 and 24 having the highest prevalence rates (CDC, 2009). It is important to note that higher rates of chlamydial infection and gonorrhea in younger women result not only from having more sex partners, but also from the relative immaturity of their immune systems and the presence of columnar epithelium on the adolescent cervix (Meyers et al., 2008). In addition to sexual activity and age, other risk factors for chlamydial infection include a recent history of STI, new or multiple sexual partners, inconsistent condom use, and exchanging sex

for money or drugs. Chlamydial infection is widely prevalent among all racial and ethnic groups in the United States, with higher prevalence rates among black and Hispanic populations. Increased prevalence rates are also found in incarcerated populations, military recruits, and patients presenting to public STI clinics (Meyers et al., 2007).

Although 75% of genital chlamydial infections in women are asymptomatic, *C. trachomatis* is a major cause of urethritis and cervicitis in women. Additionally, up to 40% of untreated cases of *C. trachomatis* may progress to pelvic inflammatory disease (PID). PID may result in ectopic pregnancy, infertility, and chronic pelvic pain. About 95% of men with *C. trachomatis* infection are asymptomatic. Genital infection in men occasionally results in acute urethritis or epididymitis and rarely in chronic complications such as prostatitis and reactive arthritis (Meyers et al., 2007).

Accuracy of Screening Tests

Nucleic acid amplification tests (NAATs), such as polymerase chain reaction (PCR) and transcription-mediated amplification (TMA), can identify chlamydial infection in asymptomatic women (nonpregnant and pregnant) and asymptomatic men. NAATs have high sensitivity (>80%) and specificity (>99%) and can be used with urine, vaginal, and cervical swabs (Meyers et al., 2007). It is important to remember that even with a test with high sensitivity, in a low-prevalence population, a positive screening result is more likely to be a false positive than an actual case. When screening a 20-year-old woman with no other risk factors other than her young age, given a prevalence rate of 1%, the positive predictive value for a positive chlamydial screen with an NAAT is only 47%. Point-of-care tests are becoming available that can be conducted in the office setting in about 30 minutes. Their sensitivity remains substantially lower than for laboratory-conducted NAATs, although their specificity is high (Mahilum-Tapay et al., 2007).

Effectiveness of Early Detection and Intervention

Screening and treatment for *Chlamydia* infection in high-risk, asymptomatic women has been demonstrated to reduce significantly their incidence of PID after 12 months of follow-up. There have been no published studies of the effectiveness of screening women not at increased risk. Although treatment of men eradicates infection, there is no evidence that screening men reduces transmission, acute infection, or sequelae in women. Potential harms of screening and treatment include the effects of false-positive test results, patient anxiety, unnecessary antibiotic use, and adverse drug reactions (Meyers et al., 2007).

Recommendation

The USPSTF recommends that clinicians routinely screen all sexually active women age 24 or younger (including pregnant women) and older asymptomatic women at increased risk for chlamydial infection. They recommend against routine screening in asymptomatic women age 25 and older (including pregnant women) who are not at increased risk. Although USPSTF found insufficient evidence to recommend for or against routine screening of men, they counsel clinicians and health care systems to focus on improving screening rates among women at increased risk, a group for whom the benefits of screening are certain (USPSTF, 2007).

The AAFP (2009) concurs with USPSTF. The CDC (2006) recommends annual screening for sexually active women 25 years old and younger and older women with new or multiple sexual partners.

Women with asymptomatic untreated chlamydial infection have high rates of morbidity from PID and its sequelae. Screening tests can accurately detect chlamydial infection in those at risk, and treatment is effective. All sexually active women age 24 and younger and all older women at increased risk for PID should be screened for chlamydial infection. The same risk factors and recommendation applies to pregnant women (USPSTF, 2007).

Gonorrheal Infection

Burden of Disease

In 2006, infection with *Neisseria gonorrhoeae* was the second most common reportable disease in the United States, with a reported rate just under 119 cases per 100,000 population. Unlike *Chlamydia* infection, which has seen increasing rates over the past decade, rates of *N. gonorrhoeae* infection have been stable since the mid-1990s. Infection rates are highest among girls and women between ages 15 and 24 years and men between 20 and 24 years. Although rates are increasing among white and Hispanic populations, the rate among blacks in 2006 (663 cases per 100,000) was almost 20 times higher than for whites. Other risk factors for infection include a history of previous gonorrhea or other STI, new or multiple sexual partners, inconsistent condom use, sex work, and drug use. The prevalence of gonorrhea varies widely among regions of the United States, with the South and Midwest having notably higher rates than the Northeast and West, and among communities (CDC, 2007).

In women, infection with *N. gonorrhoeae* is a major cause of cervicitis and PID. PID may cause ectopic pregnancy, infertility, and chronic pelvic pain. In men, gonorrhea can result in urethritis, epididymitis, and prostatitis. Gonorrheal infection is frequently asymptomatic in women. Infection in men can be asymptomatic as well, but less often than in women (Glass et al., 2005b).

Accuracy of Screening Tests

Culture isolates collected from endocervical swabs in women and urethral swabs in men remain an accurate screening test for genital gonorrheal infection. When transport conditions are suitable, the sensitivity is higher than 90%. Because culture remains the "gold standard," the specificity of culture is 100% when culture isolates are speciated. NAATs and nucleic acid hybridization tests have demonstrated sensitivity and specificity comparable to culture and compare better when transport conditions are not suitable for culture. Some newer tests can be used with urine and vaginal swabs, allowing screening without an invasive procedure (Glass et al., 2005b).

Effectiveness of Early Detection and Intervention

Screening can accurately detect gonorrheal infection, and antibiotic therapy can eliminate urogenital infections, prevent complications, and prevent further transmission. Potential harms of screening and treatment include false-positive test results, anxiety, and unnecessary antibiotic use (Glass et al., 2005b).

Recommendation

The USPSTF recommends that clinicians screen all sexually active women who are at increased risk for gonorrheal infection. Because of the lower burden of undiagnosed and untreated genital gonorrheal infection in men than women, USPSTF concluded that there was insufficient evidence to recommend for or against routine screening for gonorrhea in men at increased risk for infection. They recommend against routine screening for gonorrhea in men and women who are at low risk for infection (USPSTF, 2005).

Unlike chlamydial infection, which is relatively evenly distributed across the United States, gonorrheal infection demonstrates marked regional and local variation. USPSTF recommends that clinicians and health systems work with public health officials to understand the prevalence and distribution of gonorrhea in their communities and adjust their screening practices accordingly.

The AAFP and ACOG recommend screening sexually active women, including adolescents, at high risk for gonorrhea. The CDC recommends that clinicians screen all sexually active men who have sex with men for genital gonorrhea at least annually and for rectal and pharyngeal gonorrhea if they are at risk due to exposure. The Infectious Disease Society of America (IDSA) recommends that all HIV-positive individuals be screened for gonorrhea (Glass et al., 2005b).

Women with asymptomatic gonorrheal infection have high rates of morbidity from PID and its sequelae. Screening tests can accurately detect gonorrheal infection in those at risk, and treatment is effective. All high-risk, sexually active women (including pregnant women) should be screened for gonorrheal infection (USPSTF, 2005).

Human Immunodeficiency Virus Infection

Burden of Disease.

In 2007, about 37,000 people in the United States were diagnosed with acquired immunodeficiency syndrome (AIDS), raising the total to more than 1 million diagnosed cases since the recognition of AIDS in 1981. In 2006, more than 450,000 people in the United States were living with AIDS, and an additional 56,300 people were newly infected with HIV. From 2003 to 2007, the total number of new AIDS cases has remained relatively stable, but the proportion of HIV/AIDS cases has continued to increase steadily (CDC, 2009). With approximately 12,000 deaths in 2007, AIDS is not in the top 15 causes of death in the United States (Heron et al., 2009).

Those at increased risk for HIV infection include men who have had sex with men after 1975; men and women having unprotected sex with multiple partners; past or present injection drug users; men and women who exchange sex for money or drugs or have sex partners who do; individuals whose past or present sex partners were HIV infected, bisexual, or injection drug users; persons being treated for STIs; and persons with a history of blood transfusion between 1978 and 1985. Persons who request an HIV test despite reporting no individual risk factors may also be considered at increased risk, because this group is likely to include individuals not willing to disclose high-risk behaviors. A higher prevalence is seen in high-risk settings, such as STI clinics, correctional facilities,

homeless shelters, tuberculosis clinics, clinics serving men who have sex with men, and adolescent health clinics with a high prevalence of STIs (Chou et al., 2005).

Accuracy of Screening Tests

Standard testing for HIV infection with the repeatedly reactive enzyme immunoassay, followed by confirmatory Western blot or immunofluorescent assay, has a sensitivity and specificity greater than 99%. False-positive test results are rare, even in low-risk settings. Compared with standard HIV testing, the reported sensitivities of rapid tests on blood specimens range from 96% to 100%, with specificities greater than 99.9%. Reported sensitivities and specificities of oral fluid HIV tests are also high (>99%) (Chou et al., 2005).

Effectiveness of Early Detection and Intervention

The wide adoption in the late 1990s of the use of highly active antiretroviral therapy (HAART) regimens with three or more agents has been associated with a marked decline in morbidity and mortality for HIV-infected patients in the United States. HAART regimens are consistently effective in reducing clinical progression and mortality in persons with CD4 cell counts less than 200 cells/mm³. Appropriate prophylaxis and immunization against certain opportunistic infections have also been effective interventions in reducing morbidity (Chou et al., 2005).

Because false-positive test results are rare, harms associated with HIV screening are minimal. Potential harms of true-positive test results include increased anxiety, labeling, and deleterious effects on close relationships.

Although it is hoped that early diagnosis may lead to decreased transmission of HIV, evidence is lacking on the effect of increased screening leads on transmission (Chou et al., 2007). Additional evidence is also needed to clarify the balance of benefits and harms of early versus delayed treatment of asymptomatic patients with HIV infection.

Recommendation

The USPSTF strongly recommends that clinicians screen for HIV in all adolescents and adults at increased risk for HIV infection. They make no recommendation for or against routinely screening for HIV in adolescents and adults who are not at increased risk for HIV infection (USPSTF, 2005).

Counseling and HIV testing of high-risk individuals are recommended by the CDC and numerous professional organizations, including the AAFP, AMA, ACOG, ACP, and IDSA. The AAP considers all sexually active adolescents to be a high-risk group and recommends they be counseled and offered HIV testing. The CDC recommends that routine, voluntary testing be offered to all patients seen in health care facilities where the prevalence of HIV infection is 1% or greater and in settings serving client populations at increased behavioral or clinical HIV risk (Chou et al., 2005).

Standard and FDA-approved rapid screening tests accurately detect HIV infection, and interventions (e.g., HAART) reduce the risk of clinical progression and premature death. HIV screening should be offered to all adolescents and adults at high risk for HIV infection (USPSTF, 2005).

The following topics are discussed online at www.expertconsult.com:

- Syphilis infection
- Recommendations against routine screening for hepatitis B, C, and herpesvirus infections.

Metabolic, Nutritional, and Endocrine Conditions

Type 2 Diabetes Mellitus

Burden of Disease

The prevalence of type 2 diabetes in the United States is rising, particularly among adults with a body mass index (BMI) of 35 kg/m² or greater. From 1980 through 2006, the number of Americans with diabetes tripled, from 5.6 to 16.8 million (Norris et al., 2008). Patients with type 2 diabetes are at increased risk for microvascular and macrovascular disease. Microvascular disease leads to high rates of blindness, end-stage renal disease, and lower extremity amputations; macrovascular disease accounts for twofold to fourfold increased risk for heart disease and stroke in people with diabetes.

Accuracy of Screening Tests

Three tests have been used to screen for diabetes: fasting plasma glucose (FPG), 2-hour post-load plasma glucose (2-hour PG), and hemoglobin A_{1c} (HbA_{1c}). Sensitivity and specificity are in the range of 75% to 80% for all three tests using these thresholds: FPG = 126 mg/dL, 2-hour PG = 200 mg/dL, and HbA_{1c} = 6.4% (Harris et al., 2002). The American Diabetes Association (ADA) has recommended the FPG or 2-hour PG test for screening; the FPG is easier and faster to perform, more convenient, and acceptable to patients, and it is less expensive than other screening tests. The FPG is also more reproducible than the 2-hour PG test and has less intraindividual variation.

Effectiveness of Early Detection and Intervention

Early detection of diabetes has the potential to prevent complications of diabetes through early intensive control of cardiovascular disease risk factors and tight glycemic control. Aggressive blood pressure control in those identified with diabetes reduces the incidence of cardiovascular events and cardiovascular mortality. Patients with hyperlipidemia and diabetes who are treated with lipid-lowering agents have a similar reduction in the incidence of coronary heart disease (CHD) events as those without diabetes (RR reduction, 19%-42%) (USPSTF, 2008).

Intensive glycemic control in persons with clinically detected diabetes can reduce progression of microvascular disease. The benefits of tight glycemic control on microvascular clinical outcomes, such as severe visual impairment or end-stage renal disease, require long-term follow-up. There is inadequate evidence that early diabetes control as a result of screening provides an incremental benefit for microvascular clinical outcomes compared with initiating treatment after clinical diagnosis (USPSTF, 2008).

In patients who are screened and identified to have prediabetes, evidence indicates that lifestyle and pharmacotherapy can delay the progression of diabetes. However, there is little direct evidence that identifying persons with prediabetes will lead to long-term health benefits. Aggressive blood pressure control and lipid treatment therapy in patients with type 2 diabetes have been shown to reduce the incidence of CHD events in patients with diabetes (USPSTF, 2008). Potential harms of screening include psychological distress from a false-positive diagnosis and earlier exposure to potential adverse effects of treatment than if the diagnosis were made clinically.

Recommendation

The USPSTF (2008) recommends screening for type 2 diabetes in asymptomatic adults with sustained blood pressure (either treated or untreated) greater than 135/80 mm Hg. AAFP (2009) concurs with this recommendation. ACOG recommends FPG testing for women beginning at age 45 years, with an interval of 3 years. On the basis of expert opinion, ADA recommends screening every 3 years to detect prediabetes (IFG or IGT) or diabetes in persons age 45 and older, particularly in those with BMI of 25 kg/m² or greater. Screening is recommended in those overweight individuals younger than 45 years with one additional risk factor, including inactivity, family history of type 2 diabetes mellitus, membership in a high-risk ethnic group, gestational diabetes, hypertension, dyslipidemia, impaired glucose tolerance (IGT) or impaired fasting glucose (IFG), or a history of vascular disease (ADA, 2009).

Osteoporosis in Postmenopausal Women

Burden of Disease

One half of all postmenopausal women will have an osteoporosis-related fracture in their lifetime, including 25% who will develop a vertebral deformity and 15% who will suffer a hip fracture. *Osteoporosis* is defined as a bone mineral density (BMD) more than 2.5 standard deviations (SD) below the mean for a healthy woman, and *osteopenia* is a BMD between 1 and 2.5 SD below the mean. Among white women, it is estimated that 41% older than age 50 have osteopenia, and that 15% between ages 50 and 59 and 70% of those older than 80 have osteoporosis. Mexican American women experience similar rates. The rate among black women is approximately one-half the rate of the other groups. Including all races in the United States, an estimated 14 million women older than 50 years have osteopenia, and 5 million have osteoporosis (Nelson and Helfand, 2002).

Accuracy of Screening Tests

There are two major components of screening for osteoporosis: assessment of risk factors and BMD measurement. Older age, low body mass index (BMI), and not using estrogen replacement are associated with increased risk of osteoporosis and fracture. Other risk factors include white or Asian ancestry, positive family history, tobacco use, and low levels of weight-bearing physical activity (Melton et al., 1989). The WHO FRAX is a common assessment tool.* Other specific instruments, such as the Osteoporosis Risk Assessment Instrument (ORAI) and the Simple Calculated Osteoporosis Risk Estimation (SCORE) tool, use these risk factors to identify women at increased risk for fracture or low BMD. The ORAI has sensitivity of 94% and specificity of 41%, and the SCORE has sensitivity of 91% and specificity of 40% (Nelson and Helfand, 2002).

The BMD measured at the femoral neck by dual-energy x-ray absorptiometry (DEXA) is the most validated predictor of hip fractures. Several other methods for measuring BMD include single-photon absorptiometry, ultrasound, quantitative CT, single-energy x-ray absorptiometry, and peripheral quantitative CT. The results between tests are not highly correlated with one another, and the likelihood of a diagnosis of osteoporosis varies greatly depending on the site and type

of test used, number of sites tested, brand of densitometer, and relevance of the reference range.

Effectiveness of Early Detection and Intervention

Treating osteoporosis with bisphosphonates reduces the risk of fracture (Nelson and Helfand, 2002). Estrogen, calcitonin, and selective estrogen receptor modulators have also been used to increase bone density and reduce fractures. The benefits of these treatments are greater for women at high risk for fracture than women at lower risk. Benefits of screening increase substantially with older age, particularly for women older than 65 and for women with important risk factors. In women age 60 to 64 who have risk factors, the benefits of screening are comparable to those of women age 65 to 69.

Several potential harms are associated with screening and treatment. An unwarranted diagnosis of osteoporosis may provoke anxiety. Potential harms may also arise from misinterpretation of BMD tests. Patients may have side effects from the medication; bisphosphonates often cause gastrointestinal side effects. The cost and inconvenience of undergoing multiple confirmatory tests must be considered.

Recommendation

The USPSTF (2011) recommends that women age 65 or older be routinely screened for osteoporosis, and that routine screening begin in younger women whose fracture risk equals that of a 65-year-old woman without risk factors. AAFP supports this position. The National Osteoporosis Foundation (NOF, 2008) recommends that adults over age 50 receive 1200 mg of calcium and 800 to 1000 IU of vitamin D₃ daily. NOF recommends BMD screening in women age 65 and older and men age 70 and older, as well as in postmenopausal women and men age 50 to 69 based on their risk factor profile. ACOG endorses the NOF guidance.

Obesity

Burden of Disease

Obesity is a substantial health problem in the United States, and the percentage of the population who is overweight or obese continues to rise. Defined as a BMI of 30 or higher, the prevalence of obesity in adults in the United States has increased from 13% to 27% over the past 40 years (McTigue et al., 2003). The prevalence of overweight rose from 31% to 34%. Obesity and overweight are associated with an increased risk of CHD, hypertension, stroke, type 2 diabetes, sleep apnea, musculoskeletal disorders, gallbladder disease, and several types of cancer. Obesity is associated with a decreased quality of life and social stigmatization.

Accuracy of Screening Tests

The BMI (weight [kg] ÷ height [m²]) is the most common test for obesity screening. It is easy to measure, highly reliable, and highly correlated with body fat and body fat mass. The waist-to-hip ratio is a good predictor of cardiovascular morbidity and mortality (McTigue et al., 2003). However, the BMI has been linked with the broadest range of health outcomes and is the most common indicator used in trials.

Effectiveness of Early Detection and Intervention

Counseling and behavioral interventions produce small to modest degrees of weight loss sustained over at least 1 year (McTigue et al., 2003). High-intensity or more

*www.shef.ac.uk/FRAX/tool.jsp?locationValue=1

frequent counseling promotes greater weight loss than low-intensity counseling. Moderate intentional weight loss (5%-10% of body weight) decreases the severity of the comorbidities associated with obesity and may reduce mortality. Pharmacotherapy also promotes modest weight loss (3-5 kg); discontinuing the medication may lead to rapid regain. Obesity surgery has been performed on patients with a BMI greater than 40 or with obesity-related comorbidities and has achieved dramatic weight loss.

Potential harms associated with screening and treatment include the stigma of being labeled “obese” and the detrimental health effects from cycles of weight loss followed by regain. Medications may cause adverse effects, and their long-term safety is not well known. A patient undergoing surgery may have complications, and 25% require reoperation within 5 years (McTigue et al., 2003).

Recommendation

The USPSTF (2003) recommends that clinicians screen all adult patients for obesity and offer intensive counseling and behavioral interventions to promote sustained weight loss for obese patients. AAFP (2008) concurs with this recommendation.

Healthy Diet Counseling

Burden of Disease

Consuming a healthy diet lowers the risks of morbidity and mortality from chronic disease. Four of the 10 leading causes of death—CHD, some types of cancer, stroke, and type 2 diabetes mellitus—are associated with unhealthy diets (Ammerman et al., 2002). Despite well-established benefits of consuming a healthy diet, more than 80% of Americans of all ages eat fewer than the recommended number of daily servings of fruit, vegetables, and grain products. Also, they consume more than the recommended number of calories from saturated fat and total fat (USDHHS, 2000).

Accuracy of Screening Tests

Several brief, validated dietary assessment instruments can identify dietary counseling needs, guide intervention, and monitor change among adult patients in primary care settings. (These can be found in the article at <http://escholarship.org/uc/item/9s03p43r> jgb.) Most of these instruments can be self-administered, are easily scored, have fewer than 40 items, and take 10 minutes or less to administer. Most assessments are subject to bias and may result in underreporting of calories.

Effectiveness of Early Detection and Intervention.

Medium- to high-intensity behavioral interventions produce consistent, sustained, and clinically important changes in dietary intake of saturated fat, total fat, fruits, vegetables, and fiber. The most effective interventions generally combine education, behaviorally oriented counseling, and patient reinforcement and follow-up (Ammerman et al., 2002). More intensive interventions and those of longer duration are associated with greater benefits and more sustained changes in diet. Self-reported dietary changes are often accompanied by improved lipids, BMI, and weight. Patients with hyperlipidemia and other risk factors for CHD and diet-related chronic disease benefit the most from dietary counseling, whereas patients at average risk for chronic disease generally achieve smaller changes in diet.

Recommendation

The USPSTF (2003) recommends intensive behavioral counseling for all adults with hyperlipidemia and other known risk factors for cardiovascular and diet-related chronic disease. Counseling may be done by the primary care provider or through referral to a specialist. The AAFP (2008) recommends intensive behavioral dietary counseling for adult patients with hyperlipidemia and other known risk factors for cardiovascular and diet-related chronic disease.

Physical Activity Counseling

Burden of Disease

Sedentary lifestyles are associated with increased risks of chronic diseases, including CHD, diabetes, obesity, and osteoporosis, and increased physical activity can reduce those risks (USDHHS, 2000). Despite the well-established benefits of exercise, only about 20% of adults achieved the recommended *Healthy People 2010* level of moderate exercise: 30 minutes of moderate physical activity on most days of the week; only 15% achieved a vigorous level of physical activity for 20 minutes on 3 days of the week (Eden et al., 2002).

Effectiveness of Counseling

Existing studies on physical activity counseling are inadequate to determine the overall efficacy, effectiveness, and feasibility of counseling in a primary care setting. Combining provider counseling with behavioral interventions such as patient goal setting, written exercise prescriptions, and individually tailored physical activity regimens may be the most effective way to change physical activity levels and warrants more research. Linking patients to community-based physical activity and fitness programs may enhance the effectiveness of primary care clinician counseling (Eden et al., 2002).

Recommendation

The USPSTF (2002) states that the evidence is insufficient to recommend for or against behavioral counseling in primary care settings to promote physical activity. Organizations that include the AAFP, U.S. Department of Health and Human Services (*Healthy People 2010*), CDC, AAP, American Heart Association (AHA), and ACOG recommend that health care providers counsel all individuals about physical activity. These recommendations are based on the known health benefits of physical activity rather than on the effectiveness of counseling for promoting changes in physical activity (Eden et al., 2002).

Hormone therapy for the prevention of chronic conditions in postmenopausal women is discussed online at www.expertconsult.com.

Special Populations

Preventive Services for Children and Adolescents

Challenges in Evidence-Based Prevention

Prevention plays a critical role in all age groups. From a theoretic and practical perspective, however, greater emphasis should be placed on prevention in the earlier years because

the potential benefit is greater. As people age, chronic diseases develop, and a greater proportion of health care becomes dedicated to disease management. Because prevention is most beneficial in the younger years, one would expect that the preventive services provided to children are supported by a strong evidence base. On the contrary, there is a relatively large evidence base for determining beneficial preventive services for adults, but aside from immunizations, the evidence base for childhood services is generally much more limited (Moyer and Butler, 2004).

Reasons for this lack of evidence base include length of follow-up required to realize reduction in disease outcomes, historical adoption and therefore standardization of many childhood preventive services, ethical considerations of not offering a potentially beneficial preventive service to children, methodologic challenges in determining developmentally appropriate outcomes in children, and the paradigm that knowledge alone represents a beneficial health outcome for families.

These evidence gaps in prevention highlight the challenge of child research rather than invalidate the importance of prevention in children. The message must be made clear to physicians, parents, and children—prevention is important at all ages. Several categories of preventive services are relevant to children: immunizations, counseling and anticipatory guidance, screening tests, and preventive medications. Chapters 22, 23, and 24 discuss care for children, including preventive services.

Immunizations

Immunizations, or vaccinations, usually are injections (oral in the case of the oral polio vaccine) that, when administered to an individual, elicit an immune response that protects the individual against the pathogen when future exposure occurs. Childhood is a particularly important time for immunizations because young children are still naïve to many viruses and bacteria, presenting an opportunity for primary prevention of disease.

The CDC National Immunization Program has an Advisory Committee on Immunization Practices (ACIP) that meets regularly and annually releases a Childhood and Adolescent Immunization Schedule (www.cdc.gov/vaccines/) (CDC, 2009). A catch-up schedule is available for children who have missed previous immunizations. The ACIP, AAP, and AAFP also release the annual Harmonized Childhood and Adolescent Immunization Schedule, which has been endorsed by the three organizations. Periodic preventive care visits by family physicians provide opportunities for administration of these immunizations.

Counseling and Anticipatory Guidance

Anticipatory guidance appropriately targeted to a child's developmental stage is a critical component of preventive care. Also, although good-quality evidence supporting the efficacy of most anticipatory guidance is limited, the standard of care is to provide such advice and counseling for parents (Moyer and Butler, 2004). Anticipatory guidance involves counseling caregivers to prepare for future normal child growth and development and to prepare caregivers for how these changes may need to be accommodated to promote

development and to prevent injury or harm. Examples of anticipatory guidance include providing counseling to caregivers about various safety issues (e.g., use of infant and child car seats, bicycle helmets, water safety, poisoning prevention, childproofing the home), nutrition, appropriate dental care, and physical activity. Injury prevention is particularly important because unintentional injury is the leading cause of death for children and adolescents. In children 1 to 14 years old, the three leading causes of injury-related death are motor vehicle crashes, drowning, and fire.

Bright Futures (<http://brightfutures.aap.org/web>) is a well-known, frequently implemented example of a program that includes health supervision and anticipatory guidance dedicated to well-child care and prevention. The Bright Futures program was begun by the Maternal and Child Health Bureau (MCHB) of the federal government and is endorsed by the AAFP and AAP.

Preventive care of adolescents emphasizes anticipatory guidance and counseling. Important topics to discuss include sexual activity; alcohol, tobacco, and drug use; healthy eating and physical activity; injury prevention; and mental health. The evidence of the benefits of screening and counseling for these conditions in adolescence is not clear. The clinician must also ensure that immunizations are delivered to the adolescent according to the recommended schedule. Vaccination against hepatitis B should be administered if it was not given during infancy, and boosters for varicella; measles, mumps, rubella (MMR); tetanus, diphtheria, and pertussis are given as determined by the schedule. Adolescents, especially college students, are at increased risk for meningococcal meningitis. The risks of disease and the risks and benefits of immunization should be discussed with prospective college students.

Screening tests for infants and children are discussed online at www.expertconsult.com.

Preventive Medications

Preventive medications provide primary prevention of disease to average-risk or high-risk children. Preventive medications in childhood include fluoride for children with inadequately fluoridated drinking water and iron supplementation between ages 6 and 12 months for infants at high risk for iron deficiency anemia. Some preventive medications may be used in children with chronic diseases to prevent disease symptoms, progression, or complications; however, these medications may be considered disease management (i.e., tertiary prevention) rather than primary or secondary prevention.

Preventive Services for Pregnant Women

Preconception counseling and prenatal care largely focus on strategies to prevent or detect potential complications for the pregnant woman, fetus, and newborn. Routine preconception counseling may include risk assessment based on family history, counseling about use of folic acid for the prevention of neural tube defects, and counseling about the harms of smoking, alcohol use, and certain foods (e.g., fish with high levels of mercury) and drugs (prescription and illicit) on pregnancy outcomes.

Prenatal care includes screening tests, counseling, preventive medications, and immunizations. Screening laboratory tests include a complete blood cell count, blood type, Rh sensitivity, urinalysis for bacteriuria, screening for several STIs (e.g., syphilis, HIV, hepatitis B, gonorrhea [high risk], *Chlamydia* [high risk]), screening for neural tube defects, gestational diabetes mellitus, and group B streptococci (Kirkham et al., 2005).

Counseling is often anticipatory guidance for the upcoming stages of pregnancy, delivery, and the postpartum period. Counseling for breastfeeding is a key preventive component to prenatal care, as is the use of prenatal vitamins and influenza vaccine administration. Chapter 21 discusses care of the pregnant patient, including prenatal preventive services.

Preventive Services for Older Adults

An emphasis on a shared decision-making approach is especially important when considering preventive services for older adults. Family physicians and their older patients should consider issues that contribute to the complexity of prevention in older adults, including unique goals of prevention, life expectancy, comorbidities, potential for harm, and patient values and preferences (Harris et al., 2001).

The patient's values and preferences are always important, and shared decision making should occur *before* the preventive service is provided. Preventive aspirin therapy in elderly persons provides an illustrative example of the need for shared decision making. There are few studies on the use of aspirin for the prevention of cardiovascular disease in older adults. Older adults are at especially high risk of cardiovascular disease but also at high risk of gastrointestinal bleeding from aspirin. Some older men may decide that avoiding a myocardial infarction is of great value, and that having a gastrointestinal bleeding event is not a major problem, and they would probably decide to take aspirin (USPSTF, 2009).

Specific preventive services that are of special interest for older adults include immunizations. The CDC recommends the zoster vaccine for all adults over age 60, pneumococcal vaccine for adults over 65, and influenza vaccine annually for adults over 50 (ACIP, 2009). Other preventive interventions of special importance target common causes of disease and disability and include multifactorial interventions for older adults that improve physical function, maintain independent living, and reduce falls (AGS, 2001; Beswick et al., 2008; Gillespie et al., 2006).

Counseling

Although the leading causes of death in the United States remain heart disease, cancer, and cerebrovascular disease (stroke), in their landmark paper *Actual Causes of Death in the United States*, McGinnis and Foege (1993) concluded that 50% of U.S. mortality is caused by 10 lifestyle-related behaviors, including tobacco use, poor dietary habits, lack of physical activity, alcohol misuse, illicit drug use, and risky sexual practices. In a 2004 update, Mokdad and colleagues found that more than one third of U.S. mortality in 2000 was linked to four behaviors: tobacco use, alcohol consumption, poor diet, and physical inactivity. Changing the health behaviors of Americans has the greatest potential impact of

any current approach for decreasing morbidity and mortality and for improving the quality of life across diverse populations (Whitlock et al., 2002).

A growing body of evidence demonstrates that brief interventions integrated into routine primary care can effectively address the most common and important health risk behaviors encountered in family medicine, including smoking cessation, healthy diet, regular physical activity, appropriate alcohol use, and responsible use of contraceptives. Simple, direct, and brief advice from the physician to change lifestyle habits has been shown to be effective in encouraging smoking cessation, reducing problem drinking, and modifying some cardiovascular risk factors associated with activity and diet (Whitlock et al., 2002). If 60% to 90% of practicing physicians regularly advised patients not to smoke, an additional 63,000 smokers would quit each year (Hollis, 2000). This approach works, and patients expect and want it. More than 95% of adults report that they expect their physicians to give them information about health behaviors and assistance in changing negative ones (Vogt et al., 1998). Not surprisingly, clinician advice has been associated with increased satisfaction with medical care.

Behavioral counseling interventions have expanded beyond the limits of one-on-one interactions between physicians and patients. Physicians' efforts are enhanced when the entire health care team takes appropriate and complementary roles in delivering interventions. For example, many components of successful interventions can take place outside the traditional physician-patient encounter. The patient can complete a health risk assessment while waiting to see the doctor; a trained staff member can do in-office counseling after the clinical encounter; a patient may be referred to a community-based program; and a follow-up visit or telephone call may be arranged. To emphasize the potential impact of a team approach, if a health care team member provides an additional 10 minutes of targeted assistance to one half of the patients who received brief advice on smoking cessation from the physician, the number of people expected to quit increases from 63,000 to 630,000 (Hollis, 2000). The use of additional resources, however, does not lessen the central importance of the clinician-patient relationship in promoting behavioral change. Effective clinician communication is essential in promoting behavior change.

Appreciating the impact of behavioral change interventions requires a broad population-based perspective. A family physician may become discouraged if only 5% to 14% of those receiving an intervention make clinically significant changes, such as quitting smoking. However, even modest effects result in tremendous benefits to the community when systematically applied to the large number of those in need. The potential for substantial public health benefit from office-based behavioral change interventions will be realized only when these interventions are applied broadly and regularly (see Chapter 7).

The "5As" Framework

In 2000, building on earlier work from the U.S. National Cancer Institute, the CTFPHC proposed a framework to guide physicians and health care systems in organizing their general approach to assisting patients with behavioral counseling interventions. In 2002, USPSTF adopted the

Table 6-6 The Five “A” Components of Behavior Counseling Interventions

Assess: Ask about or assess behavioral health risks and factors affecting choice of behavior change goals or methods.

Advise: Give clear, specific, and personalized behavior change advice, including information about personal health harms and benefits.

Agree: Collaboratively select appropriate treatment goals and methods based on the patient’s interest in and willingness to change the behavior.

Assist: Using behavior change techniques, aid the patient in achieving agreed-on goals by acquiring the skills, confidence, and social or environmental supports for behavior change, supplemented with adjunctive medical treatments when appropriate (e.g., pharmacotherapy for tobacco dependence, contraceptive drugs or devices).

Arrange: Schedule follow-up contacts (in person or by telephone) to provide ongoing assistance or support and to adjust the treatment plan as needed, including referral to more intensive or specialized treatment. Intervention to help patients change unhealthy behaviors often requires repetition over time.

Modified from Whitlock EP, Orleans CT, Pender N, Allan J. Evaluating primary care behavioral counseling interventions: an evidence-based approach. *Am J Prev Med* 2002;22:267-284.

framework, known as the “5As,” for evaluating the effectiveness of behavior counseling interventions (Table 6-6). The 5As framework is a powerful tool that can assist physicians in developing and evaluating their practice’s behavior change interventions. USPSTF offers guidance on the evidence base for behavior change interventions for many specific behaviors.

Assessing Behavior

Systematic routine behavior risk factor assessment is the foundation for proactive behavioral counseling interventions and identifies all those in need of assistance. For example, having a system in place to identify and document tobacco use triples the odds of clinician intervention (Fiore et al., 2008). Assessment tools should be brief, easy to complete, and easily scored or interpreted. Assessment may range from a single focused question asked as part of taking the vital signs (e.g., Have you used tobacco products at all in the past 7 days?) to comprehensive tools known as health risk appraisals (HRAs). HRAs may be mailed or e-mailed to patients in advance of their appointments. Some are available for completion or scoring by computer; others are available on the Internet (e.g., HowYourHealth.org, MyHealthyLiving.net).

Advising the Patient

Physicians are influential catalysts for patient behavior change. By providing explicit health behavior advice, physicians establish that lifestyle changes are an important part of health care and motivate patients to change. Advice is most powerful when personalized and linked to a patient’s own concerns, experiences, or values. A warm, empathetic, and nonjudgmental style engenders cooperation and less resistance. By qualifying advice with remarks such as, “As your

physician, I feel I should tell you that . . .,” the physician conveys respect for and avoids undermining patient autonomy (Whitlock et al., 2002). Placing confidence in the patient’s ability to change and acknowledging past successes build patient’s self-efficacy. Advice messages should not be lectures and should be delivered in 30 to 60 seconds.

Agreeing with the Patient

Only when the patient and physician agree that change is desired should goals and options be explored. Assessing the patient’s motivation to change may be useful at this point, because appropriate interventions for those who are ready to change and for those who are not are likely to differ. For people with multiple behavioral risks, agreement is needed about which behavior change to focus on first. Physicians should partner with patients in considering the potential interventions. When patients are actively involved in making health care decisions, their choices are based on realistic expectations and are aligned with their own values.

Additional Assistance

Additional assistance within or outside the patient visit is likely to produce better outcomes than advice-only treatment. Busy clinicians, however, often do not have time to provide more than brief counseling (1-3 minutes). Behavior change interventions should incorporate additional team members and linkage to community resources. Many health systems use dietitians, nurse care managers, social workers, and trained medical assistants to provide assistance to patients as part of behavior change interventions. Assistance may take the form of additional behavior-specific counseling, general patient motivation and activation, or referral to a community resource. In addition to traditional print materials, interactive computer and web-based programs that assist behavior change are becoming available.

Arranging Follow-up

Behavior change requires follow-up. The physician may simply inform the patient of plans to follow up at their next regularly scheduled visit, making a note in the chart. Usually, however, initial follow-up should be scheduled within a relatively short period. Depending on the change being undertaken, follow-up may consist of a phone call a few days after a scheduled quit date, an e-mail inquiring about progress, or an in-office visit. After the initial follow-up, future contacts may often be spaced at successively longer intervals.

Theories and Models of Behavior Change

Behavior change theories and models can help physicians conceptualize the complex context in which individual behavior change occurs and the variability among patients’ acceptance of behavior counseling interventions (Table 6-7). Insights gained from applying the models may help clinicians clarify barriers and opportunities when working with a given individual and customize an intervention based on an individual’s needs, such as determining which patients may respond best to a more intensive intervention.

Table 6-7 Theories and Models of Individual Behavior Change

| Theory or Model | Focus | Key Concepts |
|---|--|---|
| Health belief model | Peoples' perceptions of the threat of a health problem and appraisal of the behavior recommended to prevent or manage the problem. | Perceived susceptibility Perceived severity Perceived benefits of action Perceived barriers to action Cues to action Self-efficacy |
| Theory of reasoned action, theory of planned behavior | People are rational beings whose intention to perform a behavior is strongly related to its actual performance through beliefs, attitudes, subjective norms, and perceived behavioral control. | Behavioral intention Subjective norms Attitudes Perceived behavioral control |
| Stages of change, transtheoretical model | Readiness to change or attempt to change a health behavior varies among individuals and within an individual over time. Relapse is a common occurrence and part of the normal process of change. | Precontemplation Contemplation Preparation Action Maintenance Relapse |
| Social cognitive theory, social learning theory | Behavior is explained by dynamic interaction among personal factors, environmental influences, and behavior. | Observational learning Reciprocal determinism Outcome expectancy Behavioral capacity Self-efficacy Reinforcement |

Modified from Whitlock EP, Orleans CT, Pender N, Allan J. Evaluating primary care behavioral counseling interventions: an evidence-based approach. *Am J Prev Med* 2002;22:267-284.

Most behavior change theories focus on the diverse, interacting levels of influence on an individual's behavior. For example, the stages of change (transtheoretical) model emphasizes that change is an ongoing process with multiple stages that often include relapse and recycling into new efforts to change. The concept of self-efficacy stresses that individual behavioral change requires the belief that change is needed and possible. Many theories recognize the dynamic interaction between intrapersonal, interpersonal, and environmental issues, including factors such as age, race, ethnicity, and socioeconomic status.

Systems Change

Family Physicians within the Health Care System

Family physicians are responsible for providing care for acute illnesses and chronic conditions. They also provide preventive services, including screening, immunizations, and

behavioral counseling. In the disease-based model of health care, preventive care is often viewed as a competing demand. Americans, however, made more than 480 million visits in 2002 to their primary care physicians. As a trusted and well-used source of information and care, the family physician has a tremendous opportunity to improve the health of individual patients and entire communities through the provision of preventive services.

The good news is that family physicians, despite limited face-to-face time with patients, already spend a significant amount of time promoting health behaviors. One large study found that physicians addressed health behaviors during one half of all visits, spending on average more than 10% of the visit promoting health (Stange et al., 2002).

Further improvements in the provision of preventive services require more than improving clinician knowledge and attitude. Improving the quality, delivery, and effectiveness of prevention in primary care office practice requires changes in the office system. The family physician and other primary care clinicians must be integrated into a larger health care delivery team.

Using the 5As Model in a System

Of the five steps in the 5As model (assess, advise, agree, assist, and arrange), the family physician is likely to be most effective when charged with focusing on the advise and agree steps. The staff member who triages the patient may be assigned the responsibility of administering a brief health risk assessment or reviewing a flow sheet of preventive services and noting on the chart if the patient is due for an immunization or screening test. During the visit, the prompted physician can advise the patient to be more physically active and explore the patient's motivation to change or recommend a flu shot or cholesterol test. Most importantly, other members of the health care team can assist patients in learning additional information, acquiring new skills, choosing between options, and creating a personalized action plan. Team members, including nurses, medical assistants, social workers, and care managers, can link patients to resources in the community to support health behavior change and arrange follow-up (see Chapter 2).

The Chronic Care Model

The chronic care model (CCM) has been proposed as a useful framework for considering the system changes necessary to construct a health care system that proactively promotes healthy behaviors and trains clinician and patients to work as partners in a collaborative care process (Glasgow et al., 2001) (Figure 6-3). The CCM identifies six essential elements of a health care system that together foster interactions between an informed, activated patient and a prepared, proactive health care team. The model defines six broad dimensions that must be considered when redesigning systems of care: organization of care, clinical information systems, delivery-system design, decision support, self-management support, and community resources (Wagner, 1998). As a model, the CCM does not provide a specific set of interventions; instead, it acts as a framework within

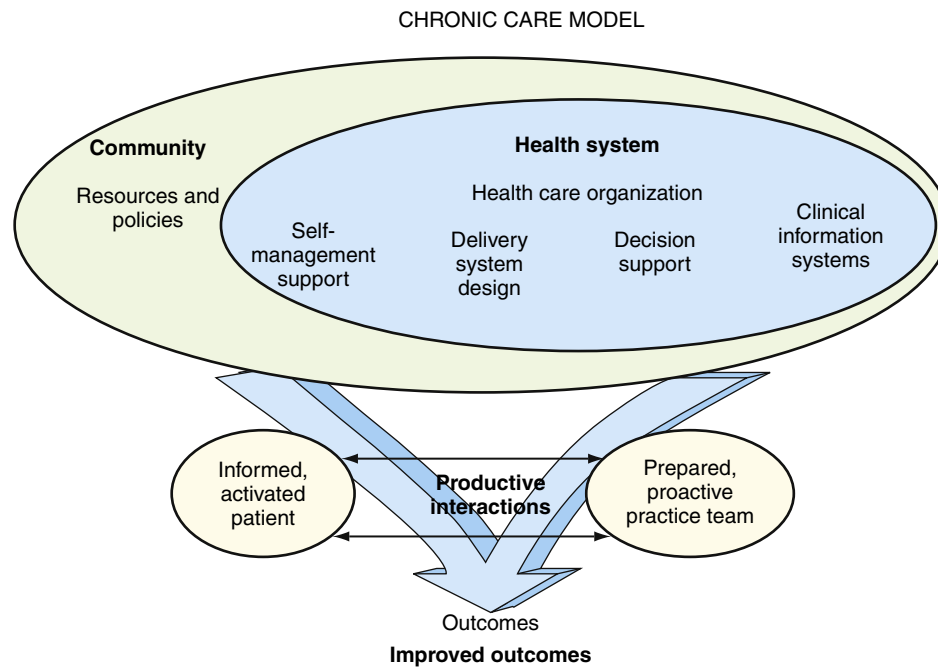

Figure 6-3 The chronic care model. (Modified from Wagner EH. *Chronic disease management: what will it take to improve chronic illness?* *Effect Clin Pract* 1998;1:2-4.)

which improvement strategies can be tailored to local conditions.

In an individual office, the application of the CCM toward improving the quality of preventive services may lead to any of the following:

- Developing a patient registry for child and adult immunizations (i.e., clinical information system).
- Implementing standing orders that all patients with diabetes receive a home glucose monitor and meet with a nurse educator (i.e., delivery system design).
- Referring all prenatal patients to a local La Leche League meeting (i.e., community resources).
- Designing a prompt to cue physicians to schedule a mammogram (i.e., decision support).
- Integrating achievement of prevention goals into physician performance bonuses (i.e., health system organization).
- Training physicians to use the techniques of motivational interviewing to set goals in collaboration with patients and identify personal barriers and supports after advising smokers to quit (i.e., self-management support).

Rethinking the Periodic Health Examination

Although the periodic health examination means many things to many people, most agree that it refers to a patient encounter focusing on health maintenance and disease prevention. Exactly which preventive services should be offered during such a periodic examination varies in practice; however, the services discussed in this chapter have been shown to improve patient-oriented health outcomes. Many of these services may be provided during regular office visits and in the context of a periodic health maintenance visit. Batteries

of tests (e.g., screening laboratory tests, ECGs) and general head-to-toe physical examinations often performed during preventive periodic health examinations (e.g., heart and lung auscultation, abdominal palpation) are not effective as general screening strategies in the general population. Instead, a customized preventive service package is most useful.

Conclusions

Preventive services should be tailored according to the individual patient's risk factors, preferences, and comorbid diseases. Although no "one size fits all" prevention plan can work for everyone, the following tenets remain true:

1. Prevention can lead to major health benefits, but all prevention attempts are not necessarily beneficial, and some services may be harmful.
2. Evidence for preventive service effectiveness can be used to prioritize preventive services for average-risk and high-risk patients in a family physician's practice.
3. Systems approaches using team models for provision of services, reminder systems, and electronic health records are critical to improving the use of evidence-based preventive services.
4. Counseling is a key component in prevention and requires health professionals trained in counseling modalities.

Providing evidence-based preventive services, including immunizations, screening tests, and behavior change interventions, is possible with planning, teamwork, and practice redesign.

EVIDENCE-BASED SUMMARY

The U.S. Preventive Services Task Force (USPSTF) grades its recommendations according to one of five classifications (A, B, C, D, I), reflecting the strength of evidence and magnitude of net benefit (benefits minus harms):

| GRADE | DEFINITION | SUGGESTIONS FOR PRACTICE |
|--------------------|--|---|
| A | USPSTF recommends the service. There is high certainty that the net benefit is substantial. | Offer or provide this service. |
| B | USPSTF recommends the service. There is high certainty that the net benefit is moderate, or there is moderate certainty that the net benefit is moderate to substantial. | Offer or provide this service. |
| C | USPSTF recommends against routinely providing the service. There may be considerations that support providing the service in an individual patient. There is at least moderate certainty that the net benefit is small. | Offer or provide this service only if other considerations support the offering or providing the service in an individual patient. |
| D | USPSTF recommends against the service. There is moderate or high certainty that the service has no net benefit or that the harms outweigh the benefits. | Discourage the use of this service. |
| I Statement | USPSTF concludes that the current evidence is insufficient to assess the balance of benefits and harms of the service. Evidence is lacking, of poor quality, or conflicting, and the balance of benefits and harms cannot be determined. | Read the clinical considerations section of USPSTF Recommendation Statement. If the service is offered, patients should understand the uncertainty about the balance of benefits and harms. |

From U.S. Preventive Services Task Force Table of Recommended Preventive Services for 2001 to April 2009.

USPSTF CATEGORY A AND B RECOMMENDATIONS

| SERVICE | POPULATION | COMMENTS |
|--|---|---|
| Screening for abdominal aortic aneurysm | Ever-smoking men ages 65-75 years: B | Never-smoking men ages 65-75: C Women: D |
| Screening for alcohol misuse | Adults: B | Adolescents: I |
| Aspirin for primary prevention of cardiovascular events | Men age 45-79 to prevent myocardial infarction (MI): A Women age 55-79 to prevent stroke: A | Men younger than 45 to prevent MI: D Women younger than 55 to prevent stroke: D Men and women 80+ to prevent cardiovascular disease: I |
| Screening for asymptomatic bacteriuria | Pregnant women: A | Nonpregnant women and men: D |
| Discussion of chemoprevention of breast cancer | Women at increased risk of breast cancer and decreased risk of adverse events: B | Women not at increased risk of breast cancer: D |
| Genetic risk assessment and BRCA mutation testing for breast and ovarian cancer susceptibility | Women whose family history is associated with increased risk for deleterious mutations in <i>BRCA1</i> or <i>BRCA2</i> genes: B | Women whose family history is not associated with increased risk for deleterious mutations in <i>BRCA1</i> or <i>BRCA2</i> gene: D |
| Screening for breast cancer with mammography | Women age 50+: B | Women 40-49: C Screening with clinical breast exam: I Breast self-exam: D |
| Counseling to promote breast-feeding | Interventions during pregnancy and after birth to promote and support breastfeeding: B | No subgroups |
| Screening for cervical cancer with Pap smear | Women younger than age 65 who are sexually active and have a cervix: A | Women over 65 who have had previous negative screens: D Women who have had total hysterectomy for benign disease: D Screening with new technologies: I Screening with HPV: I |
| Screening for <i>Chlamydia</i> | Sexually active nonpregnant women ≤ 24 and older nonpregnant women who are at increased risk: A Pregnant women < 24 and older pregnant women who are at increased risk: B | Pregnant women ≤ 24 and older pregnant women who are at increased risk: B Women ≥ 25 and older, whether or not they are pregnant, if they are not at increased risk: C Men: I Sexually active nonpregnant women < 24 and older nonpregnant women who are at increased risk: A Women > 25 , whether or not they are pregnant, if they are not at increased risk: C |

| SERVICE | POPULATION | COMMENTS |
|--|---|---|
| Screening for colorectal cancer | Adults age 50-75: A | Adults 76-85: C Adults 85+: D Computed tomography colonography and fecal DNA testing as screening modalities for colorectal cancer: I |
| Screening for congenital hypothyroidism in newborns | Newborns: A | No subgroups |
| Prevention of dental caries | Preschool children, using oral fluoride supplementation in specific areas whose water is deficient in fluoride: B | Preschool children, using risk assessment: I |
| Screening for depression in adults | Adults within a system of care: B | No subgroups |
| Screening for depression in children and adolescents | Adolescents age 12-18: B | Children and adolescents age 7-11: I |
| Screening for type 2 diabetes | Adults with hypertension or dyslipidemia: B | Adults without hypertension or dyslipidemia: I |
| Intensive behavioral dietary counseling | Adults with hyperlipidemia or other risk factors for CVD: B | Routine behavioral counseling to promote a healthy diet: I |
| Folic acid supplementation | All women planning or capable of pregnancy: A | No subgroups |
| Screening for gonorrhea | Newborns: A Sexually active women, including those who are pregnant if they are at high risk: B | Men and women at low risk: D Men at high risk: I Pregnant women not at high risk: I |
| Screening for hepatitis: B | Pregnant women: A | General nonpregnant population: D |
| Screening for human immunodeficiency virus (HIV) | All adolescents and adults at increased risk: A All pregnant women: A | All adolescents and adults not at increased risk: C |
| Screening for hypertension | Adults ages 18+: A | No subgroups |
| Screening children and pregnant women for iron deficiency anemia | Asymptomatic pregnant women: B | Asymptomatic children age 6-12 months: I |
| Iron supplementation for children and pregnant women | Asymptomatic children age 6-12 months who are at increased risk: B | Asymptomatic children age 6-12 months who are at average risk: I Nonanemic pregnant women: I |
| Screening for lipid disorders in adults | Men 35+: A Women 45+: A Men 20-35: B Women 20-45: B | Men age 20-35 and women age 20-45 with no risk factors: C |
| Screening for newborn hearing | Hearing loss in newborns: B | No subgroups |
| Screening for obesity with intensive counseling and behavioral interventions | Adults: B Children >6 years old: B | Screening with low- to moderate-intensity counseling: I Counseling for overweight, not obese: I |
| Screening for osteoporosis | Women age 65+ and younger women with risk factors: B | Men: I |
| Screening for phenylketonuria in newborns | Newborns: A | No subgroups |
| Behavioral counseling to prevent sexually transmitted infections (STIs) | Sexually active adolescents and adults at increased risk for STIs: B | Non-sexually active adolescents and adults not at increased risk: I |
| Screening for sickle cell disease | Newborns: A | No subgroups |
| Screening for syphilis in pregnant women | All pregnant women and all persons at risk: A | All persons not at risk: D |
| Screen for tobacco use and provide tobacco cessation interventions | Adults: A Pregnant women: A | Screening for tobacco use or interventions to prevent or treat tobacco use among adolescents and children: I |
| Visual impairment to detect amblyopia, strabismus, visual field defect | Children younger than 5 years old: B | No subgroups |

HPV, Human papillomavirus; CVD, Cardiovascular disease.

USPSTF CATEGORY D RECOMMENDATIONS: PREVENTIVE SERVICES NOT RECOMMENDED IN GENERAL POPULATION

| SERVICE | POPULATION | COMMENTS |
|--|---|--|
| Screening for abdominal aortic aneurysm | Women: D | Ever-smoking men age 65-75: B Never-smoking men age 65-75: C |
| Aspirin for primary prevention of cardiovascular events | Men younger than 45 to prevent myocardial infarction (MI): D Women younger than 55 to prevent stroke: D | Men age 45-79 to prevent MI: A Women age 55-79 to prevent stroke: A Men and women 80+ to prevent cardiovascular disease: I |
| Aspirin/NSAIDs to prevent colorectal cancer | Adults at average risk: D | No subgroups |
| Screening for bacterial vaginosis | Pregnant women at low risk for preterm delivery: D | Pregnant women at high risk for preterm delivery: I |
| Screening for asymptomatic bacteriuria | Men and nonpregnant women: D | Pregnant women: A |
| Beta-carotene supplements | Adults: D | Supplemental vitamins A, C, and E or folic acid or antioxidant combinations: I |

Key Points

- The two highest-yield strategies for prevention of chronic disease and death are (1) a routine annual cardiac risk assessment strategy for all adults, with intervention graded to level of risk, and (2) a strategy of primary prevention.
- The optimal strategy for the prevention of heart disease requires routine global cardiac risk assessment.
- A strategy of global cardiac risk assessment, with appropriate intervention graded to level of risk, closely approximates the effects of a primary prevention strategy.

In the hectic pace of modern family medicine, we may forget what first motivated us to become physicians. For many, it was an urge to do service, first by helping others live longer and healthier lives, then by comforting the sick and dying when we had nothing else to offer. This task often evolves into a tension between mastering the skills needed to treat illness and learning the strategies to prevent illness. Up to the present, the major emphasis in the training of primary care physicians has been on the treatment of disease.

This chapter approaches the problem of prevention from each of these perspectives: how to carry out effective prevention (1) from the traditional disease-oriented approach and (2) from a newer, general lifestyle approach. This discussion attempts to answer four practical and important questions for family physicians, as follows:

1. What is a healthy lifestyle?
2. What is the prevalence of a healthy lifestyle among patients?
3. What are the potential benefits for patients who have or who change to a healthy lifestyle?
4. What is the major obstacle to lifestyle changes in a family physician's office?

Prevention from the Disease-Oriented Perspective: A Focus on Heart Disease

To be effective, family physicians need to reduce mortality—from all causes, not just heart disease or stroke—for all their patients. Using the total number of deaths is the relevant measure of effectiveness for two reasons. First, it is simple, cleaner, and easier to measure; a person is either alive or dead. Second, the count is not affected by diagnostic error. The literature reviewed here focuses especially on *all-cause mortality* as a relevant measure of a healthy lifestyle.

In the United States the system for counting numbers of deaths is provided by the Centers for Disease Control and Prevention (CDC) through its Wisqars database. Simply type the search term `leadcaus.html` into Google, and the database will be the first link to appear. The variables for gender, age, ethnicity, and U.S. region can be changed to best fit where you are working.

The leading causes of death for all adults age 50 to 85 are listed in [Table 7-1](#). A look at this list can provide a guide to action for your practice. If the number-one cause of death is heart disease, this may be the problem to address most vigorously, perhaps delaying other preventive activities until this is done. Alternatively, some might argue for a focus on cancer, because mortality from cancer is almost as high as from heart disease (and even higher in the age group 50-59), and cancer causes much more concern among patients.

However, good reasons exist not to focus on cancer. The first problem is that "cancer," when listed as the second leading cause of death in the United States, represents deaths from "all cancers." The disadvantage is that physicians have no good tools or tests that work against "all" cancers; the single exception is discussed later. Many mammograms are needed for breast cancer, many sigmoidoscopies or colonoscopies

Table 7-1 Ten Leading Causes of Death—United States, 2006*

| Rank | Cause | Number |
|------|----------------------|---------|
| 1 | Heart disease | 598,747 |
| 2 | Cancer (all types) | 520,129 |
| 3 | Stroke | 131,312 |
| 4 | Chronic lung disease | 121,824 |
| 5 | Alzheimer's disease | 72,388 |
| 6 | Diabetes mellitus | 67,295 |
| 7 | Accidents | 57,089 |
| 8 | Pneumonia and flu | 53,676 |
| 9 | Chronic nephritis | 42,123 |
| 10 | Septicemia | 31,594 |

Data from <http://webapp.cdc.gov/sasweb/ncipc/leadcaus.html>.
 *All races, both genders; age groups: 50 to 85+.

for colon cancer, and many Pap smears for cervical cancer, to follow the conventional wisdom about how to reduce the effects of these cancers.

Such a strategy is only moderately effective. The risks of dying of breast cancer can be reduced by only 15% in the 3% of women who develop it in any decade after age 50 (Fletcher and Elmore, 2003). The risk of dying of colon cancer (incidence from 57 to about 320 for both genders ages 50-80 [Eddy, 1990]) can be reduced by only 16%. The single best strategy for reducing deaths from a cancer is cervical cancer screening; cervical cancer deaths can be reduced for the seven or eight invasive cervical cancers that occur annually per 10,000 population by 30% to 60% (Agency for Healthcare Research and Quality [AHRQ], U.S. Preventive Services Task Force [USPSTF], 2009).

Because these cancers are relatively rare, however, and because the tools are relatively inefficient, a cancer-focused approach to reducing overall mortality tends not to work. In fact, a 2002 review of cancer screening concluded that there is no evidence that cancer screening, as currently conducted, results in reductions of all-cause mortality (Black et al., 2002). Thus, even perfect compliance for all the traditionally recommended cancer programs may dramatically reduce a person's risk of dying of cancer, but it would not add a single day of life to this person's life span. Table 7-2 illustrates the failure of most cancer screening programs, even when they have a significant impact on the target cancer, to alter the ultimate bottom line: all-cause mortality.

Physicians are familiar with measuring the effectiveness of screening in terms of *relative risk* reductions. The most dramatic numbers relating to personal medical efficacy pertain to the interventions proven to work for established coronary artery disease (CAD), called *secondary prevention*. The most impressive numeric successes a good physician can achieve are the 20% to 40% reductions in heart disease events that result when persons with heart disease take statin medications regularly (4S Study, 1994; Heart Protection Study, 2002; Sheperd et al., 1994), or when patients who have had

a heart attack use a beta-adrenergic blocker after their heart attack, which reduces the risk of recurrent myocardial infarction by 22% (Yusuf et al., 1988).

Secondary prevention is often preferable to physicians because benefits of *large effect size* can be seen after relatively short periods of intervention (only a few years). Physicians who focus on cancer prevention need to wait for 20 to 40 years to know how well the program worked. For example, Pap smears are recommended from age 21 to age 65 at about 3-year intervals; colon cancer screening is recommended annually from ages 50 to 75; and breast cancer screening typically from ages 40 to 85. The published data on efficacy refer to the entire lifetime of the screening program, so it takes a long time to see the benefit of what physicians do.

A short list of the most important interventions, those with large effect size in secondary prevention, are also summarized in Table 7-2. Physicians preferring the disease treatment model for medicine who want to believe their work is important and measurably effective should select at least one strategy from this table.

The prevention of heart disease, both primary and secondary, should be the first priority for primary care physicians. The critical question is how to do this. Most physicians focus on obvious risk factors, such as smoking, hypercholesterolemia, and diabetes. These same physicians are usually surprised to discover the evidence indicates that physicians who rely on a subjective "gestalt" for risk assessment usually make significant errors (Grover et al., 1994; Volpe et al., 2004). When physicians assess clinical coronary risk based on the major cardiac risk factors, they systematically tend to overtreat modest to severe elevations of a single risk factor, even when the global cardiac risk is quite low. Similarly, if they do only subjective risk factor assessment, physicians fail to offer treatment to many patients at high global cardiac risk merely because they lack any major risk factors or have only a mild abnormality of a few risks. A common example of misdirected treatment is prescribing a statin for a 40-year-old woman with a cholesterol level of 300 mg/dL but no other risk factors; according to the Framingham equation, she has a 10-year risk of a cardiac event of 2%, which is average for her age. To treat patients appropriately, the clinician must use one of the global risk calculators mentioned later.

Why focus on *global* cardiac risk? Leading national and specialty-based expert groups have endorsed this as the most important parameter for addressing cardiac health (Grundy et al., 1999). The Adult Treatment Panel Report (ATP II) of the National Cholesterol Education Program (NCEP), the Joint National Committee of the National High Blood Pressure Education Program, and the American Diabetes Association (ADA) all advocate "adjusting the intensity of risk factor management to the global risk of the patient." The NCEP Expert Panel on Detection, Evaluation, and Treatment of High Blood Cholesterol in Adults (ATP III, 2001) stated specifically, "A basic principle of prevention is that the intensity of risk-reduction therapy should be adjusted to a person's absolute risk. Hence, the first step in selection of LDL-lowering therapy is to assess a person's risk status. . . . In ATP III, a primary aim is to match intensity of LDL-lowering therapy with absolute risk." Hypertension experts John Laragh, Bruce Psaty, and Curt Furberg have directly

Table 7-2 Comparison of Disease-Specific Mortality and All-Cause Mortality Associated with Traditional Cancer and Cardiovascular Prevention Strategies

| Intervention | Change in Disease-Specific Mortality* | Change in All-Cause Mortality† |
|--|--|--------------------------------|
| Primary Prevention | | |
| Pap smears | Cervical cancer: 20%-60% reduction after 17 or more Pap smears | 0 |
| Fecal occult blood testing (FOBT) Sigmoidoscopy Colonoscopy Digital rectal examination (DRE) | Colorectal cancer: 15% reduction after 20 or more FOBTs plus follow-up colonoscopy in patients with positive results | 0 |
| Mammography: 40-50 years Mammography: >50 years | Breast cancer: 16% reduction after 20 mammograms | 0 |
| Prostate-specific antigen (PSA) testing DRE | Prostate cancer: 0% reduction after 25 PSA tests | 0 |
| DRE, breast self-examination (BSE), physical examination | 0% reduction after 40 years | 0 |
| Statins (AFCAPS/TextCAPS Study)‡ | 37% reduction in combined myocardial infarction, unstable angina, and stroke | 0 |
| Eight major lifestyle studies (see Tables 7-3 and 7-4): chronic disease and death | 35%-83% reductions in coronary events 50%-71% reduction in stroke events 58%-93% reduction in onset of diabetes 36%-68% reduction in cancer deaths | 40%-65% |
| Secondary Prevention | | |
| 4S Simvastatin Study [§] | 34% reduction in major coronary events 42% reduction in coronary mortality in patients with heart disease | 30% |
| West of Scotland Coronary Prevention Study (WOSCOPS) [¶] | Statins reduced coronary events by 31% and cardiovascular specific mortality by 32%. | 0 |
| The MRC/BHF Heart Protection Study [¶] | 25% reduction in first-event rate for nonfatal myocardial infarction or coronary death, fatal or nonfatal stroke, and for coronary revascularization with 40-mg simvastatin in high-risk patients over 5 years in 20,536 U.K. adults age 40-80 years | 12.9% |
| Beta blockers after myocardial infarction [#] | 27% reduction of nonfatal infarction in 25 randomized trials (>23,000 patients) | 22% |

endorsed explicit global cardiac risk assessment as the new standard of care:

Most current guidelines focus primarily on the management of individual cardiovascular risk factors, such as high blood pressure, hypercholesterolemia, or diabetes. A more appropriate clinical approach to reducing cardiovascular disease risk would be based on a comprehensive evaluation of risk profile, and

accurate stratification of global (absolute) risk in individual patients. . . . The decision to treat a patient should be based on the level of global risk, rather than on the level of a single risk factor. . . . We proposed that global risk should be used as the main determination of whom to treat, how to treat, and how much to treat. . . . We propose to replace the single risk factor-based approach with the assessment of global

cardiovascular risk, both in the clinical management of individual patients and in guidelines. (Volpe et al., 2004)

Once the importance of carrying out some form of global cardiac risk assessment is accepted, a physician need only choose a method and use it consistently. A basic quality-of-care goal process standard would be to use the method of CAD risk assessment systematically for at least 85% of all adult patients over 85% of all years. There are many ways to carry out cardiac risk assessment—from the Framingham tables and equation (United States), by means of the NCEP ATP III risk calculator, to the Sheffield tables and the most recent technique, the QRISK calculator (United Kingdom) (Hippisley-Cox et al., 2008; Wallis et al., 1995). Many of these have been adapted for smart phones and personal digital assistants (PDAs) and are downloadable for free, so few major barriers to implementation exist, primarily time.

A time-efficient method that can be used in the office setting includes a preprinted list of the 10 major cardiac risk factors supported by the current literature. Consider making a list that can be incorporated into the patient's medical record, including the following:

- Age >55 (males); >65 (females)
- Male gender
- Family history of CAD
- Smoking
- Hypertension
- Diabetes
- Sedentary lifestyle
- Metabolic syndrome
- High cholesterol level
- Chronic renal insufficiency

Other considerations include major adverse life event and high perceived stress at work or home.

The purpose of this list is to classify all adults into one of three levels of risk: low, intermediate, or high. Where the dividing lines are drawn between categories is not as important as being *consistent*. In my practice, I consider up to three risk factors to be *low* risk, four to six factors to be *intermediate* risk, and more than six, *high* risk. This information (e.g., CAD Risk Score: “intermediate risk”) should go directly into the problem list so that the physician can see it each visit. The intervention itself is relatively inexpensive, requiring only 1 to 2 minutes of physician (or better, medical assistant) time and involving simple laboratory tests—lipid panel and serum creatinine. I define the “metabolic syndrome” as a triglyceride level greater than 150 mg/dL and high-density lipoprotein (HDL) level less than 40 mg/dL for men (or <50 for women), according to the Reaven (2003) criteria. A serum creatinine is obtained to estimate glomerular filtration rate (GFR) and identify the presence of chronic renal insufficiency.

For patients at *low* global cardiac risk, nothing more is required than usual care, which should include conversations about diet, exercise, not smoking, and stress reduction. For persons at either intermediate or high risk, more is required. The physician should systematically apply the best evidence for reducing cardiac risk. This is now a sophisticated and effective set of measures.

For patients at *high* risk, it would be worth having a discussion about the formal “polypill” approach (Wald and Law, 2003). This strategy recommends daily intake of folic acid,

a statin, aspirin (81 mg), along with half-doses of three different antihypertensives (hydrochlorothiazide, beta blocker, and ACE inhibitor). The proponents of this strategy claim that the polypill can reduce heart attacks and stroke (third leading cause of mortality) by more than 80% in both primary and secondary prevention. Although no reported randomized, controlled trials (RCTs) have yet proved this for primary prevention, one study showed major benefit in secondary prevention (Hippisley and Coupland, 2005), and more studies are under way.

All physicians should understand that the advances in conservative medical therapy for cardiovascular disease have kept pace and may well have outpaced the advances in the technology of heart disease (e.g., drug-eluted stents) with far fewer complications.

The power of global cardiac risk assessment lies in the synergies achieved with the simple medical interventions to address increased risk. Figure 7-1 illustrates how a single-intervention health promotion program using only “CAD Risk Assessment” and the appropriate conservative responses previously listed achieve multiple synergistic benefits across a large spectrum of diseases and the 10 leading causes of death.

The largest component of the previously described intervention program is basically the promotion of a healthy lifestyle. When applying the best evidence, it is impossible to prevent only heart disease. Appropriate interventions have a significant effect on almost all the 10 leading causes of death. Thus, even a single-minded focus on the prevention of just one disease (heart disease) inevitably leads to a broad focus on lifestyle behavioral changes.

Primary Prevention: A Focus on Lifestyle

Key Points

The five key elements of a healthy lifestyle are:

1. Not smoking.
2. Consuming 5 servings of fruits or vegetables each day.
3. Ten minutes of relaxation, silence, or meditation daily for stress reduction.
4. Maintaining BMI less than 30 kg/m² and working to bring it down toward 18.5 kg/m².
5. Exercising for at least 150 minutes a week (about 20 minutes daily), equivalent to at least brisk walking.

The five key elements may be simply communicated to patients by the numbers 0-5-10-30-150.

Only about 3% of the U.S. population has a healthy lifestyle as defined by criteria 1, 2, 4, and 5 above.

The potential benefits of a healthy lifestyle are:

- A 40% to 65% reduction in all-cause mortality.
- An 81% to 87% reduction in coronary heart disease events.
- A 67% reduction in all cardiovascular diseases.
- A 50% to 71% reduction in the risk of stroke.
- A 58% to 93% reduction in the risk of developing type 2 diabetes.
- A 36% to 60% reduction in cancer deaths.

A clinical practice may choose a broad, primary prevention approach rather than a single focus on prevention of coronary heart disease. Between 2000 and 2009, nine major

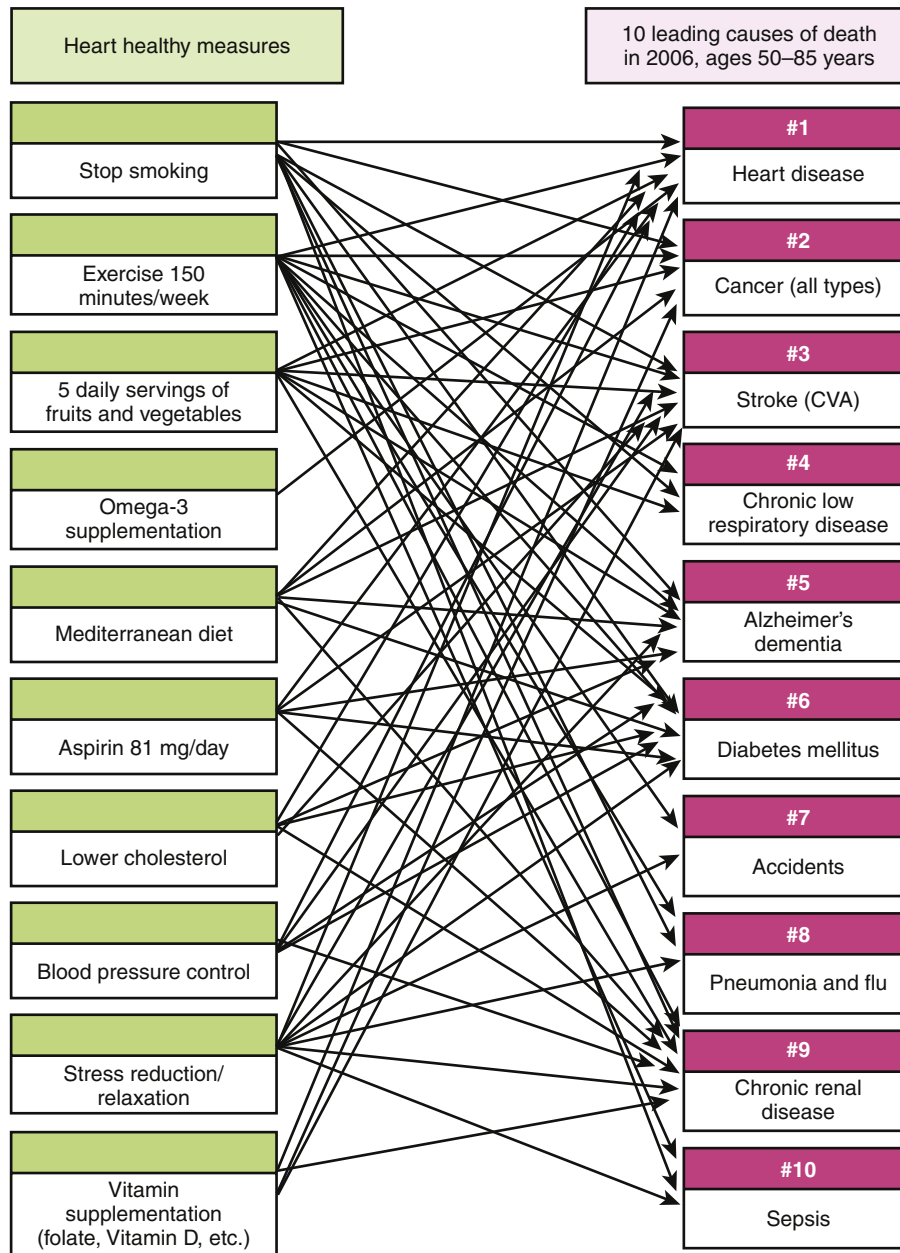

Figure 7-1 A single intervention with a simple, comprehensive medical approach to coronary risk has a significant impact on all 10 of the most common causes of death in the United States. A line is drawn from each of 10 potential cardiac risk interventions on the left side to all the causes of death that each intervention would also tend to reduce.

studies demonstrated that a healthy lifestyle is associated with large reductions in all-cause mortality and major reductions in multiple disease-specific outcomes. These studies succinctly define what should be understood by the term “healthy lifestyle.” These primary prevention studies demonstrate that persons who have a number of healthy characteristics at the beginning of a period of observation enjoy remarkable benefits over periods ranging from 4 to 20 years.

The evidence chain begins with the Nurses’ Health Study (Hu et al., 2001; Stampfer et al., 2000). In 84,129 participants followed up for 14 years, the effects of several lifestyle factors were analyzed, including not currently smoking, body mass index (BMI) less than 25 kg/m², alcohol consumption

at least 0.5 drinks per day, at least 0.5 hour daily of moderate to vigorous physical activity, and adhering to several dietary elements (increased intake of cereal fiber, marine omega-3 fatty acids, and folate; increased polyunsaturated/saturated fat ratio; and low *trans* fat intake and glycemic load). The group defined as “low risk” had all these characteristics. After 14 years, this low-risk group (3% of original study population) had an 83% reduction in coronary disease events. Another analysis of the same cohort showed that women at low risk also had a 91% reduction in the risk of developing diabetes.

In 2002 the Diabetes Prevention Program Research Group published the results of the only RCT among these lifestyle studies. This study focused solely on the outcome of type 2

diabetes among 3324 nondiabetic patients. The “standard” healthy lifestyle intervention consisted of written information provided at the beginning of the study and an annual 20- to 30- minute individual counseling session. The defined “standard” lifestyle goals included instructions to adhere to the U.S. Department of Agriculture (USDA) Food Guide Pyramid and the equivalent of an NCEP Step 1 diet; to reduce weight; and to increase physical activity. Subjects were randomized to standard lifestyle intervention plus metformin (875 mg twice daily), to standard lifestyle intervention plus placebo, or to “intensive” lifestyle intervention alone. The latter group was encouraged to achieve and maintain a weight reduction of at least 7% of initial body weight through a healthy low-calorie, low-fat diet and to engage in physical activity of moderate intensity, such as brisk walking, for at least 150 minutes per week. Subjects in this group also received a 16-lesson curriculum, taught by case managers on a one-to-one basis during the first 24 weeks after enrollment, with brief follow-up sessions monthly. After an average follow-up of only 2.8 years, the intensive lifestyle intervention was associated with a reduced incidence of diabetes (58% vs. 31% reduction with metformin, both compared to placebo). The intensive lifestyle intervention was significantly more effective than the standard lifestyle intervention plus metformin.

In the Healthy Aging: A Longitudinal Study in Europe (HALE Project), in 2539 participants age 70 to 95 at baseline, investigators found a 65% reduction in all-cause mortality and 67% to 77% reductions in disease-specific risks for coronary heart disease, any cardiovascular disease, and cancer in the group with four healthy lifestyle factors (never smoking, Mediterranean diet, 3-4 hours/week of moderate physical activity, and glass of wine or more daily) compared with the group with none of these healthy characteristics (Knoops et al., 2004).

The Women’s Health Study analyzed smoking, alcohol use, exercise, BMI, and diet among 37,636 participants age 45 or older. After a mean of 10 years follow-up, there were risk reductions of 55% for total stroke and 71% for ischemic stroke; the risk-adjusted hazard ratio for participants who scored higher on an index of lifestyle factors than those who scored lower was 0.45 for total stroke and 0.29 for ischemic stroke (Kurth et al., 2006).

In the Health Professionals Follow-up Study, 42,847 men age 40 to 75 were followed over 16 years using similar healthy lifestyle criteria. “Low risk” was defined as the absence of smoking, BMI less than 25 kg/m², moderate to vigorous activity of at least 30 minutes a day, moderate alcohol consumption (5-30 g/day), and the top 40% of the distribution for healthy diet score. Compared with men with no healthy lifestyle factors, those with all five factors had an 87% reduction in the risk of developing coronary heart disease (Chiuve et al., 2006).

In the Atherosclerosis Risk in Communities Study (ARIC), the effects of four healthy lifestyle factors (≥ 5 servings of fruits and vegetables per day, ≥ 2.5 hours of exercise per week, BMI of 18.5-30 kg/m², not smoking) were analyzed in 15,708 participants followed for only 4 years. Among subjects who had no healthy characteristics at baseline, those who changed their behavior and adopted a healthy lifestyle (all four habits) experienced a lower risk (40% reduction) of all-cause mortality and a 35% reduction in

cardiovascular disease (King et al., 2007). This study is particularly important because it indicates clearly that those with a relatively unhealthy lifestyle who change in midlife can still achieve dramatic reductions in health risks and longer life expectancy.

The European Prospective Investigation into Cancer and Nutrition (EPIC)–Norfolk study demonstrated significant reductions in all-cause mortality with increasing numbers of health factors in 20,244 participants followed for a mean of 11 years. The four factors analyzed were current nonsmoking status, engaging in regular physical activity, moderate alcohol use, and plasma vitamin C level greater than 0.88 ng/dL, as a surrogate for fruit and vegetable consumption. Individuals with all four factors had an advantage of approximately 14 years in chronologic age over those with only one of the four factors (Khaw et al., 2008).

Further follow-up analysis of the 43,685 individuals in the Health Professionals Follow-up Study and the 71,243 participants in the Nurses’ Health Study showed that a healthy lifestyle was associated over time with a 69% reduction in the risk of developing an incident stroke among men and a 79% reduction of stroke risk among women (Chiuve et al., 2008).

The most recent major study in this line of evidence that changes in lifestyle behavior lead to remarkable changes in health outcomes is the “Healthy Living Is the Best Revenge” report. Ford and colleagues (2009) used data from 23,153 German participants age 35 to 65 from the European Prospective Investigation into Cancer and Nutrition (EPIC)–Potsdam study. They analyzed end points of type 2 diabetes mellitus, myocardial infarction, stroke, and cancer and the effect of four healthy lifestyle factors: never smoking, BMI less than 30 kg/m², 3.5 hours/week of physical activity or more, and adhering to healthy dietary principles (high intake of fruits, vegetables, and whole-grain bread; low meat consumption). Fewer than 4% of participants had zero healthy factors; most had one to three healthy factors, and 9% of the group had all four factors. During a follow-up of 7.8 years, after adjusting for age, gender, educational status, and occupational status, the hazard ratio for developing a chronic disease decreased progressively as the number of healthy factors increased. Participants with all four factors at baseline (vs. those with none) had a 78% lower risk of developing a chronic disease. The risk of developing diabetes was reduced by 93%, the risk of myocardial infarction by 81%, risk of stroke by 50%, and risk of cancer by 36%.

The results of these studies are summarized in [Tables 7-3 and 7-4](#). Despite minor variations, there is now substantial consensus on what constitutes a “healthy lifestyle.” Briefly stated, a healthy lifestyle consists of the following:

1. Not smoking
2. Five (5) servings of fruits and vegetables a day
3. Body mass index (BMI) less than 30 kg/m²
4. About 150 minutes of exercise a week (~ 20 min/day)

Consider a fifth lifestyle factor: *stress reduction* or *relaxation*. The previous studies did not include this variable in their design most likely because of the difficulty in measuring effects. Nevertheless, substantial literature on this subject suggests (but does not prove) significant beneficial effects on blood pressure, smoking, alcohol abuse, cholesterol, psychosocial stress, atherosclerosis (measured by carotid artery

Table 7-3 Summary Data for the Eight Major Prospective Lifestyle Studies

| Study | N | Ages | Follow-up (years) | Smoking | BMI (kg/m ²) | Exercise (min/wk) | Diet | Other |
|---|--------|---------------|-------------------|--------------------------|--|--|---|---------------------------------|
| Nurses' Health Study (2000) | 84,129 | 30-55 in 1976 | 14 | Not currently | <25 | 210 | Top 40%* | Alcohol: ½ drink/day |
| Lifestyle or Metformin for Prevention of Diabetes (2002) | 3234† | >25 | 2.8 | Not specified | >24 | 150 | NCEP Step 1 diet | — |
| Healthy Aging: A Longitudinal Study in Europe (HALE Project) (2004) | 2339 | 70-95 | 10 | Never, or quit >15 years | --- | 200‡ | Mediterranean Diet Score = 8§ | Alcohol: >0 glass/day |

*Diet criterion: highest 40% of the cohort for consumption of a diet high in cereal fiber, marine *n-3* fatty acids, and saturated fat, and low in *trans* fat and glycemic load.

†Subjects were selected based on criteria of age >25, BMI >24, and either fasting blood glucose or post-75-g glucose load; 2-hour postprandial glucose elevated but not diagnostic for diabetes.

‡Individuals with a score in the intermediate and the highest tertile on the Voorrips or Morris questionnaire were considered the low-risk group for physical activity.

§For the Mediterranean Diet Score, the subject must have had above-average consumption of the six positive variables: (1) polyunsaturated/saturated fatty acid ratio, (2) fruits, (3) vegetables, (4) legumes, (5) fish, and (6) grains. They also must have had below-average consumption of the two adverse factors: (7) red meat and (8) dairy products.

¶Considered six dietary factors: cereal fiber, folate, polyunsaturated/saturated fat ratio, omea-3 fatty acids, *trans* fats, and glycemic load, grouped into deciles and scored as 0 to 9.

#Calculated a summary dietary score based on the Alternate Healthy Eating Index (AHEI).

#As a proxy for 5 servings of fruits and vegetables per day.

**A healthy diet was considered to consist of high intake of fruits and vegetables, whole-grain bread, and low consumption of meat.

NCEP, National Cholesterol Education Program; EPIC, European Prospective Investigation into Cancer and Nutrition.

intima-media thickness), angina, left ventricular hypertrophy, and overall mortality. A review of controlled trials using Transcendental Meditation (TM) techniques (many of which also compared TM to progressive muscle relaxation and other stress reduction techniques) found the following (Walton et al., 2004):

- Significant blood pressure reductions (11 mm Hg systolic and 6 mm Hg for diastolic) among elderly blacks (Alexander et al., 1996a; Schneider et al., 1995).
- A 13% reduction in cigarette use and smaller but significant reductions in drug and alcohol use (Alexander et al., 1994).
- Significant reductions in cholesterol after 11 months (Cooper and Aygen, 1979).
- A 30% reduction in psychosocial stress (Eppley et al., 1989).
- Implied reductions in atherosclerosis in patients with two or more risk factors for coronary heart disease of 33% after 1 year (Alexander et al., 1994, 1996a; Fields et al., 2002).

- Reduction in the likelihood of heart attack or stroke of 11% among elderly blacks (Alexander et al., 1994, 1996a).
- Greater exercise tolerance, maximal workload, delayed onset of ST-segment depression after 8 months (Zamarra et al., 1996).
- A highly significant reduction in all-cause mortality (Alexander et al., 1989, 1996b).

These studies are generally older, small in size, and of relatively poor methodologic quality (University of Alberta, 2007). However, these findings are supported by the INTERHEART study, which identifies psychosocial stress as one of the nine leading risk factors for MI (Rosengren et al., 2004; Yusuf et al., 2004).

A relaxation or stress reduction variable is added to the basic lifestyle formula for two main reasons: (1) the mounting support from clinical research and (2) the epidemiologically well-established correlation of stress to overall morbidity and mortality (Figueredo, 2009). Also, a compelling commonsense belief among the general public holds that stress is bad for health and can be reduced by various behaviors.

Table 7-4 Outcomes of the Eight Major Prospective Lifestyle Studies

| Study | Healthy Lifestyle at Baseline* | Major Findings |
|---|--------------------------------|--|
| Nurses' Health Study (2000) | 3% | 83% reduction in coronary heart disease (CHD) events; follow-up study showed a 91% reduction in the risk of type 2 diabetes. |
| Lifestyle or Metformin for Prevention of Diabetes (2002) | — | 58% reduction in diabetes compared to placebo; vs. 31% reduction with metformin and "standard" lifestyle intervention. |
| Healthy Aging: A Longitudinal Study in Europe (HALE Project) (2004) | — | 65% reduction in all-cause mortality (all 4 points); 77% reduction in CHD; 67% reduction in all cardiovascular diseases; and 68% reduction in all cancers. The lack of any healthy lifestyle characteristics was associated with a population-attributable risk of 60% of all deaths, 64% of deaths from CHD, 61% from all cardiovascular diseases, and 60% from cancer. |
| Women's Health Study (2006) | 4.7% | 55% reduction of total stroke, 71% reduction ischemic stroke, and 27% increase in hemorrhagic stroke. |
| Health Professionals' Follow-up Study (2006) | — | 87% reduction in men for CHD; 62% of coronary events might have been prevented with the five healthy lifestyle factors; in men taking medication for hypertension or hypercholesterolemia, 57% of all coronary events may have been prevented with a low-risk lifestyle. Compared with men who did not make lifestyle changes during follow-up, those who adopted two or more additional low-risk lifestyle factors had a 27% lower risk of CHD. |
| Atherosclerosis Risk Factors in Communities (ARIC) (2007) | 8.5% | During 4 years of follow-up, total mortality and cardiovascular disease events were lower for new adopters (2.5% vs. 4.2%) and 11.7% vs. 16.5% compared to individuals who did not adopt a healthy lifestyle. New adopters had 40% lower all-cause mortality and 35% fewer cardiovascular events. |
| EPIC-Norfolk (2008) | — | Adjusted relative risks for all-cause mortality for men and women who had 3, 2, 1, and 0 risk factors compared to 4 healthy behaviors were 1.39, 1.95, 2.52, and 4.04, respectively. All 4 behaviors = 14 more years of life. |
| EPIC-Potsdam (2009) | 9% | Subjects with all 4 factors at baseline had a 78% lower risk of developing a chronic disease: diabetes, 93% reduction; myocardial infarction, 81% reduction; stroke, 50% reduction; and cancer, 36% reduction. |

*Prior data on the prevalence of healthy lifestyle characteristics among U.S. adults demonstrated that only 3% had all four healthy lifestyle factors: not smoking, 5 servings of fruits and vegetables a day, 150 minutes of exercise a week, and body mass index (BMI) of 18.5 to 25 kg/m². (Reeves MJ, Rafferty AP. Healthy lifestyle characteristics among adults in the United States, 2000. Arch Intern Med 2005;165:854-857.)

Currently, the data do not precisely define the minimum time needed in meditation or relaxation to achieve health benefits; many studies use 15 to 20 minutes daily (Lane et al., 2007). A reasonable conjecture of the "minimal effective dose," which follows the work of Depak Chopra (1993), is 10 minutes a day. Chopra believes that nothing more than 10 minutes of silence is required. Progressive increases in time will enhance the benefits, but a place to start is needed, as with the BMI criterion.

Thus, the revised list of essential components for a healthy lifestyle is as follows:

1. Not smoking
2. Five (5) servings of fruits and vegetables daily
3. Ten (10) minutes of relaxation or meditation exercise daily
4. BMI less than 30 kg/m²
5. Exercise for at least 150 minutes per week

This can be conveniently expressed by the simple numeric mnemonic 0-5-10-30-150, as follows:

- 0 Cigarettes a day
- 5 Servings of fruits and vegetables a day
- 10 Minutes of relaxation or meditation daily
- 30 BMI less than 30
- 150 Minutes of exercise a week

This is a concise notation for a prescription of 0 cigarettes a day, 5 servings of fruits and vegetables every day, 10 minutes of relaxation or meditation daily, a BMI less than 30, and 150 minutes of exercise each week. For a behavioral lifestyle intervention to be practical and acceptable to most physicians, it should be brief, easily memorable, and simple to communicate to patients.

The nine studies clearly indicate that certain lifestyle characteristics are associated with important reductions in both chronic disease and death. Also, only 3% to 9% of typical populations meet the varying requirements of a healthy lifestyle; the relevant number for the U.S. population from the national Behavioral Risk Factor Surveillance System is 3% (BRFSS, 2002). There is a huge population of people who do not have a healthy lifestyle and whom physicians can help by facilitating their transition to a healthier lifestyle.

Of the studies previously described, in many ways the ARIC Study and the Prospective Diabetes Group trial are arguably the most important. These studies show directly that subjects who previously had a suboptimal lifestyle up into middle age can experience proportional benefits in health outcomes by making changes in their behavior at that time. These studies do not, however, tell us that physicians can persuade patients to make corresponding changes in their behaviors.

After the Evidence: Motivational Interviewing

Key Points

The most promising technique of active listening to help patients change behavior is motivational interviewing.

The three essential tools of motivational interviewing are:

- A menu
- An importance “ruler”
- A confidence “ruler”

Resistance is to be expected and provides the physician with the best opportunity to assist patients to work on what they need to do for *themselves*.

The previous studies are adequate to meet information objectives, but this alone is insufficient. To help patients make changes in their lives—and each of these lifestyle habits represents major behavior change—it is necessary to help them discover their own motivations to make changes and to help build confidence in their ability to undertake the task. Providing information is a physician behavior that is usually well supported in traditional medical education and training. The pitfall, however, is that most primary care physicians were trained to use this information as the basis for giving *advice* to patients. Experience confirms that simply giving advice usually is ineffective, and to the contrary, the usually unwelcome advice often heightens resistance to new behaviors.

Physicians cannot provide the motivation for patients to undertake lifestyle change, so it is necessary to ask patients what they want to do. What are their reasons for continuing a lifestyle habit that they usually know is associated with some adverse effects on their health? All patients have such reasons, or the behavior would simply go away.

Unhealthy lifestyles are perpetuated when internally the “pros” in favor of a given behavior have reached a stalemate with the “cons,” and a search for new behavior stops. The role of physicians is to help patients break the stalemate by creating opportunities for patients to reflect on their own behavior and values. A physician demonstrates respect for patients’ autonomy and their right to make decisions for themselves when, after an examination of the pros and cons,

the physician accepts wherever patients are with change in their life and allows them to guide the clinician to the areas where they are most motivated to change. The greatest problem is that family physicians were never trained to do this; it does not just happen.

The way to make it happen is by listening. This is true regardless of which evidence physicians believe and what attitudes patients have. “Long before there was any scientific basis for health care, there were healers who had learned to listen carefully” (Rollnick et al., 2008, p. 65).

The most promising new technique of “active listening” for health care practitioners is *motivational interviewing* (MI). It is beyond the scope of this chapter to provide detailed instructions in the related skills, which must be experienced and practiced over at least a few months. This section discusses the underlying principles and simple ways to start implementing these skills in medical practice. The development of skills requires sufficient understanding of the basic theory of MI to try the related clinical style with patients. Patients will then provide enough direct and immediate feedback to help physicians quickly refine their skills. The relevant basics of theory and practice are readily accessible (Rollnick et al., 1999, 2008; see also Web Resources).

The clinical method of MI was first described in 1983 as an approach to problem drinking (Stockwell and Gregson, 1986). MI is a “skillful clinical style for eliciting from patients their own good motivations for making behavior changes in the interest of their health” (Rollnick et al., 2008, p. 6). MI is a collaborative partnership between patients and their physicians based on the assumption that motivation for behavioral change is “malleable” and is formed particularly in the context of relationships. In addition, MI requires of physicians a “certain detachment from outcomes—not an absence of caring, but rather an acceptance that people can and do make choices about the course of their lives” (Rollnick et al., 2008, p. 7).

Rollnick identifies four core guiding principles of MI, using the mnemonic RULE, as follows:
Resist the “righting reflex” (i.e., “Don’t try to fix it, and don’t give advice”).

Understand the patient’s motivations.

Listen; use empathic, active listening throughout the clinical interview.

Empower the patient.

The physician needs to support patients’ beliefs that change is possible and will make a profound difference in their life.

The key change in physician behavior required is a transition from asking multiple, “get to the point,” close-ended questions, often mistakenly assumed to be efficient, to a style that employs fewer and predominantly open-ended questions. This allows patients the time to tell their stories. The benefit for patients is the feeling of being heard. For physicians, the benefit can be greater patient satisfaction; patients often feel they had more time with the physician and received more attention, whether or not the visits are actually longer. The challenge is to allow the patient to be in control.

Another good example of a systematic approach to MI in the clinical setting is the Kaiser TPMG educational program. The Brief Negotiation Roadmap offers a practical six-step sequence for physicians in practice: (1) open the encounter; (2) negotiate the agenda; (3) assess readiness; (4) explore ambivalence; (5) tailor the transition; and (6) close the

encounter. The Kaiser example offers a good illustration of the use of the three basic tools of MI: a “menu” for the agenda, a motivational “ruler,” and a confidence “ruler.”

The Process in Your Clinical Practice

The encounter for lifestyle change opens with the establishment of rapport and trust with your patient. You are assisting the patient to be in control of the encounter and trying to establish a partnership for what needs to be done, which only the patient can decide. Your role is to assess the patient’s level of healthy lifestyle activity, educational needs, emotional state, and readiness to embark on change, and to reflect these back to the patient as they become clear.

A good way to open the discussion is to present a list of options (a “menu”) that you and the patient might work on together for the encounter. Ask if this is acceptable. You can identify a patient’s readiness for behavioral change simply by asking the patient about the positive aspects of the patient’s current behavior and then listening. Follow this up with a similar question, What are the negative aspects of this behavior? To assess the current state of the tension between the positive and negative aspects, using a motivational “ruler,” ask the patient how *important* it is to change the current behavior, on a scale of 1 to 10. If the patient rates the importance of change as only a 2 out of 10, you can ask, “Why isn’t it a zero or a one?” If it is a 6, you can ask, “What would it take to make it a seven?” The goal of this interaction is simply to understand the patient’s readiness for behavioral change and to facilitate the patient’s recognition of his or her own ambivalence.

The uncovering of ambivalence is a useful step forward, not a failure on the physician’s part. Ambivalence must exist, or the behavior would have changed already. Ambivalence is the reason for the encounter. The physician must try to understand what creates the tension that results in ambivalence. Ambivalence can be addressed; a clear “no” cannot. If the patient turns out not to be ready for change, the patient is probably right. Only the patient fully understands all the competing values in his or her life. Acknowledge that directly, asking such questions as, “Where does that leave you now?” or “What are you thinking/feeling at this point?”

If the patient is ready for change, you want to find out how much and how fast. Let the patient be in charge. A good question is, “How can I help?” If the patient does not have a specific task for you right now, you can always just offer information from a clinical perspective. Ask if this is acceptable. Try to reach mutual clarity about what to expect. “How confident are you that you can cut your smoking in half this week?” On a confidence scale (1-10), physicians are seeking a level of 7 out of 10, to indicate that the patient is really confident about making a change. If the answer is less than 7, you can gently suggest considering a lower goal. For example, “Well, if you only feel a confidence of 5 about cutting your smoking in half, how confident would you feel about reducing your smoking by two cigarettes a day this week?”

When you have a firm degree of confidence (≥ 7) about a mutually agreed goal, you are ready to close the encounter. Affirm the effort the patient is making to enhance the quality of his or her health. Affirm that you will be there for the patient at each turn on this path to lifestyle change.

Basic Steps toward Self-Motivation

1. Elicit agreement with the patient that it is acceptable to talk about behavior change for any issue.
2. Ask what the patient sees as positive aspects of his or her current behavior, then ask about the negative aspects.
3. Use the motivational RULE to assess how important it is now for the patient to make a change in the target behavior.”
4. Ask how confident the patient is about making a change.
5. Resolve ambivalence. Revise the degree of anticipated change in the target behavior until the patient’s confidence level is 7 or higher. If this is not possible, explicitly acknowledge that this may not be a good time to undertake change in this area.
6. Close the encounter with encouragement toward the patient’s stated goal or an offer to be of assistance whenever the patient is ready.

Crux of the Lifestyle Dilemma: Do Physicians Believe in Primary Prevention?

Key Points

- Good, even great, evidence is not enough to lead to substantial lifestyle changes among patients.
- Traditional medical training has not prepared the majority of practice physicians in the science (evidence) of primary prevention or in the tools necessary to make it happen, such as motivational interviewing.
- Although many physicians say they believe in primary prevention, their behavior often belies this. Belief in the power and effectiveness of primary intervention strategies among primary care physicians cannot be assumed and must be explored individually with each physician.
- Physicians need to go through a series of steps, much as any patient who desires to change a behavior, to become proficient at primary prevention.
- The predicted results will reward the efforts for physicians who can take a day-by-day, long-term perspective on health.

Why not primary prevention now? Whether this means systematically performing CAD risk assessments on all adult patients, or whether the physician wants the broadest possible impact on multiple major chronic diseases through primary prevention, the rate-limiting step is the same: motivation. As with patients, too few physicians actively engage in either strategy. What would be required for lifestyle work to become a critical part of every patient encounter? Motivational interviewing theory suggests that the behavior is not important to physicians, or they lack skill in this technique.

The data cited have now been long available. Physicians do not lack an evidence base to justify such a behavior change; they lack the will. They should examine this phenomenon as a perfect problem to approach with MI skills.

The problem is usually couched in terms of patient compliance and patient resistance as the source of failure to adopt a healthy lifestyle. This may be true in part, but the physician also plays a role. The principles of MI, applied to patients, suggest that physicians need to understand patients’ perspective better and, whatever their resistance, why they do want to take care of

themselves (Rollinik et al., 2008; Ruback et al., 2005). One can never positively influence the behavior of another person without continuous, positive, empathic, nonjudgmental support.

Another barrier in providing primary prevention is that no one has directly observed a primary prevention “miracle.” Although so important to the religious conversion experience, miracles just don’t happen in primary prevention. Prevention of poor outcomes is not an observable event.

In usual practice, physicians derive the most satisfaction by testing or treating and seeing a prompt result. The relatively simple “instant gratification” of this approach is addictive. Give sublingual nitroglycerine, and the patient’s blood pressure decreases; give insulin, and the sugar level is reduced. Tap on a reflex, and the tendon jumps; order a CT scan, and unseen abnormalities become apparent. Primary prevention offers no such satisfaction, even though it may be a favorite subject of interest, with a gratifying sense of sharing a deep belief.

Motivating physicians to move toward a primary prevention lifestyle and practice (these must go together) is similar to moving a smoker toward smoking cessation. All patients who are smokers should receive at every physician visit a straightforward, simple, clear, nonjudgmental message that giving up smoking is the single most important thing they could do for their health. This message should be accompanied by a simple question, “Would you like to talk about it?” Although average results from simple, brief counseling are 2.8% quit rates (Lancaster and Stead, 2004), because of the large patient populations, this rate is actually quite important. Physicians must be willing to accept intermediate behavioral outcomes in this range: 3% to 5% increases in smoking cessation (Butler et al., 1999), exercise (Hillsdon et al., 2007; Lawlor and Hanratty, 2001; Ogilvie et al., 2007; Peterson, 2007; Sherman et al., 2007), eating 5 servings of fruits and vegetables (Step toe et al., 2003), other healthy nutrition practices (Hunt et al., 1995), reducing problem drinking (Fleming, 2005; Ockene et al., 1999), accident prevention (Miller and Galbraith, 1995), and general healthy lifestyle advice (Christian et al., 2008; Steptoe et al., 2001).

Each physician should reflect on the following questions:

1. “Do I believe that primary prevention can really work, and that it can substantially outperform other strategies to promote health?” As noted, belief is required. Exposure to high-quality primary prevention information can help, especially with urging from a colleague or mentor. We cannot assume that physicians believe; we have to ask. Belief is a journey, and the physician must explore personal history and professional socialization, first asking, “On a scale of 1 to 10, how great is my belief that primary prevention is the right thing to do and the key to the best results in medicine?”
2. “If I do believe in primary prevention, do I think it is *important*?” The physician must be convinced that this is a worthwhile focus. The physician’s belief in the relative importance of preventive interventions is influenced by example, information, patient satisfaction, and organizational support. If primary prevention is *not* important, it does not deserve to be practiced. If the physician thinks it is even somewhat important, however, primary prevention warrants further consideration.
3. “If I believe in primary prevention, and I believe it is of paramount importance, am I convinced that I can do it?” Confidence is also relative and susceptible to both information and example. The physician needs to ask,

“On a scale of 1 to 10, how confident am I that I can integrate the behaviors necessary for primary prevention into my life and work flow?”

The evidentiary basis, practice, and strategies of motivational interviewing are new enough that many physicians are not even familiar with the term. Many of these physicians, however, intuitively respond to the process and may think,—“I’ve done that; I just didn’t know what it was called.” Usually, however, MI is only targeted at patients with high-risk medical conditions. As a strategy, it has succeeded dramatically for certain patients, but MI has not penetrated far into the U.S. health care environment since it was introduced to a wide audience in 1992. MI simply is not a formal part of most practices, mainly because the power of the intervention has been aimed at the wrong strata of system participants.

Insufficient data and insight surround the major question, “How do we nurture physicians in their career development to have firsthand knowledge of the power to change and evolve personally?” If the United States is to become a healthier country, current health care reform policies should address this question directly. Primary prevention can then become a natural, integral part of the health care process, an act as simple as breathing.

Summary

The answers to the four questions posed at the beginning of this chapter should now be fairly clear.

What is a healthy lifestyle?

A healthy lifestyle consists of five essential elements:

1. Not smoking (0 cigarettes)
2. Five (5) servings of fruits and vegetables daily
3. 10 minutes of relaxation, silence, or meditation daily for stress reduction
4. BMI less than 30 kg/m²
5. 150 minutes of exercise over the course of each week.

This list may be communicated succinctly to patients by the simple numeric mnemonic 0-5-10-30-150.

What is the prevalence of a healthy lifestyle among patients?

For the general U.S. population, the prevalence of a healthy lifestyle defined by the four criteria above is 3%. This means that a large number of patients could benefit by being encouraged to adopt a healthy lifestyle.

What are the potential benefits for patients who have or who change to a healthy lifestyle?

The potential benefits of a healthy lifestyle are:

1. A 40% to 65% reduction in all-cause mortality.
2. An 81% to 87% reduction in coronary heart disease events.
3. A 67% reduction in all cardiovascular diseases.
4. A 50% to 71% reduction in stroke.
5. A 58% to 93% reduction in the risk of developing type 2 diabetes.
6. A 36% to 60% reduction in cancer deaths.

What is the major obstacle to lifestyle changes in a family physician’s office?

The major obstacle to the behavioral changes required to live a healthy lifestyle is a lack of physician training and skills in motivational interviewing. This is the major challenge to the training of physicians for the 21st century. The effectiveness of improved training and greater organizational support in health care systems for healthy physician lifestyles, as well as enhanced listening and MI skills, should be a major focus of the primary care research agenda for the future.

EVIDENCE-BASED SUMMARY

- Individual global cardiac risk assessment performed regularly and followed by appropriate graded interventions is the most effective strategy for preventing heart disease (SOR: C).
- Living a healthy lifestyle or changing to one is potentially more effective than focused cardiac risk reduction, because it not only reduces adverse cardiac events and death to a similar degree, but also is associated with major reductions in chronic diseases (diabetes, stroke, all cardiovascular disease, and even cancer) as well as large proportional reductions in all-cause mortality (SOR: B).
- A healthy lifestyle consists of the following:
 - Not smoking (SOR: A)
 - 5 servings of fruits or vegetables each day (SOR: B)
 - 10 minutes of relaxation, silence, or meditation each day (SOR: C)
 - Maintaining a BMI less than 30 kg/m² (SOR: B)
- The most promising new technique of active listening to assist patients in making behavioral changes is motivational interviewing (SOR: C).

Key Points

- Interpreting the medical literature is a task any physician can do, particularly when using common, evidence-based summaries that are available at low or no cost.
- The studies should report statistically significant results that are applicable to the physician's population of patients and that should evaluate important patient-oriented outcomes, including potential harms.
- When potentially changing practice behavior, the physician should assess whether the evidence is from high-quality studies replicated over time.
- The medical literature is an evolving body of evidence, and each physician should develop a personal plan to keep up with important changes in medicine and strategies to answer more immediately important clinical questions at the point of care.
- Using summary measures, such as the number needed to treat or harm and attributable risk, can make decisions about patient care more collaborative and transparent

Building Clinical Evidence from Published Research

Evidence-based medicine (EBM)—asking clear, relevant clinical questions, finding appropriate studies, critically appraising the literature, and implementing changes in practice behavior—has become an essential part of medical care. Most busy physicians do not have the time or the background to answer critically the questions that arise in

practice. Primary care physicians identify 2.4 clinical questions for every 10 encounters (Barrie and Ward, 1997), but they spend less than 15 minutes on average with each patient. Evidence about common primary care problems is accumulating at an overwhelming pace, and the broad scope of family medicine presents important challenges. Other barriers to the use of EBM include lack of evidence that is pertinent to an individual patient, quick access to information at the point of care, and potentially negative impacts on the art of medicine (McAllister et al., 1999). How can diligent physicians narrow the gap between their current behaviors and best practices?

In this chapter, hormone replacement therapy (HRT) for postmenopausal women is used as a case example to understand the evolution of medical practice and the changing landscape of evidence and to review concepts important to interpreting the medical literature. These concepts form the basis for practical EBM tools that family physicians can use to answer important clinical questions.

In Chapter 10, information from the Women's Health Initiative (WHI) about HRT is considered, and similar epidemiologic and statistical issues are covered. Chapter 10 emphasizes the importance of how risk data are framed or presented to the patient and the primacy of patient preference (i.e., ability to make informed decisions about therapy). Unfortunately, evidence concerning the ideal manner of presenting information to patients and clinicians and promoting informed decision-making is still scant. This chapter and Chapter 10 take a slightly different approach to similar clinical questions, and together, these two chapters provide the background for the motivated family physician

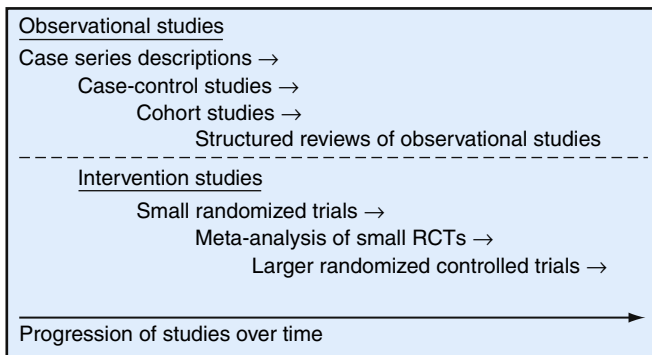

Figure 8-1 Common progression of research in building the strength of evidence; RCTs, randomized, controlled trials.

to better understand concepts of risk and probability and to foster enhanced physician-patient decision-making.

Evidence for interventions such as HRT usually begins with observational studies, including unblinded case series, case-control studies, and cohort studies, and it culminates in randomized, controlled trials (RCTs) (Figure 8-1). To better understand how we arrived at the current clinical understanding of HRT and its effects on heart disease, we review the progression of research studies and evidence over the past 30 years. A series of observational studies in the 1970s and 1980s led to regular prescribing of HRT to prevent a number of significant health conditions in postmenopausal women.

Case-Control Studies

Case-control studies are often the first step in a progression of building clinical evidence because they are relatively inexpensive and rapid studies to complete. Case-control studies always look backward in time (i.e., retrospective studies) to determine a statistical association between an *exposure* and an *outcome*. To complete a case-control study of the association of HRT and coronary heart disease (CHD), a researcher would identify a group of *cases* (i.e., women with CHD) and a group of *controls* (i.e., women without CHD) and look back in time to determine how many women in each group had taken HRT. The association between exposure (i.e., HRT) and outcome (i.e., CHD) in a case-control study is typically summarized by a statistical measure called an *odds ratio*. An odds ratio is an estimation of the true relative risk for the outcome in question. A common form of bias in a case-control study is *recall bias*: errors in accurately determining whether cases and controls had exposure to HRT in the past.

Cohort Studies

Cohort studies are often the next step in building the strength of evidence regarding an association between an exposure and an outcome. Cohort studies typically look forward in time (i.e., prospective studies) and are generally more expensive and take longer to complete than case-control studies. However, they provide a more accurate estimate of the relative risk for women who take HRT and those who do not. A cohort study is also an *observational study*—one that observes outcomes in groups but does not assign participants to a particular exposure or treatment. In a cohort study of HRT and CHD, a researcher would identify a group of women taking HRT and a similar group of women who

have chosen not to take HRT, and the researcher would then follow them over time and count the number of CHD events. Because outcome events may be uncommon in each group and may take many months to occur, cohort studies often require large numbers of participants and long follow-up periods to show significant differences between groups.

The primary statistical measure from a cohort study is *relative risk*. This is a ratio of the rate of CHD events among women who choose to take HRT divided by the rate among women who choose not to take HRT. A common form of bias in cohort studies related to prevention is the *healthy user bias*, when participants who choose one preventive measure (e.g., HRT) also tend to make healthier lifestyle decisions (e.g., diet, exercise) that may also prevent the measured outcome (i.e., CHD).

Beginning with case-control studies and then using larger cohort studies, observational research showed that HRT might reduce the incidence of CHD, fractures, and colorectal cancer. These observational studies also suggested that the same therapy might cause harm, with a slightly increased risk of breast cancer, stroke, and venous thromboembolism. On balance, however, even a small positive impact of HRT on preventing CHD was thought to far outweigh the potential adverse effects of HRT.

Structured Reviews and Meta-Analysis

After a number of studies are completed, whether cohort studies or initial small RCTs, these are often reviewed and summarized in publications called *structured reviews*. Occasionally, data from a series of studies are combined using a statistical technique called *meta-analysis*, which allows increased statistical power to determine the weight of evidence from a series of studies. The use of HRT was greatly increased during the 1990s based on a number of case-control and cohort studies and on three meta-analysis studies that further suggested that HRT was protective against CHD (Pettiti, 1998).

In 1991, an editorial in the *New England Journal of Medicine* concluded that “a consensus of epidemiologic reports has demonstrated that women who are given postmenopausal estrogen therapy have a reduction of about 40% to 50% in the risk of ischemic heart disease as compared with women who do not receive such therapy” (Goldman and Tosteson, 1991). HRT became a de facto standard for postmenopausal women through the 1990s.

The Power of Randomized, Controlled Trials

In RCTs, study participants are randomly allocated to two or more groups and then assigned to receive an intervention such as HRT or to receive no active treatment (i.e., placebo or to continue with their usual care). RCTs greatly add to the confidence of measured results because the structure of an RCT helps to eliminate many of the inherent biases that are in observational studies. For example, in cohort studies of HRT and CHD, it is hypothesized that women who choose to take HRT are generally healthier and have better healthy lifestyle practices than women who do not choose to take HRT. Because participants in an RCT are randomly assigned to treatment and control groups, they are less likely to have differences in other factors that might prevent or promote heart disease.

Table 8-1 Understanding Study Results

| |
|---|
| Typical summary rates from randomized, controlled trials: |
| Incidence rate = $\frac{\text{Number of new cases of disease over a defined period}}{\text{Number of persons at risk during the period}}$ |
| Relative risk (RR) = $\frac{\text{Incidence rate among the treated group}}{\text{Incidence rate among the placebo group}}$ |
| Summary measures that may be more meaningful for clinicians: |
| Attributable risk (AR), or risk difference = (Incidence rate among treated group) – (Incidence rate among placebo group) |
| Number needed to treat (NNT) or number needed to harm (NNH) = Reciprocal of AR, or 1 / AR |

The decreased likelihood of a healthy user bias in an RCT may explain why HRT appeared to be protective in cohort studies but later proved to be harmful. Because RCTs have this inherent ability to remove many important potential forms of bias (but are not immune to biases themselves), a physician can have more confidence that they reflect the true association between the HRT treatment and CHD outcomes. Despite decades of work, dozens of observational studies, and structured reviews that strongly suggested a protective effect of HRT for CHD, a single, large RCT trumped them all and caused a sudden reversal in physicians' prescribing behavior.

The results of the WHI study, released in 2002, sent a shock wave through the medical community. For the first time, a large, randomized trial showed that HRT—given to otherwise fairly healthy postmenopausal women—caused a statistically significant increase in CHD events. Within days of the release of the WHI primary results, many women called their physicians to decide whether they should continue with HRT. Many physicians drastically changed their prescription of HRT based on the WHI; within 9 months, prescriptions of the most popular formulation of HRT decreased by as much as 61% (Majumdar et al., 2004). Perhaps more than any other single study in modern medical history, the WHI report dramatically changed a widespread, common medical practice.

Understanding the Statistical Significance of Study Results

Reports from RCTs such as the WHI study frequently include relative risk as a summary measure of differences between the treatment and placebo groups (Table 8-1). To arrive at the relative risk, the researcher first measures the incidence rate of an outcome in each of the two study groups (i.e., treatment and placebo). The incidence rate for each group is a ratio of the number of new outcome events, such as CHD events, divided by the number of patients at risk for the outcome in that group over a specific period. In multiyear studies, the average annual incidence rate is often reported as a summary measure. In a placebo-controlled RCT, the relative risk is then calculated as a ratio of the incidence rate for the treatment group divided by the incidence rate for the placebo group (Table 8-2).

Table 8-2 Examples of Summary Rates from the Women's Health Initiative (WHI) Study

The following equations show how to take a summary rate commonly reported in published studies (i.e., relative risk) and calculate a summary measure (e.g., number needed to treat, number needed to harm) that may be more useful in describing the results to clinicians and patients. The example considers the average annual incidence rates and relative risk for coronary heart disease (CHD) events in the WHI study on the effects of hormone replacement therapy (HRT):

$$\begin{aligned} \text{Average annual incidence among HRT – treated women} \\ = 37 \text{ CHD events / year / 10,000 women} \end{aligned}$$

$$\begin{aligned} \text{Average annual incidence among placebo – treated women} \\ = 30 \text{ CHD events / year / 10,000 women} \end{aligned}$$

$$\text{Relative Risk of CHD} = \frac{37 \text{ CHD events / 10,000 women}}{30 \text{ CHD events / 10,000 women}} = 1.29 \text{ (adjusted)}$$

The relative risk describes a relative 29% increase in CHD events. It may be more useful to consider the absolute difference in incidence rates between the two groups to understand the magnitude of the potential risk for a given patient:

$$\begin{aligned} \text{Attributable risk (AR)} &= \frac{37 \text{ CHD events}}{10,000 \text{ women}} - \frac{30 \text{ CHD events}}{10,000 \text{ women}} \\ &= \frac{7 \text{ additional}}{10,000 \text{ women}} \text{ CHD events} \end{aligned}$$

The number needed to harm (NNH) can be calculated to describe, on average, how many women must be treated for 1 year to cause one additional CHD event attributable to HRT:

$$\text{NNH} = \frac{1}{7 \text{ CHD events / 1000 women}} = \frac{10,000}{7} = 1430$$

Data from Ebell MH, Messimer SR, Barry HC. Putting computer-based evidence in the hands of clinicians. *JAMA* 1999;28:1171-1172.

How can a physician determine whether the reported relative risk from a study is significant enough to influence clinical decisions? Typically, the statistical significance of the summary measure is reported, which in this case is relative risk. Statistical significance is usually summarized in published studies by a *p* value for a given summary measure. The *p* value describes the statistical probability that the observed difference between the groups could have happened simply by chance alone. A *p* value of less than 0.05 is the arbitrary cutoff most often used for "statistical significance." A "*p* < 0.05" means that there is less than a 1 in 20 (5%) probability that a difference as large as that observed would have occurred by chance alone; a *p* = 0.04 means a 1 in 25 (4%) probability; a *p* = 0.06 means a 1 in 16 probability (6%).

Although frequently used, *p* values provide only limited information: the chance that any difference found is caused by chance, or random error. A *p* value alone gives no indication of the clinical significance of a finding and provides no information regarding the likelihood that a finding of "no difference" is caused by chance, or random error.

Confidence intervals are much more informative than *p* values. When relative risk is reported as the summary result of a study, the 95% confidence interval (CI) is often used to give an

indication of the precision of the estimated relative risk. The 95% CI describes the range within which there is a 95% probability that the true relative risk (RR) is in that range. An RR of 1.0 indicates no difference. For example, if a study reported an RR of 2.5 with a 95% CI of 2.3 to 2.7, we could be reasonably certain (95% certain) that the true RR was no less than 2.3 and no greater than 2.7. Our conclusion would be that the estimated RR of 2.5 is fairly precise. However, if RR was reported as 2.5 with a 95% CI of 1.1 to 5.0, the true RR could be as low as 1.1 (almost no difference) or as high as 5.0 (a fivefold difference), an obviously imprecise estimate of the relative risk.

Confidence intervals also provide a better measure than *p* values of the precision for concluding that there is no difference in a relative risk. Any 95% CI that includes RR = 1.0 indicates that there may be “no difference.” However, a RR of 1.1 with a 95% CI of 0.99 to 1.11 is almost certainly a finding of no difference (i.e., a narrow confidence interval), whereas an estimated RR = 1.4 with a 95% CI interval of 0.99 to 1.7 is much less precise (i.e., a wide confidence interval). Even though the 95% CI contains 1.0, there may still be a true difference, just not detected in this study.

Interpreting Study Results: Statistical and Clinical Significance

Although the WHI showed a statistically significant increase in the relative risk of CHD events among women who were randomly assigned to take HRT, it is important to consider the absolute difference in CHD events between the two groups to understand the strength of the association and to discuss the risk of HRT treatment with individual patients. Calculating *absolute risk* (in addition to relative risk) is a helpful way to understand the level of risk that HRT may add for a group of women who are at risk for CHD events (see Table 8-2).

In the WHI study, the relative risk of CHD for participants who took HRT was 1.29, with a 95% confidence interval that did not cross 1.0 (95% CI, 1.02 to 1.63). This figure (RR = 1.29) can generally be interpreted as HRT being associated with a 29% increase in CHD events. This summary measure was reported widely in medical journals and the mainstream press.

When reported in terms of relative risk, the weight of the association between HRT and CHD sounds ominous (i.e., a 29% increase). However, in terms of absolute risk attributable to HRT treatment, a less portentous picture emerges (see Table 8-2). In the WHI study, women taking HRT had an average rate of CHD events of 0.37% per year, an average of 37 events per 10,000 women each year, and those in the placebo group had an annual rate of 0.30%, or 30 events per 10,000 women each year. Although the adjusted RR of CHD is 1.29 (0.37 divided by 0.30), the *attributable risk* or risk difference between the two groups is 0.07% (0.37 minus 0.30). In other words, approximately seven additional cases of CHD occurred for 10,000 women using HRT during each year over the course of the study. The attributable risk of the treatment group can be summarized as the *number needed to harm* (NNH) or, if a study reports a beneficial effect, the *number needed to treat* (NNT). In this case the NNH was approximately 1430; on average, for every 1430 patients treated with HRT, one additional CHD event occurred (i.e., the inverse of the risk difference, 0.07, or 10,000 divided by 7) (see Table 8-2). The NNH or NNT is often a more understandable and

useful summary of study outcomes when physicians and patients weigh the risks and benefits of a particular therapy.

Other Keys to Interpreting Clinical Evidence

Pearls

- Use a personal digital assistant (PDA) or computer online, with bookmarks for helpful EBM sources, to apply evidence at the point of care.
- Although full access to the Cochrane Database can be expensive, helpful summaries are available for free.
- Attend an information mastery or EBM workshop to solidify your grasp of basic concepts and application of this information to daily practice.
- Becoming a reviewer of Clinical Inquiries, HelpDesk Answers, or PURLs can consolidate your skills in EBM.
- Make it a habit to spend 10 minutes each day reviewing important systematic reviews or evidence-based summaries of relevance to your practice.

One of the major tasks in interpreting whether the results of a study should change practice is to determine whether all relevant patient-oriented outcomes were considered. It is important to distinguish among physiologic outcomes (e.g., serum calcium), intermediate outcomes (e.g., bone density), and patient-oriented outcomes (e.g., fractures). Whenever possible, practice decisions should be based on outcomes patients would deem important. For example, in a trial of HRT for osteoporosis, a decrease in fracture incidence would be a more convincing outcome than a change in a physiologic parameter such as bone density. Likewise, all important harms (i.e., risks) and financial end points (i.e., costs and savings) should be reported. In a trial of a new antiresorptive agent, the rate of esophagitis, gastritis, and esophageal perforation may be important harms to elaborate, along with such measures as patient satisfaction, costs and savings of care, and global well-being.

When assessing the benefits and harms of such a new treatment, appropriate competing alternatives (including no treatment at all) should be compared. Typically, such a comparison may take the form of a “balance sheet,” a table comparing each intervention in terms of benefits, harms, and economic end points. Many studies are randomized, placebo-controlled trials in which patients receive an active intervention or a placebo or sham intervention. Alternatively, a study may use an *active comparator*, an intervention already known to be effective. Each of these approaches has pros and cons, but the most important point to remember is that just because a study shows statistical significance in a single measure, it does not mean that appropriate patient-oriented outcomes were considered.

When a study shows no effect, the question of *power* is raised. Put in simple terms, power is the ability to detect the effect of an intervention; it depends on the number of patients in the study, the magnitude of effect of the intervention, and the variability of the effect from one subject to another. For some interventions, even a small effect may be important. For example, many nonpharmacologic treatments for hypertension (e.g., salt restriction) have relatively modest, but important effects. Clinicians should generally be skeptical of small studies that show negative results.

Examining the confidence intervals is the easiest way to assess whether the study sample was too small and therefore did not have the statistical power to detect a clinically important difference (as reflected by wide confidence intervals).

Even when a study is positive or shows statistically significant results, it is important to consider whether the findings are clinically significant and applicable to your practice. For example, if a study showed a drug reduces the risk of heart attack by one in a million patients, we would probably be skeptical about its utility. Likewise, the findings showing that daily borscht reduces fractures in a study done in Russian dockworkers may or may not be applicable in the United States. The acceptability of an intervention (e.g., electroconvulsive therapy for depression) may vary. Moreover, the ability to replicate the findings of a study done in a typical research setting is often reduced in real-world practice. An intervention for osteoporosis requiring daily injections may be demonstrated to be efficacious, but in the average practice setting, its effectiveness may be much more limited.

Clinicians frequently rely on the synthesis of many studies, rather than a single study, to change our practices. Such reviews can be *systematic*, in which rigorous attempts are made to uncover all studies, published and unpublished, in English and in other relevant languages, or they may be more limited reviews that consider only a portion of the published literature. Some use formal mathematical methods to combine the results of studies (i.e., meta-analysis), and others are *qualitative* and synthesize data according to an author's overall judgment. Common biases to consider related to published reviews include whether all sources of evidence were considered; how disparate results were combined; whether relevant patient-oriented outcomes were assessed; if there was adequate attention to the quality of the studies and their generalizability; and whether the authors analyzed why differences in outcomes may have occurred, based on such factors as study design, population, and intervention. Published reviews, including systematic reviews and clinical guidelines, have become increasingly important tools for the busy clinician.

Clinicians may hone critical appraisal skills through involvement with local journal clubs, working with the Family Physicians' Inquiries Network (www.fpin.org). Although it is important to understand basic concepts for interpreting medical literature, sifting through original research studies can be a tedious, impractical process for busy clinicians. Many practical EBM tools have emerged in recent years to help physicians quickly access comprehensive, expert reviews of published studies in the middle of a busy practice (Table 8-3). The ability to critique articles using a structured approach is facilitated by using widely available worksheets and tools (see Web Resources). Although many taxonomies exist for level of evidence, two of the most widely available are the Centre for Evidence-Based Medicine (CEBM) and the taxonomy used in this book. The Strength of Recommendation Taxonomy is specifically tailored to family medicine (Ebell et al., 2004).

Using Evidence at the Point of Care

Physicians have many sources of clinical information, from throwaway or non-peer-reviewed journals to evidence-based, searchable databases. Each of these has advantages, disadvantages, and different methods of access (Table 8-4).

Table 8-3 Distinguishing Characteristics of Evidence-Based Medicine

| Characteristic | Description |
|--|---|
| Explicit methods | Databases are searched and search strategies described. |
| Focus on patient-oriented outcomes | Concentrates on clinical research that reports patient-oriented outcomes. |
| Systematic searches | The searches are systematic and thorough so that important evidence is not missed. |
| Standardized critical appraisal | Important sources of potential systematic and random error are assessed in each study. |
| Hierarchy of study design | More weight is given to stronger study designs. |
| Designation of levels of evidence | Each study is designated with respect to the strength of the study design and its quality of evidence. |
| Grading of accumulated recommendations | Each recommendation is graded according to the strength of the evidence from research studies that support the recommendation. |
| Verifiable findings | The explicitness of the methods of searching and critical appraisal allows others to verify or refute findings and recommendations. |

One model to help busy physicians stay clinically current, called *information mastery*, has been advocated by Slawson and Shaughnessy (1999), Ebell and colleagues (1999), and Geyman (1999). In this model, physicians seek the answer to clinical questions through secondary sources of information that have been created by experts through a review of the medical literature. Secondary sources include the following (Table 8-5):

- Evidence-based summaries, such as Cochrane Collaboration reviews, Patient-Oriented Evidence that Matters (POEMs), Clinical Inquiries, and Priority Updates from the Research Literature (PURLs), as published in the *Journal of Family Practice*.
- Systematic reviews, including PubMed and Clinical Inquiries.
- Guidelines, written by professional societies and accessed through sites such as the National Guideline Clearinghouse (www.ngc.gov).
- Evidence-based databases, such as Essential Evidence Plus, DynaMed, and PEPID PCP.

The following example describes the type of relevant information that a busy clinician can access using two of these EBM resources.

Case Example

A 55-year-old woman sees you because she is experiencing severe vasomotor symptoms (i.e., hot flashes). These symptoms are keeping her awake at night. She had a total

Table 8-4 Examples of Reference Materials on Hormone Replacement Therapy for the Busy Physician

| Type of Literature | Advantages | Disadvantages | Availability | Examples |
|-------------------------------------|--|--|--------------------------------|---|
| Textbooks | Comprehensive review of topics | Long period from concept to printing; book/CD space requirements; cost; reading time | Print: hardcover and paperback | Berek Novak's <i>Gynecology</i> (\$150) |
| Unsolicited medical journals | No cost | Some not peer reviewed; unpredictable topics; large volume of materials; may have industry sponsorship | Print; some articles online | <i>Female Patient</i> (complimentary) |
| Subscription peer-reviewed journals | Peer reviewed; pertinent | Cost and subscription management; stacks of journals; need to appraise critically | Print and online | <i>Obstetrics and Gynecology</i> (\$368 annually for non-ACOG member) |
| Evidence-based searches | Peer reviewed; pertinent topics | Cost; CD management; summaries have learning curve | CD-ROM and online | Cochrane Reviews: abstracts (complimentary) and full reviews (subscription) |
| Searchable evidence databases | Searchable; rapid; focused search possible; point of care access | Learning curve for searches | PDA and online | Essential Evidence Plus (\$79) |

CD, Compact disk; ACOG, American College of Obstetricians and Gynecologists; PDA, personal digital assistant.

abdominal hysterectomy and oophorectomy 1 year ago because of uterine fibroids. She is concerned about the dangers of HRT. What is the current evidence to support HRT for this patient? How should you counsel this patient?

A PubMed search (<http://www.ncbi.nlm.nih.gov/entrez/query/static/clinical.html>) was performed using the "clinical queries" home page. Using the field *therapy* as the clinical study category and emphasis—*broad, sensitive search* were chosen. The search terms were *hormone replacement therapy* and *vasomotor symptoms*. An excellent, evidence-based summary from *Women's Health* (Pinkerton et al., 2009) reviews the use of estrogen and other hormonal replacement therapies, various antidepressants, clonidine, gabapentin, and dietary and herbal supplements. The search and review of this article took approximately 3 minutes.

Another PubMed reference found by doing a search (<http://www.ncbi.nlm.nih.gov/sites/entrez>) using the keywords *hormone replacement therapy* and the limit, *Meta-Analysis*, uncovered a recent Cochrane review. "Long-term hormone therapy for perimenopausal and postmenopausal women" summarizes the literature and discusses current recommendations on the use of HRT (Farquhar et al., 2009). This summary considered 19 trials of almost 42,000 women and concludes that in relatively healthy women, combined continuous hormone therapy (HT) significantly increased the risk of venous thromboembolism or coronary event (after 1 year's use), stroke (after 3 years), breast cancer, and gallbladder disease. Long-term estrogen-only HT significantly increased the risk of venous thromboembolism (after 1-2 years), stroke (3 years), and gallbladder disease (7 years) but did not significantly increase the risk of breast cancer. Furthermore, the authors conclude that "we need more evidence on the safety of HT for menopausal symptom control, though short-term use appears to be relatively safe for healthy

younger women." This evidence took another 3 minutes to review.

A search using the online version of UpToDate using the keywords *hormone replacement therapy* quickly led to a review, "Postmenopausal hormone therapy: benefits and risks." A detailed description of evidence and cross-links with specific topics was found, including patient education handouts. A link to a summary of treatment of women with menopausal symptoms (www.uptodate.com/online/content/topic.do?to picKey=r_endo_f/9609) concludes:

Most postmenopausal women, with the exception of women with breast cancer or known cardiovascular disease, who have symptoms of vaginal atrophy and/or vasomotor instability are good candidates for estrogen therapy (for the shortest duration possible depending upon symptoms). The recommendations outlined below are consistent with those of the North American Menopause Society.

Likewise, using the Essential Evidence Plus search engine online uncovers 141 references when using the keywords *hormone replacement therapy*, including guidelines, evidence summaries, POEMs, and a patient education handout. A similar search at the FPIN website was also quite valuable. The decision of which platform and database to use is largely personal. Some of the distinctive characteristics of each resource are outlined in Table 8-5.

This case outlines how a physician with access to searchable databases can quickly review a wide array of clinical evidence and published guidelines. Such resources are based on systematic evaluations of evidence and can provide clinicians with practical guidance at the point of care. EBM, information mastery, and the application of knowledge at

Table 8-5 Examples of Evidence Sources

| Information Source Access | Description | Cost |
|---|---|---|
| PubMed http://www.ncbi.nlm.nih.gov/pubmed/ | Service of National Library of Medicine; 19 million citations back to the 1950s; includes links to many sites with full-text articles. | No charge |
| National Guideline Clearinghouse www.ngc.gov | Collection of guidelines, regularly updated; sponsored by Agency for Healthcare Research and Quality (AHRQ), U.S. Department of Health and Human Services. | No charge |
| U.S. Preventive Services Task Force (USPSTF) www.ahrq.gov/clinic/prevenix.htm | Federal prevention guidelines; public health focus; AHRQ is lead agency for project. | No charge |
| Bandolier www.medicines.ox.ac.uk/bandolier | British site; PubMed and Cochrane Library searched monthly for published systematic reviews and meta-analyses; excellent glossary, "What is series," covers common terms and acronyms. | No charge |
| Canadian Task Force on Preventive Health Care www.ctfphc.org | Canadian site; practical guide for health care providers, planners, and consumers for preventive health interventions. | No charge |
| Essential Evidence Plus www.essentialevidenceplus.com | Database of filtered, synopsised, evidence-based information; quarterly updates; searches a full spectrum of evidence-based resources, including POEMs and Cochrane abstracts, 325 diagnostic calculators and support tools, and summaries of evidence-based practice guidelines; POEMs are evidence-based summaries of single articles, not complete bodies of evidence; EBM presentation tools. | 30 days free; \$79/year |
| Cochrane Database www.cochrane.org/reviews/index.htm | An international, nonprofit, independent organization that produces and disseminates systematic reviews of health care interventions and promotes the search for evidence in the form of clinical trials and other studies of interventions. | \$310/year; abstracts free; often available from institutions |
| TRIP (Turning Research into Practice) www.tripdatabase.com | British site; central search engine for high-quality medical literature from wide range of sources: evidence-based records, clinical guidelines, clinical questions and answers, electronic textbooks, and medical images; more than 13 million peer-reviewed journal articles | Free searches |
| ACP Journal Club www.acponline.org/journals/acpj/jcmenu/htm | Tied to subscription to <i>Annals of Internal Medicine</i> ; regular structured reviews of important articles and informed commentary; focused on internal medicine; sponsored by American College of Physicians. | \$520/year |
| Family Physicians Inquiries Network (FPIN) www.fpin.org | Virtual learning community with growing point of care that answers clinical questions on basis of evidence-based content tools using structured, critical reviews of the literature; evidence graded and explicit; number of participants available (Clinical Inquiries and HelpDesk Answers); comprehensive point-of-care content (see PEPID below and PURLS); system identifies all new practice recommendations from newly emerging research findings. | Graduated trial available for handheld or online searching |
| DynaMed www.ebscohost.com/dynamed/ | Point-of-care reference tool organized around over 3000 clinical topics; systematically reviews over 500 medical journals and provides useful summaries of the literature, in an increasingly evidence-based manner. | \$395 for individual; discounts, trainee pricing available |
| UpToDate www.uptodate.com | Online, computer, and point of care accessible; comprehensive; qualitative reviews with many explicit descriptions of evidence, but recommendations not tied to a specific strength of recommendation taxonomy; expert opinion often mixed with more evidence-based recommendations. | \$495; \$195 for trainees |
| Physicians Electronic Portable Information Database (PEPID) PCP www.pepidonline.com | Online and handheld point of care accessible; integrated and hyperlinked; 2700 clinical topics, 6000-drug database, 1000 calculators and decision aids, all linked in a single application; includes all USPSTF recommendations; evidence based guidelines, all Clinical Inquiries, HelpDesk Answers, and Priority Updates from the Research Literature (PURLs) from FPIN. | \$209.95 |

the point of care remain works in progress. By developing a basic understanding of these resources and tools, physicians' care for patients can be more effective, safe, and efficient.

Evidence Levels

A: Randomized, controlled trials (RCTs); meta-analyses; well-designed, systematic reviews

B: Case-control or cohort studies, retrospective studies, certain uncontrolled studies

C: Consensus statements, expert guidelines, usual practice, opinion

A glossary of EBM terms is provided in eAppendix 8-1 online at www.expertconsult.com.

Pitfalls

- Do not assume that statistical significance is the same as clinical significance.
- Do not rely on pharmaceutical representatives or experts who may be biased in their presentation of information.
- Consider the potential harms and economic effects of an intervention.
- Do not assume that results even from a well-done study are applicable to your population of patients.
- Do not fail to use the many comprehensive sources of evidence-based information.

Key Points

- Information technology must support the core office functions for finances, personnel, and clinical quality.
- Information management is essential for quality patient care and efficient practice operations.
- Well-organized clinical information at the point of care means better decisions for patients.
- Registries are required for a population approach to complete and timely care.
- Information technology must help the team with care management and care coordination tasks.
- Computers can enhance patient and care team relationships through communication, education, and self-management support.
- Quality measures and reporting capability must be embedded in the EHR.
- Decision support tools ensure patient safety and timely, evidence-based care.

We live in a world that is so rich with information that managing, filtering, and organizing the data has become our most important challenge as we strive to use information technology (IT) to help us deliver reliable, high-quality care to our patients.

In the past the goal for family physicians was to have the *electronic health record* (EHR) selected, implemented, and working efficiently. Unfortunately, many EHR systems focused primarily on recording the office visit and support for billing and coding decisions. Over time, systems evolved to provide better support for office workflow, electronic prescribing, and clinical information management. Real-time interoperability and widespread health data exchange

remain challenges for clinical practice and for the U.S. health care system.

Information technology and the installation of hardware and software in the practice should not be a goal in and of itself. Computers must be configured and connected to support the key management functions of the medical office for finances, personnel, and clinical quality. For this reason, we organize this chapter by considering each of the core functionalities required for efficient medical office functioning. We describe how health information technology should be used to greatest advantage and address the need for integration, connectivity, and data exchange.

Components of Patient Care

Care of the Individual

Individual patient care will continue to be at the heart of what we do as family physicians. Documenting, organizing and transmitting the record of patient care over time must be well done, efficient, and communicated clearly to others. Electronic health records should help physicians document an accurate and complete account of the patient's care, including history, physical findings, laboratory tests, imaging results, advice from other specialists, medications, preventive measures, and screening efforts. A problem and medication list helps to present this information in a tabular form for easy reference and summarizes most of the important information that should accompany the patient wherever he or she receives care. The personal health record should capture the majority of this information so that all providers have access, as needed.

Most EHR systems rely on templates to enter information in discrete, searchable fields. There is always tension between the need for providing sufficient detail (granular data) and

the burden of entering too much detail without additional benefit to patients or physicians. At times, free text may be necessary to communicate precisely what is happening, such as a complex symptom history. Other information, such as routine physical findings, treatment plans, medications, and tests are more useful if entered in a tabular format (granular data) so that they can be identified and used to generate orders, check for allergies or interactions, feed decision support tools, and generate documents for transmission to others.

Personal health records for individuals are critical to ensure that important information about the patients' medical problems, current treatments, usual sources of care, and medications go with them whenever they need evaluation or treatment. Electronic health records should be able to interact with the personal health record to keep it accurate and up-to-date. In essence, the personal health record is a "snapshot" of the EHR at a point in time. It should be updated whenever there are any changes. The Continuity of Care Record (CCR) standard provides a format for the collection and transmission of this important data.

Care of a Population

In addition to caring for individuals, the office care team has the responsibility to monitor and manage their ability to care for the population they serve. This may apply to a particular condition (e.g., diabetes) or preventive services (e.g., immunizations, recommended screenings). Although the care each individual receives is important, the aggregate of the care that all patients with a particular condition receive is a better indication of the effectiveness of the overall approach to care.

Registries are used to track and organize information about all patients with a particular condition. For example, a registry for diabetes would include all patients in the practice who have been identified as diabetic. It should provide the office team with information about the patient's most recent visit (e.g., glycosylated hemoglobin and lipid levels, blood pressure results), eye exam date, and patient self-management goals. Many registries provide information for proactive contact with patients whose clinical parameters are missing or out of range. Registries provide the opportunity for patient care and contact between visits, in addition to highlighting needed services during the visit.

Ideally, EHRs should be able to integrate the registry function into the workflow and draw data from appropriate sources automatically. If this function is not integrated into the EHR, stand-alone and web-based products are available to help manage a population of patients.

Care Management Support

Patients often find themselves caught in a fragmented and disconnected health care system. Electronic systems can help track referrals to other specialists, laboratory test results, or imaging results to ensure that the recommended care has been accomplished. When patients are referred to other providers or to the hospital, they should be accompanied by the necessary clinical information so that the best decisions can be made, resulting in timely and efficient diagnostic testing or treatment.

Electronic health records should be able to produce a summary of important clinical information that is readable, transportable, and computable; the CCR standard provides a mechanism to do all three. The format allows data to be read by any browser software or to be converted to the readable formats of most EHRs.

Pharmacies now have the capability to capture and transmit data about prescription fills and renewal authorizations. If these data are made available to the physician, he or she can be on the alert for patients who have discontinued medications for a variety of reasons. Pharmacy benefits managers (PBMs) have data on formularies, drug prices, patient responsibility (co-payments), and coverage rules for each health plan contract. This information can be transferred to the EHR to aid in decision support for the physician as the prescription is generated.

Managing Patient Relationships

Electronic health records can store information about individual patient preferences, including primary language, end-of-life wishes, cultural beliefs or rituals, usual caregivers, nicknames, and extended family connections.

Secure e-mail can provide easy and efficient access to health care services and information for many patients. A *patient portal* allows patients to view sections of their EHR, request prescriptions or appointments, and report the results of home monitoring. Patient portals are also used to help direct patients to preferred Internet-based resources for education and support.

Patient self-management support shifts some of the responsibility for chronic illness care or lifestyle modification directly to the patient. Electronic systems can aid by sending automated reminders, education, and encouragement to patients between visits. Systems can track progress toward patient-oriented goals and report back to the office care team.

Social networking is now part of everyday life for a sizable portion of the U.S. population. Innovative uses of social networking can provide regular communication with patients, allowing for the development of support groups and enhancing interactions with patients between face-to-face visits. Just as the EHR must integrate into the physician workflow, the patient support strategies must integrate into their daily routines and tools.

Monitoring and Improving Quality and Performance

Measurement of clinical care has become increasingly important for documenting and improving the level of evidence-based care we provide. Performance measures should be built into the process of care to serve as reminders and permit the efficient capture of quality data for reporting. The National Quality Forum now endorses clinical performance measures for many of the common conditions that family physicians treat.

Comparative effectiveness research (CER) is used to determine if different treatments or procedures used in the care of the same condition have significantly different patient outcomes. If research shows that one treatment is clearly more efficacious than another, all physicians should be promoting

that treatment for most patients. EHRs help researchers collect data at the point of care and provide a platform for public health surveillance.

Measurement is the key to any quality improvement effort, whether streamlining patient flow or improving health outcomes for diabetic patients. As a general rule, measures for clinical care require data that the physician would want to have available to make the best diagnostic and treatment recommendations for the patient. This information can be organized on a flow sheet or template in the EHR for the dual purpose of ease of access by the care team and ease of data collection for quality measures. *Quality measures* can be used for both internal quality improvement and external reporting. An increasing portion of physician compensation will be attached to performance measures over time, so the degree to which these measures can be integrated into the system of care will determine the quality of patient care and the level of practice revenue.

Decision Support

Family physicians must acknowledge that they cannot remember everything about every patient. Decision support tools integrated into the office workflow help determine the correct diagnosis, help avoid patient harm from medication interactions or allergies, and provide ready access to the latest treatment guidelines. Electronic prescription writers can be configured to help with dosing decisions related to age, weight, renal function, and concurrent medications. These tools can also provide information about cost, formulary compliance, and availability of generic substitutions.

Office Business and Management Functions

Key Points

- In addition to scheduling and billing functions, information technology must facilitate intraoffice communications and workflow.
- Automating repetitive tasks saves time, improves efficiency, and enhances other patient care.
- Systems should record and analyze a broad set of demographics to enhance the care of diverse populations.
- Electronic monitoring of information allows data-driven decision making about staffing and resource allocation.

Well-developed information systems have long been available for practice management functions such as billing, collections, scheduling, and general accounting. These functions can now be supplemented with information from the clinical record to improve quality, efficiency, and reliability. Intraoffice communication through e-mail and workflow support will help automate routine or repetitive tasks and eliminate wasted time looking for team members. Having all the necessary information enhances payment levels and reduces claim denials.

With patient populations becoming more diverse, family physicians need to expand the demographics they track. In addition to name, address, and payer information, physicians must now record data on primary language, family

relationships, cultural preferences, and even genetic information that might affect treatment decisions or medication selection.

Computer systems should also provide the information needed to manage productivity and personnel. Family physicians should make decisions about staffing levels or adding clinicians based on reliable data. Calculations of patient panel size by clinician, productivity per full-time equivalent (FTE) provider, and supply/demand for appointments will support good business decisions.

Integrating and Connecting Systems and Functions

Key Points

- Information technology systems must be configured to integrate all the core office functions seamlessly.
- Easy access to the Internet and decision support tools enhances patient care.
- Interoperability or the efficient transfer of data among disparate computer systems is essential to achieve the full potential of health information technology.
- Continuing professional development and medical education must be integrated into patient care.

Workflow Management

In a typical day, the family physician's work involves face-to-face visits, outside inquiries from patients, ordering or checking of laboratory results, consultations with colleagues, prescription refills, and interactions with office staff. Managing all these tasks in an efficient manner allows the physician to spend more time with patients and still maintain a personal life.

Information technology can help organize and cue the work for easy access and disposition. Ideally, the system will have a "workflow screen" that shows all pending tasks in a well-organized way. The physician can then quickly choose to answer a message or check off lab reports while moving from one examination room to the next. Efficient intraoffice e-mail communication facilitates work distribution and completion by connecting the entire office staff in an asynchronous manner.

Organizing Information for Point-of-Care Decision Making

Most EHR systems can be configured to organize needed information for a particular patient or condition so that it is presented in a clear and concise way. Some templates actually integrate treatment goals or guidelines and provide highlights or reminders when the patient's parameters are out of range. For example, if you are seeing a diabetic patient whose BMI or blood pressure is high or whose LDL level is above the recommended target, you would get a prompt to modify the treatment plan. When help is needed about what test might substantiate a suspected diagnosis, the computer should be able to assist. Treatment plans and follow-up recommendations can be printed, transmitted, and tracked over time and provide reminders as needed for both patients and office staff.

Health Information Exchange

Having all the information about tests, medications, consultations, and hospitalizations is essential if we are to make the best decisions for our patients. To have timely transfer of data from one point of care to another, there must be real-time exchange of information that is managed securely. Many U.S. regions now have health information exchange projects, which should become more useful over time as more practices have fully capable EHR systems.

Professional Development

Family physicians must be committed to lifelong learning and professional development. Traditional classroom or lecture formats may not serve practicing physicians as well as

online interactive learning environments. The ability to look up information quickly while the patient is present will be a necessary part of care in the future. Practice-based improvement and point-of-care learning are now required competencies for physicians of all specialties.

Conclusion

Information technology must support the core functions of medical care. Diagnostic and therapeutic decisions, patient self-management support, and follow-up are all aided by effective computer systems. Electronic health record use, electronic prescribing, and data availability at the point of care are fast becoming the “standard of care” that all family physicians must strive to achieve.

| Making Clinical Decisions | 124 | Incorporating Patient Preferences | 127 |
| Focusing the Question | 125 | Conclusion | 129 |
| Finding the Evidence | 125 | | |

Key Points

- Taking care of patients requires clinical decision-making skills.
- Most physicians rely on “mindlines” formed by previous knowledge and experience.
- A lag exists between the publication of new evidence and its incorporation into clinical practice.
- Clinicians should use evidence-based medicine techniques to update their mindlines.

During a 15-minute follow-up visit for her diabetes, Mrs. Smith, a 78-year-old white patient who has a history of well-controlled type 2 diabetes mellitus, hypertension, asthma, and mild dependent edema, requests a refill of her hormone replacement therapy (HRT). Glancing at her chart, you note that she has been taking 0.625 mg daily of conjugated estrogen (Premarin) since a hysterectomy for excessive bleeding at age 53. She is also taking 1000 mg of metformin twice daily, 20 mg of lisinopril daily, 25 mg of hydrochlorothiazide daily, and fluticasone plus albuterol (Advair; 250/50 µg twice daily) and using an albuterol metered-dose inhaler as needed. Before reaching for your pen, you wonder if HRT is the right choice for Mrs. Smith.

Anyone engaged in primary care faces scenarios such as this on a daily basis. Such a seemingly simple request requires that clinicians rapidly assess the current medical evidence as it applies to the particular patient, communicate the risks and benefits using language the patient understands, and recommend a course of action based on the patient’s preferences. This is a daunting task, but most clinicians do it without a second thought. By analyzing how clinical decisions are made, physicians can better understand how to integrate evidence-based medicine and patient preferences to improve the efficacy and efficiency of clinical practice.

Making Clinical Decisions

A typical family physician sees a patient every 15 minutes and addresses three separate problems during the visit (Beasley et al., 2004). Busy clinicians operating in such an environment must make snap decisions regarding patient care. Ethnographic studies of actual physician decision making in primary care offices indicate that physicians rely on “mindlines” to guide them (Gabbay and le May, 2004). Physicians develop these mindlines as a preconceived, conceptualized, and standardized approach to a particular clinical scenario. For example, for a child with fever and tonsillar exudates, one physician’s mindline may be to treat with penicillin, and another physician’s mindline may be to obtain a culture and treat if the results are positive for *Streptococcus*. The foundation of these mindlines is the tacit knowledge physicians acquire during their early training. For example, the best predictor of a clinician’s knowledge about hypertension treatment is his or her year of graduation from medical school (Evans et al., 1984). Subsequently, these mindlines are continuously refined by patient care experiences, interactions with colleagues, discussions with trusted experts, and to a lesser extent, focused reading. Mindlines allow the clinician a mechanism to cope with the demands of a busy office practice. If not continuously updated and refined, however, such mindlines can quickly become stale and outdated.

A significant lag often occurs between the publication of landmark clinical studies that change medical practice and their general adoption by the medical community. Often, an opinion leader or trusted expert must adopt the new clinical practice first before others in the medical community feel comfortable changing their own practices (Slawson et al., 1994). This supports the concept that interactions with colleagues and discussions with trusted experts are the primary influence in shaping physician mindlines. The challenge is for the physician to use the tools of evidence-based medicine to shape her or his own mindlines and become an opinion leader.

To make sound clinical decisions, the clinician must first check his or her mindline. If there are knowledge gaps in the mindline, it can be updated by asking a focused clinical

question and using the techniques of evidence-based medicine. Next, the clinician discusses potential risks and benefits of treatment options with patients, determining their preferences. By integrating the medical evidence with patients' preferences, a shared clinical decision is reached.

You recall learning in medical school that HRT reduced the risk of cardiovascular disease and osteoporosis. Because your patient, Mrs. Smith, is clearly at risk for both, you have always refilled her conjugated estrogen (Premarin) since first seeing her 25 years ago. When a bone density scan 4 years ago showed no evidence of osteopenia, you congratulated yourself for all those years of prescribing HRT. However, a colleague recently presented a paper at an educational conference and, based on the results of the Women's Health Initiative (WHI) study, recommended that all women be taken off estrogen replacement therapy. The estrogen was originally started because of concerns about osteoporosis, but now you wonder whether Mrs. Smith should continue it.

Focusing the Question

Key Points

- Identify the existence of a knowledge gap.
- Determine the information source most likely to answer the type of question.
- Develop a focused question consisting of four parts: patient's problem, intervention, comparison intervention, and outcome of interest.

Many studies have documented that important clinical questions arise during the day-to-day care of patients (Dee and Blazek, 1993). The number and types of questions depend on the clinical setting and the experience of the physician. The most common generic questions involve choosing which drugs to prescribe, determining the cause of a condition, and deciding what diagnostic study to order (Ely et al., 2000). Studies also show that answers are not sought for most questions that arise, but that physicians who seek answers are usually successful in finding them (Ely et al., 1999). Previous studies that documented little dependence on computerized resources for finding answers may reflect that the studies were conducted when computers were not extensively used in the course of routine patient care (Covell et al., 1985; Osheroff and Bankowitz, 1993).

After identifying a knowledge gap relevant to making a clinical decision, the next step is finding the information necessary to close the gap. To find the necessary information, an answerable question must be developed. There are two general types of clinical questions: background and foreground. *Background questions* are the "who, what, why, and how" questions usually answered in textbooks and asked by medical students; for example, What oral drugs are used in the treatment of diabetes? *Foreground questions* focus on the specifics surrounding care of a patient; for example, Which is more effective in reducing fasting blood sugar level in an obese patient with type 2 diabetes—metformin or glyburide? It is unlikely that a textbook could adequately answer this second question.

Being able to identify the type of question helps direct the physician to the best source of information for answers.

Most of the questions that arise out of patient care can be categorized as foreground questions, because they are specific to a particular patient's case. Although unlikely to be found in textbooks, the ability to answer these questions at the point of care is essential to providing the best care in a timely manner. A *focused clinical question* must be developed to find the information efficiently (Richardson et al., 1995). Unfortunately, this critical step is often overlooked, causing needless frustration when searching for answers among thousands of hits in a search engine. Sackett and colleagues (2000) propose that "educational prescriptions" be used to teach this important skill to physicians in training.

The four components of a focused clinical question are (1) the patient's problem, (2) the intervention, (3) the comparison intervention, and (4) the outcome of interest. *Patient-oriented outcomes* are always better than disease-oriented outcomes because they are *direct measures* rather than secondary markers. For example, a study documenting that a new drug reduces total cholesterol by 20% (secondary marker) is important, but not as persuasive as a study documenting a decrease in cardiovascular death (direct measure).

Whether Mrs. Smith should remain on estrogen therapy is a complex question. You know that the WHI study assessed multiple outcomes of importance for this patient population, including the impact of hormones on heart disease, fracture rates, venous thromboembolism, colon cancer, and breast cancer. The question of whether Mrs. Smith should keep taking estrogen cannot be answered without weighing the risks and benefits of the therapy and the importance of each of these outcomes to the patient. Mrs. Smith's primary concern is the prevention of osteoporosis because her mother had severe osteoporosis with multiple fractures during her life. This additional information helps to guide the development of a relevant, focused clinical question for Mrs. Smith: In postmenopausal women at risk for osteoporosis (i.e., the patient's problem), is continuation of estrogen replacement therapy (i.e., the intervention) better than changing to bisphosphonate therapy (i.e., the comparison intervention) for prevention of osteoporotic fractures (i.e., the outcome of interest)?

Finding the Evidence

Key Points

- Usefulness = (Relevance × Validity)/Work
- Conflicting evidence is often the result of "medical chatter."
- POEMs and guidelines require the least amount of work to find relevant and valid results.

Having identified a focused question, the astute clinician is ready to find the information needed to answer it. The usefulness of medical information can be modeled in the following equation (Slawson et al, 1994):

$$\text{Usefulness} = \frac{(\text{Relevance}) \times (\text{Validity})}{(\text{Work})}$$

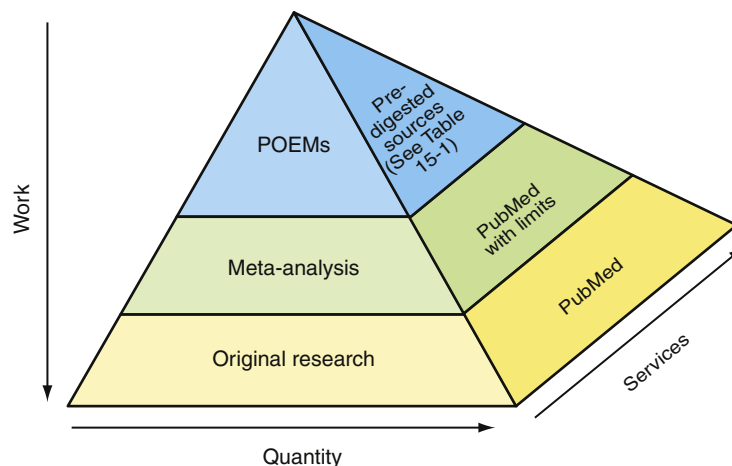

Figure 10-1 Evidence pyramid.

As the formula shows, busy clinicians should concentrate their efforts on easily obtained, valid evidence that is highly relevant (i.e., patient-oriented evidence). Such a strategy focuses attention on useful information and makes wise use of limited time and resources.

As shown in Figure 10-1, the work required to find useful medical information is inversely proportional to its quantity. At the bottom of the pyramid is original research. Although plentiful, much of it represents “medical chatter” among researchers (Slawson et al., 1994). Researchers are intimately familiar with published data in their narrow field of study and are able to place the article in its proper context. A busy clinician reading a single article in a relatively unfamiliar field is akin to overhearing a snippet of conversation at a dinner party. It may be dangerous to base decisions on such snippets without knowledge of the larger context. Checking the relevance and validity of such studies requires knowledge of statistical methods and study design. It is too time-consuming to be useful for answering clinical questions that arise during a patient visit.

At the next level of the pyramid are *systematic reviews* and *meta-analyses*. These types of studies focus on a single topic and attempt to draw conclusions from the volume of previously reported data. Although an improvement, the clinician still must explore the methodology used to select and analyze the data to ensure relevance to the clinical question. Often, these types of reviews focus on disease-oriented outcomes rather than patient-oriented outcomes, potentially making them less relevant. Disease-oriented outcomes, such as an increase in bone mineral density, may be a secondary marker for fracture risk, but they are inherently less relevant to the patient.

At the peak of the pyramid are *patient-oriented evidence that matters* (POEM) reviews (Table 10-1). Clinicians must decide if the POEM is relevant to their clinical question, but the amount of work required is greatly reduced. POEMs offer the most useful type of information for answering clinical questions that arise during patient visits. Unfortunately, a POEM does not exist for every clinical question. In these cases the clinician must step down the pyramid until relevant information is found.

The medical evidence often tells conflicting stories, as with HRT. This is particularly problematic at the original research or bottom level of the evidence pyramid. Differences in

methodology, study populations, statistical power, and bias often explain the different conclusions and result in medical chatter. Putting such articles in their proper context is difficult at best for the practicing clinician. Moving up the evidence pyramid helps alleviate conflicting evidence, yielding results that are more reliable.

Often, minimal or no reliable medical evidence is available to answer a clinical question. In these cases, practicing clinicians must rely on their clinical experience and background medical knowledge—their mindlines.

Haynes (2001) defined another pyramid that is relevant to answering clinical questions. This is the pyramid of services for finding the best evidence. It is depicted as the third dimension of the evidence pyramid (Figure 10-1). At the bottom of the pyramid are tools to find the original studies.

The National Library of Medicine maintains a database of more than 15 million articles, called MEDLINE. Various engines are available to search MEDLINE and other databases for articles that may be used to answer clinical questions. For example, PubMed (www.pubmed.gov) provides tools to help clinicians search for meta-analyses and systematic reviews through the use of *limits* and *clinical queries* (Ebbert et al., 2003; Haynes and Wilczynski, 2005; Sood et al., 2004).

As in Mrs. Smith's case, there may not be a single study that addresses the specific question posed. In looking for the best evidence to inform clinical decision making, it is important to determine the standard of care for the patient's condition. Clinical guidelines, which are typically updated every 2 years, may be a useful resource. An excellent clearinghouse for clinical guidelines is sponsored by the Agency for Healthcare Research and Quality (AHRQ, www.guidelines.gov), although the listed guidelines are neither reviewed nor endorsed by AHRQ. Clinicians must critique the guidelines for validity and relevance in their own setting. This resource is higher up the services pyramid and reflects some interpretation and synthesis of original research and clinical practice.

You review the Institute for Clinical Systems Integration guideline for osteoporosis prevention and HRT at www.guidelines.gov, as well as the risk/benefit data from the www.WHI.org site (Figure 10-2). These guidelines tell you that HRT should not be used simply for prevention of osteoporosis in the absence of other significant menopausal symptoms. You reflect on your colleague's words: "Get everyone off that stuff!" It is time to have a discussion with Mrs. Smith regarding her estrogen therapy.

Incorporating Patient Preferences

Key Points

- There has been a cultural shift from paternalistic to shared decision making.
- The degree of shared decision making depends on risk, benefit, and a patient's preferences.
- Decision aids can help patients understand complex probabilities.

Until the 1980s, medical decision making was physician driven. Such decision making required and perhaps engendered patients' trust in their physicians. With such paternalistic care, patients effectively ceded decisional authority to their physician through implied consent. Physicians made the decisions, patients accepted them, and most patients preferred it that way. Many patients still prefer this type of interaction (Goldfarb, 2004). How many times do family physicians explain the risks and benefits of a procedure, only to have the patient respond, "So Doc, what would you do?"

In 1980 a small, influential group was formed: the Society for Medical Decision-Making. Over the years, the society's work has spawned two other movements: evidence-based medicine and shared decision making. *Evidence-based medicine* (EBM) seeks to provide physicians with the empirical data necessary to make wise clinical decisions through critical appraisal of the literature. *Shared decision making* occurs when physicians communicate the evidence to patients with sufficient clarity that they can become fully informed partners in their own health care decisions. Probabilistic evidence

Figure 10-2 Women's Health Initiative (WHI) site.

alone should not guide decision making; patient preferences and values must be considered for a decision to be shared. As a result, shared decision making has been called an “ethical” process. The physician not only informs the patient before making the decision, but also seeks to empower the patient to become an active participant in decision making.

“Doctor,” Mrs. Smith interjects as you finish clicking through the guideline pages. “I know you’re concerned about me being on these hormones. But, I really am doing well, and I don’t want to stop them unless I have to.”

The cultural change toward active patient participation in medical decision making occurred rapidly. One survey of patients seeing their physician for chronic disease management between 1986 and 1990 found that 69% preferred “to leave decisions about my medical care up to my doctor.” In contrast, a study only 10 years later found that 84% of women with node-negative breast cancer preferred a shared role in decision making regarding adjuvant chemotherapy. One week after using a decision aid to explore the risks and benefits, an additional 10% said they preferred a shared role in the decision (Arora and McHorney, 2000). This cultural shift toward greater patient involvement in clinical decision making may stem from the increased availability of medical knowledge in the public domain and an increasingly consumerist society (Guyatt et al., 2004).

Physician reactions to this cultural change range from self-interest in avoiding legal liability to selfless beneficence in seeking to include patient preferences (McGuire et al., 2005). Increased patient participation in medical decision making is associated with increased trust, higher patient satisfaction, and greater compliance with treatment, particularly lifestyle changes. In some cases, this leads to an improvement in disease outcomes (Epstein et al., 2004; O’Conner et al., 2003; Trachtenberg et al., 2005).

Shared decision making is substantially different from *informed consent*, a legal doctrine focused on disclosure of risk and benefit to the patient or the surrogate rather than on partnership in medical decision making. Shared decision making also differs from *medical consumerism*, in which patients obtain information from various media sources

before actively interviewing their physicians and making their own decisions about their health care. Shared decision making involves the creation of a physician-patient partnership, one of the six principal aims of health care in the 21st century, as identified by the Institute of Medicine’s 2000 report (Sheridan et al., 2004).

A busy family medicine practice involves straightforward and complex medical decision making. The degree to which decision making is shared with the patient varies according to the risk of the intervention, certainty of the benefit, and the patient’s desire for autonomy. Figure 10-3 illustrates how these three dimensions of risk, certainty of benefit, and patient preferences interact to determine whether shared decision making is necessary.

For decisions involving low risk and a single best course of action, shared decision making is unlikely to be helpful. Physicians are free to make the decision as long as they explain what needs to be done and why. The TV image of the wise family doctor making a diagnosis of strep throat and then sitting back in his chair to elicit patient involvement in the decision about whether to treat with penicillin is laughable to most patients, of little benefit, and a sure way to put the physician behind schedule.

Conversely, when multiple alternatives of almost equal benefit exist, the decision necessarily involves patient preferences. For example, in a young healthy patient with elevated lipid levels, the patient should share in the decision regarding initiation of a statin versus continued aggressive lifestyle changes. Such involvement is more likely to yield patient compliance with the mutually agreed course of action.

When the choice involves significant risk or moral beliefs and the certainty of benefit is low, the patient should be encouraged to make the decision, with the physician acting as an informant rather than a co-participant (Whitney et al., 2004). An excellent example occurs with first-trimester screening for Down syndrome and trisomy 18.

Physicians must be flexible, adjusting to the patient’s desire for involvement in decision making. Some patients want collaborative decision making, whereas others feel more comfortable with traditional physician-directed decision making (McGuire et al., 2005). This is shown as the third dimension in Figure 10-3.

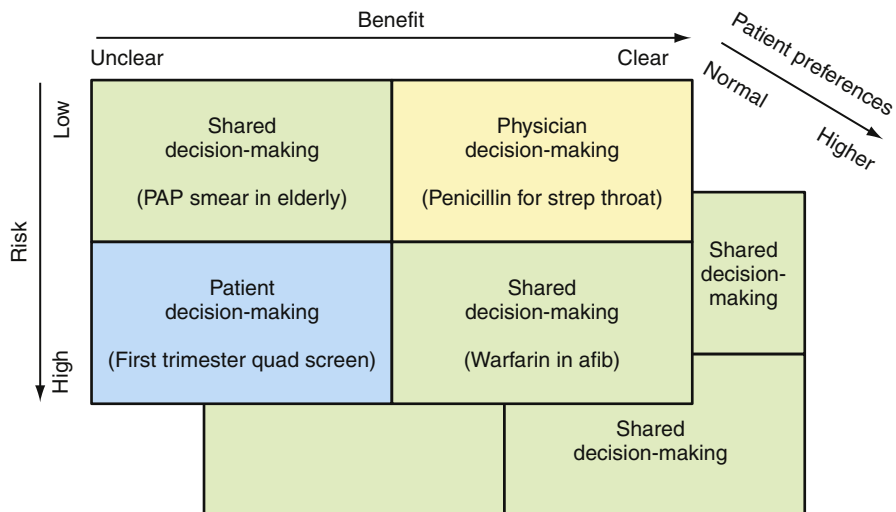

Figure 10-3 Shared decision-making model.

The desire to communicate data effectively to patients has resulted in development of many decision support tools, such as pamphlets, audio/videotapes (CDs), personalized counseling, smartphone apps, and interactive computer programs on the Internet. These tools inform patients about complex risk/benefit balances and help them determine their personal preferences and reach a decision by weighing the possible outcomes. An excellent example is the Atrial Fibrillation Treatment Decision-Making Aid offered by the University of Ottawa.* This tool informs patients about atrial fibrillation and strokes, estimates risks and benefits, and helps rank the patient's outcome preferences. Based on these data, a worksheet guides the physician and patient in a shared decision-making process (Ottawa Health Decision Centre, 2006, <http://decisionaid.ohri.ca/>).

Because working through such decision aids can be time-consuming and impede workflow in a busy clinic, they are often best assigned as homework, with a recheck visit at a later date to engage in shared decision making.

Mrs. Smith needs more patient-oriented evidence to help her share in the decision to continue or stop the HRT. Following the links on the Ottawa Health Decision Centre website, you bring up the decision aid, "Osteoporosis Decision Aid: Should I take hormone replacement therapy?" You print it, hand Mrs. Smith a pen, and head off to see your next patient while she ponders the information.

Decision making often is not as complex as Mrs. Smith's case, and no written decision aid may exist. A family physician may only have 2 or 3 minutes during a 15-minute patient encounter to explain the complex probabilities of risks and benefits for a particular intervention. Various statistical constructs have been proposed to communicate these probabilities to patients in an understandable manner.

The ideal format depends on the patient's condition and ability to understand probabilities. The relative risk ratio (RRR), absolute risk ratio (ARR), and *number needed to treat* (NNT) are reasonable constructs that can communicate the expected magnitude of benefit. Although the NNT has been proposed as an intuitive concept, a Danish trial showed that patients have difficulty understanding the magnitude of osteoporosis treatment benefit when presented in terms of NNT. Conversely, when explained as postponement of hip fracture, their treatment decisions reflected a better sense of the actual benefit (Christensen et al., 2003). Sheridan and colleagues (2003) similarly found that patients frequently misinterpreted the NNT but found the ARR and RRR more intuitive. The Evidence-Based Medicine Working Group has proposed more clearly communicating treatment benefit by using the construct of "likelihood of being helped versus harmed" (McAlister et al., 2000).

When you return to her examination room 15 minutes later, a satisfied Mrs. Smith declares, "I appreciate you giving me all the information, but what do you think I should do?" You review the decision aid with her, discussing the risk/benefit ratios; you note that she has identified the benefits of decreased fractures and

menopausal symptoms as more important than the risk of harm from blood clots, heart disease, stroke, or breast cancer. She states, "Doc, I know that my diabetes raises my risk of heart disease, but I just don't want to fall and break my hip and have to spend the rest of my life in a nursing home. Besides, I really enjoy not having the hot flashes."

You reflect for a moment on the Heart and Estrogen/progestin Replacement Study (HERS) study results (Hulley et al., 1998) that showed a decrease in cardiovascular risk with HRT in years 3 to 5 of the study. You have heard some of the controversy surrounding the WHI results (2002) and the possibility that lower rates of cardiovascular disease might have been seen with longer exposures to estrogens if the trial had been continued.

You inform Mrs. Smith that you cannot really be sure, but because she has been receiving HRT so long, you do not believe her risk of heart attack is increased. You also make sure she understands the absolute risks of breast cancer and blood clots. She replies, "Well, Doc, I've been on estrogen for 25 years, and I never had a problem with my heart or my mammograms. I just don't want to wind up like my friends who've gone off estrogen and have hot flashes every night—you know what I mean?"

Clicking the pen, you say, "Well, Mrs. Smith, you seem to have a good understanding of your situation. Shall we continue that Premarin?"

Conclusion

Clinical decision making is the intersection of the science of evidence-based medicine and the art of shared decision making occurring within the bounds of the health care system (Figure 10-4). People yearn for a relationship with their physician, someone who listens to their needs and guides them through the medical system (Future of Family Medicine, 2004). Who is better equipped to perform outstanding clinical decision making and foster excellent physician-patient communication than the family physician? By forming close longitudinal relationships, family physicians have the opportunity to truly know their patients and to understand their values, their preferences, and their fears. When combined with evidence-based medical knowledge, it is no wonder patients trust and value their family physician.

Key Points

- Terms and definitions that describe CAM are diverse and evolving.
- Integrative medicine combines CAM and conventional medicine.

The level of integration of conventional and CAM therapies is growing. That growth generates the need for tools or frameworks to make decisions about which therapies should be provided or recommended, about which CAM providers to whom conventional medical providers might refer patients, and the organizational structure to be used for the delivery of integrated care. The committee believes that the overarching rubric that should be used to guide the development of these tools should be the goal of providing comprehensive care that is safe and effective, that is collaborative and interdisciplinary, and that respects and joins interventions from all sources. (Institute of Medicine, 2005)

In these tumultuous times of health care reform, family physicians find themselves on a threshold: a place of great professional promise as well as uncertainty. Will they step through this historic doorway with newfound meaning and professional identity? Will they create new practice models, new ways of delivering care, and new methods of

collaborating across the spectrum of healing practices and health professionals? Work is already underway with initiatives such as TransforMed and P4. In addition, the field of family medicine has taken the lead and is currently pioneering work bringing complementary and alternative medicine (CAM) and integrative medicine into residency training and clinical care (Benn et al., 2009).

How will these relatively new and evolving areas of health care optimize and revitalize the practice of family medicine? This chapter describes these new fields, assesses proposals by U.S. medical organizations, and addresses the challenges for practitioners applying current research techniques to these diverse and complex healing approaches and systems. Core principles and specific examples of CAM encountered by the practicing family physician are presented with relevant evidence and helpful tips.

Complementary and alternative medicine is based on multiple healing traditions practiced long before conventional Western medicine. Emerging from diverse cultural traditions worldwide, these approaches to health and healing offer the wisdom of their unique perspective on the human condition. Many traditional practices, including those of conventional medicine, share common roots and philosophies and uphold the sacred call to relieve the suffering of others. Family physicians should keep an open mind as they explore these dimensions of CAM.

What Is Complementary and Alternative Medicine?

Various definitions have been used to describe the array of approaches and philosophies commonly referred to as “CAM.” As the field has evolved, so has the terminology. Unconventional, unproven, alternative, complementary, holistic, integrative, and integral are some of the most common examples of terms in current use.

Historically, medical pluralism has long existed in the United States (Kaptchuk and Eisenberg, 2001a). Over the past few decades, *alternative medicine* has become a more recognized entity within conventional medicine. Because of the public’s growing use of CAM, the National Institutes of Health (NIH) created an Office of Alternative Medicine (OAM) in 1992, with the intention of bringing its scientific expertise “to more adequately explore unconventional medical practices” (NCCAM, 2000). Because of Americans’ ongoing and increasing use of CAM, the OAM was expanded to the *National Center for Complementary and Alternative Medicine* (NCCAM) in 1998, guided by the following mission statement (2000): “We are dedicated to exploring complementary and alternative healing practices in the context of rigorous science, training researchers, and disseminating authoritative information to the public and professional communities.” After a decade of work in the field, NCCAM has become a leading resource for helping the public and health professionals better understand this rapidly growing area of medicine. The center’s name has led to the more widespread use and recognition of CAM as the defining term for this field. NCCAM’s free website contains a wealth of information, including the following definitions (2000):

Complementary and alternative medicine is a group of diverse medical and health care systems, practices, and products that are not considered part of conventional medicine. Although some scientific evidence exists, the list of what is considered to be CAM changes continually as the therapies that are proved to be safe and effective become adopted into conventional health care and as new approaches to health care emerge.

Alternative medicine is used in place of conventional medicine. *Complementary medicine* is used together with conventional medicine.

Integrative medicine combines mainstream medical therapies and CAM therapies for which there is some high-quality scientific evidence of safety and effectiveness.

The NCCAM further classifies CAM into five categories, or domains (Figure 11-1). Examples of alternative or whole medical systems include homeopathy, naturopathy, and Ayurveda (eAppendix 11-1 provides a glossary of CAM terms online at www.expertconsult.com). Although there are a variety of approaches to the complex taxonomy of CAM (Kaptchuk and Eisenberg, 2001b), the NIH system is most often used.

Another term, *holistic medicine*, also describes these practices and philosophy. The American Holistic Medical Association (AHMA), founded in 1978, is a membership organization for physicians and other health professionals seeking to practice a broader form of medicine than that currently taught in allopathic medical schools (Table 11-1). “Holistic medicine is the art and science of healing that addresses care of the

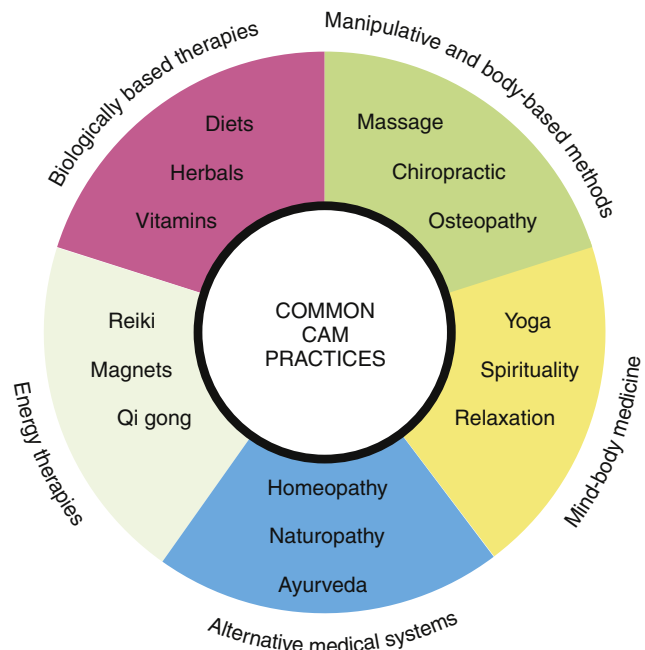

Figure 11-1 The National Center for Complementary and Alternative Medicine (NCCAM) groups complementary and alternative medicine (CAM) practices into five domains, recognizing that there can be some overlap among them. *Biologically based therapies* use substances found in nature, such as herbs, special diets, or vitamins (in doses outside those used in conventional medicine). *Energy therapies* involve the use of energy fields, such as magnetic fields or biofields (i.e., energy fields that some believe surround and penetrate the human body). *Manipulative and body-based methods* are based on manipulation or movement of one or more body parts. *Mind-body medicine* uses a variety of techniques designed to enhance the mind’s ability to affect bodily function and symptoms. *Alternative or whole medical systems* are built on complete systems of theory and practice. Often, these systems have evolved apart from and earlier than the conventional medical approach used in the United States.

whole person—body, mind, and spirit. The practice of holistic medicine integrates conventional and complementary therapies to promote optimal health and to prevent and treat disease by addressing contributing factors” (AHMA, 2005).

In 1981, the nursing profession, guided by a group of nurses dedicated to bringing the concepts of holism to every arena of nursing practice, founded the American Holistic Nursing Association (AHNA). “Holistic nursing embraces all nursing that has as its goal enhancement of healing the whole person from birth to death. Holistic nursing recognizes that there are two views regarding holism: that holism involves identifying the interrelationships of the biopsychosociospiritual dimensions of the person, recognizing that the whole is greater than the sum of its parts, and that holism involves understanding the individual as a unitary whole in mutual process with the environment” (AHNA, 2005).

Integrative medicine, a term brought into popular use by Andrew Weil, MD, founder and director of the innovative University of Arizona Center for Integrative Medicine, describes how CAM and conventional medicine is practiced together (Rakel and Weil, 2003):

Integrative medicine is healing oriented and emphasizes the centrality of the doctor-patient relationship. It focuses on the least invasive, least toxic, and least costly methods to help facilitate health by integrating allopathic and complementary therapies. These are

Table 11-1 Important Events in Complementary and Integrative Medicine

| Year | Event |
|------|--|
| 1978 | American Holistic Medical Association is founded. |
| 1981 | American Holistic Nurses Association is founded. |
| 1992 | U.S. Office of Alternative Medicine (OAM) is established. |
| 1996 | U.S. Food and Drug Administration (FDA) approves acupuncture needles for use by licensed practitioners. |
| 1998 | National Center for Complementary and Alternative Medicine (NCCAM) is established, replacing OAM. |
| 1999 | Consortium of Academic Health Centers for Integrative Medicine (CAHCIM) is formed in response to increasing public interest in complementary and alternative medicine (CAM) and grows to 46 members by 2010. |
| 2000 | American Board of Medical Acupuncture is established, with a certifying examination for physicians to demonstrate proficiency in the specialty of medical acupuncture. |
| 2000 | President Clinton appoints James S. Gordon, MD, to chair the first White House Commission on Complementary and Alternative Medicine Policy (WHCCAMP). |
| 2002 | WHCCAMP submits final report with administrative and legislative recommendations for maximizing the benefits of CAM for all Americans. |
| 2005 | Institute of Medicine (IOM) releases report on CAM in the United States. NCCAM releases 5-year strategic plan. |
| 2006 | CAHCIM sponsors the first North American Research Conference on Complementary and Integrative Medicine. |
| 2009 | IOM Summit on Integrative Medicine and the Health of the Public. CAHCIM sponsors a second research conference. NCCAM prepares its third strategic plan. |

based on an understanding of the physical, emotional, psychological, and spiritual aspects of the individual.

In general, the terms *holistic* and *integrative* seem to best convey the ideal blending of conventional and unconventional medicine “in that both imply a balanced, whole-person-centered approach and involve a synthesis of conventional medicine, CAM modalities, and other traditional medical systems, with the aim of prevention and healing as a basic foundation” (Lee et al., 2004).

The term *integral* has recently emerged in the literature. First noted several decades ago in the book *Mind, Body and Health: Toward an Integral Medicine* (Gordon et al., 1984), its original use may be traced to the work of Sri Aurobindo, an Indian mystic and political leader. The term has been popularized by contemporary philosopher and transpersonal psychologist Ken Wilber (2005), as applied in the context of his *integral theory*. Many thought leaders in the field of health and healing, including the Institute of Noetic Sciences (IONS), support these concepts and encourage further research into what may be considered the beginnings of a paradigm shift

in medicine (Schiltz, 2005). The following excerpt captures the essence of the deep change and transformation that integral medicine calls for (Wilber, 2005):

The crucial ingredient in any integral medical practice is not the integral medical bag itself—with all the conventional pills, and the orthodox surgery, and the subtle energy medicine, and the acupuncture needles—but the holder of that bag. Integrally informed health-care practitioners, the doctors, nurses, and therapists, have opened themselves to an entire spectrum of consciousness—matter to body to mind to soul to spirit—and who have thereby acknowledged what seems to be happening in any event. Body and mind and spirit are operating in self and culture and nature, and thus health and healing, sickness and wholeness, are all bound up in a multidimensional tapestry that cannot be cut into without loss.

Family physicians know this to be true. They practice with the intention to care for the whole patient within the context of a continuous healing relationship while honoring the rich complexity and interplay of family, community, and environment. They acknowledge the personal and interpersonal effects of health and illness and are trained to consider the behavioral and social aspects of a person’s life as well as the biomedical factors.

Now is the time not only to reclaim its roots, but also to move primary care into expanded dimensions and possibilities of health and healing. Family medicine is the ideal discipline to champion this movement and to actualize changes that will begin to heal the failing U.S. health care system. Whether it is called holistic, integrative, or integral, family physicians are collectively evolving toward a more compassionate and sustainable system of care that may ultimately be called *good medicine*.

Complementary and Alternative Medicine Use in the 1990s

Key Points

- Almost 40% of U.S. adults and 12% of children use CAM therapies.
- The number of adult Americans using CAM rose by 38% between 1990 and 1997 and has remained stable between 2002 and 2007.
- CAM is used more by women, by those with higher levels of education and income, and by those who were recently hospitalized.
- Most patients do not disclose CAM use to their physicians.
- Most patients use CAM *and* conventional care together.

The first major study of CAM use in the United States was conducted in 1990 by David Eisenberg and colleagues (1993), who published a landmark paper in the *New England Journal of Medicine*. Serving as a wake-up call to conventional medicine, the data from this national telephone survey of 1539 English-speaking adults estimated that one of three Americans (34%) had used a CAM therapy in the prior year. The study estimated that those using CAM had made 425 million visits to complementary medicine practitioners—more than all office visits to primary care

physicians in that same time frame! The out-of-pocket costs for these CAM services were approximately \$14 billion a year. The striking statistics alerted mainstream medicine and prompted further inquiry into the growing phenomenon of the public's use of CAM.

In 1997, Eisenberg and colleagues conducted a follow-up to the 1990 study, again using a national telephone survey of English-speaking adults (2055). The findings, published in the *Journal of the American Medical Association* in 1998, showed that the number of Americans using CAM rose by 38% (60 to 83 million) and that visits to CAM practitioners increased from an estimated 427 million to 629 million. Overall, 42% of Americans were estimated to be using at least one CAM therapy in the prior 12 months. With regard to costs, conservative estimates put expenditures for CAM professional services at \$21.2 billion, with approximately \$12.2 billion paid as out-of-pocket expenses (Eisenberg et al., 1998).

Most concerning was the finding that although CAM use had increased over the 7-year period, the number of patients informing their doctors of such use had not changed—approximately 60% to 70% of CAM users in 1990 and 1997 did not discuss their use of CAM with their physicians. Lack of communication was noted again in a 2006 NCCAM/AARP survey of adults 50 or older revealing only one-third of CAM users had talked to their physicians about their CAM use (AARP, 2007). Given this fact and the potential for untoward side effects, it is essential that physicians and all other health professionals ask patients about their use of CAM. In addition to NCCAM's "Time to Talk" campaign, several approaches have been suggested (Eisenberg, 1997); Table 11-2 lists an ABC format especially useful for the busy clinician (Sierpina, 2001).

Complementary and Alternative Medicine Use in the 21st Century

Data on the U.S. population's use of CAM was collected in 2002 and 2007. Considered the most comprehensive and reliable findings on American's use of CAM, these studies were conducted by the NCCAM and the National Center for Health Statistics (NCHS), part of the Centers for Disease Control and Prevention (CDC). For the first time, detailed questions regarding CAM were added into the 2002 edition of the NCHS National Health Interview Survey (NHIS), an annual study interviewing tens of thousands of Americans about their health- and illness-related experiences. The

Table 11-2 Guidelines for Advising Patients Who Seek Alternative Therapies

| Ask; don't tell. |
| Be willing to listen and learn. |
| Communicate and collaborate. |
| Diagnose. |
| Explain and explore options and preferences. |

2002 and 2007 studies were completed by ~30,000 families through adults 18 years or older who spoke English or Spanish. The study reflected CAM use during the 12 months before the survey. The 2007 survey included expanded questions on 36 types of CAM therapies commonly used in the United States—10 practitioner-based therapies, such as acupuncture, and 26 other, self-care therapies not requiring a practitioner. CAM therapies included in the surveys are listed in Table 11-3, and the terms are defined in eAppendix 11-1.

As shown in Figure 11-2, CAM use increased from 36% of U.S. adults in 2002 to 38% in 2007, or almost 4 of 10 adults (Barnes et al., 2004, 2008). For the first time, the 2007 survey collected data on CAM use in children (<18 years), showing 12% use, or 1 in 9 children. The top 10 CAM therapies for both adults and children are shown in Figure 11-3. Significant increases in adults' use of deep breathing, meditation, massage, and yoga occurred over the 5 years of the study. Another notable NCCAM/AARP study focused on CAM use in adults older than 50 years. Approximately two-thirds (63%) had used one or more CAM therapies (AARP, 2007). The most common reasons cited for not discussing CAM included: the physician never asked (42%), the patient did not know they should ask (30%), and there was not enough time during the office visit (19%). Of those using CAM, 66% did so to treat a specific condition and 65% for overall wellness. For details on CAM costs in the U.S., see eFigures 11-1 to 11-3 online at www.expertconsult.com.

Table 11-3 Complementary and Alternative Medicine (CAM) Therapies Included in 2002 and 2007 National Health Interview Surveys

| | |
|----------------------------|---|
| Acupuncture* | Natural nonvitamin and nonmineral products (e.g., herbs, other products from plants, enzymes) |
| Ayurveda* | Naturopathy* |
| Alternative practitioner*† | Osteopathic manipulation** |
| Biofeedback* | Prayer for health reasons |
| Chelation therapy* | Prayed for own health |
| Chiropractic care* | Others ever prayed for your health |
| CAM† | Participate in prayer group |
| Deep breathing exercises | Healing ritual for self |
| Diet-based therapies | Progressive relaxation |
| Vegetarian diet | Qi gong |
| Macrobiotic diet | Reiki* |
| Atkins diet | Tai chi |
| Pritikin diet | Traditional healers** |
| Ornish diet | Bontanica |
| Zone diet | Curandero |
| Energy healing therapy* | Espiritista |
| Folk medicine | Hierbero |

| Feldenkreis | |
| Pilates | |
| Trager | |

Definitions of these therapies are provided in the glossary of eAppendix 11-1.

*Indicates a practitioner-based therapy.

†Indicates addition to 2007 survey.

Who Is More Likely to Use CAM, and Why?

Consistent with data from the 2002 NHIS study, CAM use by adults in 2007 was more prevalent among women; adults age 30 to 69; those with higher education level, not poor, or living in the West; former smokers; and those hospitalized in the prior year (Barnes, 2008). CAM use was positively associated with number of health conditions and number of physician visits in the previous year. When concerned about cost or inability to pay for conventional care, adults were more likely to use CAM. For children, the 2007 data show no gender difference. For all therapies combined, CAM use was highest among adolescents age 12 to 17 years (16%) versus children age 5 to 11 years (11%) or preschool children age 0 to 4 years (8%). Children's use of CAM increased as their parents' education or income level increased, and when families were unable to afford conventional medical care. Children with a parent or other relative who used CAM were about five times as likely (23%) to use CAM as children whose parent did not (5%).

Figure 11-4 shows the disease or condition for which adults and children are most likely to seek CAM. The 2002 survey also addressed the important question: Why do people use CAM? Previous studies revealed general issues of the over-use of technology and a reductionist approach to care, managed-care time constraints limiting visits and eroding the physician-patient relationship, and the explosion of Internet-based information on CAM. Astin (1998) found that along with being more educated and reporting poor health status, most alternative medicine users were not dissatisfied with conventional medicine, but rather found these health care alternatives to be more congruent with their own values, beliefs, and philosophic orientations toward health and life. Only 4.4% reported relying primarily on CAM therapies for their health care. A subsequent study of patients using both CAM and conventional care also found that use of CAM did not primarily reflect dissatisfaction with conventional care (Eisenberg et al., 2001).

Reasons for CAM use reported in the 2002 NHIS study are shown in Figure 11-5, with slightly more than one half of all respondents believing CAM *combined with* conventional medicine would be helpful.

Figure 11-2 Complementary and alternative medicine (CAM) use by U.S. adults (2002, 2007) and Children (2007).

(From Barnes PM, Bloom B, Nahin R. *Complementary and alternative medicine use among adults and children: United States, 2007*. CDC National Health Statistics Report No 12. December 2008.)

Trends in CAM Use

The 2002 and 2007 NHIS data show that although the overall prevalence of CAM use by adults had remained relatively stable (36% and 38%, respectively), there have been significant increases in some therapies, including acupuncture, deep-breathing exercises, massage therapy, meditation, naturopathy, and yoga (see Figure 11-3). Several factors may account for this growth, including increasing state licensure of some of the practices and greater public awareness of their use through the press and Internet resources. Characteristics of adult and pediatric CAM users are similar in that education, poverty status, geographic region, number of health conditions, physician visits in the prior year, and delaying or not receiving conventional care because of cost are all associated with CAM use. Overall reasons for CAM use fall into two equal categories: (1) treating a variety of health problems, especially pain, and (2) promoting general health and wellness. Much of CAM use is "self-care" and is mostly used with conventional care.

Important U.S. Reports

Key Points

- The White House Commission on CAM created a blueprint for public policy and health care transformation in 2002.
- The Institute of Medicine's 2005 CAM report and 2009 summit called for expanding research, education, and clinical application.
- CAM challenges conventional research methods.
- CAM creates opportunities for innovative studies.
- The NIH National Center for Complementary and Alternative Medicine 2010 Strategic Plan will set an agenda for more CAM research.

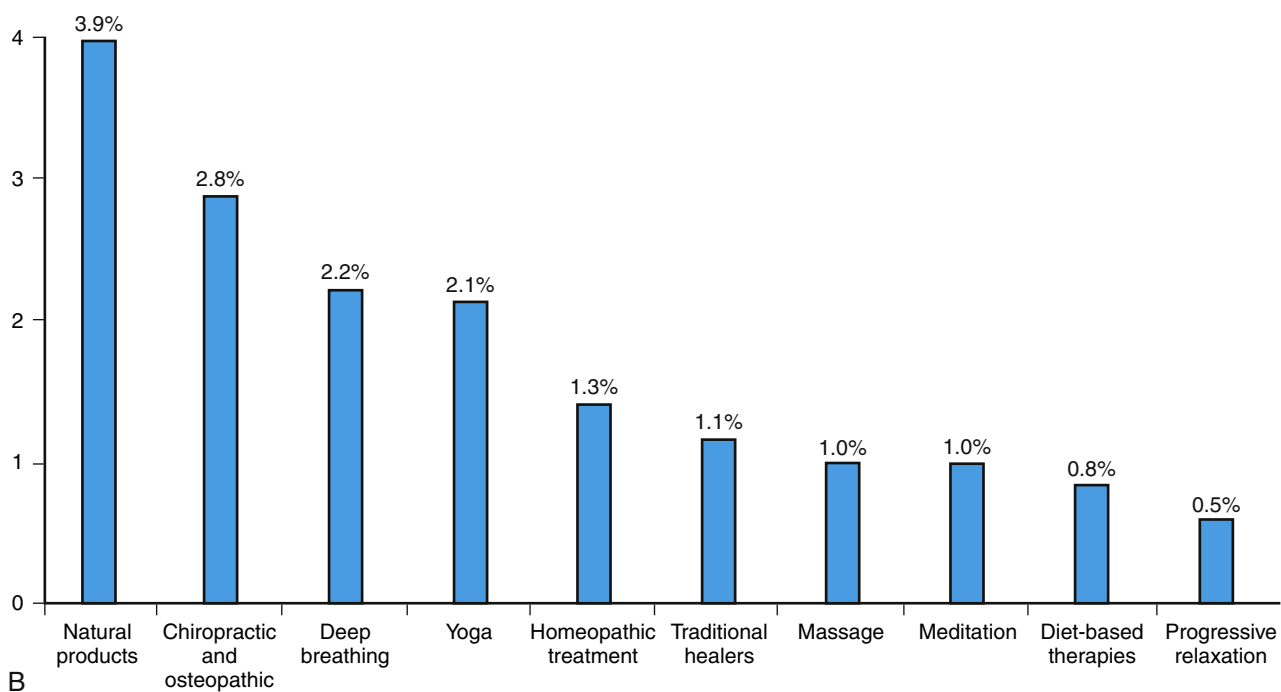

Over the past two decades, several important reports have addressed CAM and integrative medicine in the United States. This section summarizes the major themes and recommendations.

White House Commission 2002 Report

The White House Commission on Complementary and Alternative Medicine Policy (WHCCAMP) 2002 report was the culmination of 18 months of in-depth work of a committee of 20 appointed commissioners. Their task was to provide the president, through the secretary of Health and Human Services, with a report containing legislative and administrative recommendations that would ensure a public policy that maximized the potential benefits of CAM to all. Specifically, the commission addressed the coordination of research to increase knowledge about CAM products; the education and training of health care practitioners in CAM; the provision of reliable and useful information about CAM practices and products to health care professionals; and guidance regarding appropriate access to and delivery of CAM. Table 11-4 lists the 10 guiding principles the commission endorsed for their process of making recommendations. The final report lists 29 recommendations and more than 100 action steps as a blueprint for shaping future CAM policy.

A

B

Figure 11-3 A, Ten most common CAM therapies among adults in 2007. B, Ten most common CAM therapies among children in 2007. (From Barnes PM, Bloom B, Nahin R. Complementary and alternative medicine use among adults and children: United States, 2007. CDC National Health Statistics Report No 12. December 2008.)

Institute of Medicine 2005 Report and 2009 Summit

The Institute of Medicine (IOM) of the National Academy of Sciences acts as a private, nonprofit, society of scholars engaged in research dedicated to the promotion of science and technology for the public good. Because of the American public's increasing use of CAM and the many concerns regarding safety, efficacy, and information access, a report was commissioned and a committee charged to explore the emerging scientific, policy, and practice questions. The

300-page report released in 2005 gave specific recommendations in the domains of research, education, and clinical care; new and innovative approaches to research were considered essential. The IOM Committee Chair placed a "call to action" to researchers (Bondurant, 2005):

Ignoring CAM is not an option. The widespread use of CAM by patients is a mandate to the scientific community to improve our relatively weak scientific understanding of CAM practices. Moreover,

Figure 11-4 **A**, Disease or condition for which CAM therapies are most frequently used among adults in 2007. **B**, Disease or condition for which CAM therapies are most frequently used among children in 2007.

(From Barnes PM, Bloom B, Nahin R. Complementary and alternative medicine use among adults and children: United States, 2007. CDC National Health Statistics Report No 12. December 10, 2008.)

health professionals have a duty to their patients to bring these 2 worlds of contemporary medical practice together. The path to this outcome begins with adopting the same standards of evidence.

In 2009, IOM and the Bravewell Collaborative convened a 3-day summit, Integrative Medicine and the Health of the Public. More than 600 scientists, academic leaders, policy experts, health practitioners, advocates, and other participants from various disciplines examined the practice of integrative medicine, its scientific basis, and its potential for improving health. Note how the recurring themes and shared

values listed in Table 11-5 resonate with the principles of family medicine and the foundations of the patient-centered medical home (PCMH). Family physician Victor Sierpina shared a vision for integrative medicine and the physician of the future (Table 11-6).

NCCAM Strategic Plan 2010

Now in its third cycle of 5-year strategic planning, NCCAM continues to explore CAM healing practices in the context of science, train CAM researchers, and disseminate authoritative information to public and professional communities.

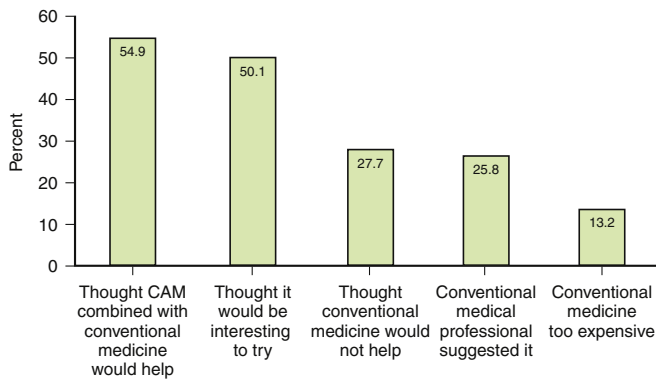

Figure 11-5 Reasons people use complementary and alternative medicine (CAM) therapies.

(From Barnes PM, Towell-Griner E, McFann K, Nahin RL: *Complementary and alternative medicine use among adults: United States, 2002*. CDC Advance Data Report No 343, 2004.)

Table 11-4 Guiding Principles: 2002 White House Commission on Complementary and Alternative Medicine Policy

| |
|--|
| 1. A wholeness orientation in health care delivery |
| 2. Evidence of safety and efficacy |
| 3. The healing capacity of the person |
| 4. Respect for individuality |
| 5. The right to choose treatment |
| 6. An emphasis on health promotion and self-care |
| 7. Partnerships are essential for integrated health care |
| 8. Education as a fundamental health care service |
| 9. Dissemination of comprehensive and timely information |
| 10. Integral public involvement |

NCCAM’s course for 2010–2014 is to create priority areas of CAM research to focus efforts that would best serve public need while meeting fiscal realities, as guided by four factors: (1) scientific promise, (2) extent and nature of practice and use, (3) amenability to rigorous scientific inquiry, and (4) potential to change health practices.

Nahin and Straus (2001) and Ahn and Kaptchuk (2005) discuss the unique challenges that CAM presents to conventional research approaches in evidence-based medicine (see Chapter 8). Many CAM study therapies are complex and heterogeneous compared with the more familiar single-drug trial of biomedicine. As such, innovative research strategies, such as those for sham acupuncture, will need to be continually developed. CAM may help the science of medicine to further evolve, as reflected on by Linde and Jonas (1999):

The continuing interface between orthodox and unorthodox medicine today provides the opportunity for new research strategies and methodologies to arise. By purposefully maintaining a creative tension between the established and frontier, we can advance scientific methods and more clearly define the boundaries and purpose of the scientific process for medicine.

Table 11-5 Recurring Perspectives from IOM Summit on Integrative Medicine and the Health of the Public

Vision of optimal health: Alignment of individuals and their health care for optimal health and healing across a full life span.

Conceptually inclusive: Seamless engagement of the full range of established health factors—physical, psychological, social, preventive, and therapeutic.

Lifespan horizon: Integration across the life span to include personal, predictive, preventive, and participatory care.

Person-centered: Integration around, and within, each person.

Prevention-oriented: Prevention and disease minimization as the foundation of integrative health care.

Team-based: Care as a team activity, with the patient as a central team member.

Care integration: Seamless integration of the care processes, across caregivers and institutions.

Caring integration: Person- and relationship-centered care.

Science integration: Integration across approaches to care (e.g., conventional, traditional, alternative, complementary), as the evidence supports.

Policy opportunities: Emphasis on outcomes, elevation of patient insights, consideration of family and social factors, inclusion of team care and supportive follow-up, and contributions to the learning process.

From Institute of Medicine (IOM). *Integrative Medicine and the Health of the Public: a summary of the February 2009 summit*. Washington, DC, National Academies Press, 2009, p 5.

Table 11-6 How the Physician of the Future Will Function

| The care process is... | The doctor’s role will be... |
|---|---|
| Patient centered | A navigator |
| Team based | Part of a multidisciplinary team |
| High-touch, high-tech | Grounded in the community |
| Genomic and personalized Preventive Integrative | Support of social and environmental policies promoting health |
| And supports patients through... | And will follow... |
| Complementary and alternative practices | Evidence-based, outcome-focused practices |
| Belief that the body helps heal itself | Principles for creations of healing environments |
| | The lead of empowered patients |

Integrating Complementary and Alternative Medicine into Practice

Key Points

- Nutrition, mind-body medicine, and spirituality are core elements of integrative medicine practice.
- Strong evidence supports mind-body medicine for coronary artery disease, low back pain, and headache.
- Acupuncture is a safe and efficacious adjunctive treatment for several musculoskeletal conditions.
- Energy medicine researchers use current technologies to explore the frontiers of CAM.

Because the field of CAM and integrative medicine is so broad and includes so many different approaches and modalities, this section reviews core elements and then explores three common CAM modalities with evidence of efficacy: acupuncture, yoga, and homeopathy. Energy medicine, an important frontier of the CAM field, is also discussed.

Core Elements of Integrative Medicine

Nutrition, mind-body medicine, and spirituality are considered core elements of an integrative medicine approach and often are applied during patient consultation. These elements also tend to be cost-effective and patient empowering. Considered the foundation of good health and enhanced healing, nutritional principles are key elements in most treatment plans.

The adage “food is medicine” is becoming ever more important as the United States faces impending epidemics of diabetes and obesity. When the new food pyramid was released by the U.S. federal government (MyPyramid.gov), critics such as Walter Willett commented, “This is a huge lost opportunity to convey information about healthy food choices that could benefit Americans enormously.... The pyramid tells nothing of healthy food choices” (Mitka, 2005).

Other options are considered in the Healing Foods Pyramid (Figure 11-6). While developing the best nutrition advice for the diverse people seen at the University of Michigan’s Integrative Medicine Clinic, family physician Monica Myklebust found various recommendations for the prevention and treatment of obesity, mood disorders, heart disease, diabetes, chronic pain, and inflammation. The result of her work is a user-friendly tool that brings all of these data together. Omega-3 fatty acids, antioxidants, medicinal seasonings, soy, chocolate, and tea are all considered. For example, green tea offers a variety of health benefits, with emerging evidence for prevention of cancer, stroke, and cardiovascular disease (Schneider and Segre, 2009). Health concerns regarding the sources of U.S. food and recommendations for organic and wild food are discussed. The Healing Foods Pyramid is available as a web-based interactive version (www.med.umich.edu/umim/clinical/pyramid). The top is left open to be filled in by what individuals feel may complete and customize their pyramid.

A particular aspect of nutrition that has received increasing attention for its value in lessening inflammation is that of fish oil (i.e., omega-6 and omega-3 fatty acids). Omega-3 fatty acids consist of eicosapentaenoic acid (EPA) and

docosahexaenoic acid (DHA) and are mostly found in fatty fish, such as herring and salmon. Because inflammation plays a role in several common conditions, such as cardiovascular disease, asthma, arthritis, psoriasis, and inflammatory bowel disease, research has explored the role of omega-3 fatty acids in reducing symptoms and improving outcomes. Practical applications for recommending fish oil in the primary care setting included the following (Oh, 2005):

1. The American Heart Association recommends 1 gram (g) per day for all patients with documented coronary artery disease through diet or through supplementation.
2. For patients with mild or persistent hypertriglyceridemia, use of 2 to 4 g per day of fish oil may lower levels by 20% to 50% to reach ATP III goals.
3. For those with rheumatoid arthritis, doses of 2.6 to 6 g per day for at least 8 to 12 weeks are optimal and may reduce or eliminate nonsteroidal anti-inflammatory drug (NSAID) use.

Monitoring for clinical bleeding and for low-density lipoprotein (LDL) cholesterol and glycemic response should be considered for patients taking doses higher than 3 g/day, especially if they are diabetic. Unfortunately, because our waters are polluted with heavy metals, avoiding fish known to have high methyl mercury levels (especially by women who are pregnant and of childbearing age) is an important precaution when discussing fish oil use with patients (Williams, 2005). Along with fish oil consumption, other dietary modifications are also known to help lessen inflammation; Table 11-7 shows guidelines for prescribing an anti-inflammatory diet (Rakel, 2003; Rakel and Rindfleisch, 2006).

Mind-Body Medicine

The area of CAM with perhaps the most extensive research base is mind-body medicine, which encompasses a diverse array of practices that overlap many traditions and whole systems of care. Astin and colleagues (2003) concluded, “There is now considerable evidence that an array of mind-body therapies can be used as effective adjuncts to conventional medical treatment for a number of common clinical conditions.” They found strong evidence to support mind-body approaches in the treatment of low back pain, coronary artery disease, headache, insomnia, preparing for surgical procedures, and in the management of disease-related symptoms of cancer, arthritis, and urinary incontinence.

Given the relative ease of learning and employing such techniques, NCCAM has made research into mind-body medicine a priority. Mind-body medicine approaches may enhance healing and optimize health. They may be recommended to most patients for health maintenance and disease management and could easily be incorporated into a PCMH through group visits or health coaches. In addition, a recent study of 70 primary care physicians who participated in an intensive mindfulness education program over 1 year showed dramatic improvements in mindfulness skills, burnout, mood disturbance, and empathy (Krasner et al., 2009). An accompanying editorial noted that the study “demonstrates that training physicians in the art of mindful practice has the potential to promote physician health *through* work.” Also,

Figure 11-6 The Healing Foods Pyramid emphasizes “healing foods,” which are known to have healing benefits or essential nutrients; plant-based choices, which create the base and may be accented by animal foods; variety and balance of color, nutrients, and portions sizes; a healthful environment; and “mindful eating” to savor and focus on the food being eaten.

(Courtesy Monica Myklebust, MD, and Jenna Wunder, MPH, RD, University of Michigan Integrative Medicine Clinical Services, Regents of the University of Michigan. <http://www.med.umich.edu/unim/clinical/pyramid/>)

recognizing and enhancing the meaning derived from the practice of medicine using these skills may “protect against burnout and promote patient-centered care for the benefit of both physicians and their patients” (Shanafelt, 2009).

Online **eAppendix 11-2** (www.expertconsult.com) highlights a well-known and well-studied mind-body technique called *mindfulness-based stress reduction* (MBSR) and includes a short audio sample of mindful breath work for the interested reader to try.

Spirituality

Another area thought to be integral to a whole-patient integrative medicine approach to care is spirituality. This broad and controversial subject is well reviewed (e.g., Sierpina and

Sierpina, 2004); some key issues are considered here. Working definitions and terms from the Samuelli Conference on Definitions and Standards in Healing Research (Dossey, 2003) include the following:

Spirituality encompasses the feelings, thoughts, experiences, and behaviors that arise from a search for that which is generally considered sacred or holy. Spirituality is usually considered to involve a sense of connection with an absolute, imminent, or transcendent spiritual force, however named, as well as the conviction that meaning, value, direction, and purpose are valid aspects of the universe.

Religion is the codified and ritualized beliefs and behaviors of those involved in spirituality, usually taking place within a community of like-minded individuals.

Table 11-7 Guidelines in Prescribing an Anti-Inflammatory Diet

1. Omega-3 and omega-6 fatty acids are essential polyunsaturated fatty acids (i.e., they cannot be made by the human body).
2. The ratio of omega-6 to omega-3 fatty acids in the average Western diet has steadily increased in the past 100 years. The standard American diet has a ratio of omega-6 to omega-3 of more than 20:1, but the ideal range is less than 4:1.
3. To follow an anti-inflammatory diet, take the following steps:
 - a. Decrease red meat, poultry, and dairy intake.
 - b. Increase the intake of omega-3 fatty acids, such as cold-water fish, flaxseed, walnuts, and green leafy vegetables.
 - c. Even one meal of cold-water fish weekly reduces the risk of cardiac arrest. Consuming fish twice each week is ideal. If this is not possible, fish oil supplements can be taken at a dose of 500 to 2000 mg twice daily.
 - d. An alternative is ground flax seeds or flaxseed oil. Flax should be freshly ground because it can spoil after exposure to light or heat. Supplementation can be provided with 500 to 2000 mg of flax oil twice daily.
 - e. Reduce foods that contain omega-6 fatty acids, including the following:
 - (1) Margarine.
 - (2) Oils made from corn, cottonseed, grapeseed, peanut, safflower, sesame, soybean, or sunflower (avoid partially hydrogenated oils).
 - (3) Foods with a long shelf life, such as crackers and chips.
 - f. Cook with monounsaturated oils such as olive or canola oil.
4. Consider this dietary approach to treat the following:
 - a. Heart disease or associated risk factors.
 - b. Inflammatory rheumatic disorders.
 - c. Autoimmune diseases.
 - d. Chronic pain.
5. Low-carbohydrate, high-protein diets tend to have high omega-6 fat content and should be used with caution.
6. It may take up to 6 months to see the full clinical effects of an anti-inflammatory diet.

From Rakel D, Rindfleisch A: Integrative medicine. In *Essential Family Medicine: Fundamentals and Case Studies*. Philadelphia, Saunders, 2006.

Prayer is communication with an absolute, imminent, or transcendent spiritual force, however named. Such communication may take a variety of forms and may be theistic or nontheistic in nature, as in some forms of Buddhism. *Intercessory prayer* is an appeal to such a force to influence another person or thing. *Healing prayer* is an appeal to such a force for the healing and recovery of self or others. *Directed prayer* is offered with a specific outcome in mind. *Nondirected prayer* is offered with no specific outcome in mind, such as, "Thy will be done," or "May the best outcome prevail."

Given recent statistics on prayer from the 2002 National Health Interview Survey (NHIS) and Gallup Polls over the past six decades (showing that more than 90% of Americans believe in God or a universal spirit), it is not surprising that proponents and critics have agreed that taking a spiritual history is essential to a comprehensive and culturally sensitive medical consultation. Just as challenging as asking patients about substance abuse, domestic violence, and sexual practices, a spiritual history helps elucidate how spiritual beliefs or religious practices may impact health and health-related choices. Such discussions may be most relevant during times of a new diagnosis, loss of a loved

Table 11-8 Spiritual Assessment Tools

| FICA Mnemonic |
|--|
| F: Faith or belief—What is your faith or belief? |
| I: Importance and influence—Is it important in your life? How? |
| C: Community—Are you part of a religious community? |
| A: Awareness and addressing—What would you want me as your physician to be aware of? |
| How would you like me to address these issues in your care? |
| HOPE Mnemonic |
| H: Hope—What are your sources of hope, meaning, strength, peace, love, and connectedness? |
| O: Organized—Do you consider yourself part of an organized religion? |
| P: Personal spirituality and practices—What aspects of your spirituality or spiritual practices do you find most helpful? |
| E: Effects—How do your beliefs affect the kind of medical care you would like me to provide? |
| Three Questions |
| 1. What helps you get through tough times? |
| 2. Who do you turn to when you need support? |
| 3. What meaning does this experience have for you? |

one, onset of depression, or terminal illness. Continuity of care and sensitivity to the biopsychosocial aspects of a patient's life foster the rapport to facilitate such discussion. Such inquiry may also help engage support systems or identify deep conflicts. Although not all physicians may be comfortable addressing spirituality with their patients, referrals to colleagues in pastoral care and chaplaincy are options to consider.

Interviewing seven physicians recognized as leaders in the field of healing research, Egnew (2005) found that "healing was defined in terms of developing a sense of personal wholeness that involves physical, mental, emotional, social and spiritual aspects of human experience." The central theme in the responses provided an operational definition of healing: "Healing is the personal experience of the transcendence of suffering."

Various models have been suggested as guides to taking the spiritual history (Table 11-8) (Anandarajah and Hight, 2001; Kinney, 1999; Puchalski and Romer, 2000).

Acupuncture, Yoga, and Homeopathic Remedies

Three areas of CAM are most likely to be encountered in the family physician's office: acupuncture, yoga, and homeopathic remedies (see Chapter 52 online for herbs and supplements). As shown in Table 11-9, these three areas are components of whole systems or *nonallopathic* medical systems of care: *acupuncture* within traditional Chinese medicine (TCM), *yoga* as a part of Ayurveda, and *homeopathic remedies* as the mainstay of homeopathy. Many

Table 11-9 Nonallopathic Medical Systems**Traditional Chinese Medicine**

Philosophy: Qi and other substances flow through the body through various channels, or meridians. Yin and yang (i.e., passive and active) and the five elements (i.e., wood, fire, earth, metal, and water) have competing influences on various body parts. Excesses or deficiencies of these cause illness. Pain is blocked qi.

Diagnostics: A specific diagnosis is not needed. Information is gathered by the four kanbing: looking (i.e., observation of posture, coloring, gait, demeanor, appearance of the tongue); asking about the status of the 11 basic areas, including body temperature, sleep, fluid metabolism, pain, and digestion; listening to the body's sounds, including breathing, voice, and peristalsis; and palpation of the affected site and the pulse. The pulse is thought to have three parts that correlate with the status of different parts of the body.

Therapeutics: Acupuncture is the insertion of needles into various points along the qi meridians. Moxibustion is the burning of moxa (*Artemisia vulgaris*) on or near meridian points. Gua sha is pressing the skin with a hard, round-edged instrument to create petechiae. Cupping is the creation of a vacuum in a cup and applying the vacuum pressure to the skin. Tui na is manipulation or massage with specific hand movements. Plum blossom is a cluster of needles that is moved along a meridian. Herbal therapies typically are combinations of multiple herbs mixed specifically for the individual patient.

Ayurveda

Philosophy: The concept emerged in India 5000 years ago, and it incorporates five elements and three types of energy, or doshas. Vata is the dosha associated with movement, pitta governs metabolism, and kapha maintains structure. Diet, lifestyle, and relationships shape a person's energy and define health status. Ancient texts divide illnesses according to subspecialties, many of which are the same as for biomedicine.

Diagnostics: Factors that may have weakened the person's defenses are considered, such as genetics, trauma, diet, habits, seasonal affects, climate, age, balance of the doshas, emotions, metabolism, and acts of God. A full physical examination includes evaluation of pulses, speech and voice, eyes, tongue, and the appearance of the urine and feces.

Therapeutics: Approaches include prevention, detoxification, reestablishment of one's unique constitutional balance. Foods, emotions, and behaviors are used to adjust dosha levels. Panchakarma is used to remove aggravated doshas and toxins. Components of panchakarma include therapeutic vomiting, use of purgatives or laxatives, nasal administration of medications, blood purification (traditionally by blood-letting, now more often with teas), and therapeutic enemas.

Naturopathy

Philosophy: The body is able to heal itself by means of the healing power of nature. Healing occurs through a diet of natural, unrefined foods; adequate exercise; avoidance of environmental toxins; proper elimination of body wastes; and positive thoughts and emotions. Key principles in patient care include doing no harm, taking a preventive approach, and focusing on maintenance of health rather than just on the treatment of disease. The naturopath's goals are to educate, empower, and motivate.

Diagnostics: Methods may draw from any number of approaches, including laboratory testing not commonly performed in a biomedical setting.

Therapeutics: Approaches can include nutrition, botanicals, homeopathy, Chinese medicine, physical medicine (e.g., ultrasound, massage, manipulation), hydrotherapy (e.g., baths, steams, wraps, colonic irrigation), and various detoxification regimens.

Homeopathy

Philosophy: Homeopathy is based on the law of similars, which holds that medicines can produce the same symptoms in healthy people that they cure in those who are ill. Remedies are used in the smallest quantity possible, which can often mean they are diluted to the point that not even a molecule of the original therapeutic substance remains in solution.

Diagnostics: A detailed history is taken relating to the specific nature of symptoms. For example, otitis media is treated differently based on the mood of the child, which ear is sore, the nature of the fever, and the nature of the pain.

Therapeutics: A remedy that has elicited a similar set of symptoms in a healthy patient is given in minute quantity to the ill person. The degree to which a remedy is diluted is given as a Roman numeral. For example, a 6X solution has been diluted to one tenth of its strength six times (i.e., to 10^{-6} of the original strength), and a 200C solution has been diluted to 1/100 of its original strength 200 subsequent times (i.e., to 10^{-400} of its original strength).

From Rakel D, Rindfleisch A: Integrative medicine. In Essential Family Medicine: Fundamentals and Case Studies. Philadelphia, Saunders, 2006.

family physicians have pursued professional training in these fields and are now integrating new skills and perspectives into their practice. The Society of Teachers of Family Medicine (STFM) *Group on Hospital Medicine and Procedural Training* has proposed that acupuncture become an advanced procedure within the scope of family medicine training (Kelly, 2009).

Although challenging to research, trials have shown acupuncture efficacious as an adjunctive therapy in osteoarthritis of the knee (Berman et al., 2004) and as a complement to standard therapy for the debilitating effect of pelvic girdle pain during pregnancy (Elden et al., 2005). Cochrane reviews have shown that acupuncture benefits patients with chronic low back pain, neck pain, and headache (migraine

Table 11-10 Commonly Used Movement Therapies

| Therapy* | Description | Research |
|------------------|--|--|
| Hatha yoga | Focuses on the use of postures (asanas) and breathing exercises (pranayama); traditionally used in India to purify the body and maximize the impact of meditation practice; many different schools; must be used with caution by those with glaucoma, retinal detachment, or at high risk for muscle strain or fracture. | Most trials are quite small. Positive benefits likely for musculoskeletal and other types of pain, lowering autonomic nervous system sympathetic tone; decreasing histamine effects of FEV ₁ in asthmatic patients; reducing blood pressure; headaches, diabetes, osteoarthritis, rheumatoid arthritis; overall improvement in balance, endurance, and vitality. |
| Tai chi | Developed more than 5000 years ago; movement and breathing, often associated with specific flowing movement patterns, are used to affect the flow of energy, or qi. | Useful adjunctive therapy for arthritis and cardiovascular disease. Helpful for improving postural stability and decreasing fall risk in older adults. |
| Qigong (Qi gong) | Part of traditional Chinese medicine; also used to cultivate qi; includes breathing exercises, meditation, and physical movement; used in the martial arts and to generate energy to be used in healing. | Most studies conducted in China. Potentially useful for hypertension, decreasing overall stroke and mortality rates compared with controls, decreasing peripheral vascular resistance, increasing bone density; improvement of blood flow to brain (e.g., adjunctive treatment for memory loss, dizziness, insomnia, vertigo); improvement of cardiac output, ejection fraction, and valve function. |
| Feldenkrais | Developed by Moshe Feldenkrais in the 1950s; gentle movements and manipulation enlisted to retrain the body with new movement patterns. | Limited randomized trial-based research. Used to promote flexibility and posture, decrease back pain, and improve vocal cord function. |

From Rakel D, Rindfleisch A. Integrative medicine. In *Essential Family Medicine: Fundamentals and Case Studies*. Philadelphia, Saunders, 2006.

*Other therapies include *Alexander technique*, which uses minimal effort to maximize efficiency of muscle use and alleviate problems associated with poor posture, and *Pilates*, which also uses exercises and other techniques used to strengthen postural muscles. FEV₁, Forced expiratory volume in 1 second.

and tension) (Kelly, 2009). A meta-analysis evaluating 33 randomized, controlled trials (RCTs) of acupuncture for acute and chronic low back pain concluded that acupuncture effectively relieves chronic low back pain, although no evidence suggests that it is more effective than other active therapies (Manheimer et al., 2005).

Excellent reviews of acupuncture's theory, efficacy, and practice (Kaptchuk, 2002; Nielsen and Hammerschlag, 2004) cite the 1997 NIH Consensus Development Panel findings on acupuncture. After reviewing all available evidence from RCTs up to 1997, the panel concluded that clear evidence shows that acupuncture is efficacious for adult postoperative and chemotherapy nausea and vomiting and for postoperative dental pain. The panel also reported that acupuncture should be considered a useful adjunct for addiction, stroke rehabilitation, osteoarthritis, headache, low back pain, tennis elbow, menstrual cramps, carpal tunnel, and fibromyalgia (NIH, 1998).

Yoga, a widely popular and rapidly increasing CAM practice in the United States, has its roots in ancient India and is a Sanskrit word that means "yoke" or "union." The original goal of practicing these postures was to purify and prepare the body for higher states of consciousness. *Hatha yoga*, as described in Table 11-10 along with other types of movement therapies, has many different styles and is the most popular form taught and practiced in the United States today. Because most yoga instructors are not medical professionals, it is recommended to refer a patient to a teacher with several years' experience. A study

of the efficacy of yoga on pregnancy outcome ($N = 335$) concluded that an integrated approach to yoga during pregnancy was safe and that it improved birth weight and decreased preterm labor and intrauterine growth retardation with no complications (Narendran et al., 2005). A recent study of 90 patients with chronic low back pain who participated in a 24-week trial of yoga twice a week showed those receiving the yoga intervention experienced decreased levels of pain, functional disability, and depression (Williams et al., 2009). The International Association of Yoga Therapists (IAYT) is a worldwide organization for yoga teachers, therapists, and researchers (www.iayt.org). The Yoga Alliance (www.yogaalliance.org), formed in 1999, sets minimum training standards for yoga teachers. Both organizations provide sound resources for professionals and the public.

Perhaps the most controversial of CAM therapies, *homeopathy* seems to defy biomedicine's attempts to decipher its mechanism of action. Particularly perplexing is the concept that the more dilute the remedy, the more potent is its effect. Founded by the German physician Samuel Hahnemann (1755–1843), homeopathy is still widely accepted and practiced in Europe and is now experiencing a renaissance in the United States. A brilliant linguist and scholar, Dr. Hahnemann developed the Principle of Similars, in which "like cures like" based on his medical translation work and personal experience of malaria symptoms after taking *Cinchona* bark, which was then the treatment for the disease. A critical overview of homeopathy by Jonas

and colleagues (2003) reviewed the research regarding specific conditions and the placebo effect. After analyzing systematic reviews of clinical trials, the authors concluded, "Despite skepticism about the plausibility of homeopathy, some randomized, placebo-controlled trials and laboratory research report unexpected effects of homeopathic medicine. However, the evidence on the effectiveness of homeopathy for specific clinical conditions is scant, is of uneven quality, and is generally poorer quality than research done in allopathic medicine."

Known for his groundbreaking research showing homeopathic treatment of allergic rhinitis more effective than placebo (Taylor et al., 2000), David Reilly of Glasgow, Scotland, commented on the increasing scientific validation for homeopathy over the past decade. Noting that studies reviewed show positive evidence for overall effect and citing the growing prospective, observational research that indicates beneficial outcomes, Reilly (2005) points out that homeopathy can offer therapeutic options when conventional care has failed or reached a plateau, no conventional treatments exist, conventional treatments are contraindicated, side effects of conventional treatments are not tolerated, and patients are reluctant to accept conventional care. An important distinction clouds other areas of medical research: "The two dimensions of care need to be considered: the direct effects of the remedy and the therapeutic impact of the method of approach on the patient." Believing that the homeopathic approach is helping to reintroduce a holistic perspective in medical practice, Reilly concludes, "The evidence mosaic for homeopathy reinforces clinicians' and patients' experiential knowledge that this approach can make a valuable contribution to care, especially when applied with a whole person perspective and integrated with conventional knowledge."

Energy Medicine: Frontier Science of Complementary and Alternative Medicine

The practice of CAM presents many challenges to Western science. How does acupuncture work, and what is qi? How can dilute homeopathic remedies induce effects on biologic systems? What are the *chakras*, or energy centers, so integral to yoga and Ayurveda? These mysteries present us with opportunities for new discoveries and an expansion of our healing capacities (eAppendix 11-3). Many scientists are showing how research in biophysics and biomagnetism is helping to elucidate the subtle energies of

Table 11-11 Precautions in Complementary and Alternative Medicine

| |
|---|
| 1. Primum non nocere (first, do no harm). |
| 2. Patients may encounter complications if they abandon effective, conventional therapies in favor of complementary and alternative medicine (CAM). |
| 3. Medicolegal issues and certification or qualification requirements of practitioners are important topics, not covered in this chapter. |

biologic systems, including those of humans. Advanced technologies such as functional magnetic resonance imaging and infrared thermography are demonstrating amazing images that seem to correlate with empiric knowledge (eAppendix 11-4).

Open-minded scientists are helping to bridge the worlds of CAM and conventional medicine by linking research findings to those of clinical practice (Oschman, 2002). "Let us document each of these fascinating clues. We will connect the dots by describing an information system in the body that is the missing link for many phenomena that have seemed hopelessly inexplicable in the past. It is a system that is responsible for extraordinary feasts of perception, movement, and healing" (Oschman, 2003, p. xiv).

Conclusion

Complementary and alternative medicine is an evolving area of health care used by approximately 4 in 10 adults and 1 in 9 children in the United States. As a diverse system of varied approaches and philosophies of healing, CAM is usually incorporated into conventional health care as integrative medicine. CAM presents opportunities to expand the current research paradigm to meet the challenges of studying its multidimensional approach to health and healing. Prominent organizations such as the IOM have placed a call to action to the medical community to advance knowledge and clinical applications in this field. Family physicians, specialists in caring for the whole person though a continuous, healing relationship, are in the ideal discipline to advance the integration of safe and effective CAM into their repertoire to optimize the health of their patients (Table 11-11). Ultimately, complex terminology will subside as the essence of integrative medicine becomes good family medicine.

EVIDENCE-BASED SUMMARY

1. Fish oil supplementation can benefit heart health (Bucher et al., 2002; Wang et al., 2004), hypertriglyceridemia (Balk et al., 2004), and rheumatoid arthritis (Fortin et al., 1995; MacLean et al., 2004) (SOR: A).
2. Acupuncture should be considered as a treatment option for common painful conditions such as chronic low back pain (Furlan et al., 2005; Yuan et al., 2008), neck pain (Fu et al., 2009, Trinh et al., 2006) and headache (migraine, tension) (Linde et al., 2009a, 2009b) (SOR: A).
3. Green tea is associated with decreased risk of stroke and cardiovascular disease (Kuriyama et al., 2006) and may help prevent cancer of the breast (Sun et al., 2006a), gastrointestinal tract (Sun et al., 2006b), and prostate (Kurahashi et al., 2008) (SOR: B).
4. Yoga reduces functional disability, pain, and depression in people with chronic low back pain (Williams et al., 2009) (SOR: B).
5. Mindful communication may improve physician well-being and attitudes associated with patient-centered care (Kearney et al., 2009; Krasner et al., 2009) (SOR: C).

Rapport comes from the French *en rapport*, which means “in harmony with.” Rapport is most easily established during the patient’s first visit, and achieving rapport enhances the likelihood that the patient will comply with the treatment plan. When rapport has been established, patients are more likely to forgive a less than perfect experience or an unexpected poor clinical outcome.

Even the most knowledgeable and skilled physician will have limited effectiveness if he or she is unable to develop rapport with patients. Unfortunately, rapport is one of those intangibles that is more than the sum of its parts. Rapport is not analyzed easily within any one body of knowledge. The basis of rapport, however, is the development of communication skills that instill in patients a sense of confidence and trust by conveying sincerity and an interest in their care and well-being. The patient’s satisfaction and compliance with the physician’s instructions (both measures of rapport) depend on the ability of the physician to communicate understanding, compassion, and genuine interest in the patient and to display a thorough approach to solving the patient’s problems. Patient satisfaction also is related to the physician’s efforts in educating patients about the disease process and motivating them to participate in their treatment.

Failure of communication between physician and patient also can affect the outcome of treatment, often as seriously as an error in treatment. More complaints against physicians result from a breakdown of the caring aspect of the doctor-patient relationship than from the technical quality of treatment.

Most complaints against physicians—and those that too frequently lead to legal action—are the result of a lack of communication between physician and patient. The potential for a serious problem always exists when a patient is inadequately informed regarding a diagnostic procedure, treatment, prognosis, or anticipated cost. The misunderstandings that result cause unnecessary expense and grief for both parties.

Similarly, the worries that result from distorted information can jeopardize the physician-patient relationship. When a patient is discussed on hospital rounds or with a colleague in the office, take care that the discussion is not within the patient’s hearing distance or within that of other patients. Patients overhearing the conversation may believe the comments apply to them, or they may know the patient involved and relay the information in a distorted manner. Fragments of such conversations, overheard by the patient or others, are too easily taken out of context and can become the focus of fearful fantasies that only serve to increase uneasiness and apprehension.

Compassion, interest, and thoroughness are essential components of successful patient care. These features traditionally have been embodied in the term *bedside manner*, which also connotes qualities of concern, kindness, friendliness, wit, and cheerfulness, all of which result in an atmosphere of trust and confidence between physician and patient. The physician with the best bedside manner may be the one who makes no special effort to communicate these feelings but acts in a concerned, natural, and comfortable manner.

Oliver Wendell Holmes said that to be effective, the physician should “speak softly, be well-dressed, have quiet ways and have eyes that do not wander” (1883, p. 388). Lack of eye contact may be interpreted as a lack of concern. A good first impression is certainly a great help in establishing rapport. You do not get a second chance to create a first impression. The physician should approach the patient in an assured, confident (but not cocky or arrogant) manner and present a personal appearance that is acceptable to the patient. Empathetic frankness and honesty are important factors in instilling confidence and trust.

Personal appearance is a significant part of nonverbal communication. Patients consider house staff who wear white coats with conventional street clothes as more competent than those who wear scrub suits. If white coats are worn, the

patient sees only the collar, tie, and shoes, and it is therefore important to keep these items neat.

Posture is also important in conveying an image of confidence and competence. Standing erect, moving briskly with head up and stomach in, is better than slouching. Energetic people seldom slump; they sit upright and appear alert. A listless or lethargic appearance can be interpreted as lack of concern.

Before entering the examining room or hospital room to see a patient, review the record briefly and become familiar with the patient's name and its proper pronunciation. If the pronunciation is unusual or difficult, place phonetic markings on the chart as a reminder for future use. Repeat the patient's name when first given it to confirm the pronunciation, and then use the name twice in the first minute to help it register. Review the medical record for particular aspects of the previous visit that should be remembered and commented on, such as the illness treated at that time, family conditions, or other problems. Patients will believe that the well-informed physician is truly interested in them. Additional courtesy, such as opening the door and assisting patients with their coats (especially elderly patients), shows a consideration that aids in establishing and maintaining rapport.

Respect

Patients should believe that their comments are being listened to, carefully considered, and taken seriously. They must believe that the physician values their comments and opinions before trusting him or her with information of a more personal nature. As long as the physician's attitude toward the patient embodies respect, concern, and kindness and a sincere effort is made to understand the patient's difficulties, the patient will overlook or forgive myriad other problems.

Oliver Wendell Holmes advised patients to "Choose a man who is personally agreeable, for a daily visit from an intelligent, amiable, pleasant, sympathetic person will cost you no more than one from a sloven or a boor, and his presence will do more for you than any prescription the other will order" (1883, p. 391).

A lack of confidence, rather than an excess of it, may lead physicians to appear aloof and unconcerned. Too often, physicians think that a godlike image of omnipotence is necessary for the maintenance of the patient's respect and confidence. It is usually a lack of self-confidence that causes physicians to retreat behind this protective image, which limits their ability to help. Secure physicians are freer to establish close personal relationships with patients without fearing their position will be threatened. A physician with a positive self-image is also willing to recognize and admit the limits of personal competence and feels comfortable seeking help from a colleague when such consultation is of value to the patient's care.

The bond of mutual respect is enhanced if the physician makes positive statements about other people. Patients find it difficult to respect a physician who is regularly detractive, making negative statements about other people or other physicians. Any comments that can be interpreted as "building yourself up by tearing someone else down" merely accomplish the reverse.

The effectiveness of physicians depends on the degree of their insight into the limitations of their personalities and the psychological defenses that distort their perceptions of patients. Physicians must recognize patients or situations that make them unreasonably angry or provoked (e.g., a whining, complaining individual who shows no interest in being rehabilitated, preferring a role of social dependency). The physician's emotions, if they go unrecognized, can serve as a barrier to the development of mutual respect. If the physician is aware of negative feelings toward a patient, an effort can be made to avoid showing signs of irritation or anger. It has been said that clenching of the physician's fist is a clinical sign of a hysterical patient. The physician should attempt to remain objective and analyze the situation for its diagnostic value.

Patients with trivial complaints or somatic manifestations of emotional disease sometimes are given less attention than those with clear-cut organic abnormalities. The frequency with which a physician complains about the triviality and inappropriateness of patients' problems has been found to be related to the volume of patients seen and the degree to which the physician feels overburdened. The more patients that physicians see and the more overloaded their practices, the more likely they are to describe patients' complaints as trivial, inappropriate, or bothersome. Physicians who have more time or take more time per patient, and who investigate the patient's complaints more thoroughly, frequently uncover significant factors and less often tend to view the complaints as trivial. Respect for patients involves taking their fears and apprehensions seriously and withholding value judgments. Patients who frequently seek help for nonspecific somatic and functional complaints may be depressed (Widmer et al., 1980).

Patient Satisfaction

A close relationship exists between rapport and patient satisfaction, and this chapter deals with the many facets of that relationship. It is important that the physician make an effort to understand what patients are "going through" (not only their pain and discomfort, but also the effect these have on their lives) and communicate this understanding to them.

Most studies indicate that patient satisfaction depends on information and the degree to which the patient understands the illness. Joos and associates (1993) found that patients whose desires for information and attention to emotional and family problems went unmet were significantly less satisfied with their physicians than those whose desires were met. Even patients with chronic diseases who had lived with the problem for years had questions they wanted answered. Their satisfaction was related more strongly to the desire for information and affective support than to whether the physician conducted examinations and tests. The greater the patients' satisfaction, the more likely they are to comply with treatment recommendations.

Although patient satisfaction is strongly associated with the length of the visit, it can be further enhanced by spending some time talking about nonmedical topics. Even brief chatting about the weather or something nonmedical can give the impression that more time was taken with the patient,

thereby reducing the feeling of being rushed through the visit (Gross et al., 1998).

Patient Dissatisfaction

In a typical business, only 4% of customers voice their dissatisfaction. The other 96% say nothing, and 91% never return. This has led to many practices conducting regular patient satisfaction surveys so that problems can be identified.

Communication

The patient should be able to gain access to the clinician on the phone, by e-mail, or by an early appointment, without having to run an obstacle course created by an overly protective staff. Delay in returning a phone call may result in a patient remaining home all day waiting; if the call is not returned at all, the negative effect on rapport is great.

Unwillingness to make communication convenient for the patient usually results in a spiral of increasingly frequent attempts to reach the physician and mounting frustration for everyone. In contrast, physicians who give a high priority to communicating discover that most patients are considerate and even protective of the physician's time. At the beginning of a practice, patients do a certain amount of testing to determine a physician's accessibility; physicians who pass the test find that they are rarely inconvenienced by unnecessary calls or patient visits.

Verbal Communication

Much of the communication process in the clinical interview centers on verbal interchange. Symptoms, past medical history, family medical history, and psychosocial data are transmitted primarily by verbal means. The chief complaint is extremely important because it explains why patients believe they need the physician's help.

Patients who do not mention a concern and who withhold requests are less satisfied with their care and experience less improvement in their symptoms. Bell and colleagues (2001) found that 9% of patients had one or more unvoiced desires and were most hesitant to ask their physician for referrals and for physical therapy. These patients were also less likely to trust their physician. This is an important reason to be sensitive to subtle clues that the patient may be suppressing something important to them. What the patient does *not* say may be as important as what the patient says.

"Slips of the tongue" or major areas of omission (e.g., a married person who never mentions a spouse) may signify problem areas that, when explored, help establish the interviewer as a perceptive person who understands the underlying issues. The interviewer constantly must consider, "Why is the patient telling me that?" Even simple, casual remarks may be the patient's way of broaching issues of great concern; the man who says, "Oh, by the way, a friend of mine has been having some chest pain when he walks a lot. Do you think that sounds serious?" may actually be talking about his own concern that he is unable to face directly. A child may be brought to the office

with a trivial problem so that the mother has a chance to discuss with the physician something that is troubling her; the child is a calling card, signaling the need to open the communication channel. The physician who is sensitive to these subtle clues and encourages the patient to discuss what is actually troublesome will find that the rapport established allows future interviews to be much more open and direct.

Hand-on-the-Doorknob Syndrome

The patient's parting phrase is sometimes a clue to the primary reason for the visit, or it may reflect another issue of great concern that is emotionally threatening and could not be voiced until adequate courage was summoned at the moment of departure. It sometimes surfaces as a last, desperate attempt to communicate because, with a hand on door, escape is readily accessible if the physician's reaction is unfavorable. Reasons for this hidden communication by the patient are important and must be recognized and addressed. Because of fear of rejection or humiliation, the patient may test the physician with minor complaints before mentioning the real reason for the visit (Quill, 1989). The physician must be alert to any unusual behavior during an interview (e.g., slips of the tongue, unexpected responses, overenthusiastic denials) and should search further for the underlying reason for the visit when a patient presents with a trivial complaint that appears inappropriate. It is a good practice to ask the patient routinely at the end of a visit, "Is there anything we have not covered, or anything else you would like to ask me?"

Patients with a fear of cancer, for example, often are unable to voice their concern to the physician. Instead, they present with somatic complaints or contrived reasons that necessitate a complete examination. They are hopeful that the examination will allay their fears without it being necessary to express them openly. A female patient presenting for a complete physical examination actually may be concerned over the possibility of a carcinoma of the breast, which her elder sister recently had had at the same age or for which a friend recently had surgery. Such situations emphasize the need for a complete family history and a discussion of any patient concerns in an effort to allow these feelings to surface. Attention then should be paid to alleviating the anxiety. Apprehension regarding cancer is widespread, and the only cure for this fear often is a therapeutic conversation with the physician.

Physicians in private practice who have established rapport during an ongoing relationship with patients communicate more easily than do physicians seeing a patient for the first time in an emergency department (ED). Korsch and Negrete (1972) showed that ED physicians did more talking than the patients, although their perception was just the opposite. This was attributed to interaction with unfamiliar patients by house staff in a setting where the stress level is high and the orientation therapeutic. However, Arntson and Philipsborn (1982) found that physicians in private practice for 26 years who knew their patients and saw them in a low-stress situation for diagnosis or health maintenance also talked more than the patients (twice as long). One difference in the two settings was a strong, reciprocal

affective relationship between physician and patient in the private office. If either made an affective statement, the other would respond similarly, whereas in the ED, patients expressed twice as many affective statements as did the physicians.

Vocabulary

The use of appropriate vocabulary assists in establishing rapport by ensuring easy and accurate communication. Phrasing questions in simple language appropriate to the patient's level of understanding and avoidance of medical jargon help establish a sense of working together. The patient's cultural background and educational level should be considered, and the physician should avoid using slang or a contrived accent, because the patient will detect the artificiality and consider this patronizing.

Patients prefer to be enlightened, and they demand maximum insight into their care. It is best to start all explanations at a basic level and proceed only as rapidly as the patient's understanding permits. An analysis of 1057 audiotaped patient interviews with 59 primary care physicians and 65 surgeons showed that in 9 of 10 cases, patients did not receive good explanations of proposed treatments or tests (Braddock et al., 1999).

Medical terminology should be avoided unless it is familiar to the patient. For example, some patients have interpreted "lumbar puncture" to mean "an operation to drain the lungs." No longer does the physician gain a therapeutic advantage by writing prescriptions in Latin or impressing the patient with medical terms.

Metaphors can be harmful and are often used without the physician being aware of the negative connotation, unknowingly raising the patient's anxiety level. Attempts to coerce a patient into having surgery with phrases such as "you are living on borrowed time" may cause anxiety and increase postoperative morbidity (Bedell et al., 2004).

Physicians should be sure of what patients mean to convey by their word selection and make certain they are operating at a common level of understanding. When the patient says he or she "drinks a little," inquire further to clarify "a little." If the patient "spits up blood," determine whether it is truly spitting or really vomiting. A major barrier to accurate interpersonal communication is the tendency of people to react to a statement from their own points of view, rather than attempting to interpret it from the speaker's vantage point. If a question exists regarding the clarity of the interpretation, it is best to repeat it to the speaker's satisfaction. Contract negotiators have found that when parties in a dispute realize that they are being understood and each party sees how the situation appears to the other, there is less need to exaggerate and act defensively. Korsch and Negrete (1972) found that some of the longest interviews between physician and patient were caused by failures in communication; they had to spend considerable time trying to "get on the same wavelength." An analysis of the conversations revealed that less than 5% of the physician's conversation was personal or friendly in nature, and that although most of the physicians believed that they had been friendly, fewer than half of patients had this impression.

Nonverbal Communication

Verbal communication occupies so much of daily social interaction that nonverbal communication often is ignored. However, much that is said is unspoken. Communications specialists have demonstrated convincingly that nonverbal messages play a major role in validating or contradicting verbal messages, with great influence as communication symbols in their own right.

Communication between two people is usually one-third nonverbal. What is said verbally often is emphasized nonverbally, and personal attitudes and emotions usually are communicated at the nonverbal level. Nonverbal communicative signals are under less censorship from conscious control than are verbal messages, so they are likely to be more genuine.

Charles Darwin held that there is a unique pattern of nonverbal actions for each emotion. In *Expressions of the Emotions in Man and Animals* (1872), Darwin suggested that emotional expressions are evolutionary remnants of previous adaptive behavior that persist even though currently useless. Snarling as a sign of aggression is one example. Although recent knowledge indicates that emotional expression is learned and genetically mediated, Darwin's idea of a unique pattern of actions has been shown for depression and anxiety and is likely in the future to be demonstrated for other emotional states.

Paralanguage

Paralanguage is the voice effect that accompanies or modifies talking and often communicates meaning. It includes velocity of speech (e.g., fast, slow, hesitant), tone and volume of voice, sighs and grunts, pauses, and inflections. Urgency, sincerity, confidence, hesitation, thoughtfulness, gaiety, sadness, and apprehension all are conveyed by qualities of voice. McCaskey (1979) believes that the literal interpretation (i.e., definition) of words accounts for only 10% of communication between two people, whereas facial expression and tone of voice account for up to 90% of the communication.

There is a real difference between verbal and vocal information. The *verbal message* refers to the words literally transmitted. The *vocal message* includes the emotional quality, the tone of voice, and the frequency and length of pauses—information that is lost when the words are written. Tone of voice, for example, can reverse the meaning of words. Sarcasm is a common example of a contradiction between vocal and verbal messages. Comparative studies have shown that when the vocal and verbal messages transmit contradictory information, the vocal is more accurate.

Physicians should be alert to subtle changes of tone, such as when patients ask whether everything will be all right. Are they asking for reassurance, showing fear, or doubting the diagnosis? Rather than concentrating exclusively on *what* patients are saying, the astute physician will concentrate on *how* they are saying it.

In a study of recordings of surgeons who had been sued and those who had not, the sued group could be identified by their tone of voice. They sounded dominant, whereas the nonsued group sounded less dominant and more concerned. "In the end it comes down to a matter of respect, and the simplest way that respect is communicated is through tone of voice" (Gladwell, 2005, p.43).

Touch

A close personal interest in the patient can be communicated by the appropriate use of touch. The most socially acceptable method in this country is a handshake, enabling the physician to establish early contact with the patient. The handshake, properly used, can convey to the patient sincerity and interest as well as security and poise. It is an inoffensive intrusion into the other person's area of privacy and can be extended under certain circumstances to include the application of the left hand to the lower or upper arm. This technique is often used by politicians to emphasize sincerity and concern (Figure 12-1). A variation of the politician's handshake is the "double-hander," which some equate to a miniature hug.

The handshake as a traditional greeting of friendship began by the raising of exposed hands by two approaching individuals to give evidence that they held no weapons. This proceeded to the grasping of hands or, in the Roman society, the forearms. In the United States, a firm handshake is most acceptable. Usually, the limp or "wet dishrag" handshake indicates lack of interest or insincerity, especially if it is rapidly withdrawn. A moist palm is a sign of nervousness or apprehension, and the "halfway there," fingers-only handshake indicates reluctance or indecision. However, the handshake continues to be modified culturally, and a person should be extremely wary of misinterpreting another person's handshake without understanding his or her cultural background.

In the past in China, the Confucian code of etiquette dictated that there should never be a touching of persons, and even today, Chinese officials may appear reluctant to grasp an extended hand; a Chinese man formerly shook his own hand (Butterfield, 1982). Some young people in the United States have modified the traditional palm-to-palm handshake to a grasping of the thumb and thenar eminence and continue to develop new variations reminiscent of the secret handshakes of fraternal groups.

Touching can be an effective method for communicating concern or compassion and can break down some of the

Figure 12-1 The politician's handshake.

defensive barriers to communication. Caution should be exercised, however, not to use it excessively or earlier than is socially permissible. If used without adequate preparation, touch can be interpreted as an invasion of privacy and a forward and inconsiderate act. During the physical examination, it is best to talk before touching by explaining to the patient what will be done next. Studies of primates have shown that touching gestures usually are considered nonaggressive and calming in nature. When used properly by the physician, touch can be facilitative and welcome.

The tremendous symbolic value of touch as a healing power was demonstrated during the Middle Ages, when people sought relief from scrofula (i.e., tuberculous lymphadenitis) through the king's touch, or royal touch, despite the notoriously low cure rates. This power has been transferred to physicians, and patients often feel better after a routine physical examination. Friedman (1979) stated that 85% of patients leaving a physician's office feel better even if they have not received medication or treatment, and 50% of patients in the waiting room feel better in anticipation of the help they will receive.

Touch, or "laying on of hands," may promote healing, especially if it is imbued by the patient with a special symbolic value. Franz Mesmer (1734–1815) was among the first to emphasize the medical importance of laying on of hands. Mesmer, however, believed that there was a magnetic power in his hands, which he called "animal magnetism" and which he applied to ailing individuals. His theory was unscientific, and although he became famous for successfully treating a number of hysterical patients, he finally was discredited by a committee that included Benjamin Franklin and Antoine Lavoisier. They found his treatments to be without magnetism and essentially useless. They did agree, however, that he had helped many people and had brought about many cures. They attributed these cures to unknown factors rather than to the animal magnetism he claimed. Mesmerism was the forerunner of hypnosis, initially called "artificial somnambulism," developed by Puysegur, a disciple of Mesmer.

The magic of touch can be good medicine, especially when combined with concern, support, and reassurance. *Stroking*, a special kind of touching, describes a physical or symbolic recognition of a person's finer attributes. A stroke may be a kind word, a warm gesture, or a simple touch of the hand. Infants deprived of touch and stroking suffer mental and physical deterioration. Adults also require stroking to maintain a healthy emotional state. Stroking occurs when an interchange between two people leaves one or both with a good or fulfilled feeling.

Lightly touching someone's elbow for less than 3 seconds can give you up to three times the chance of getting what you want (Pease and Pease, 2004). Elbow touching works better in places where touching is not the cultural norm, such as Great Britain and Germany.

Body Language

The astute physician will cultivate observational skills that enable the detection of hidden or subtle clues to diagnosis contained in the patient's nonverbal behavior. *Kinesics* is the study of nonverbal gestures, or body movements, and their meaning as a form of communication. However, specific gestures and their interpretation are of importance only when

judged in the context of the circumstances surrounding them. Body language alone does not reveal the entire behavioral image any more than verbal language does alone. Just as one word does not make a sentence or even have much meaning without the sentence, a single gesture has clinical relevance only as part of a sequence of actions. Although they have significance, individual signs are not reliable when they stand alone; they are meaningful only when considered in the context of a person's total behavioral pattern.

When there is *congruence* between the verbal and nonverbal message—when the gesture conveys the same message as the spoken word—communication and its meaning are probably in agreement. When a person indicates something different from the other, however, the *nonverbal* message usually is more accurate. Unless body language, tone of voice, and words spoken all match, look more closely for the reason.

Attempts by the patient to mask feelings can be detected readily by observing body behavior. True feelings are more likely to leak through conscious efforts to conceal feelings. Likewise, a physician's attempt at deception will be detected by patients and can destroy confidence and damage rapport. Positive verbal communication (e.g., "You're looking better today") accompanied by negative nonverbal cues will be interpreted by the patient as insincere. For example, a patient who is not told the true nature of a terminal illness usually knows it anyway and may distrust family, friends, and physician if they persist in the charade.

In a medical school commencement address, Alan Alda (star of TV's *M*A*S*H*) challenged new physicians to be able to read a patient's involuntary muscles as well as their radiographic studies. He asked, "Can you see the fear and uncertainty in my face? If I tell you where it hurts, can you hear in my voice where I ache? I show you my body, but I bring you my person. Will you tell me what you are doing and in words I can understand? Will you tell me when you don't know what to do?" (*Time*, May 28, 1979, p. 68). The physician will see the fear and uncertainty in the patient's face only if she or he is looking at the patient rather than the medical record. Alda's statement reflects the concern and compassion that patients desire. By using appropriate body language, the physician can convey this attention and concern in the most effective manner possible.

Body Position

The body position when sitting can show various degrees of tension or relaxation. The tense person sits erect with a fairly rigid posture. A person who is moderately relaxed has a forward lean of approximately 20 degrees and a side lean of up to 10 degrees. A very relaxed position (usually too relaxed for physicians interacting with patients) is a backward lean (i.e., recline) of 20 degrees and a sideways lean of more than 10 degrees.

Higher patient satisfaction is associated with a physician's forward body lean and rotation of the torso toward the patient. Larsen and Smith (1981, p. 487) found that "the patient also responds more favorably to the physician who relaxes his chin in his hands and gazes directly at the patient, rather than a physician who elevates his chin (unsupported) as if to imply a more superior status." Physicians whose communication styles have been considered patient oriented have been observed to change body position more frequently than physicians whose conversations were physician centered.

An attempt should be made, whenever possible, to sit rather than stand when interviewing a patient. Rapport is improved if the physician does not intimidate the patient by placing him or her in a submissive position. Patients feel more comfortable and less helpless speaking in a sitting position rather than prone. Sitting on the patient's bed is usually not recommended, but for some patients, it is an effective means of establishing closeness and conveying warmth in a relaxed yet attentive manner.

Mirroring

When good rapport exists between two people, each will mirror the other's movements. Some people unconsciously establish rapport with another by mirroring that person's movements or body posture (Key, 1980) (Figure 12-2). Disruptions in this mirroring may signal that one member disagrees with what the other has said or feels betrayed or insulted but cannot express this idea verbally. If the physician notices

Figure 12-2 Joseph Califano (left), Secretary of Health, Education and Welfare, mirrors his boss, President Jimmy Carter, through his posture and gestures. (From Key MR [ed]: *The Relationship of Verbal and Nonverbal Communication*. New York, Mouton Publishers, 1980, p.v.)

this sudden disruption of mirroring activity by the patient, more attention should be focused on the comment that led to the change of position. Renegotiation or further explanation may be indicated. A powerful way to establish rapport is to match intentionally the body language of another.

Head Position

Typically, the head is held forward in anger and back in defiance, anxiety, or fear. It is down or bowed in sadness, submissiveness, shame, or guilt. The head tilted to one side indicates interest and attention (Schefflen, 1972) (Figure 12-3); under certain circumstances, this can be a flirtation. The erect head indicates self-confidence and maturity.

When listening to a patient, the physician should show interest and concern by an attentive position, which is best illustrated by sitting forward in the chair with an interested, attentive facial expression and the head slightly tilted. Darwin was one of the first to notice that animals assume a head tilt when listening intently.

Face

The human face can create more than 7000 expressions using 44 muscles (Cleese, 2001); some say 10,000 expressions are possible (Ekman, 2003).

Darwin (1872) proposed that cultures throughout the world express similar emotions or states of mind with remarkably uniform body movements. His information was gathered from missionary friends working with aborigines, persons under hypnosis, infants, and patients with mental disease. He also studied blind and deaf persons who, without benefit of learning from others, were observed to raise eyebrows when surprised and shrug their shoulders to indicate helplessness.

Darwin held that the facial expression of emotion, when undisguised, is independent of culture and is identical throughout the world. The facial expressions of joy, sadness, and anger are the same in the Australian aborigine, the American farmer, and the Norwegian fisherman (Ekman,

Figure 12-3 This woman signals attentiveness and seriousness by holding very still, cocking her head, and looking intently at the speaker. (From Schefflen AE. *Body Language and the Social Order—Communication as Behavioral Control*. Englewood Cliffs, NJ, Prentice-Hall, 1972.)

2006). Various cultures, however, do disguise the facial expression in different ways. In American culture, the mouth is used most often to disguise feelings. A person in a social gathering may be smiling, although inwardly sad or angry. The eyebrows, eyes, and forehead are least affected by these cultural disguises and are the most consistently dependable indicators of emotion. As Shakespeare wrote, "I saw his heart in his face" (*The Winter's Tale*, Act I, Scene II).

Ekman and Friesen (1975) found that the facial expressions of fear, disgust, happiness, and anger were the same in countries with widely disparate languages and cultures. They used composite facial photographs to show how each part of the face contributes to the expressions of emotion, especially surprise, fear, disgust, anger, happiness, and sadness. In American culture, when people want to disguise their true feelings and convey a more socially acceptable impression, they do so by smiling. This may be especially true in patients who are sad or depressed. Figure 12-4 is a composite showing sadness in the eyes, brow, and forehead being masked by a smile.

Smile

A genuine smile can be helpful in quickly establishing a friendly atmosphere and developing a warm, interpersonal relationship. A grin can be the physician's most effective weapon for breaking down resistance or apprehension in patients, especially children or young adults. A number of studies have shown that patients are more positively disposed to physicians who smile. The smile must be genuine, however; patients can easily spot a phony smile.

Smiles are controlled by the zygomatic major muscles that connect to the corners of the mouth and the orbicularis oculi muscles. The latter are not under conscious control and

Figure 12-4 Masking sadness by smiling (see eyes and forehead). (From Ekman P, Friesen WV. *Unmasking the Face: a Guide to Recognizing Emotions from Facial Clues*. Englewood Cliffs, NJ, Prentice-Hall, 1975.)

reveal a true smile that involves characteristic creases around the eyes. A genuine smile lights up the whole face; one that does not is more likely a deception (Ekman, 2005).

Micro-Expressions

Ekman and Friesen (1975) also described micro-expressions, a valuable indication of masking or deception. "Micro-expressions are caused by the face's all too rapid efficiency in registering inner feelings" (Morris, 1977, p. 110). Most facial expressions last more than 1 second, but micro-expressions last only about one fifth of a second (Ekman, 2003). This is approximately the time it takes to blink an eye, and micro-expressions easily can be missed if the physician is not carefully observing the patient. Micro-expressions tend to occur when emotion is concealed unwittingly by repression or deliberately by suppression. They can be seen if the patient begins to show a true facial expression, senses this, and immediately neutralizes or masks the expression. Some micro-expressions are complete enough to show the true emotion felt, but most often, they are squelched to such an extent that the physician has only a clue that the patient is concealing some emotion.

Most expressions last about 2 seconds (0.5-4 seconds). Surprise is the briefest expression (Ekman, 2003).

Eyes

The eyes are probably the principal organs of expression. They are so important to a person's appearance that when anonymity is desired, only the eyes need to be covered. The eyebrows have been shown to have 40 different positions of expression and the eyelids 23. Consider the magnitude of possible combinations when all facial elements are involved

as indicators of expression. The message conveyed by each position can be further modified by the length of a glance and its intensity.

In most cultures, good rapport is enhanced when one's gaze meets the other's 60% to 70% of the time. When we talk, we maintain eye contact about 40% of the time and 80% when listening. Ninety percent of the gaze will be in a triangular area between the eyes and the mouth (Pease and Pease, 2004). On meeting, two people will scan each other's face for about 3 seconds, then briefly gaze downward. An upward eye break may be disconcerting or convey a lack of interest (Lewis, 1989). (See eFigure 12-1 online at www.expertconsult.com.)

The eyes can give more information for some emotions than others. Knapp (1978) found that the eyes were better than the brow, forehead, or lower face for the accurate portrayal of fear but were less accurate for anger and disgust. Even the lower eyelid alone can convey considerable information. In Figure 12-5, it is apparent that the person in B depicts more sadness than the one in A, but the pictures differ in only one respect: the lower eyelid.

It has long been known that *pupils* dilate when the person sees something pleasant and contract when something unpleasant is viewed. This involuntary signal can be a valuable indication of what is really going on. Asian jade dealers wore dark glasses so that no one could see their pupils dilate when they discovered an especially valuable piece of jade. Likewise, a magician doing card tricks can tell when a preselected card is seen by a subject because of the sudden pupil enlargement. In one experiment (Hess, 1975), the pupils of males dilated when the men were shown photographs of nude females and constricted for nude males. Homosexuals demonstrated the opposite. Dilated pupils also can indicate

Figure 12-5 Sadness shown in the eyes and forehead (the mouth is neutral). The importance of the eyelids can be seen because the person on the right (B) is obviously sadder than the one on the left (A) but differs only in that a sad lower eyelid has been substituted for a neutral lower eyelid.

(From Ekman P, Friesen WV. *Unmasking the Face: a Guide to Recognizing Emotions from Facial Clues*. Englewood Cliffs, NJ, Prentice-Hall, 1975.)

that listeners are interested, whereas constricted pupils suggest that they do not like what is being said (or viewed).

Sincerity is expressed with the eyes. The best method for conveying sincerity is frequent eye contact, a technique most appropriately used when listening to the other person. One trait of good listeners is that they constantly look at the speaker. A listener who does not maintain eye contact but continues to look down or away from the speaker, may be shy, depressed, or indicating rejection of the speaker or the comments being made. One patient said, "I had one student doctor who looked at his toes instead of me. If he ever opens a practice, I don't believe I would trust him." Conversely, speakers frequently may break eye contact when talking and are permitted a distant stare when formulating ideas and selecting phrases. However, they still should try to make frequent, although less prolonged and intense, eye contact.

A special form of human-to-human awareness is conveyed by eye contact. Prolonged eye contact, or staring, can be offensive. Monkeys can be provoked to combat by a person staring at them because of the threat of aggression that this represents. Under other circumstances, however, staring can be flirtatious, emphasizing that the meaning of eye behavior depends on other factors in the situation.

The acceptability of eye contact varies significantly among different cultures. In the United States, focusing the eyes on the speaker indicates respect and attention, regardless of the age of the individuals involved. However, Mexican Americans tend not to maintain as much eye contact while listening as do other Americans and may look away from the speaker more often. This is not a sign of disrespect or inattention. In Latin American countries, a younger person may be thought disrespectful if his or her eyes meet those of the adult who is speaking. A physician could be considered seductive in that culture if he or she maintained steady eye contact while talking to a patient. In the United States, it is impolite to maintain eye contact with a stranger for more than 3 seconds, but Europeans believe that longer periods of eye contact are normal. The physician needs to consider the patient's cultural background when interpreting the meaning of eye contact behavior. Looking away from the speaker from time to time may be a sign of respect and sensitivity rather than the opposite. At the same time, the physician's failure to look a patient in the eye can be dehumanizing and can cause the patient to feel more like an object than a person. Patients are most comfortable when the physician looks at them approximately 50% of the time and are uncomfortable when eye contact is avoided.

The frequency of eye contact also can provide clues to whether the patient is anxious or depressed. The eyes of anxious patients blink frequently or dart back and forth. They look at the interviewer as frequently as low-anxiety patients but maintain eye contact for less time on each gaze. Similarly, the patient may interpret the physician's lack of eye contact as indicative of anxiety or discomfort, even rejection.

Frequent blinking of the eyes can be a sign of pressure or stress. In a political debate between Senator Bob Dole and President Bill Clinton in 1996, Dole blinked an average of 105 times per minute, showing more pressure than Clinton's 48 times per minute.

Depressed patients maintain eye contact only one-fourth as long as nondepressed patients. Downward contraction of

the mouth and a downward angling of the head are also cues to depression. As with the anxious patient, there is no difference in frequency of eye contact in the depressed patient; the difference is only in the duration of contact.

Patients with abdominal pain caused by organic disease are more likely to keep their eyes open during palpation of the abdomen than those with nonspecific pain (Gray et al., 1988). The patient with genuine abdominal tenderness may apprehensively watch the physician's hand as it approaches the tender area.

Hands

The hands will be droopy and flaccid with sadness, fidgety or grasping in anxiety, and clenched in anger. When a speaker joins her or his hands, with fingers extended and fingertips touching, it is called *steeping* and indicates confidence and assurance in the comments being made (Figure 12-6).

Palms usually are held in the palm-in position. Turning the palms outward can be a subtle courting behavior (usually used by women), but it more likely indicates a warm and friendly greeting (Davis, 1975).

The hands of an anxious patient can be observed to shake when holding a pen, to twitch, or to be braced unnaturally. The white-knuckle pose of tightly locked fingers can be an effort to mask anxiety.

Hands can be a subtle indicator of the urge to interrupt. Be alert for this sign in a patient so that important information will not be suppressed, and the patient can be given every opportunity to supply valuable information. Indications of this urge to interrupt are a slight raising of the hand or perhaps the index finger only, pulling at the earlobe, or raising the index finger to the lips. The latter gesture also may indicate an attempt to suppress a comment and should alert the physician to inquire further and elicit the hidden information. A patient listening in "The Thinker" position, with the index finger across the lips or extended along the cheek, or one sitting with elbows on the table and hands clenched in front of the mouth, although listening intently, may not believe or understand the physician's words (Figure 12-7).

Figure 12-6 Steeping.

Figure 12-7 The defensive or “doubting Thomas” position.

The physician should take additional time to amplify the issue or explain the diagnosis or treatment regimen further.

Arms

Although folded arms are found in all cultures, this is considered a discovered action rather than an inborn trait because it is a natural position of comfort that is as easily discovered by the African tribesman as the New York banker. It is the subtle ways in which the arms are held that can give clues to underlying emotions. Crossed arms can be a defensive posture, indicating disagreement with another’s view, or it can be a sign of insecurity. It can also be nothing more than a position of comfort and should, as with all other signs, be considered in the context of the individual’s total behavior.

Notice the manner in which the arms are crossed. Are they relaxed in the normal position of comfort, or are they in a hugging posture, reflecting insecurity or sadness and indicating a need for reassurance? Anger can be seen in clenched fists that are held tightly against the body in a holding-back manner, preventing them from hitting (Figure 12-8). If the patient has assumed a position of resistance or defensiveness, sitting with arms and legs crossed and perhaps with body turned away, search for the reason for this defensiveness and try to eliminate it. Perhaps a recommendation that the patient stop smoking is threatening and difficult to accept. In that case, it is important to make an additional effort to explain the rationale for the recommendation; do not hurry over it with a brief comment or admonition.

Legs

Although crossing the legs is a common position of comfort, it can also indicate a shutting out of or protection against the outside world. If crossed legs in a patient confirm the total kinesic picture of resistance, including crossed arms and other signals discussed earlier (Figure 12-9), make every effort to identify the reason for the resistance and correct it before proceeding further. Likewise, locked ankles can indicate defensiveness. Diagnostic information obtained from a

Figure 12-8 The resistant position, suggesting suppressed anger.

resistant patient is likely to be incomplete, and instructions are unlikely to be followed.

Notice the position of the feet and their movement. As with fidgety hand movements, anxiety is associated with the fidgety, constantly moving foot. An anxious or scared person may sit forward in the chair with feet placed in the ready-to-run position, with one foot in front of the other. The angry person is more likely to place the feet widely apart in a position of stability, whereas the feet of a sad person tend to move in a slow, circular pattern.

Gestures

The thumbs-up sign in the United States means “good going,” but in some Islamic countries, it is the equivalent of an upraised middle finger. Similarly, the extended hand with palm forward means “stop” in the United States, but in West Africa, it is an insult greater than the upraised middle finger.

Joining the thumb and index finger in a circle to indicate “OK” is an insult in many Latin American countries and in France means zero or worthless. In Texas, raising the index and little finger with the middle two fingers folded down is the “Hook ‘em Horns” gesture of the University of Texas Longhorns, but in parts of Africa this gesture is a curse and in Italy it means your spouse is unfaithful.

American television and the movies have dulled these differences worldwide, although some still exist. In the 1978 movie *Inglorious Bastards* (remade in 2009) the American posing as a German was detected because he displayed the number 2 using index and middle fingers, whereas Europeans would hold up the thumb and index finger with the thumb being number 1.

Figure 12-9 The defensive position.

Preening

Preening gestures, such as the male pulling up socks, adjusting a tie, or combing hair and the female adjusting clothing or using a mirror to review makeup, may not necessarily be seductive in nature but can be an attempt to establish rapport and good interpersonal relations. If the preening is intended to be flirtatious, however, the woman may cross her legs, place a hand on her hip, caress her leg, or stroke the arm or thigh in some fashion. The flirtatious male typically uses gaze holding and head tilt to accentuate normal preening gestures or may stretch to make himself look larger. Both genders may use “accidental” touching as a flirting signal. When someone’s attention is completely focused on the other, legs, knees, and feet are usually extended in the direction of the other. The physician should remain alert to the accentuation of normal preening gestures into courtship actions to identify the seductive patient and deal with the issue early, before unknowingly encouraging the patient to proceed further along this course.

Respiratory Avoidance Response

The respiratory avoidance response involves a frequent clearing of the throat when no phlegm or mucus is present. All animals exhibit a respiratory avoidance response as a means of clearing something unpleasant or undesirable from the respiratory tract. This action also can be a nonverbal indication of disgust or rejection. When physicians find themselves

Figure 12-10 The nose rub, a variation of the respiratory avoidance response.

doing this, they should observe the accompanying circumstances and notice whether posterior pharyngeal mucus is truly present.

Nose Rub

Another component of the respiratory avoidance response is the nose rub (Figure 12-10). This involves a light or subtle rub of the nose with the index finger and signals rejection of a statement being made by the subject or by another individual. The nose rub to relieve an itch is usually vigorous and involves a repeated series of rubs, whereas that of the respiratory avoidance response is soft and consists of one or two light strokes, often involving nothing more than a light flick of the nose. Morris (1977, p. 111) described the nose flick as “a reflection of the fact that a split is being forced between inner thoughts and outward action.” It can be associated with lying or with the struggle to appear calm while suppressing anger or discomfort. During Bill Clinton’s testimony to the grand jury regarding his affair with Monica Lewinsky, he rarely touched his nose when telling the truth, but when he lied he gave a split-second frown, then touched his nose. During the testimony he touched it 26 times (Pease and Pease, 2004). Variations of the nose rub include pulling at the earlobe, scratching the side of the neck or rubbing one eye. Someone aware of the nose rub will often notice it in themselves and realize they are uncomfortable with what is being said by themselves or others. Watching for this during interviews on television may indicate the person being interviewed is uncomfortable with the question, or the person asking may realize it is a “testy” point.

This sign can be quite useful in patient interviewing. For example, the physician may ask a patient, “How are things at home?” The patient may answer, “Fine,” but then clears his or her throat and lightly rubs the nose with the index finger. He or she is actually saying, “I don’t like what you are

asking me," or "I feel uncomfortable with my answer; things really aren't going very well at home." If there is a cause to pursue the issue further, a simple comment such as "Really?" or "You mean not even an occasional argument?" may lead to a flood of information masked by the previous response.

Verbal-Nonverbal Mismatch

Another indication that what a patient is saying may be in conflict with what is being felt is a verbal-nonverbal mismatch, such as when the patient answers "fine" to "how are things between you and your husband" while looking sad and avoiding eye contact (Quill, 1989). If the patient answered negatively to the question, "Have you ever had a venereal disease," and at the same time exhibited a nose rub, this topic should be followed up with a similar inquiry later, perhaps while doing the physical examination, when the patient may feel more comfortable after better rapport has been established.

Other clues that the patient may not be telling the truth or that there are repressed feelings are asymmetric facial expressions and a prolonged smile or expression of amazement. Almost all authentic facial expressions fade after 4 or 5 seconds (Ekman, 1985).

Neurolinguistic Programming

Neurolinguistic programming (NLP) involves the eye movements performed while thinking and depends on whether a person is thinking visually, aurally, or kinesthetically. A right-handed person who is visually oriented will look up and to his or her left when recalling something visually, but up and to the right if creating something visually or, in other words, making it up or lying. Similarly, a right-handed person will look sideways to his or her left when recalling sounds and sideways to the right when imagining sounds. A person who is looking up and to his or her right (i.e., your left) probably is imagining things he or she has never seen before. This technique is used by police investigators when interviewing suspects. A left-handed person will respond in opposite directions (Zellmann, 2004, Brooks, 1989) (Figure 12-11).

Detecting Lying

In addition to looking up and to the right to create an image or a fact, a person who is lying is also likely to do the following:

- Cover the mouth with hand.
- Rub or flick the nose.
- Scratch the neck.
- Pull at the ear, or rub behind the ear.
- Rub one eye.

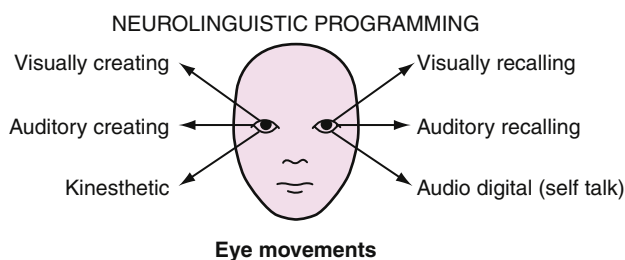

Figure 12-11 Neurolinguistic programming.

- Blink excessively (although absence of blinking is also possible).
- Have a micro-expression indicating something is different than what is said.
- Avoid making eye contact.
- Use arms and hands less.
- Be defensive rather than aggressive.
- Change manner or posture abruptly.

The liar will also rarely touch the other person or point a finger at them or others, and the story will not include negative details (Lieberman, 1998). The liar is not comfortable with silence and may speak more than normal to convince the other. Persons suspected of lying should be encouraged to talk because verbal and nonverbal clues will then be easier to detect (Vrij, 2005). Liars are also likely to slouch, unlike a confident person, who will sit upright. Remember that it takes a combination of verbal and nonverbal clues to detect lying, and no single action is likely to be dependable other than to raise doubt or suspicion.

Proxemics: Spatial Factors

Proxemics is the study of how people unconsciously structure the space around them. This structuring varies with every culture. North Americans, for example, maintain a protective "body bubble" of space about 2 feet in diameter around them when they interact with strangers or casual acquaintances. Violators of that space are considered intruders and cause the person to become defensive (Figure 12-12). In the Middle East, no such bubble exists, and it is proper to invade this area. In fact, not to do so may be interpreted as unfriendly and aloof. Arabs prefer to stand close enough to touch and smell the other person. Americans, however, if forced to stand close together, as on a crowded subway, will use their eyes (i.e., distant gaze) to maintain a more proper distance. An arm's length is a good measure of the appropriate personal distance for most people. A wife can stand inside her husband's bubble, but she will be unhappy if another woman invades this sphere of privacy, and vice versa.

Robert Frost said, "Good fences make good neighbors." In suburbs and small towns, people are more likely to talk to each other while in their backyards if a fence indicates the boundary than if there is a communal yard (McCaskey, 1979). Marking the boundary helps maintain territoriality and actually brings the neighbors closer together than when there is no fence.

Intimate space has been classified as that ranging from close physical contact to 18 inches, *personal space* from 18 inches to 4 feet, *social space* from 4 feet to 12 feet, and *public space* from 12 feet and beyond. Placing a desk between two people shifts personal space to social space. The office desk also can be a barrier to communication when it is placed between the physician and patient, thereby emphasizing the illusion of the physician's importance and power. There may be occasions when this is desired, but it usually is not necessary in a family physician's office. Office furniture should be arranged so that a minimum number of obstacles lie between physician and patient.

Automobiles magnify the size of one's personal space up to 10 times. Compare the relationship of two people having a conversation with that of "road rage" when one invades the other's space by cutting in front of them.

Hidden or Masked Communication and Patients’ Expectations

Although the average person has a symptom about every 6 days, he or she visits a physician only once every 4 months. Some people visit a physician much more frequently than others for the same symptom. The group who visits more frequently tends to have a higher level of anxiety, fear, grief, or frustration. It is the physician’s responsibility to search for, identify, and treat organic disease if it is present, but in about one half of cases, none will be found. It is equally important to identify the reason for these visits—the basis for the heightened concern or increased anxiety. A person may see a minor symptom as a potential catastrophe if she or he thinks it may be a sign of cancer similar to that causing a parent’s death. Is the patient really there “just for a blood pressure check,” or because of concern about the condition of his or her coronary arteries since a friend recently had an acute myocardial infarction? If the physician deals only with the symptoms, the real concerns may go undetected, and the result will be a dissatisfied and non-compliant patient.

Barsky (1981, p. 492) cautioned, “Patients who express dissatisfaction with their medical care should be questioned about this, as they may be dissatisfied because their real motivation in seeking care has not been illuminated.” He also advised the physician to investigate the patient’s current life stresses when visits are made if there is no change in clinical status.

Patients may come to a physician because of what they imagine is causing their symptoms rather than because of the symptoms themselves. Identifying what patients hope can be done for them—focusing on their expectations for the visit—often reveals hidden reasons for the visit. The physician should be sure to address the patient’s expectations and make certain that the interpretation is correct. Rapport and satisfaction will be enhanced if the physician identifies and satisfies the patient’s expectations for the visit. Dissatisfaction results when these expectations go unmet.

Listening Well

A good family physician must be a good listener. Of all the communication skills essential to rapport, the ability to listen well is probably the most important. All the information in the world about body language, vocal messages, and nonverbal cues is of limited value unless it helps the family physician be a better listener.

As Lown (1996) states, “In the brief time available to take a history, the aim is to obtain, in addition to essential facts, insight into the human being. This seems easy, but listening is the most complex and difficult of all the tools in a doctor’s repertory. One must be an active listener to hear an unspoken problem” (p. 10). The appearance of readiness to listen is aided by bending forward and maintaining eye contact. The physician can discourage a patient from talking by looking away or writing in the medical record. Well-chosen questions can be rendered useless by inappropriate nonverbal behavior. Even great questions are of no value if you do not know how to listen.

For many people, the opposite of talking is not “listening” but rather “waiting to talk.” It is impossible to listen attentively when you are planning what to say next. Besides, learning to listen is more difficult than learning to ask good questions (Dimitrius and Mazzarella, 1999).

The average listening efficiency of most people is only 25% because we do not concentrate on what is being said. Effective listening requires focus on what is being said and on voice tone, facial expression, and body movements. Hearing what someone says and truly listening to what they are saying is quite different (Zellmann, 2004).

Analyses of physician-patient interviews reveal that, on average, the physician rather than the patient does most of the talking, although when questioned, physicians usually imagine the reverse. In general, the less the physician says during an interview, the more the patient will say.

Boredom is one of the most difficult states to conceal. It is very difficult to appear attentive and interested if you are bored, and it takes considerable effort to appear interested (Dimitrius and Mazzarella, 1999).

Silence

Silence can be as effective a means of eliciting further information as direct questions. The timing is important, however, and silence should be used as a technique only when the physician is relatively certain that there is more information to follow the last statement. A shift of position or a nod and a smile, properly timed and coupled with silence, can be more effective than an encouraging comment. Nonverbal encouragement to continue is less distracting and may be more facilitative than the verbal form.

Attorneys use silence in the courtroom to get witnesses to say more than they had intended. They wait silently as if the witness has not given a complete answer, and usually they do receive additional information. Silence can be effective as long as the patient feels more inclined to fill the void than the physician. This is of value, however, only when there is more information to be obtained. It is said that Charles DeGaulle thought that silence was the ultimate power tool, and in his speeches, he gained control by looking at the audience, never breaking eye contact, and saying nothing.

Interruption

The patient may be following a line of thought and may be about to open up more but must stop and refocus if the physician captures the patient's attention with a question. The physician should interrupt a patient's statement only if it is necessary to change the conversation to a new topic, clarify an issue, elicit information not produced spontaneously, offer reassurance, or reduce patient anxiety.

Physicians usually use closed-ended questions to interrupt the patient and thereby inappropriately control the interview. Beckman and Frankel (1984) found that 69% of patients (52 of 74) had only 18 seconds to complete their initial complaint before being interrupted by their physician. This usually occurred after the patient stated only a single concern, and it effectively halted the further flow of information from the patient. This prematurely terminates opportunities for patients to present their primary concerns. Only one of the 52 patients subsequently returned to and completed the opening statement. In these recorded office interviews, only 23% of the patients were permitted to complete their list of problems uninterrupted; when they were,

the complete statements usually took less than 60 seconds, and none required more than 2.5 minutes.

Humor

The art of medicine consists of amusing the patient while nature cures the disease.

Voltaire

Humor can be helpful in establishing rapport and can strengthen the physician-patient relationship. It can be used to "break the ice" and is most useful if it communicates the feeling that "we are all in this together." Humor is an effective way for physicians to appear human while supporting and empathizing with their patients. Physicians who score high in empathy also tend to have a good sense of humor (Hampes, 2001). Empathic humor can promote a stronger physician-patient relationship and enhance the effectiveness of other, more traditional as well as nontraditional forms of therapy (Berger et al., 2004).

Care must be taken, however, because humor can be a two-edged sword that can cut either way if used inappropriately. The least risk is when the humor is self-deprecating or focused on neutral topics such as the weather or parking. It can even alienate the patient if they feel the joking around is inappropriate at the very time they want serious attention paid to their problem.

More research is needed on the value of humor in medicine so that we will know when and how to use it effectively. Norman Cousins, former editor of the *Saturday Review*, had ankylosing spondylitis. He received 3 hours of pain relief after watching comedy videotapes of "The Three Stooges" and "Abbott and Costello" but obtained only 1/2 hour of pain relief from an oral analgesic. Some physicians write prescriptions for patients to laugh out loud three times each day. In India, Laughter Clubs convene at the beginning of each day to laugh out loud. Even a fake laugh makes one feel better throughout the day.

Physicians who express interest in patient opinions and who use humor more often are sued less often. Tasteful humor can reduce anxiety and create a bond of friendship, but humor used inappropriately can magnify the distance between patient and physician, especially if it belittles the patient.

Key Points

- Encouragement of healthy lifestyles by family physicians and acceptance of responsibility for health behaviors by patients are part of a new paradigm of the physician-patient relationship.
- Enhanced patient satisfaction and realistic expectations as a result of education can reduce risk of malpractice actions.
- Use a SOAPE note to document adding education to your plan.
- Match your message to each patient's stage of change.
- Use feedback, reinforcement, individualization, facilitation, and multiple channels when providing education.
- Learn brief techniques of motivational interviewing to be more successful in facilitating behavior change.

Family medicine has long embraced the concept of patient education as an integral part of patient care. It is an official policy of the American Academy of Family Physicians (AAFP) that "family physicians should take a leadership role in improving the health of the American public by providing accurate and meaningful patient education." The AAFP produces guidelines for residency curriculum in patient education; includes patient education materials in its journal, *American Family Physician*; and sponsors an award-winning resource (FamilyDoctor.org). The Joint Principles of the Patient-Centered Medical Home (2007) include patients' active participation in medical decision-making and the use of information technology to support patient education.

Patient education continues to evolve. Patients who are informed are more likely to be active participants in their care and adhere to treatment (Epstein et al., 2004). Although physicians have technical knowledge about medical conditions

and treatments, patients have more knowledge about their own experience, values, and cultural considerations. Effective patient-centered education requires physicians to individualize information according to each specific patient's needs, values, and culture, and consider these when working with patients to make treatment decisions (Falvo, 2004).

Rationale

Most people want to be better informed about every aspect of their health care. Apart from patients' expectations and satisfaction, there are a number of compelling reasons for physicians and other health providers to educate patients. The most important of these is better adherence to therapies (Gray et al., 2004; Rogers et al., 2005). Although the results of typical patient education efforts are modest (Haynes et al., 2002; Schroeder et al., 2004; van Eijken et al., 2003), education has the potential to improve health outcomes and reduce morbidity. Additional benefits to the physician include practice marketing through enhanced patient satisfaction (Aragon, 2003; Ganz, 2002) and prevention of malpractice actions (Eastaugh, 2004; Wissow, 2004).^{11,12}

Existing data suggest that the most effective interventions available to clinicians for reducing the incidence and severity of the leading causes of disease and disability in the United States are those that address the personal health practices of patients (USPSTF, 1996). This implies movement of health care providers and patients toward a nontraditional relationship, in which encouragement of healthy lifestyles by providers and acceptance of responsibility for health behaviors by patients become the cornerstones of a new preventive care

paradigm. Education of patients is critical to the implementation of this paradigm.

Opportunities

Education of the patient or the family can make a contribution to every medical interaction. Every recent medical school graduate is familiar with the SOAP note format (i.e., subjective data, objective data, assessment, and plan) for documenting a medical encounter. Adding education (E) to the plan by using a SOAPE note serves as a reminder to educate patients and to document the education.

All excellent family physicians are also excellent teachers of patients. Such physicians typically incorporate education continuously during the interaction with the patient, not as a separate step. When taking a history, the physician can assess attitudes, knowledge, and skills. When performing an examination, the physician can instruct about the purpose of the examination and the meaning of findings. When discussing a diagnosis, the physician can share its meaning and the process of decision making in approachable terminology. When suggesting therapy, the physician can assess understanding, willingness, and barriers to implementation.

Although patient education may largely occur in the context of individual provider-patient interactions, there are many additional opportunities to become involved in health education. Health education is a regular part of curricula in schools, may be found in workplace programs in many communities, and is routinely featured in the mass media. Family physicians who have become involved in health education can have greater impact from the ripple effects of networking in their community. Involvement can begin with small, manageable actions. Physicians can offer to come for question-and-answer sessions during health classes, offer to be a consultant to the school board regarding health curricula, or become a team physician for junior high or high school teams. Media involvement can come from volunteering to comment on current issues in health for local radio and television stations or from writing a regular health column for the local newspaper.

Within their own practice, many family physicians struggle to include all the education they want to provide. There are a variety of creative solutions to this problem. The physician can expand services to include group classes for common topics such as smoking cessation, perinatal care, and healthy diet. Group visits can be done for patients with chronic problems that need regular monitoring, such as diabetes and hypertension (Loney-Hutchinson et al., 2009). Also, patient education can be made the responsibility of the entire practice, involving office nurses, medical assistants, and receptionists as a team. Larger practices may have access to dietitians or pharmacists.

It is important not to overlook existing resources in the community that can be used to expand what is offered in the physician's office. These include national and local disease-specific support organizations such as the American Diabetes Association (ADA), American Heart Association (AHA), American Cancer Society (ACS), American Lung Association, Weight Watchers, and Alcoholics Anonymous (AA). Educational resources in the form of groups or short courses may also be sponsored by local libraries, YMCA chapters, churches, or other community organizations.

Principles of Patient Education

The system of patients accepting the advice of all-knowing physicians in an unquestioning and docile manner no longer applies. Instead, physicians should strive toward a doctor-patient partnership in which the patient sees the physician (and physicians see themselves) as a health consultant. In such a role, the question becomes how to educate most effectively. Research has consistently demonstrated that patient benefits are greatest when interventions follow sound educational principles, including the following (Simons-Morton et al., 1992):

Feedback means that the patient is informed about progress toward goals and objectives.

Reinforcement refers to encouragement or rewards for patient progress.

Individualization takes into account the needs, desires, and characteristics of the patient and demands that specific goals and objectives are negotiated for each patient.

Facilitation refers to materials, cues, and skill training that assist the patient in making changes.

Relevance to the learner means that the content is appropriate for an individual patient's circumstances.

Multiple channels imply combined learning strategies and a team approach to education.

These principles have been incorporated into the U.S. Preventive Services Task Force (USPSTF) recommendations for patient education and counseling shown in Table 13-1.

A Model of Health Behavior Change

Stages of Change

The purpose of patient education efforts often is to inform and to change behavior. Typically, the goal is to improve adherence to therapeutic regimens, encourage new lifestyles, or help the patient adopt other behaviors that prevent disease and disability. One of the most useful ways to understand the process of behavior change is the *transtheoretical model*, often called the "stages of change" model (Zimmerman et al., 2000). This model proposes stages called precontemplation, contemplation, preparation, action, and maintenance (Table 13-2). *Precontemplation*, *contemplation*, and *preparation* can be thought of as stages of motivation and readiness for change. In at-risk populations, typically 40% are precontemplators, 40% are contemplators, and 20% are in preparation (Prochaska and Velicer, 1997). Research has shown improvements in process and outcome measures when stage-matched interventions and recruitment methods are used (Prochaska et al., 2005). Although the model is described in a linear fashion, experience has demonstrated that patients naturally move back and forth among stages.

This model emphasizes the critical importance of the *stage of change*. Fortunately, it can usually be assessed with simple questions. Given typical constraints of time and resources in a primary care practice, most patient education efforts should focus on patients in the stage of *preparation*. Giving such patients the proper cue or knowledge to make a beneficial change is generally easy to provide. For simple

Table 13-1 USPSTF Recommendations for Patient Education and Counseling

| |
|--|
| Frame the teaching to match the patient's perceptions. |
| Fully inform patients of the purposes and expected effects of interventions and when to expect these effects. |
| Suggest small changes rather than large ones. |
| Be specific in recommending new behaviors. |
| Emphasize that it is easier to add new behaviors than eliminate established ones. |
| When feasible, link new behaviors to established ones. |
| Use the "power of the profession." |
| Obtain explicit commitments from the patient. |
| Use a combination of strategies. |
| Involve office staff. |
| Refer to community agencies, voluntary health organizations, reference material, and even other patients. |
| Monitor progress through follow-up contact. |
| From US Preventive Services Task Force: Guide to Clinical Preventive Services. Baltimore, Williams & Wilkins, 1996, p 953. |

behaviors (e.g., stretching before exercise), simple recommendations or an instructional pamphlet may be sufficient to accompany the physician's strong statement of support for the new behavior. For more complicated behaviors (e.g., dietary changes), one or more additional scheduled visits with the physician, a dietician, or other provider may be needed to set goals, convey knowledge or skills, and reinforce behavior change. A basic implementation of this thinking for health promotion has been called the "five As": *ask, advise, assess, assist, and arrange*. This approach has been promoted primarily for tobacco cessation (Kenford and Fiore, 2004).¹⁹

An important implication of the stages-of-change model is that encouraging action for patients in the precontemplation or contemplation stage is wasted energy. Instead, if the behavior is an important one, the goal should be to increase the patient's *readiness* for change. Research has shown that an increase in the "pros," or perceived benefits of change, is the most common finding when patients move from precontemplation to contemplation. Contemplators are usually weighing the perceived pros and cons of change in a manner that leaves them ambivalent about this decisional balance. Research indicates that movement from contemplation to action is most strongly associated with a decrease in the perceived cons of change. To reduce the cons for contemplators, the physician needs to identify these through open-ended questioning.

When and How to Intervene

When patients are unmotivated for change in the stage of precontemplation, the physician should decide whether to invest the time to intervene through assessment and

Table 13-2 Stages of Health Behavior Change

| |
|---|
| Precontemplation: Not intending to take action in the foreseeable future, usually measured as the next 6 months. |
| Contemplation: Intending to change in the next 6 months; aware of the pros and cons of changing, leading to procrastination. |
| Preparation: Intending to take action in the immediate future, usually measured as the next month; have a plan. |
| Action: Have made specific overt modifications to behavior within the last 6 months. |
| Maintenance: Working to prevent relapse, increasing confidence; typically lasts 6 months to 5 years. |
| From Prochaska JO, Velicer WF. The transtheoretical model of health behavior change. <i>Am J Health Promot</i> 1997;12:38-48. |

attempted modification of beliefs, confidence, supports, or barriers. The decision often hinges on factors such as the level of risk for the patient, the time available at that visit, competing demands, and the physician's own experience and confidence level. At a minimum, an open-door policy should be adopted. The physician must convey the message that she or he is willing and ready to help the patient make changes when the patient becomes motivated to make them. Stage of change should be assessed on a regular basis as the patient is cared for over time.

If the physician takes up the challenge of the precontemplator, how can the pros and cons of change be assessed and addressed in the context of routine office visits? A useful approach for physicians is *motivational interviewing* (Miller and Rollnick, 2002). This approach is characterized by *collaboration* between physician and patient; by *evocation*, enhancing motivation by drawing on the patient's own perceptions, goals, and values; and by *autonomy*, in which the patient's right and capacity for self-direction are affirmed and informed choice is facilitated. Practical strategies for motivational interviewing can be integrated with a stages-of-change model of behavior change (Rollnick et al., 1999).

Because many patients are not motivated, and the health rewards of behavior change are often not immediate, physicians must also take steps to avoid "burnout." A long-term view is often helpful. The goal is to change readiness in increments over time and to be ready to detect a change in motivation that will allow meaningful change in behavior. It can also be the case that events will take place that cause a dramatic shift, usually caused by a change in perceived risk. These events are opportunities to explore health beliefs in the hope that they have changed. In the meantime, the best strategy is to be nonjudgmental, to feel rewarded for small changes that patients make, and to accept that some people will not change despite one's best efforts. If, for example, the annual smoking quit rate in a practice increases to 10% from a baseline of 5% of smokers per year, physicians should not despair about the other 90%, but instead congratulate themselves on doubling the rate of smoking cessation and leave the door open to the other 90%.

Planning for Patient Education in Your Practice

Key Points

- Employ all the people and places in your clinical setting—front and back office staff; waiting and examination room environments—to promote the most efficient and effective education for your patients.
- Familiarize yourself with resources in the community that can augment the education provided in your office.
- Consider how other family members will affect your patients' success in changing behaviors or learning how to self-monitor a chronic condition.
- Develop a simple system for you and your staff to store and retrieve printed patient education materials.
- Adjust your approach for patients with low health literacy.
- Explore Internet resources so that you can refer patients to reliable, high-quality sites.

Who Will Be Involved

Formal studies and anecdotal reports have consistently indicated that involvement of all of the office staff in patient education increases the total impact and saves the physician time. The physician always needs to be involved in defining the educational goals, delivering brief messages about the importance of goals, prescribing an educational process, and following up regularly to assess progress. Depending on the physician's interest and the nature of the problem, the education can be given by the physician or delegated to office nurses and other staff. Reception staff can suggest printed materials or other available modalities to patients while they wait or can be involved in giving patients printed materials prescribed by the physician. Group classes can be offered in the evening, organized around common topics within the practice. If these are run in conjunction with existing evening clinic hours, group classes can be a time-efficient method of delivering education to select patients. In larger practices, interested staff can form a patient education committee who uses a quality improvement process to foster patient education.

Available community resources should not be overlooked, including professionals such as dietitians and diabetes educators who may be hired on a full-time or part-time basis by a larger practice or who can split their time as a "circuit rider," spending a few hours each week at several practices. Many communities have existing programs for smoking cessation, weight loss, stress reduction, and exercise. Physicians can spend some of their time or their staff's time to become familiar with the programs, their costs, and schedules. In some cases, physicians' involvement as a medical consultant can lead to an improved program.

Remember that almost all patients have a family context. For example, whether a spouse smokes is an important factor in a smoking patient's efforts to quit. Similarly, if a patient needs to learn about dietary change to lower cholesterol and the spouse does all the food preparation for the household, the instruction will not be likely to affect the target behavior without involvement of that spouse.

Using Verbal Instruction

The most common form of patient education lies in talking to patients within the context of routine physician-patient contacts. This interaction serves as the foundation for further education that may be provided in the form of printed materials, video materials, classes, or other instructional modalities. Information must be given in a relevant way, embedded in expectations that are shared between provider and patient.

An atmosphere of acceptance, but not necessarily approval, is the first prerequisite to effective communication. This implies that the physician maintain a nonjudgmental stance when inquiring about the patient's experiences, beliefs, and behaviors. Physicians must demonstrate that they understand the patient's perspective, even if they do not agree with it. These crucial steps lead to a teaming with the patient toward achievement of common goals.

Medical jargon should be avoided. One approach to helping patients decode the jargon is to embed synonyms in the information provided; for example, "There is an atherosclerotic lesion or *blockage* in one of the coronary arteries, *the blood vessels that carry blood to the heart muscle itself.*"

Specificity and clarity are equally important principles. It is best *not* to use language such as, "Cut down on the fat you eat," "Exercise more," "Avoid heavy lifting," or even "Take your medicine three times each day." In the case of exercise, for example, the physician can indicate the type of exercise, how often to do it, how long to do it, how intensely to do it (e.g., by using a target pulse), and how to warm up and cool down before and after, as well as any warning symptoms. This level of specificity helps to ensure that a motivated patient will have the necessary information to change behavior effectively.

A final tip for effective verbal instruction is to keep checking the patient's understanding of the information. At a minimum, patients should be encouraged to ask questions and seek clarification. A better strategy is to ask patients to summarize their understanding of the information they have been given. Questions are most effectively stated in a way that accepts blame for any misunderstandings and is therefore not condescending: "Just so I can be sure that I've been clear about the information I've given you, would you repeat back to me in your own words what you are to do?" (Falvo, 2004).

Using Printed Materials

Printed materials are the next most frequently used patient education modality after verbal instruction. Unfortunately, these materials are often used alone, or without sufficient preceding verbal instruction, as a surrogate for provider-patient interaction. Printed materials can be classified into two types: prescriptive and nonprescriptive. Although there is some overlap between the two, *prescriptive* materials are usually given by the provider to the patient with a specific goal in mind. Their use is often triggered by the onset or recurrence of a medical problem. For example, if the patient has strained the lower back muscles, a brochure may be given that explains back mechanics, avoidance measures to prevent repeat injury, and a physical program to improve flexibility and strength during and after healing. This material can supplement the physician's instructions about the care of this injury.

In contrast, *nonprescriptive* materials are put out for patients to take freely or read as desired, usually in a waiting room or examination room area. These materials are more general and topic oriented, serving as “general health education” rather than patient education. Examples include a brochure that describes the four basic food groups and a pamphlet that describes common sexually transmitted diseases. Although serving more to *inform* than to change behavior, nonprescriptive materials may lead to patient questions and expand opportunities for patient education during the office visit.

Physicians are responsible for the accuracy of any materials they distribute. Hundreds of materials are available free of charge or at low cost. Sources of such materials are primarily pharmaceutical companies, national voluntary associations (e.g., ACS, AHA), and medical specialty societies such as the AAFP and American Academy of Pediatrics (AAP). Several issues are important to consider before using existing materials. First, is the content appropriate? Materials provided by pharmaceutical companies may advertise a product or present information in a biased way. Voluntary organizations’ guidelines may not agree with the physician’s judgments about proper screening and treatment. Second, is the material clearly presented, with a reading comprehension level appropriate for the patients served by the practice? A third type of concern is logistical. Will additional copies of the material continue to be available for replenishing supplies, or will the material go out of print? This is particularly a concern for pharmaceutical-funded campaigns. Is the format of the material suitable for storage and display in whatever system is used in the practice?

Writing Your Own

For a variety of reasons, a practice probably will want to develop some of its own printed materials. Besides the advantage of control over content and format, this also carries the responsibility for accuracy and development of a good product. Practices can begin with a planning process that identifies the most important needs, based on common educational issues and the quality and usefulness of existing materials for these issues. Because accuracy is critical, a recent literature search is done to broaden the knowledge base before starting to write. This is most important if a physician is writing about a topic for a nonprescriptive material to use in the waiting room. However, it remains a useful process for prescriptive materials, even if the goal is simply to put down in writing the physician’s usual advice for a problem.

A common pitfall is to try to include too much information in the material. Restrict the content to three or four salient teaching points. Avoid jargon, extensive use of statistics, and fear messages. Be clear with advice and specific with instructions. Use short words and short sentences to improve readers’ comprehension. Ideally, test material on colleagues and patients before final reproduction in quantity. Such a review process can be invaluable.

Simple line drawings with a few labels are usually more effective than complex illustrations, with the added benefit of better reproduction. Subheads help readers find information, and sparing use of bold and italic type help to emphasize terms when needed. Use the active tense, avoid negatives, and do not use absolutes such as *never*, *must*, and *always*. Expert writers recommend use of the first person in phras-

ing questions and the use of the second person in answering them: “How often and how long should *I* exercise?” “For best results, *you* should exercise for at least 30 minutes, at least 3 times each week.” When laying out material, leave plenty of white space on the page, avoid long strings of capital letters, use a font with serifs, and use a 10- or 12-point type size.

Health Literacy

More than 90 million adults in the United States have poor literacy, leading to greater difficulty navigating the health care system and increased risk for poorer health outcomes (Andrus and Roth, 2002; Berkman et al., 2004). *Health literacy* refers to patients’ ability to read and understand instructions, to give informed consent, and to comprehend, absorb, and retain information presented. Low-health literacy skills are not limited to patients with low intelligence, those with lower educational levels, or those of lower socioeconomic status.

Patients experience low literacy in a number of ways. Although some individuals may never have learned to read, others may be able to read the words but are unable to attach meaning to what is written. Difficulties may reflect differences in level of language use between the physician and patient or language barriers when the patient and physician are from different cultures. Regardless of the cause, if patients are unable to read or understand the material presented, they receive little benefit.

The best method of assessment of the degree of literacy involves observing, being alert to cues, and conducting sensitive and timely direct questioning. Several instruments have been developed to assess medical literacy (Davis et al., 1998). A good example is the *rapid estimate of adult literacy in medicine* (REALM), a word recognition test designed for patients in health care settings (Davis et al., 1993).

In some situations, visual presentation of concepts may help patients comprehend and remember information presented. In other cases, giving smaller amounts of information over several visits may be the most effective means to enhance patients’ ability to absorb information. Written materials given to the patient should contain only essential information that is arranged in logical sequence and related to what the patient must know or do, rather than in-depth explanations.

When the literacy problem involves fluency or vocabulary, the physician should be especially cautious not to use jargon or assume that all “common” words or terms will be familiar to the patient. Using terms the patient knows and analogies of familiar themes may be helpful in assisting the patient to understand and remember concepts. When language is the specific problem, the physician may find it useful to use a third party fluent in both languages to assess the patient’s understanding of the material presented.

Role of Computers

Most patients can access the Internet. Unfortunately, this easy access to information is a double-edged sword. Many sites provide opinion, hearsay, and outright falsehoods with the same authoritative style as peer-reviewed evidence from published medical research. Patients are poorly equipped to tell the difference.

As more and more of their patients go online, physicians should keep abreast of some of the more reliable web resources so that they can make useful recommendations to patients and respond to misinformation that patients may encounter. An extremely useful resource is familydoctor.org, produced by AAFP. Some group practices and even solo physicians have established their own websites that provide information to patients and links to other sites that may be useful.

Some computer-based electronic health record (EHR) systems have designed patient education as an integral part of the software. For example, the provider can be reminded to give recommended preventive health habit counseling based on the patient's age, gender, risk factors, and past documentation of counseling. Drawings, diagrams, pictures, graphic displays of growth parameters or laboratory data, and other visual aids can be called up on the computer screen to use in patient teaching in the examination room. A list of available educational materials can be automatically generated for the provider based on the reason for the visit, medications, orders, or diagnoses; the system can print these on demand and track which materials are given to the patient.

Other Materials and Modalities

It is helpful to supplement printed materials with models, anatomic charts, and other visual aids that can be used during the process of instruction. Such materials can be invaluable in trying to explain what a 3-ounce serving of meat looks like, or how a herniated lumbar disk presses on nerves in the back. Models and charts can be purchased from supply houses or sometimes are offered at no charge by pharmaceutical companies who market a related product.

Office Systems and Design

One of the ways to be most effective in patient education is to view the practice setting in its totality as an educational experience for patients. From this perspective, health providers can critically examine each physical area and each staff person for the potential to contribute to patient education. For example, in the waiting area, which typically has comfortable chairs and a magazine rack or television, physicians can add nonprescriptive educational brochures, decorate the walls with posters that reinforce simple educational messages, and even play educational programs or use computer-assisted instruction. Examination rooms can have posters and racks of printed materials, particularly materials that patients may hesitate to pick up while others are watching. Some practices use monthly or quarterly health themes and rotate posters and materials that relate to the theme.

Most practices need to establish some mechanism for storing, retrieving, indexing, and ordering printed materials. There is no single best way to do this. Physical systems range from racks to filing cabinets to shelves to computer-based programs that print materials on demand. Functionally, the important aspects of any system are that providers know what types of material are available, agree with their content, know how to find desired materials, periodically review existing materials for applicability and accuracy, and are able to order or produce more as stocks run low. It is often practical to delegate responsibility for many of these tasks to office personnel. Office staff may also be quite eager to participate in a patient education committee that identifies priority areas and reviews printed and other materials before they are added to the practice's resources.

Key Points

- Listening is a key element for any successful interview.
- Building bridges of understanding helps to manage the various difficulties of the interview.
- Being sensitive to various forms of diversity, including disabilities, religious issues, and ethnicity, will enhance communication and participation by the patient.

The art of interviewing is a skill that is fully developed only through experience. Although various decision trees and protocols can be followed as the clinician seeks to confirm or rule out a preliminary hypothesis, the process of the interview often determines whether the therapeutic relationship is beneficial or deleterious to the outcome. Ritter and Wilson (2001) observed that listening is a key element in establishing the “three Rs” of interviewing: *rapport*, *respect*, and *relationship*. The quality of the relationship between the physician and patient is itself therapeutic, and the quality of this relationship will enhance or deter trust in the physician’s care and the patient’s adherence with the physician’s recommendations.

Asay and Lambert (2009) discuss Michael Lambert’s extensive, quantitative studies of contemporary psychotherapy, which validate that 30% of any therapeutic change is based on the quality of the relationship between the clinician and the client (LOE Grade A). This relationship is based on listening, mutual respect, empathy, and acceptance of the client.

Norfolk and associates (2007) note that the empathy necessary for rapport is based on trust and cooperation between physician and patient, and “rapport” is defined by

the quality of the “doctor’s understanding of the patient’s perspective on his or her problem.” Empathic skills “are *internal* diagnostic skills running parallel to those used to assess the patient’s clinical presentation, and they allow the doctor to first identify significant clues to the patient’s thoughts and feelings.” These clues for understanding the patient’s perspective may be verbal, nonverbal, or both (LOE Grade A).

In this regard, listening is a multisensory process. The physician listens to what is spoken, “listens” with the eyes for nonverbal behaviors, and “listens” with the fingers as examinations are completed. Rapport, respect, and relationship are enhanced by the physician taking the time to listen and understand the patient’s concerns. This listening is often framed by a time constraint of 10 to 20 minutes in the examination room with the patient. It is not the actual amount of time the physician spends with the patient but the *perceived* quality of time that is critical to the patient’s experience (Pollock and Grime, 2002). The physician conveys interest and concern for the patient by giving the *impression* of having time for the patient and being unhurried. Some patients feel disrespected by medical staffers who do not acknowledge the patient’s own time commitments or personal beliefs and feelings (Lacy et al., 2004).

All interviews have content and a process. The *content* is the subject matter of the interview, or what is discussed. The *process* is rapport, or how the interview flows as the content is discussed. It is the nonverbal, emotional quality of the interaction. Rapport is a key to being a successful healer, especially in the current medical environment of technologic sophistication and managed-care limitations (see Chapter 12).

The Listening Environment

An important element in the listening environment is the physician's sense of attention with the patient, and whether the patient feels the physician is listening to his or her concerns (Table 14-1). If the physician is running behind schedule, has had several difficult encounters during the day, or is tired from lack of rest, the patient will often pick up on various subtleties in the physician's behavior that communicate a "lack of presence" to the patient (i.e., countertransference). Some patients may feel the need to help a hurried physician and may withhold important information (Pollock and Grime, 2002).

Health care providers generally seek to collect as much information as possible while avoiding unnecessary information gathering that uses up valuable time. However, the interpersonal dialogue during the interview is vitally important, and the additional information often provides essential clues for more effective differential diagnosis and therefore more comprehensive treatment planning and case management.

The following LISTEN paradigm is only a suggestion, and health care clinicians should modify it for their own practice situation and environment. The purpose of the paradigm is to provide a structural mnemonic that moves the conversation logically and holistically throughout the interview. As determined by the clinician, any particular part of the interview may be expanded as the situation warrants, and any part may be minimized. By covering each part at least minimally, the clinician can achieve a general overview of the functioning and strengths of the patient or client, as follows:

L: *Listening is active and empathic*, as the clinician maintains a friendly countenance and good eye contact, while responding in a *respectful and affirming* way to the person. Active listening includes verbal and nonverbal listening. It means to *look and listen*, to listen with the *eyes and the ears*, assessing the person's behavior and facial responses. It includes an assessment of dress, grooming, and observable hygiene, such as apparent body and clothing cleanliness, as well as dental health.

I: *Interpersonal communication* refers to the quality of the *interaction* between the clinician and the person

throughout the interview. The clinician assesses the fluency and appropriateness of the person's speech and vocabulary. Does the conversation have a *natural flow and pacing*? Is it tense or strained? Does the person's hearing and understanding appear to be adequate for the conversation? Is the conversation characterized by a sense of *mutuality and care*, or is it more limited to just question and answer? The clinician inquires about the person's other interpersonal relationships, including *familial and social* (i.e., family and friends).

S: *Somatic, sensory, sense, and sensitivity* characteristics are highlighted. The clinician inquires about the person's *physical body and behavior* habits, *healthy and unhealthy*, such as exercise or substance abuse. What is the relevant medical history, including behavior? The interviewer assesses the person's *sensory experience* of the internal world, and his or her perception of the external world. Is the person in touch with internal and external *reality*? The clinician asks patients how they understand what is happening to them. How do they *make sense* of the experience of being interviewed or ill? What *meaning* does it have for them within their own personal history? The clinician is *sensitive* to the *contextual issues* such as family, gender, ethnicity, education, religion, and socioeconomic levels because they may influence the interviewing experience and the therapeutic process.

T: The clinician assesses the *thinking or cognitive abilities* of the person. Are reasoning and *problem solving* adequate for life decisions and for *daily living and self-care*? The clinician also assesses *intelligence* and evaluates whether there are deficits that may hinder adequate decision making.

E: *Emotion* is another area of focus. As the interview proceeds, the interviewer evaluates the *consistency and congruence* of the *affective and emotional* responses of the person during the conversation. How *expressive* is the person affectively? How well do the nonverbal behaviors match the emotional expressiveness in the person's voice throughout the conversation?

N: *Normal and now* are considered. The clinician assesses what the *normal resources and strengths* are for this person. How can these resources be used for collaboration in healing? The assessment is made in the *now*, in the *present*: How is this person *normal*? What *positive person strengths* do patients bring to the current situation for their potential *cooperation in the healing process*?

The Ritter LISTEN paradigm provides the clinician a moment-in-time assessment of this person, who is on a journey of growth and change. The conclusions are tentative because they do not indicate how the person will be in the future. Nevertheless, the LISTEN assessment provides information for holistic treatment planning and intervention (see Table 14-1).

The physical environment of the room should be welcoming and inviting, creating a sense of comfort to the patient. Sometimes, a nonmedical picture, such as a group picture of the staff or a family picture, can enhance the conversation.

In initiating the interview, the physician should sit down and strive to maintain good eye contact. By having comfortable chairs for the patient, the intention is conveyed that the physician desires for the patient to be comfortable during

Table 14-1 Ritter LISTEN Paradigm for Interviewing and Assessment

the visit. Taking notes on what the patient is saying is appropriate, but it should not interrupt the flow of the conversation or break a sense of continuity. By allowing patients to tell their story in the opening minutes of the interview, the physician gains a context for understanding how they view the problem being presented. Sometimes, the seemingly irrelevant information being presented by a patient becomes valuable contextual information for diagnosis, treatment, and compliance.

Maximizing the Time

When the physician invites the patient to move to the examination table, there is a cognitive shift for the patient that is explicit and implicit. Explicitly, it is a change of place that conveys that a shift is taking place in the process of the visit. Implicitly, it prepares the patient for the more physical aspects of the visit. It may even be appropriate for the physician to offer assistance to the patient during this transition.

As the physician examines the patient, each action is preceded by an explanation of what the patient can expect to happen next. These brief informative comments build respect and rapport because the patient is more at ease not having to guess what is going to happen. In this regard, each intervention is a request for informed consent. "I am now going to listen to your heart." The implied question is, "Is that all right?" Each statement carries this implied question, which is a way of being respectful and conveying the message that the patient is participating in the actual care being given and received. It is a collaborative and interactive conversation.

The Interview Process

As the physician talks with the patient, the natural flow of the conversation is itself a part of the diagnostic environment. How the patient interacts with the physician in the closeness and intimacy of the examination room is descriptive for how the patient relates with others outside the office context, whether at home or at work or at leisure and play.

During the interview, the physician's own feelings and intuitions can help the physician understand how the patient is dealing with the illness (Borrell-Carrió et al., 2004). Sometimes, in the scientific world of medicine, physicians may believe that keeping their own feelings out of the process is the best way to be objective and relevant. However, if the physician is mechanical and distant because of discomfort with personal sensitivity, the patient will quickly notice the distance.

Psychiatrist Harry Stack Sullivan (1954) observed that the work of the physician is to be a "participant-observer" in the process of the interview. The physician maintains a scientific observer perspective, while also being available and present to the patient as a fellow human in the journey of life. As the physician becomes more sensitive and aware of the interview process, there is the experience of "reciprocal emotion," the continuous reflecting of another's feelings. The openness of the interview is further enhanced by

the physician "mirroring" the body posture of the patient, such as crossing a leg, leaning forward, or leaning back (see Chapter 12).

Basic Communication

People often speak out of one particular language sensory system, and sometimes they express levels of understanding with a particular sensory language. In this regard, another form of mirroring is listening for which sensory system the patient is using and then joining that language system. Of particular importance are the visual, auditory, and kinesthetic language systems. For example, one person may say, "I see what you mean," and another may say, "I hear what you are saying," and another may say, "I am getting a *feeling* for what you mean."

When these sensory words are used, the physician can join that sensory system in the conversation: "Do you *see* what I am saying?" or "How do you *hear* what I am recommending?" or "How do you *feel* about my recommendations?" In each case, the physician is joining the patient's preferred way of expressing understanding.

The interviewing physician also learns to monitor personal feelings during the interview. Is there a hunch, an intuitive thought, or an uncomfortable feeling that is not logical, or even unrelated to the visit? It is important for the physician to pay attention to these internal messages so that important information is not missed. For example, a patient's seemingly harmless or even sarcastic remark about "most people in the medical field" may alert the physician to make an extra effort to build bridges of rapport, respect, and relationship with the patient, to increase the probability of compliance. A comment about car problems may mean follow-up appointments are at risk.

The conversational "give and take" during the interview provides the opportunity for the physician to learn about the context of the patient's life and relationships. More than just taking medical information, it is a *biopsychosocial* understanding of the patient (Brown, 2000; Engel, 1977, 1980). Coulehan and Block (2001) observe, "Good clinician communication *does* prevent malpractice suits. A patient who feels that the clinician listens to and understands him or her is not likely to sue that person, *even if there is a bad outcome*" [italics added].

Another element in the context of the relational environment is compassion, the "feeling with" the patient in the experience of illness and distress. As Raket (2000) states:

Good interpersonal skills enhanced by compassion enable the physician to dissect out the tangled mass of personal difficulties that so often form the core of functional disease or magnify the symptoms of an organic condition. We all know that a broken spirit underlies a great deal of the problems we encounter in practice.

The physician is the one who, by rapport, respect, and interpersonal relationship, humanizes for the patient the medical experience of laboratory and technology. The physician models for the patient a real person who is in a relationship with another real person.

The Participating Patient

Patients are more likely to accept recommendations from the physician if they feel they are a part of the process of treatment. Physicians often have different agendas than do patients for the clinic visit. The physician wants to find the problem, identify it, and bring hope and healing to the person. The patient wants to tell a story, to help better understand the illness, as well as find healing and recovery.

The patient can be encouraged to tell the story, even within the time constraints of the visit, with a statement such as, "We have about 15 minutes together today. How do you want to use this time? What do you want me to know?" In this way, the physician structures the time for the patient, and also gives the patient the freedom to express what he or she thinks is important. As the diagnosis and recommendations are made, the physician may ask the patient a question such as, "How do you want to participate in your treatment?" As Stone and colleagues (1998) observe, the physician is encouraging *adherence* rather than insisting on *compliance*: "Compliance implies an involuntary act of submission to authority, whereas adherence refers to a voluntary act of subscribing to a point of view."

Pearl

"Communicating your understanding of the patient's experience of the illness is one of the most therapeutic techniques we can use. The more I listen, the more my patients understand" (Platt and Gordon, 2004).

Pitfall

Be careful not to lose the human being in the discussion of the disease entity. Avoid identifying the patient by the disease rather than by a personal description, such as the woman, man, boy, or girl who *has* the disease; the people are not the disease.

Pearl

The person is not the problem. The problem is the problem.

Difficult Patient Situations

Difficulties sometime arise during patients' visits that are not anticipated. For example, a patient may be feeling so poorly that without realizing it, cooperation is difficult. It is the physician's task to make the patient feel at ease and as comfortable as possible. In other cases the staff may not have fully prepared the patient for the physician. It is the physician's demeanor that sustains the interview with a sense of ease as the difficulty is addressed or the omitted information attained.

Sometimes, the patient is difficult from the very beginning because of the illness, personality, or the process of moving through the office system. Already under the stress of not feeling well, the negative attitude of the difficult patient is

only exacerbated by the many small issues that may arise in the interview. Some patients are irritated about having to wait; having no clear diagnosis; or being denied their request for an antibiotic to treat a viral infection.

Psychiatrist Beryl Lawn (2004) says that the difficult patient is most often afraid; it is this deep fear that something is wrong that the patient cannot control. The personality of the difficult patient may lack the flexibility or resilience that is necessary for coping with other people and with day-to-day living. In the stress of the medical environment, difficult patients may become angry and try to take control of the process as a way of controlling their inner fears of inadequacy.

Sometimes, stepping back or to the side provides the upset patient with some personal space to regain composure. The physician then continues the interview, without trying to analyze or explain the difficult behavior. It is the work of reconnecting with the patient, of maintaining respect and working to establish rapport and relationship.

Another difficulty is the patient's ambivalence, such as hesitancy in making a medical decision or a lifestyle change decision. The physician may offer a respectful response such as, "I cannot decide for you. However, I do believe that it is an important decision, and I will respect whatever you decide." In this way, the physician assures the patient that medical treatment will be continued, regardless of how the ambivalence is managed. Some people are paralyzed by ambivalence, and they may remain at this point of indecision for some time. Some people do nothing until some externally imposed deadline, such as a job application drug screening, makes the decision for them (Ubel, 2002).

Whatever the difficulty, the physician maintains rapport, respect, and relationship with these difficult patients by listening for their concerns. By giving the impression of being unhurried and having time to listen, the physician maintains relationship and conveys to the patient that the physician-patient relationship will continue, undamaged by the present difficulty. In this way the relationship becomes a part of the healing process.

Barriers to Effective Communication

Time Demands

Time is one of the greatest challenges for the busy practitioner. Nothing disrupts effective communication more than patients' perception that the physician does not have time to address their problem.

Barriers

- Walk-in patients, who reduce physician time spent with prescheduled appointments.
- Insufficient length of time scheduled for complexity of the visit.
- Hidden agendas of the patient.
- Time for dictation and documentation.

Bridges

- Open-access scheduling. Predict urgent care needs, and create adequate same-day appointment times (Murray and Tantau, 2000).

- Improved triage on the phone. Have appointment staff ask patient if the scheduled amount of time will be sufficient to cover all the issues, or mark certain patients for an extended visit if they typically require extra time.
- Ask patients to bring a problem list with them, and ask them to show the list to the physician at the onset of the appointment. Items can be prioritized and time properly allotted for the visit. Schedule follow-up appointments for lower-priority items.
- Consider dictating or documenting while still in the room with the patient. This will lengthen the contact time with the patient and allow the patient to add any missing information to the record, as needed.

Interruptions

A continuous flow of information during the interview and examination is important for effective dialogue to occur. Interruptions in this process can distract the physician and inhibit open communication on the part of the patient.

Barriers

- Pagers going off
- Phone calls
- Knocks on the door

Bridges

- Consider having a triage nurse hold your pager while you are in the office. Pages can be answered promptly without interrupting the patient-physician communication. Urgent requests can be brought to your attention after the appointment has concluded, or the visit can be interrupted for emergencies. A bonus is that any additional information you may need, such as a chart or a laboratory report, can be brought to you at the time of the page information.
- Have a strict policy regarding phone interruptions. Most messages can be screened by staff, and if necessary, a brief message can be forwarded to you.
- Consider having several set times for answering messages. The staff can inform the caller of a time to avoid unnecessary callbacks.
- Knocks on the door disrupt the flow of the conversation, and they may alarm a patient if they occur during the more intimate parts of an examination. Limit door knocks to an absolute minimum.

Technology

New technologies, including electronic health records (EHRs) and handheld computers such as personal digital assistants (PDAs), have greatly improved data access. However, these same innovations may create barriers to meaningful interaction (Ventres et al., 2005).

Barriers

- Data (i.e., EHR) retrieval from a device requires loss of eye contact with the patient.
- Data entry into a device requires time and may be a distraction.

Bridges

- Always inform new patients what you are doing when viewing a computer screen. This assures the patient that you are actively retrieving information for the issues at hand.
- Try to maintain eye contact while viewing a paper chart or a computer device.
- Read back data, such as history, examination notes, and prescriptions, to the patient to summarize the visit and ensure accuracy.

Complementary and Alternative Medicine

The use of complementary and alternative medicine (CAM) therapies by patients has become commonplace. Discussions about the current or past use of CAM modalities is important for developing a clear understanding of the patient's beliefs and preferences and for avoiding potentially harmful interactions.

Barriers

- Negative or cynical attitude of the physician toward all CAM and toward patients who use CAM.
- Patient fears or indifference toward informing the physician about their use of CAM.
- Lack of a standardized history questionnaire that includes an inquiry about patient CAM practices.

Bridges

- Approach questions regarding CAM with an open and respectful tone, similar to taking a sexual history or inquiring about alcohol and tobacco use.
- Use a preprinted form or routinely ask patients to list all dietary supplements they take.

Religion and Spiritual Issues

There is currently more emphasis on being sensitive to the spiritual concerns of a patient (Levin et al., 1997; McCord et al., 2004). Some physicians believe that religion and spirituality discussions should be left to clergy and chaplains, who certainly should be included in patient care. However, Cumella (2002) suggests expanding Engel's biopsychosocial model to a biopsychosocial-spiritual model.

In the decade from 1994 to 2004, the percentage of U.S. medical schools offering curricula on spiritual history taking increased from 13% to 66% (Fortin and Barnett, 2004). In a 2004 survey, 43% of adults said they would welcome a discussion of spiritual matters with their physician during the taking of an initial medical history, and 77% said it is appropriate during a serious illness (McCord et al., 2004). However, only 10% report ever being asked by their physician about their faith and the possible impact their beliefs may have on their health care (Maugans and Wadland, 1991). Family physicians indicated that lack of time was the primary reason for omitting a spiritual history; 53% said a lack of training limited their ability to take a spiritual history, and 59% were concerned with projecting their own beliefs onto the patient (Ellis and Vinson, 1999).

However, taking a spiritual history can provide valuable information regarding a patient's perception of the disease and possible effects on treatment options and outcomes, as well as the availability of resources and social support for the patient. Some patients are not religious and have no interest in religion; some tend to become more religiously interested in times of crisis; and others are intensely religious. Some patients consider themselves to be spiritual, even though they do not identify with a particular religion or religious group.

Being religiously sensitive often includes being ethnically and culturally sensitive, and it is helpful for the physician to be comfortable with the level of religious concern that the patient may bring into the interview. For some patients and some physicians, all important decisions, including medical decisions, have some religious basis. When a physician is not sensitive to the patient's overall decision-making process, a patient who expresses appreciation at the end of the visit may then ignore all the physician's recommendations, because the patient feels the physician did not really understand what the illness means to the patient. In this regard, it is important for physicians to be aware of their own religious and spiritual heritage, whether it is absent, limited, or intense, because the values and beliefs and ethics of their religious heritage helped form their own decisions in patient care. Just as the patient's religion may influence medical decisions, so a physician's religious heritage may affect medical recommendations.

When taking a spiritual history, as with other elements of the review, it is often helpful to use open-ended questions that are nonjudgmental, such as the following:

Do you have a religious background?

Do you practice a particular faith?

Are you a spiritual person?

A "no" answer to these questions is probably a stop point for further questions. The physician may go on to another subject in the interview. However, if the answer is "yes," the physician may inquire about how the patient's religious heritage is a resource in a time of illness or may be relevant to medical decision making. If deemed appropriate, the physician may indicate her or his own religious heritage and then discuss how the patient and physician can relate to one another's religious backgrounds.

Some physicians may find the following brief interview assessment helpful (Pulchaski and Romer, 2000)—FICA:

Faith: Do you consider yourself to be a spiritual or religious person?

Importance: How important is your faith to you?

Community: Are you a part of a spiritual or religious community?

Address: How would you like me to address these issues in your health care?

Because religious faith and spirituality are an important part of some patients' lives and experiences, an awareness of this information further enhances the establishment of rapport, respect, and relationship, and it clarifies the physician's commitment to holistic treatment of the patient. It is what Odell (2003) calls "including versus imposing" the clinician's religious or spiritual views in the interviewing process.

Pearl

Any discussion of religion and spirituality should always seek to focus on the patient's beliefs, not on the physician's beliefs.

Cultural Competency

Cultural issues include disabilities and ethnicity. For example, there is a clear cultural divide in the deaf community between those who use sign language ("signers") and those who are referred to, often derisively, as "audists," or lip readers. The signers sometimes believe the audists have betrayed their disability by trying to "act as if it is not real." A signer is obviously deaf, but a lip reader is not. In addition to deaf patients, the following guidelines apply to patients with other physical and mental disabilities:

1. Be sensitive to patients with mental and physical disabilities.
2. Treat an adult as an adult. Do not patronize the patient.
3. Remember that a disability does not define intelligence.

One of the problems in being sensitive to cultural diversity is stereotyping similarities. Language, dress, or skin color may or may not be evidence of a particular ethnicity. Two people with the same skin color or the same language may be of totally different cultures. An American black, whose family has been in the United States for 200 years, has more in common with an American white than with a recent black immigrant from east Africa. A Hispanic person from Central America has an entirely different cultural experience than a Puerto Rican from New York City. A South Korean is very different from a Hmong from Laos, and a Japanese person and a Chinese person are not from the same culture or language.

The following recommendations address ethnicity in the primary care practice:

1. Provide pictures and magazines in the waiting room that reflect the cultural diversity of your patient population.
2. Provide written materials, such as home instructions and medication instructions, in the language of your patient population.
3. In all forms of diversity, avoid stereotyping similarities.
4. Pay attention to the languages that patients speak. If they speak only limited English, do not assume they understand what you are recommending medically. Ask questions. What is your country of origin? How long has your family been in the United States? What is your primary language?
5. Different cultures have different religious and cultural understandings of illness. How do you understand what the problem is that you are having?
6. Some cultural groups include other family members or healers in decision making. Being open and respectful, the patient is more likely to accept what the physician says. Ask questions to determine the situation. Are there others who will be included in the decision making for your medical care?
7. Be sensitive to the patient's language and to the patient's level of literacy when giving written instructions.
8. Thank the patient for coming and helping you understand their concerns.

Pearl

Avoid stereotypes and the myth of similarity.

Assessing for Unhealthy Alcohol Use

When physicians suspect that a patient has a problem with unhealthy alcohol use, they can ask a validated, single-question screening test (Smith et al., 2009): How many times in the past year have you had x or more drinks in 1 day? (for men, $x = 5$; for women, $x = 4$). Any response other than zero (0) is considered positive for unhealthy alcohol use. The question is 81.8% sensitive and 79.3% specific for disclosing unhealthy alcohol use. The single-question screen is recommended by the National Institute on Alcohol Abuse and Alcoholism (NIAAA) (LOE Grade A).

Interviewing Specific Groups

Because family medicine is a specialty of breadth as well as depth, the clinical interview can be challenging. Communicating effectively with patients and family members who have various communication abilities and various agendas is a challenging task that is never fully mastered. However, experience achieved through years of clinical practice does result in learned techniques that can help the clinical interview flow smoothly and create a pleasant experience for the patient and physician. The development of a healthy patient-physician relationship is itself therapeutic and is enhanced by the conduct of a productive clinical encounter. Successful approaches of practicing clinicians for communicating with typical patient types are listed in the Pearls.

General Interview Perspective: Be Careful

Be cautious when accepting the flattery of patients who are critical of the care they received from other physicians; these patients may have a long history of failed patient-physician relationships caused by unreasonable expectations.

Avoid being “inserted” into the middle of a family conflict by well-meaning family members. It is generally not helpful to agree to keep a secret (“Don’t tell them I told you this, but...”). It is better to agree to discuss the subject and to insist on honesty with the patient (“Your daughter has shared with me that she is concerned about your drinking [or ability to live alone or angry outbursts]”). Playing along with the secret is usually unfair to patients and not in their best interest. Instead, it is often a perpetuation of the family’s enabling behavior that has led to the perpetuation of the patient’s problem, and at the least, it makes further communication with the patient and the formulation of plans difficult and uncomfortable.

Even though it may be tempting to appear an expert to the patient, a wise general policy is to avoid criticism of other health providers, whether verbally to the patient or in the medical record. When commenting on contentious issues and complex situations, appraisal from multiple perspectives is critical for understanding, and information should always be complete and in context. However, this broader perspective is almost never available at the patient interview.

Criticism of office staff behavior in the presence of the patient is inappropriate and may be damaging to the patient-physician relationship. Share constructive criticism only with staff members and only in private.

Age Considerations for the Interview

In the following age categories, various techniques are suggested for establishing and maintaining rapport, respect, and relationship between the physician and the patient. However, techniques are not magic bullets. They are baseline suggestions, tools for a lifetime of learning about the concerns and the medical needs of the people who come to the physician for care.

Infants and Babies

1. Babies’ future behavior during physician appointments is in part determined by the cumulative experience of each office visit. Try to avoid unpleasant portions of examination when clinically acceptable.
2. Enter the examination room quietly, and keep movements slow and to a minimum.
3. Listen carefully to the caregiver. Parents tend to know when there is something wrong with their child. Pay attention to their concerns.
4. Babies are experts at body language; this is their primary form of communication.
5. Avoid invading the infant’s space initially.
6. Smile at mom or dad and speak softly.
7. Sit down and try to get your face to the level of the baby’s face while still maintaining appropriate distance.
8. Smile at the baby, and make eye contact.
9. Notice baby’s body language. If appropriate, tickle or play with the baby.
10. Perform as much of the examination as possible with the baby in the caregiver’s arms before moving to the examination table.
11. Minimize the need to restrain the baby during the examination; this should be the last resort.
12. Many smiles to the baby will help decrease fear and resistant behavior.

Toddlers and Children

1. If the child is playing with a toy or reading a book, pretend to be interested in the item. Do not take the item away from the child unless it is offered to you; promptly return it.
2. As you visit with the caregiver about the reason for the visit, observe the child for the current level of activity (e.g., sleepy, fussy, irritable, lethargic) and for developmental milestones. However, keep your attention on the caregiver while gathering history. Do not be distracted by a rambunctious child. If your eyes wander to the child, the parent may lose track of what he or she is thinking. The parent will focus attention on the child’s behavior and may interpret your gaze as disapproval of the child’s behavior. This subtle glance at the child is not a good way to maintain a positive relationship with the parent.
3. Ask the parent to hold the child in the lap to begin the examination; perform less invasive portions of examination

first to begin to build the child's trust, such as listening to the heart with the stethoscope, before touching the child with your hands.

4. If the child is very anxious about the examination, pretend to examine their stuffed animal, or examine their parent to demonstrate what you are doing, and then examine the child in the same fashion, such as looking in his ears.
5. Male clinicians particularly need to use a soft voice. Higher pitches tend to be less frightening. Play with the child during the examination; look for bunnies in the ears, or listen for breakfast in the tummy.
6. Save the most unpleasant portions of examination for last, such as a throat examination with a tongue depressor.
7. Offer the child a "peace offering" at the end of the visit, such as a sticker or other age-appropriate item.
8. End interview with positive gestures toward the child: wave bye-bye, "give me five," or other exit gestures.

Adolescents

When older adolescents are accompanied by parents, consider using the first few minutes of the interview to allow the parents the opportunity to verbalize their thoughts and concerns about the child. Then, politely, invite the parents to step outside the examination room while you complete the interview. You may want to bring the parents back into the room at the conclusion of the examination for any final discussions, while carefully keeping confidentiality issues in mind.

1. Greet the adolescent patient with a smile, good eye contact, and a firm handshake.
2. Depending on age and social skills, many adolescents are withdrawn and quiet. Frequently, if this behavior is ignored, and continued attempts are made to draw the patient into conversation, the behavior will improve.
3. For many adolescent interviews, the HEADSSS technique is a helpful way to structure the interview in a thorough and time-conserving manner (Lukefahr, 2005):
 - Home:* How is home life? Are both parents in the home? Siblings? Who else lives there? What is the atmosphere (e.g., friendly, supportive, conflicted, angry, critical)?
 - Education or employment:* How is school? Grades? Good student? Favorite and most difficult subjects? How get along with fellow students and teachers? Employment? After school? Odd jobs? Babysitting?
 - Activities:* School? Sports? Clubs? Community? Religious? Other?
 - Drugs:* Use any illegal substances? Legal? Tobacco? Alcohol? How often? Any use by family members in the home?
 - Sexual status:* Are you active sexually? Have you ever had any kind of sexual contact with another person, even once? Protection? Any worries about sexually transmitted diseases or pregnancy?
 - Suicide:* Have you ever considered hurting yourself or killing yourself? Ending your life? Any attempts? Previous family history of suicide? Hurting or killing someone else?
 - Safety:* Any violence or abuse in the home? Neighborhood?
4. Conclude the interview with the same good eye contact, a smile, and a firm handshake. Thank the patient for the conversation.

Pearl

The words and body language of the physician and staff should always reflect genuine concern and respect for the adolescent patient, regardless of the adolescent's appearance or behavior in the office.

Adult Patients

1. Briefly review the established patient's record before entering the room; it is important that the patient know you are at least somewhat familiar with his or her history.
2. Knock on the closed door of the examination room before opening; this demonstrates to the patient a respect for privacy, as well as your courtesy and concern.
3. Smile and maintain eye contact as you warmly shake the patient's hand and pleasantly greet him or her. Then, greet the others in the examination room in a similar fashion. Greeting the children demonstrates a family-centered approach to care.
4. Visit for a short time by exchanging pleasantries. Ask about the family, hobbies, and other activities.
5. Ask the patient, "How can I help you today?" or "What brings you here today?"
6. Allow the patient to speak freely for at least 2 minutes without interruption. (This is longer than it seems.)
7. Maintain eye contact, smile, and mirror the body position of the patient to communicate attentiveness and congruence.
8. Before concluding the interview and the examination, ask the patient if there is anything else he or she wants to discuss.
9. Conclude the interview with the same good eye contact, a smile, and a firm handshake.

Elderly Patients

1. Greet the patient with good eye contact, a smile, and a comfortable handshake.
2. Be aware that the elderly patient may be struggling in various degrees with issues regarding decreasing physical abilities, changing body image, cognition or mental function, loss of social friends and family to illness or death, and a deeper level of spirituality, especially regarding end of life.
3. Address patients using the surname and Mr., Mrs., or Ms.; do not call them by their first name unless they have previously made it clear that this is their preference. When in doubt, assume a more formal approach.
4. Visit for a short time by exchanging pleasantries. Ask about the patient's family, hobbies, and other activities.
5. Ask the patient, "How can I help you today?" or "What brings you here today?"
6. Allow the patient to speak freely for at least 2 minutes without interruption (this is longer than it seems).
7. Be aware of any visual or auditory acuity problems; adjust speech rate and tone accordingly.

8. If the topic is appropriate and time permits, consider discussing the patient's feelings regarding end-of-life issues. Offer help in developing a living will, and encourage patients to discuss their feelings with the closest family members.
 9. Offer an elderly patient your hand as he or she moves to the examination table. Good practice is to have one hand on the patient's arm or hand and the other on the back. This is a caring gesture as the patient steps up and sits on the examination table, and it helps with positioning and balance.
 10. Conclude the interview with the same good eye contact, a smile, and a comfortable handshake.
5. Ask family members or friends accompanying the patient for their perspectives.
 6. Be patient during the interview; upset human behavior changes slowly.
 7. Attempt to close the encounter with some type of agreed-on contract and plans for the next scheduled visit.

Specific Concerns

Demented Elderly Patients

1. Despite dementia, eye contact, a smile, and a comfortable handshake are still appropriate ways to greet the patient.
2. Next, greet the patient's caregiver-spouse, adult child, or nursing home staff member as you would a patient, and thank the person for being present.
3. If possible, arrange the examination room so the patient is nearest to you and the caregiver is seated farther away and out of the patient's peripheral visual field; this allows the caregiver to communicate by body language without the patient's awareness; the responses are necessary to determine the accuracy of the patient's responses to your questions.
4. If possible, address the patient rather than the caregiver, and ask the patient's permission before you begin talking with the caregiver about the patient. "Do you mind if I ask your daughter a few questions about how you're doing?"
5. Speak slowly and clearly and in short sentences.
6. Always remember to review the patient's current medications and to record each one accurately in the chart.
7. If patient is wheelchair bound, avoid moving the patient to the examination table; most examinations can be performed adequately without this difficult and time-consuming effort.
8. At the conclusion of the visit, remember to *ask the patient first* and then the caregiver if they have any questions.
9. Conclude the interview with the same good eye contact, a smile, and a comfortable handshake, *first with the patient* and then with the caregiver.

The Difficult Patient

1. Allow the difficult patient to vent his or her feelings.
2. Listen patiently and allow the patient to tell his or her story.
3. Avoid a judgmental attitude. View the patient's disruptive behaviors as an *opportunity* to learn more about his or her needs and concerns.
4. Maintain a calm and confident demeanor; control the expression of emotion to what is appropriate for a medical professional.

The Somatizing Patient

1. Patients who somatize experience emotional distress or difficult life situations as physical symptoms.
2. Up to 60% of somatizing patients have coexisting depression, and some studies have suggested an association between somatization disorder and a history of sexual or physical abuse (Kroenke et al., 1994).
3. Part of the pathophysiology of somatization is *the need to be sick*.
4. Realize that the patient is truly suffering, and acknowledge this through a concerned attitude.
5. The BATHE technique (background, affect, trouble, handling, empathy) is a helpful way to structure the clinical interview (Stuart and Lieberman, 2002).
6. Frequent, regularly scheduled visits allow patients to feel they are being followed closely and decrease the need for emergency department visits.
7. Patients' frequent requests for laboratory and x-ray studies are best addressed with compromise and assurance that the regular visits can ensure that any serious problem will be found early.
8. Patients' frequent telephone calls can be handled by discussing limits on the number and length of calls and by offering to increase (temporarily) the frequency of the office visits.

Giving Bad News

1. Breaking "bad news" is an unpleasant task that must be approached with the patient's best interest in mind.
2. Patients generally desire frank and empathetic disclosure of a terminal diagnosis or other bad news.
3. The ABCDE technique is used for sharing bad news (Rabow and McPhee, 1999):
Advanced preparation. Be familiar with relevant clinical information, and be prepared to discuss basics of treatment and prognosis.
Build a therapeutic environment and relationship. Have family support present; meet everyone. Warn that bad news is coming, and use appropriate touch.
Communicate well. Learn what is already known. Share additional information frankly, using common language and compassion; allow for silence and tears. Ask the patient to restate what has been said. Allow time for questions.
Deal with reactions. Assess and respond to emotional reactions. Be aware of body language. Be empathetic and supportive, and avoid criticizing other health professionals.
Encourage and validate. Explore what the news means to the patient. Offer realistic hope. Inquire about patient's emotional and spiritual needs, and offer resources for assistance as indicated.

Conclusion

The art of interviewing is a skill that is learned, developed, and enhanced through clinical practice. It is an ongoing process that will change as the physician engages people of different ages from a variety of circumstances and with a variety

of health concerns. Through each interview, listening is a key element for establishing and maintaining rapport, respect, and relationship with the patient. More than just a collection of techniques, listening is the ability to be fully present in the moment of the interview with the person who has come for help and care. It is the art of interviewing and building bridges of continuity to a long-term relationship of trust and care.

The use of the clinical laboratory to evaluate patients for the presence or absence of disease transcends medical and surgical specialties. Physicians in all areas of medical practice are dependent on laboratory testing to arrive at a correct diagnosis. Because many factors increase the uncertainty associated with a test result, physicians need to understand the limitations of interpreting test results.

Clinical decision making using diagnostic laboratory testing is based on the assumption that a given test is accurate and precise. Diagnostic test *accuracy* is the ability of a test to distinguish patients with a disease from those who are disease free (Leefflang et al., 2008). Test accuracy is not necessarily fixed; accuracy may vary among patient populations and with different clinical conditions. *Precision* is a measure of the reproducibility of a test measurement when the same specimen is rechecked under the same circumstances. Sources of imprecision include biologic variability and analytic variability. *Biologic variability* is the variation in a test result in the same person at different times because of physiologic processes, constitutional factors, and extrinsic factors (McClatchey, 2002) (Table 15-1). *Analytic variation* refers to the variation in repeated tests on the same specimen and relates to analytic technique and

specimen processing. With current technology, biologic variation plays a larger role than analytic variation in most laboratory tests.

The Concept of “Normal”

The result of a laboratory test is compared with a reference standard, which traditionally has indicated values that are seen in healthy persons. Using the terms “normal results” or “normal range” implies that there is a clear distinction between healthy and diseased persons, when in reality there is considerable overlap.

The current standard of comparison for laboratory results is the *reference range*, which is frequently defined by results that are between chosen percentiles (typically the 2.5th to 97.5th percentiles) in a healthy reference population. Several problems are encountered when deriving a reference range. Often, the reference population is not representative of persons being tested. Differences in gender, age distribution, race, ethnicity, or the setting (hospitalized vs. ambulatory patients) between the reference population and the person receiving the test may be present. The person being tested

should be tested under similar physiologic conditions (e.g., fasting, sitting, resting) as the reference population. The size of the reference population may be too small to include a representative range of the population.

Two statistical methods, parametric and nonparametric, are generally used to define the reference intervals. The *parametric* method applies when the results of the sample population fits a normal gaussian distribution, with a bell-shaped curve around the mean. In this case, the 2.5th and 97.5th percentiles can be calculated using statistical formulas. When the reference values do not follow a normal distribution, *nonparametric* methods are used, arranging the results from the reference subjects in ascending order, and identifying values between the 2.5th and 97.5th percentiles as within the reference range.

Reference ranges for a particular test can be the manufacturer's suggested reference range or may be modified because of differences in the population using the laboratory. The Clinical Laboratory Improvement Act of 1998 (CLIA) has defined three requirements for reference values: the normal or reference ranges must be made available to the ordering physician; the normal or reference ranges must be included in the laboratory procedure manual; and the laboratory must establish specifications for performance characteristics, including the reference range, for each test before reporting patient results. Using the manufacturer's reference range is valid when the analytic processing of the test is the same as that done by the manufacturer and when the population being tested is similar to the reference population used to define the reference range. When selecting a reference range that includes 95%

Table 15-2 Probability that a Healthy Person Will Have an Abnormal Result with Multiple Tests

| Number of Independent Tests | Probability of Abnormal Result (%) |
|--|------------------------------------|
| 1 | 5 |

of the test results, 5% of the population will fall outside the reference range for a single test. When more than one test is ordered, the probability increases that at least one result will be outside the reference range. Table 15-2 compares the number of independent tests ordered with the probability of an abnormal result being present in healthy persons.

Evaluating a Test's Performance Characteristics

Given that tests are not totally accurate or precise, one must have a way to quantify these shortcomings. A test's ability to discriminate diseased from nondiseased persons is defined by its sensitivity, specificity, and positive and negative predictive values. Table 15-3 shows how each is calculated. Sensitivity and specificity are inherent technical aspects of a test and are independent of the prevalence of disease in the population tested. However, given that diseases have a spectrum of manifestations, sensitivity and specificity are improved if the population is heavily weighted with patients who have advanced (vs. early) illness.

Sensitivity is defined as the percentage of persons with the disease who are correctly identified by the test. *Specificity* is the percentage of persons who are disease-free and correctly excluded by the test. The *positive predictive value* is defined as the percentage of persons with a positive test who actually have the disease, whereas the *negative predictive value* is the percentage of persons with a negative test who do not have the disease. Predictive value is influenced by the sensitivity and specificity of the test and the *prevalence* (the percentage of people in a population who at a given time have the disease).

Separating Diseased from Disease-Free Persons

Under ideal circumstances, sensitivity and specificity approach 100%. In reality, they are lower. The best currently available test to decide who is diseased or disease-free could

be imperfect and have sensitivities and specificities in the 80% range. Moreover, discrepancies between a test's efficacy and its effectiveness are common. *Efficacy* is a test's performance under ideal conditions, whereas *effectiveness* is its performance under usual circumstances. Tests under development are evaluated under highly rigorous criteria, but in clinical practice, inadvertent error can be introduced into the technical performance or interpretation of the test results. Also, test values for the diseased and disease-free populations overlap.

A cutoff value may be chosen to separate "normal" from abnormal (Figure 15-1). This decision is arbitrary and involves selecting a balance between sensitivity and specificity. The receiver operating characteristic (ROC) curve is a graphic analysis used to identify a cutoff that minimizes false-positive and false-negative results (Figure 15-2). The sensitivity and specificity are calculated for a number of cutoff values, with the variables $1 - \text{Specificity}$ plotted on the x axis and Sensitivity plotted on the y axis. Each point on the curve represents a cutoff for the test. A perfect test would have a cutoff that allowed both 100% sensitivity and 100% specificity. This would be a point at the upper-left corner of the graph. The most efficient cutoff for a single test is the one that gives the most correct results, represented by the value that plots nearest to the upper-left corner of the graph.

Table 15-3 Diagnostic Test Performance Characteristics

| Finding | Disease Present | Disease Absent |
|---------------|---------------------|---------------------|
| Test positive | True positive (TP) | False positive (FP) |
| Test negative | False negative (FN) | True negative (TN) |

Sensitivity = $TP / (TP + FN)$; Specificity = $TN / (TN + FP)$.
Positive predictive value = $TP / (TP + FP)$; Negative predictive value = $TN / (TN + FN)$.

The optimal cutoff depends on the purpose of the test and essentially is a risk/benefit analysis. In situations where disease detection is most important, the cutoff may be chosen that maximizes sensitivity at the expense of decreasing specificity. If disease exclusion is the goal, sensitivity and negative predictive value need to be maximized. It is important that negative results be *true* negatives as opposed to false negatives, so that a negative test has correctly excluded the individual as having disease. Similarly, if disease confirmation is the goal, specificity and positive predictive value are critical. It is important that positive results are *true* positives and not false positives, so that healthy persons are not misidentified, especially when treatments (e.g., surgery) have serious risks.

The predictive value of a test is directly related to the pretest probability of disease. When the prevalence of disease is high in the population, a positive test result is expected and a negative result is not expected, because the disease is common. Similarly, when the prevalence is low, a negative test result is anticipated because few people have the disease. These characteristics of predictive value become clinically useful when one compares the outcome of a positive or negative test result with the pretest probability of disease (Figure 15-3). Prevalence (pretest probability of disease) is plotted against predictive value for a positive and negative test. Note that a test result loses its ability to discriminate those who have disease from those who do not at the extremes of prevalence. If disease probability is low, a positive or negative result does not change the post-test probability much—it is still low. On the other hand, if disease probability is high, the post-test results, whether positive or negative, do not substantially alter an already high probability of disease being present. The predictive value has the greatest power to discriminate those with disease from those who are disease free in the mid-pretest probability range, near 50%. A positive test result suggests a higher post-test probability of disease than a negative result.

Figure 15-1 Effect of changing a test's cutoff value on disease classification.

(Modified from Cebul RD, Beck LH. *Teaching Clinical Decision Making*. Westport, Conn, Praeger, 1985, p 4.)

Figure 15-2 Receiver operating characteristic (ROC) curve showing the effect of changing the cutoff values for separating disease from no disease. (From Tetrault GA. *Laboratory statistics*. In Henry JB (ed). *Clinical Diagnosis and Management by Laboratory Methods*, 20th ed. Philadelphia, Saunders, 2001.)

Multiple Test Ordering

For many diseases, more than one test is available for diagnostic or screening purposes. The dilemma then becomes whether a positive result on several tests must be present before the diagnosis is confirmed, or whether a single positive test is sufficient to label the person as diseased. The various possibilities will have an impact on sensitivity and specificity if the tests are viewed separately. Consider the example in which two tests are available for the diagnosis of a disease. Three combinations can lead to an affirmative diagnosis:

1. If one of the two tests is positive, the diagnosis is made.
2. A positive result for both tests is required before the diagnosis is confirmed.
3. The second test is performed only if the first is positive, and the person is labeled as diseased only if the second is also positive.

The first combination will increase sensitivity and decrease specificity in comparison with each test alone, and the second combination will decrease sensitivity and increase specificity. These effects on sensitivity and specificity for multiple test ordering are similar to shifting the cutoff point for a single test.

The value of performing a second test only when the first is positive generally comes into play when the first test is significantly less expensive and easier to administer than the second but is less specific, although highly sensitive. The second test is highly sensitive and specific but more costly to perform on large populations, especially for screening purposes. An example is the enzyme-linked immunosorbent assay (ELISA) and Western blot test for human immunodeficiency virus (HIV) testing. The ELISA has a high sensitivity and is relatively inexpensive and easy to perform, but it is less specific. The Western blot test has high sensitivity and specificity, but it is more expensive and more difficult to perform. Using the ELISA first identifies almost everyone with the disease, whereas the Western blot excludes the fraction of persons incorrectly labeled as

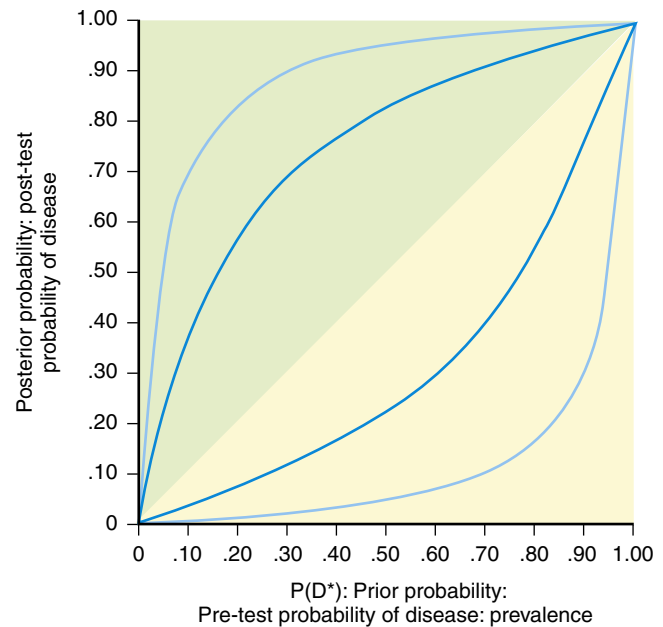

Figure 15-3 The relationship between pretest and post-test probability of disease based on a positive or negative test result. (From Sackett DL, Haynes RB, Guynett GH, et al. *Clinical Epidemiology*, 2nd ed. Boston, Little, Brown, 1991, p 92.)

having disease (false positives) by the ELISA test. This testing sequence has improved sensitivity and specificity over each test alone and is more cost-effective than initially performing both tests.

Considerations for Ordering Tests

In addition to diagnostic accuracy, the other important consideration in test ordering is the ultimate effect on the patient. What actions will be taken, based on the test results? What are the expected benefits or harms that might occur, based on a positive or a negative result? Will ordering a particular test be more likely to help than harm the patient? Unfortunately, at present, randomized controlled trials (RCTs) that examine the outcomes of test-and-treatment strategies are not available for most clinical situations. Thoughtful systematic reviews of diagnostic test accuracy, linked with clinical evidence examining treatment options, may be the best available evidence to help guide decisions on diagnostic testing (Cornell et al., 2008).

The following section presents an overview of 40 commonly ordered tests. Each section discusses the physiologic significance of the test, a typical range of reference values, and a listing of some common disease states that might explain an abnormal result. The reference ranges for each

test are intended as guides and may differ from the reference ranges used by different laboratories, depending on the reference population and the test methodology.

Albumin

Albumin is a transport protein that is produced mainly in the liver and maintains osmotic pressure. Albumin has a long half-life (20 days) and a small (~5%) daily turnover. In humans, albumin levels rise from birth up to age 1 year, thereafter remaining stable at approximately 3.5 to 5.5 grams per deciliter (g/dL) throughout adult life. Albumin levels are reduced with advancing liver disease, nephrotic syndrome, protein-losing enteropathy, malnutrition, and some inflammatory diseases (Table 15-4). Elevations of serum albumin are unusual except in dehydration.

In severe acute infection, reduced albumin production combined with increased catabolism causes a reduction in serum albumin levels beginning in 12 to 36 hours and reaching a maximum nadir in about 5 days. As a marker for malnutrition, however, albumin levels decline relatively late. Albumin levels are most helpful in the evaluation of edema, liver disease, and proteinuria.

The difference between the serum albumin level and the albumin in ascites fluid, the serum-ascites albumin gradient (SAAG), can help differentiate portal hypertension from other causes of ascites. SAAG greater than 1.1 g/dL is seen with portal hypertension; SAAG less than 1.1 g/dL suggests

another cause of the ascites, such as peritoneal inflammation or malignancy.

Most of the albumin filtered through the kidneys is reabsorbed, so significant urinary albumin is a sign of abnormal renal function. Large amounts (>300 mg/dL) of albumin can be detected on standard urine dipsticks. *Microalbuminuria* is defined as a persistent increase of urinary albumin that is below the detectable range of the standard dipstick test. Microalbuminuria is a marker for early diabetic nephropathy and also predicts macrovascular disease. Urinary albumin can be assayed from a spot urine specimen, which is corrected by the urine creatinine, or a 24-hour urine collection. A 24-hour urinary albumin excretion in mg/day equates to the same numeric value for the spot urine albumin (mg)/creatinine (g) ratio. Therefore the reference ranges for each test are normal <30, microalbuminuria 30-300, and clinical albuminuria >300. Factors that may interfere with the test accuracy include strenuous or prolonged exercise, upright posture, hematuria, menses, genital or urinary infections, congestive heart failure, uncontrolled hypertension or uncontrolled hyperglycemia, and high protein or high salt intake.

Alkaline Phosphatase

Alkaline phosphatase (ALP) is found in a wide variety of tissues, including the liver, bone, intestine, and placenta. The reference value for ALP depends on age and gender, with higher levels in childhood, adolescence, and pregnancy. A typical reference range in an adult is 25 to 100 U/L. In adults, the source of an elevated ALP is the liver, bone, or medication (Table 15-5). Typically, hepatic elevations of ALP are suggestive of cholestatic liver disease or biliary tract dysfunction. Mild ALP elevations (one to two times above reference range) can occur with parenchymal liver disease, such as hepatitis or cirrhosis. Marked ALP elevations occur with infiltrative liver disease or biliary obstruction, intrahepatic or extrahepatic. A persistently elevated ALP level can be an early sign of primary biliary cirrhosis. In cholestatic liver disease, bilirubin and *gamma-glutamyltransferase* (GGT) levels are increased as well, with less prominent elevations in aminotransferase levels. To confirm a hepatic source of an elevated ALP level, one can simultaneously measure GGT, which is elevated in obstructive liver disease but not with bone disease. Imaging studies of the liver, by sonography or computed tomography (CT), can define an anatomic basis for obstruction in the setting of an elevated ALP level of hepatic origin.

Aminotransferases

Liver chemistry tests are widely used to assess hepatic function. Common markers of hepatocellular damage are the aminotransferases, *aspartate aminotransferase* (AST) and *alanine aminotransferase* (ALT). While AST is also found in other tissues, such as the heart, blood, and skeletal muscle, ALT is more specific for liver. The aminotransferases are released by hepatocytes with cell injury or death. The reference range is approximately 10 to 40 U/L for AST and 15 to 40 U/L for ALT. The magnitude of the elevation of aminotransferases and the ratio of AST to ALT can help suggest the cause of liver disease. Mild elevation (<5 times the upper limit of normal) of the ALT or AST, with ALT > AST, is frequently found with chronic liver disease, including chronic viral hepatitis, fatty

Table 15-5 Causes of Increased Alkaline Phosphatase Levels

| Bone Origin |
|----------------------------------|

| Temporal arteritis |

liver, and medications. Probably the most common cause of persistently elevated unexplained aminotransferases is fatty infiltration of the liver. Less common causes of mildly elevated aminotransferases with ALT > AST include autoimmune hepatitis, hemochromatosis, alpha-1 antitrypsin disease, Wilson's disease, metastatic disease, and cholestatic liver disease. Mild aminotransferase elevations with AST > ALT are more suggestive of alcohol-related liver disease, but can also occur with cirrhosis and fatty liver. With alcoholic hepatitis, AST levels typically are approximately twice ALT levels, but the AST levels rarely are greater than 300 U/L. Marked elevations (greater than 15 times upper limit of normal) of AST and ALT suggest significant necrosis, such as seen in acute viral or drug-induced hepatitis, in ischemic hepatitis, or as can occur with acute biliary obstruction (Green and Flamm, 2002). However, the magnitude of elevation of the aminotransferases does not necessarily correlate with the severity

Table 15-6 Pattern of Liver Function Elevation

| Test | Hepatocellular Disorders | Obstructive Disorders |
|-------------------------------|--------------------------|-----------------------|
| Bilirubin | + | ++ |
| Aminotransferases | +++ | + |
| Alkaline phosphatase | + | ++ |
| γ -Glutamyltransferase | + | ++ |
| Albumin | Decreased | Normal |

of underlying liver disease or the prognosis. In fact, normal or minimally elevated aminotransferases may be seen in patients with end-stage liver disease. When AST is elevated without elevation of ALT, one should consider extrahepatic causes, particularly myocardial or skeletal muscle sources. When AST and ALT are elevated approximately the same, a hepatic origin is most likely. Table 15-6 compares the differences in liver function tests between hepatocellular and obstructive disorders.

Lactate dehydrogenase (LDH) is elevated in liver disease but is nonspecific; it is also found in skeletal muscle, cardiac muscle, blood, and some pulmonary disorders. Measurement of LDH rarely adds useful information to the evaluation of liver disease. GGT is a microsomal enzyme that is inducible by alcohol and certain drugs, including warfarin and some anticonvulsants. Although not specific for alcohol abuse, GGT is the most sensitive liver enzyme for alcohol abuse.

Amylase and Lipase

Pancreatic disease, particularly *acute pancreatitis*, is often associated with elevations in amylase and lipase. Table 15-7 lists common causes of elevated amylase and lipase. Lipase levels have greater sensitivity and specificity for pancreatic disease than amylase levels. Because there are many different assays for amylase and lipase, with different reference ranges, physicians should consult their laboratory's reference range to determine their upper limits of normal. Amylase and lipase values increase 3 to 6 hours after the onset of acute pancreatitis, both peaking at approximately 24 hours. Amylase levels fall to normal in 3 to 5 days; lipase levels return to normal in 8 to 14 days. Because of exocrine insufficiency caused by recurrent pancreatitis, amylase levels tend to be lower when alcohol is the cause of pancreatitis, as opposed to gallstone or drug-induced pancreatitis. Pancreatitis is likely when the amylase is elevated to three times the upper limit of normal. When lipase levels are more than five times normal, pancreatitis is virtually always present. A normal amylase value, however, does not exclude pancreatitis, especially when induced by hypertriglyceridemia.

Antinuclear Antibodies

Antinuclear antibodies (ANAs) are autoantibodies against parts of the cell's nucleus. Combined with clinical features, ANA testing can help diagnose certain collagen vascular

Table 15-7 Causes of Elevated Amylase and Lipase Levels

disorders (Table 15-8). The likelihood that an ANA test will help with diagnosis depends on the pretest probability of disease. ANA tests are reported as negative (no staining) or positive at the highest cutoff of dilution of the serum that shows immunofluorescent nuclear staining. If positive, the description of the pattern is noted. When the ANA test is positive, testing for specific nuclear antigens should be guided by the clinical findings.

Although the ANA is 95% sensitive for *systemic lupus erythematosus* (SLE), it is not specific and is seen in other diseases. Higher titers are more specific for SLE but may be seen in the other autoimmune diseases. About 20% of normal people have an ANA titer of 1:40 or higher, and 5% have a titer of 1:160 or higher. Less than 5% of patients with definite SLE have a negative ANA titer. Because of the high prevalence of positive ANAs in normal people, physicians need to reserve the diagnosis of SLE for patients who have clinical findings compatible with SLE. ANA titers correlate poorly with relapses, remission, and severity of disease and are not helpful in monitoring the course or response to therapy. ANA testing should be ordered when a connective tissue disease is considered, but it is not generally helpful in the evaluation of nonspecific complaints, such as fatigue or back pain (Solomon et al., 2002).

For patients with a positive ANA titer, further testing for specific nuclear antibodies can be obtained, guided by the pattern of ANA staining and the clinical findings. The interpretation of testing for specific nuclear antigens can also be difficult; most of the “specific” antigens are not 100% specific for a particular disease and need to be interpreted in the clinical context. The anti-DNA test is highly specific for SLE, with about 95% specificity but only 50% to 60% sensitivity, and it can be used as a confirmatory test in patients with a positive ANA. Similarly, the anti-Sm (Smith) test is also highly specific for SLE, but with 30% sensitivity. Anti-SSA/Ro and anti-SSS/La are often used to diagnose Sjögren’s syndrome but can also be found in SLE. Anti Scl-70 is found in scleroderma but is not a requirement for diagnosis.

Table 15-8 Conditions Associated with Positive Antinuclear Antibody (ANA) Test

Bilirubin

Bilirubin is produced by catabolism of hemoglobin in extrahepatic tissues. Hepatocytes conjugate the bilirubin, and it is then excreted into bile. Blood bilirubin levels are a function of production rate and biliary excretion. Total bilirubin is a combination of lipid-soluble *unconjugated* bilirubin and water-soluble *conjugated* bilirubin. Total bilirubin is less than 1.5 mg/dL and is normally primarily unconjugated bilirubin. The initial step in the evaluation of an elevated bilirubin level is to distinguish conjugated (direct) from unconjugated (indirect) hyperbilirubinemia.

Probably the most common cause of unconjugated hyperbilirubinemia is *Gilbert’s syndrome*, a benign condition that affects up to 5% of the population. In Gilbert’s syndrome, only the unconjugated bilirubin is elevated; the rest of the liver enzymes are normal. Other causes of unconjugated hyperbilirubinemia include hemolysis, ineffective erythropoiesis (as in megaloblastic anemias), or a recent hematoma. With normal hepatic function, hemolysis is not associated with bilirubin levels greater than 5 mg/dL. In an asymptomatic person with mildly elevated unconjugated hyperbilirubinemia (<4 mg/dL), a presumptive diagnosis of Gilbert’s syndrome can be made if there are no medications that cause elevated bilirubin, there is no evidence of hemolysis, and the liver enzymes are normal (Green and Flamm, 2002).

Conjugated hyperbilirubinemia generally occurs with defects of hepatic excretion, including extrahepatic obstruction, intrahepatic cholestasis, cirrhosis, hepatitis, and toxins. Bilirubinuria is a fairly sensitive marker for biliary obstruction and may occasionally be found before jaundice is evident.

Blood Urea Nitrogen and Creatinine

Blood urea nitrogen (BUN) is a byproduct of protein metabolism and is produced by the liver. The reference range for BUN level is 7 to 18 mg/dL. A rise in BUN can be seen with worsening renal function. However, an elevated BUN level is not specific for intrinsic renal disease and can be seen with prerenal causes of azotemia such as hypovolemia and congestive heart failure, postrenal causes of obstructive nephropathy, and gastrointestinal bleeding. At low flow rates, the renal tubules will increase reabsorption of urea, thereby elevating BUN proportionately more than creatinine. BUN can also be reduced in severe liver disease, malnutrition, the syndrome of inappropriate antidiuretic hormone secretion (SIADH), or occasionally the third trimester of pregnancy.

Creatinine is a product of muscle metabolism, and production is related to muscle mass, age, gender, and race, and dietary meat intake. Creatinine is filtered by the glomerulus and secreted by the proximal tubule. Creatinine levels increase as renal function is reduced. At normal renal function, most of the urinary creatinine excretion is from glomerular filtration, with about 5% to 10% from tubular secretion. As the *glomerular filtration rate* (GFR) declines, a larger proportion of creatinine excretion comes from secretion; therefore, direct measurements of creatinine clearance overestimate GFR with progressive reductions in renal function. Some drugs, including cimetidine, trimethoprim, fenofibrate, salicylates, and pyrimethamine, can block the secretion of creatinine and falsely elevate creatinine levels, particularly in the setting of a low GFR. Although serum creatinine has long been used to estimate renal function, current guidelines from the National Kidney Foundation recommend using *estimated* GFR (eGFR) from serum creatinine to report kidney function. Many clinical laboratories now automatically report the eGFR using the Modification of Diet in Renal Disease (MDRD) equation. This equation uses age, serum creatinine, and gender to estimate the GFR, expressing GFR in mL/min/1.73 m². Limitations of the eGFR include lack of standardization of creatinine assays in different laboratories and underestimation of GFR in healthy persons. In addition, the equations were developed in persons with chronic kidney disease and may not accurately calculate GFR in elderly, nonwhite, or healthy persons (Stevens and Levey, 2005).

The BUN/creatinine ratio can help differentiate prerenal and postrenal causes of renal insufficiency from intrinsic renal disease. Ratios of 10:1 suggest intrinsic renal pathology; ratios greater than 20:1 suggest prerenal or postrenal causes.

Calcium

The total calcium level is a measurement of free (also called *ionized*) calcium, protein-bound calcium, and a chelated fraction. Approximately 50% of total calcium is ionized, 40% to 50% is bound to albumin, and 5% to 20% is bound to other ions. Only the free or ionized portion of calcium is physiologically active. Because of the binding of calcium

with albumin, simultaneous measurements of calcium and albumin need to be performed to interpret calcium abnormalities. For every 1 g/dL that serum albumin is decreased below 4 g/dL, the estimated serum calcium is corrected by adding 0.8 mg/dL to the measured calcium level. An alternative is to measure ionized calcium levels in patients with abnormalities of serum albumin. The reference range for serum calcium is 8.5 to 10.5 mg/dL and for ionized calcium, 4.65 to 5.28 mg/dL. Serum calcium measurements are not precise enough to differentiate normal levels from mildly elevated calcium levels reliably; therefore a number of measurements are needed to confirm true mild hypercalcemia.

The etiology of *hypercalcemia* is either hyperparathyroidism or malignancy in more than 90% of hypercalcemic patients. In the ambulatory setting, most patients with hypercalcemia have hyperparathyroidism. Typically the hypercalcemia of hyperparathyroidism is modest, with calcium levels less than 11 mg/dL and minimal symptoms. Hospitalized patients are more likely to have malignancy as a cause of hypercalcemia. Calcium levels greater than 13 mg/dL are usually associated with malignancy. Intact *parathyroid hormone* (PTH, parathormone) levels can differentiate hyperparathyroidism from other causes of hypercalcemia. Nonhyperparathyroid causes of hypercalcemia will give low or "normal" intact PTH levels in a setting of hypercalcemia, whereas the PTH level will be increased in hyperparathyroidism. Occasionally, patients with a family history of hypercalcemia show a reduction in calcium excretion and have familial hypocalciuric hypercalcemia. Other causes of hypercalcemia are related to increased gastrointestinal (GI) absorption, increased bone resorption, and decreased renal excretion (Table 15-9).

Perhaps the most common cause of a low total calcium level is a *low albumin level*. When hypocalcemia is found, one should establish that the serum albumin is normal. If serum albumin is also reduced, one should perform the above correction to confirm true hypocalcemia. Another important cause of hypocalcemia is *hypomagnesemia*, which can lead to PTH resistance or reduced PTH secretion. Correction of the magnesium deficiency usually results in correction of the hypocalcemia. Other causes of hypocalcemia include chronic kidney disease, vitamin D deficiency, malabsorption, acute pancreatitis, transfusion with citrated blood, rhabdomyolysis, hypoparathyroidism, and pseudohypoparathyroidism, and occasionally bisphosphonate therapy.

Carcinoembryonic Antigen

Carcinoembryonic antigen (CEA), an oncofetal glycoprotein antigen, has been mainly used in the evaluation of patients with adenocarcinomas of the GI tract, especially colorectal cancer. CEA may be elevated in benign as well as malignant diseases (Table 15-10). CEA is not recommended as a screening test for occult cancer (including colorectal) because of its low sensitivity and specificity, but it may be used as supportive evidence in a patient undergoing diagnostic evaluation because of signs and symptoms of colon cancer. Its main value is in monitoring for persistent, metastatic or recurrent colon cancer after surgery. A preoperative elevation should return to normal in 6 to 12 weeks (CEA half-life, 2 weeks), if all disease has been resected. The liver metabolizes CEA, and therefore hepatic diseases can result in delayed clearance. Treatment (surgery, radiation, chemotherapy) may produce

Table 15-9 Causes of Calcium Abnormalities

| Calcitonin |

transient artifactual elevations. CEA has a 97% sensitivity for detecting recurrence in the patient whose postoperative CEA value has returned to normal, and 66% sensitivity for recurrence in the patient with normal preoperative levels.

The adult reference range for CEA is 2.5 ng/mL or less for nonsmokers and 5.0 ng/mL or less for smokers. The degree of CEA elevation correlates with tumor bulk at diagnosis and therefore with prognosis. Values less than 5 ng/mL before therapy suggest localized disease and favorable prognosis, whereas

Table 15-10 Conditions Associated with Elevated Carcinoembryonic Antigen (CEA) Level

| Disease | Patients with Elevated CEA (%) |
|--|--------------------------------|
| Carcinoma of endodermal origin (colon, stomach, pancreas, lung) | 60-75 |
| Colon cancer | |
| Overall | 63 |
| Dukes Stage A | 20 |
| Dukes Stage B | 58 |
| Dukes Stage C | 68 |
| Lung cancer | |
| Small cell carcinoma | About 33 |
| Non-small cell carcinoma | About 67 |
| Carcinoma of nonendodermal origin (e.g., head and neck, ovary, thyroid) | 50 |
| Breast cancer | |
| Metastatic disease | ≥50 |
| Localized disease | About 25 |

| Liver disease (alcoholic cirrhosis, chronic active hepatitis, obstructive jaundice) | Variable |
| Renal failure, fibrocystic breast disease, hypothyroidism | Variable |
| Healthy persons | |
| Nonsmokers | 3 |
| Smokers | 19 |
| Former smokers | 7 |

levels greater than 10 ng/mL suggest extensive disease and a worse prognosis. About 30% of patients with metastatic colon cancer have normal CEA levels. Benign diseases do not usually produce CEA levels greater than 5 to 10 ng/mL. For an individual patient, repeat testing or longitudinal monitoring should be conducted at the same laboratory with the same methods because of variability among assays. A 20% to 25% increase in plasma concentration is considered a significant change. A rising CEA level may detect recurrent disease 2 to 6 months before it is clinically apparent.

Chloride

Chloride is the most abundant extracellular *anion*. Measurements of serum chloride are not useful for routine screening but may help in the evaluation of acid-base disturbances.

The reference range of chloride is 98 to 109 mmol/L. In volume expansion, serum chloride generally increases, and in volume depletion, serum chloride is reduced. *Hypochloremia* occurs with loss of chloride-containing body fluids, such as with prolonged vomiting, burns, diuretic use, and salt-wasting nephropathy. Hypochloremia is commonly seen with metabolic alkalosis. *Hyperchloremia* occurs with non-anion gap metabolic acidosis, usually related to diarrhea or renal tubular acidosis, and with administration of large amounts of sodium chloride.

Urine chloride levels are useful in the evaluation of metabolic alkalosis. Low urine chloride (<10 mmol/L) is present with chloride-responsive causes of alkalosis, such as vomiting with volume depletion. Elevated levels of urine chloride (>20 mmol/L) are present in conditions associated with mineralocorticoid excess, such as hyperaldosteronism and hypercortisolism.

Coagulation Studies

The most common coagulation studies, *prothrombin time* (PT) and *partial thromboplastin time* (PTT), are used to evaluate patients with clotting disorders or to monitor patients taking heparin or oral anticoagulants. It is helpful for the laboratory to know whether a patient is taking an anticoagulant at testing. Hospitalized patients with nonsurgical diagnoses, who do not have liver disease or a history of anticoagulant use, do not benefit from routine PT and PTT testing. These are poor screening tests for postoperative bleeding in patients without historical risk factors, physical findings, or a medication history that suggests an increased bleeding risk (Eckman et al., 2003). Preoperative PT and PTT should be reserved for patients with known or suspected coagulation disorders and those receiving anticoagulation therapy.

Prothrombin time, a simple and inexpensive test for evaluating the extrinsic coagulation pathway, is the time in seconds for citrated plasma to clot after the addition of calcium and thromboplastin. Test accuracy depends on proper collection and instrument technique. Common uses include monitoring anticoagulant therapy with warfarin, evaluating liver function (because the liver synthesizes most of the clotting factors), and screening for coagulation disorders of the extrinsic system. PT is prolonged by defects in factors I (fibrinogen), II (prothrombin), V, VII, and X. The normal range for PT is 11 to 13 seconds.

Previously, PT measurements exhibited variability across laboratories because of differences in thromboplastin sensitivity. To correct for the type of thromboplastin used, the World Health Organization (WHO) recommends using the *international normalized ratio* (INR) to report PT results for patients taking oral anticoagulants. Now widely accepted, the INR is calculated as follows:

$$\text{INR} = (\text{Patient PT} / \text{Mean normal PT})^{\text{ISI}}$$

The ISI is the international sensitivity index of the thromboplastin used at the local laboratory. Provided by the test's manufacturer, ISI reflects the responsiveness of the thromboplastin used in the PT test. The reference range for the INR in the non-anticoagulated patient is 0.9 to 1.1. The PT is prolonged in persons with vitamin K deficiency, including those

with fat malabsorption syndromes, recent broad-spectrum antibiotic use, and premature infants. In addition, the use of warfarin, many drugs and herbs, severe liver disease, alcoholism, deficiencies of clotting factors, and circulating anticoagulants can prolong the PT. The PT is not affected by platelet disorders or platelet count. The target INR varies with specific indications. In general, an INR goal of 2.5 (range, 2.0-3.0) is generally accepted for the treatment of venous thromboembolic disease and atrial fibrillation, and 3.0 (range, 2.5-3.5) for patients at risk for arterial thromboembolism, including those with mechanical heart valves.

The *activated* partial thromboplastin time (aPTT, or simply PTT) is a simple, inexpensive test for evaluating the intrinsic coagulation pathway, monitoring heparin therapy, screening for hemophilia A and B, and detecting clotting inhibitors. PTT is the time in seconds for citrated plasma to clot after a contact activator is added to plasma and incubated at 37° C for 5 minutes. Thromboplastin and calcium are added and the time to clot formation is recorded, which should be within 10 seconds of the control. PTT is abnormally prolonged in most patients with coagulation disorders (~90%) and is therefore the best screening test in persons suspected of having a clotting disorder. PTT screens for all coagulation factors that lead to thrombin formation except VII and XIII. These factors include factors I, II, V, VIII (antihemophilic), IX (Christmas), X, and XII (Hageman). PTT is useful to evaluate patients with a known, suspected, or active bleeding disorder; consumptive coagulopathy (e.g., disseminated intravascular coagulation); disorder of fibrin clot formation; or fibrinogen deficiency. In addition, PTT is prolonged with deficiency of the Fletcher (prekallikrein) and Fitzgerald factors, warfarin or heparin therapy, lupus anticoagulant, and vitamin K deficiency. PTT is significantly shortened by hemolysis, is affected by high or low hematocrit, but is not affected by platelet dysfunction or count. A prolonged PT or PTT can be caused by either a factor inhibitor or a deficiency of a clotting factor. To differentiate the two, a mixing study can be performed. When the abnormality is corrected after mixing with normal blood, a factor deficiency is likely. Failure to correct after mixing suggests the presence of a factor inhibitor.

When monitoring heparin therapy, the most widely used target for anticoagulation is a PTT 1.5 to 2.5 times the upper limit of normal. Now, however, because of the great variation in thromboplastins used in different PTT assays, PTT results vary widely among laboratories. Therapeutic heparin levels, as measured by antifactor Xa units, are approximately 0.3 to 0.7 antifactor Xa IU/mL. With plasma concentrations of heparin at 0.3IU/mL, investigators have found that mean PTT values ranged from 48 to 108 seconds, depending on the laboratory methods used. The American College of Chest Physicians recommends against the use of a fixed PTT therapeutic range for the treatment of venous thrombosis; instead, they recommend that each laboratory determine the PTT range that corresponds to a therapeutic heparin level: 0.3 to 0.7 IU/mL by factor Xa dilution. Anti-factor Xa levels may also be used to monitor appropriate anticoagulation doses in patients with obesity or renal failure, because these groups are more likely to be over-anticoagulated using weight-based heparin dosing (Hirsch et al., 2008).

Cobalamin (Vitamin B₁₂) and Folic Acid Deficiency

A deficiency of vitamin B₁₂ or folic acid may be suspected when a macrocytic anemia (MCV >100 fL) is present. Vitamin B₁₂ and folate deficiency causes a megaloblastic anemia, which is one type of macrocytic anemia.

The hematologic picture is identical for both folate and vitamin B₁₂ deficiency. *Megaloblasts* are enlarged blastic cells (precursors to the erythroid and myeloid cell lines) found in the bone marrow and caused by aberrant DNA synthesis. The peripheral blood smear typically shows the presence of oval macrocytes, hypersegmented neutrophils (>5% neutrophils with 5 lobes or any neutrophil with 6 lobes). *Anisocytosis* (size variation) and *poikilocytosis* (shape variation) of the red blood cells (RBCs) are often present, so the RBC distribution width (RDW) is increased. The reticulocyte count is usually decreased. Thrombocytopenia is present in 12% and leukopenia in 9% of cases; occasionally, B₁₂ or folate deficiency will present with pancytopenia. Coexisting disease such as iron deficiency, inflammatory process, renal failure, or thalassemia trait also may normalize the mean corpuscular volume (MCV) value in the patient with vitamin B₁₂ or folate deficiency.

The clinician must distinguish folate from B₁₂ deficiency, because supplementing one will not correct the symptoms from deficiency of the other, i.e., folate replacement will not improve the neuropsychiatric abnormalities caused by vitamin B₁₂ deficiency. The neurologic signs and symptoms, such as paresthesias, memory loss, dementia, and weakness, may precede hematologic abnormalities. Vitamin B₁₂ and folate deficiency often coexist because some causes overlap (Table 15-11).

Because vitamin B₁₂ is a cofactor in the conversion of methylmalonic acid to succinyl coenzyme A (CoA) and homocysteine to methionine, deficiencies of vitamin B₁₂ will lead to increased levels of methylmalonic acid and homocysteine. Folate is required in the conversion of homocysteine to methionine, but not in the conversion of methylmalonic acid to succinyl CoA. Folate deficiency is associated with elevated homocysteine, but not methylmalonic acid. The reference range for vitamin B₁₂ is often listed as 200 to 900 pg/mL;

however, it is now recognized that a significant portion of patients with vitamin B₁₂ levels of 200 to 400 pg/mL have symptoms of vitamin B₁₂ deficiency.

Folate levels greater than 4 ng/mL are considered normal; levels of 2 to 4 ng/mL are indeterminate. A person in negative folate balance will become serum deficient before tissue folate stores decrease; therefore a low serum folate level indicates a negative folate balance, but not necessarily tissue folate deficiency. Intake of folate may normalize serum levels initially, so serum folate levels should be determined before a hospitalized or potentially deficient patient is fed, takes vitamins, or is given a transfusion. Measuring RBC folate levels is not recommended because it is difficult to interpret. Instead, testing for methylmalonic acid and homocysteine can help determine if patients with levels in the low-normal range actually have vitamin B₁₂ or folate deficiency. Folic acid is absorbed in the upper small bowel, whereas B₁₂ is absorbed mainly in the ileum with the help of intrinsic factor, which is secreted by the gastric parietal cells. Nutritional factors and malabsorption syndromes are principal reasons for deficiency of both vitamin B₁₂ and folic acid. Hemolysis will falsely elevate serum folic acid levels.

Complete Blood Count

The complete blood count (CBC) measures circulating blood cells, including RBCs, white blood cells (WBCs), and platelets (Table 15-12). Current technology uses electronic cell counters that can count and size the cells, providing an estimate of cell volume (MCV) and variation in cell size (RDW), and give a five-part WBC differential, including neutrophils, lymphocytes, monocytes, eosinophils, and basophils (Teferi et al., 2005). Typically, peripheral blood smears are prepared for manual review only when requested or when automated hematology analyzers flag abnormal results. By analyzing large numbers of cells, current instruments can generate more accurate data than by manual review for most parameters. Indications for manual review of a blood smear include the evaluation of hemolysis, RBC inclusions, myelodysplasia, megaloblastic changes, thrombocytosis, throm-

Table 15-11 Cobalamin (Vitamin B₁₂) and Folate Deficiency

| Most Common Cause | Vitamin B ₁₂ Deficiency | Folate Deficiency |
|---------------------------------|--|--|
| Inadequate intake | Strict vegetarian diet (rare) Alcoholism, elderly patients | Malnutrition Alcoholism |
| Increased need | Pregnancy, lactation | Pregnancy, lactation, infancy Neoplasia, hyperthyroidism, hemolysis |
| Defective absorption or storage | Decreased intrinsic factor (e.g., pernicious anemia, congenital deficiency of intrinsic factor, gastrectomy) Zollinger-Ellison syndrome Pancreatitis Ileal mucosal disease (e.g., sprue, regional enteritis, surgery, lymphoma) Tapeworm infestation, other parasites Bacterial overgrowth in blind-loop syndrome Drugs (e.g., colchicine, aspirin, metformin) | Malabsorption caused by: Drugs (e.g., anticonvulsants, antituberculosis agents, oral contraceptives, folate antagonist) Jejunal mucosal disease (e.g., amyloidosis, sprue, lymphoma, surgery) Liver disease (cirrhosis, hepatoma) |

bocytopenia, leukocytosis, and immature or abnormal cells (Bain, 2005).

Red Blood Cells

A mild *anemia* is the most common abnormality found on a CBC. Factors that help determine whether further testing should be performed include the degree of anemia and the presence of other abnormalities in the CBC. The first step is to classify the anemia, based on MCV, as microcytic (<80 fL), normocytic (80-100 fL), or macrocytic (>100 fL). With a *microcytic* anemia, the most important test is the ferritin level, which is diagnostic of iron deficiency anemia when less than 12 ng/mL. With a *normocytic* anemia, potentially treatable causes should be excluded

(e.g., recent bleeding, hemolysis, renal insufficiency, vitamin deficiency). Other causes of a normocytic anemia (e.g., anemia of chronic disease, primary bone marrow disorder) may need a bone marrow biopsy for definitive diagnosis. For a *macrocytic* anemia, important determinations are the medication history, alcohol use, and vitamin B₁₂ or folate deficiency.

Erythrocytosis refers to a hematocrit above the reference range. In *true* erythrocytosis, the total circulatory RBC mass is increased, whereas in *relative* erythrocytosis, the RBC mass is normal, but the plasma volume is decreased, so the hematocrit is elevated. With true erythrocytosis, elevated erythropoietin levels suggest a secondary cause and can help distinguish secondary erythrocytosis from polycythemia vera (Table 15-13).

Table 15-12 Complete Blood Count Components

| Test | Description | 95% Reference Range Conventional | Reference Range International |
|--|---|---|--|
| Hemoglobin (Hb) | Measure of oxygen-carrying capacity of blood expressed as grams per unit volume (usually deciliters; g/dL). | M: 13.5-17.5 g/dL F: 12.0-16.0 g/dL | 135-175 g/L 120-160 g/L |
| Hematocrit (Hct) | Measure of solid elements of blood (mostly RBCs), as percentage of whole blood (remainder is plasma). Hct = MCV × RBC. Expressed in%, usually about three times Hb. Both Hct and Hb usually are low in anemia, but may not be apparent early in acute blood loss, because plasma volume needs about 12-24 hours to equilibrate. | M: 39%-49% F: 35%-45% | 0.39-49, volume fraction 0.35-0.45, volume fraction |
| Red blood cell (RBC) mass | Erythrocyte count; true measure of cells/L. | M: $4.3-5.7 \times 10^6$ cells/ μ L F: $3.8-5.1 \times 10^6$ cells/ μ L | $4.3-5.1 \times 10^{12}$ $3.8-5.1 \times 10^{12}$ |
| Red cell indices | MCH, MCHC, MCV. <i>Note:</i> In early anemia, MCV may change before Hb and Hct. | | |
| Mean corpuscular hemoglobin (MCH) | Hb divided by RBC; represents the content (weight) of Hb in average RBC; not as useful as MCHC. | 26-34 pg/cell | 0.40-0.53 fmol/cell |
| Mean corpuscular hemoglobin concentration (MCHC) | Hb divided by Hct, concentration of Hb per unit volume of packed RBCs. Appearance of erythrocytes on peripheral smear is affected by Hb concentration in cell; low, hypochromic; normal, normochromic; high, hyperchromic. | 31.37% Hb/cell or g Hb/dL RBCs | 4.81-574 mmol Hb/L RBCs |
| Mean corpuscular volume (MCV) | Hct × 1000 divided by the RBC count; reflects RBC size; small, microcytic; normal, normocytic; large, macrocytic. <i>Note:</i> Presence of microcytosis and macrocytosis in same sample may result in normal MCV. | 80-100 fL 1 fL (femtoliter) = 10^{-15} L = 1 cubic micrometer (μ m ³) | 80-100 fL |
| Red cell distribution width (RDW) | Estimate of RBC size variability (anisocytosis); standard deviation (SD) of RBC size divided by MCV. | 11.5-14.5 | 11.5-14.5 |
| Reticulocyte count (%) | Expressed as percent of reticulocytes per 1000 RBCs counted. | 0.5%-1.5% | 0.005-0.015 (number fraction) |
| Reticulocyte count (absolute) | Reticulocyte (%) × RBC count; more meaningful expression of erythropoiesis. | $50 \times 10^3/\mu$ L | 50×10^9 /L |
| Platelet count | | $150-450 \times 10^3/\mu$ L | $150-450 \times 10^9$ /L |

Table 15-13 Classification of Erythrocytosis

| Relative Erythrocytosis | |

White Blood Cells

The WBC count is often requested to support a diagnosis of infection or an inflammatory process. The WBC count is useful as a means of monitoring the course of a disease or response to treatment. The cell types that make up the WBC count include neutrophils (segmented and band forms), lymphocytes, monocytes, eosinophils, and basophils. *Bands* are immature neutrophils, and *segmented* forms are mature neutrophils. To diagnose neutropenia, the *absolute neutrophil count* (ANC) should be determined. The ANC is obtained from the cell counter or calculated by multiplying the total WBC count by the percentage of bands plus mature neutrophils (segmented forms):

$$\text{ANC} = \text{WBC count} \times (\% \text{ Bands} + \% \text{ Segmented forms})$$

When severe neutropenia, the ANC drops below 500 cells/mm³, and the patient is at risk for infections. Causes of neutropenia include drug reactions, bacterial and viral infections, hematopoietic diseases, cachexia, hypersplenism, and autoimmune diseases. Lymphocytopenia is present when the lymphocyte count is less than 1500 cells/mm³ in the adult or 3000 cells/mm³ in children. Causes of lymphocytopenia include immunosuppressant drugs, corticosteroid therapy, viral infections (including HIV), and genetic immunodeficiencies.

Leukocytosis, or an elevated WBC count, occurs when the total WBC count is greater than 10,000 cells/mm³. An elevated WBC count may be the result of a reactive process (leukemoid reaction) or leukemia. Leukemoid reactions can

result from infections, toxic conditions, neoplasms, myeloproliferative diseases, and other hematologic disorders. The first step in the evaluation of leukocytosis is to determine what type of WBC is elevated. Leukocytosis may be caused by neutrophilia, eosinophilia, basophilia, monocytosis, or lymphocytosis (Table 15-14).

Platelets

Platelets, cellular fragments of the bone marrow precursor-cell megakaryocytes, are essential to clot formation and have a life span of about 10 days. Clinically, a disorder in platelets is usually suspected in a patient with excessive bleeding, typically from a mucocutaneous source or after trauma. Clinical evidence of bleeding does not occur until the platelet count drops below 50 to 70 × 10³/μL. Platelet counts of less than 10 to 20 × 10³/μL are associated with major spontaneous bleeding. *Thrombocytopenia* may be caused by disorders of production, distribution, or destruction (Table 15-15). In evaluating thrombocytopenia, first examine the peripheral smear for platelet clumping, or repeat the test using sodium citrate as the anticoagulant. *Thrombocytosis*, or an increased platelet count, may be caused by a reactive process or a myeloproliferative disorder. Reactive processes do not usually produce platelet counts greater than 1000 × 10³/μL. Common causes of thrombocytosis include iron deficiency, acute blood loss, inflammatory disorders, malignancies, splenectomy, and myeloproliferative disorders.

Carbon Dioxide or Bicarbonate

Acid-base disturbances are often recognized by abnormalities in the carbon dioxide (CO₂) content of blood, which is composed primarily of bicarbonate (HCO₃⁻), with small amounts of carbonic acid and dissolved carbon dioxide. The reference range for CO₂ is 22 to 29 mmol/L. A reduced serum bicarbonate concentration frequently suggests *metabolic acidosis*, particularly when combined with a low pH. An elevated serum bicarbonate level frequently occurs with *metabolic alkalosis*. Bicarbonate is often used as a buffer for excess acid production, and levels are reduced in metabolic acidosis. In the evaluation of acidosis, calculation of the serum *anion gap* is helpful in determining the cause of the acidosis, as follows:

$$\text{Anion gap} = \text{Na} - (\text{Cl} + \text{CO}_2)$$

The normal range is 10 to 12 mmol/L. An increased anion gap generally indicates the presence of metabolic acidosis with elevation of unmeasured ions, such as lactic acid, phosphates, sulfates, and ketoacids. A normal anion gap acidosis is seen with bicarbonate losses and increased chloride resorption and most frequently occurs with chronic diarrhea, but also with certain types of renal tubular acidosis. Low anion gaps can occur with hypoalbuminuria, congestive heart failure, and occasionally, multiple myeloma.

An elevated serum bicarbonate level frequently occurs in the setting of metabolic alkalosis. Metabolic alkalosis can be generated by loss of acid, such as in vomiting, but normally the kidney corrects the abnormality promptly by excreting excess bicarbonate. To maintain a metabolic alkalosis, the kidney must not be able to excrete excess bicarbonate. This

Table 15-14 Common Causes of Leukocytosis or Leukopenia Stratified by White Blood Cell (WBC, Leukocyte) Type

| Condition | Description |
|---------------------|---|
| Leukocytosis | |
| Neutrophilia | Infections, leukemia, rheumatic and autoimmune disorders, neoplastic disorders, chemicals, trauma, endocrine and metabolic disorders, hematologic disorders, drugs |
| Eosinophilia | Infectious diseases, parasitic infections, allergic diseases, myeloproliferative and neoplastic diseases, cutaneous diseases, gastrointestinal diseases |
| Basophilia | Allergic reactions, chronic myeloid leukemia, myeloid metaplasia, polycythemia vera, ionizing radiation, hypothyroidism, chronic hemolytic anemia, splenectomy |
| Monocytosis | Infections, neoplastic disorders, gastrointestinal disorders, sarcoidosis, drug reactions, recovering from marrow suppression |
| Lymphocytosis | Viral infections, lymphocytic leukemia, other infectious diseases, neoplastic disorders |
| Leukopenia | |
| Neutropenia | Overwhelming bacterial infection, viral infection, drug reaction, ionizing radiation, hematopoietic diseases, hypersplenism, anaphylactic shock, cachexia, autoimmune disease |
| Eosinopenia | Acute stress (usually physical), acute inflammatory states, Cushing's syndrome, corticosteroids |
| Basopenia | Sustained treatment with glucocorticoids, acute infection or stress, hyperthyroidism |
| Monocytopenia | Onset of steroid therapy; hairy cell leukemia |
| Lymphocytopenia | Immunodeficiency disorders, adrenocortical hormone excess, chemotherapeutic drugs, irradiation, impaired drainage of intestinal lymphatics, advanced lymphomas and carcinomas |

From Speicher CE. The Right Test, 3rd ed. Philadelphia, Saunders, 1998.

abnormality usually occurs in the setting of volume depletion, when sodium reabsorption is enhanced and the sodium must be accompanied by an anion to maintain electroneutrality. In the absence of available chloride in the urine, bicarbonate is reabsorbed with sodium, thereby maintaining the alkalosis. As mentioned earlier, urine chloride levels can assist in determining the cause of the metabolic alkalosis.

C-Reactive Protein

An acute-phase reactant glycoprotein, C-reactive protein (CRP) is associated with inflammation. CRP is one of the first proteins to become elevated after an inflammatory process has begun and disappears rapidly when inflammation subsides. In healthy persons, CRP levels are usually less than 0.8 mg/L and are often below the detection limit for standard assays. Serum levels may increase dramatically to exceed 100 mg/L in the presence of bacterial and viral infections, inflammation, severe trauma, surgery, neoplastic proliferation, tissue injury, or necrosis, and transplant rejection. Moderate elevations may be seen with myocardial infarction, autoimmune diseases, rheumatic fever, pregnancy, and postoperatively, as well as in obese persons and women taking estrogen replacement therapy or with an intrauterine device in place. CRP is not affected by age, race, or food intake and does not have significant circadian variation. Drugs that may reduce or suppress CRP levels by controlling inflammation include statins, fibrates, niacin, nonsteroidal anti-inflammatory drugs (NSAIDs), steroids, salicylates, angiotension-converting enzyme (ACE) inhibitors, and beta-adrenergic blockers. CRP has some advantages over erythrocyte sedimentation

rate (ESR). The CRP rises before the ESR, returns to baseline sooner, and is less influenced by altered physiologic states.

The levels of CRP used to assess atherosclerotic risk are much lower than those associated with inflammation (Myers et al., 2004). More sensitive immunoassays were developed to measure levels lower than those detected in conventional assays. These *highly sensitive* CRP tests (hsCRP; Cardiac-CRP) can accurately measure to a lower limit of 0.3 mg/L. Many studies have found that hsCRP levels predict the long-term risk of myocardial infarction, ischemic stroke, peripheral vascular disease, and all-cause mortality in healthy subjects. The hsCRP also predicts outcomes in patients with stable coronary artery disease, acute coronary syndromes, and after percutaneous coronary intervention. In 2004 the American College of Cardiology and American Heart Association (AHA) recommended hsCRP testing to further evaluate patients judged to be at intermediate risk for the development of coronary heart disease (those with 10-year CHD risk of 10% to 20%). CRP levels are divided into tertiles: low risk (<1.0 mg/L), average risk (1.0-3.0 mg/L), and high risk (>3.0 mg/L). A CRP in the highest tertile is associated with a twofold risk of major coronary events compared with a CRP in the lowest tertile. Unexplained levels of hsCRP levels higher than 10 mg/L should be repeated and evaluated for noncardiovascular causes, such as infection or inflammation (Smith et al., 2004).

Erythrocyte Sedimentation Rate

The ESR is one of the oldest laboratory tests still in clinical use. The test measures the distance that erythrocytes (RBCs) fall in a column of anticoagulated blood in 1 hour. Plasma

Table 15-15 Causes of Thrombocytopenia

| Sepsis |
| Cardiopulmonary bypass |
| Toxemia of pregnancy, eclampsia |
| Splenic Sequestration |

proteins known as *acute-phase reactants* facilitate erythrocyte aggregation, which in turn affects the rate at which the solid component of blood will settle in a capillary tube. The plasma proteins most responsible for this aggregation (rouleaux formation), in decreasing order, are fibrinogen, beta (β -) globulins, alpha (α -) globulins, gamma (γ -) globulins, and albumin. Inflammatory, infectious, neoplastic, and collagen vascular diseases increase the ESR. The ESR is helpful in the diagnosis of *polymyalgia rheumatica* and *temporal arteritis*; otherwise, it is both nonsensitive and nonspecific. In studies of patients with biopsy-proven temporal arteritis, 90% of patients had an ESR greater than 30 mm/hr with mean ESR of 90 mm/hr. About 4% of patients with biopsy-proven temporal arteritis have a normal ESR (Smetana and Shmerling, 2002). When there is strong clinical evidence for temporal arteritis and a normal ESR, however, a temporal artery biopsy or a trial of corticosteroids should be considered. Although

Table 15-16 Factors Affecting the Erythrocyte Sedimentation Rate (ESR)

| Increase | Decrease | No Effect |
|---|--|---------------------------|
| Anemia | Polycythemia | Body temperature |
| Macrocytosis | Microcytosis | Recent meal |
| Female gender | Spherocytosis | Aspirin |
| Advanced age | Extreme leukocytosis | NSAIDs |
| Second- and third-trimester pregnancy | Sickle cell disease | First-trimester pregnancy |
| Hypoalbuminemia | Excessive anticoagulant | |
| Tilted ESR tube | Short ESR tube | |
| High room temperature | Low room temperature Clotted blood sample | |
| NSAIDs, Nonsteroidal anti-inflammatory drugs. | | |

used to follow the response to corticosteroid therapy in polymyalgia rheumatica and temporal arteritis, ESR should be used in conjunction with clinical findings. Typically, ESR drops within a few days of corticosteroid therapy, falling to a level that is higher than normal. In addition, relapse can occur without ESR elevation.

Table 15-16 lists physiologic, pathologic, and technical factors that alter ESR, which is higher in women than men and higher in older persons. To determine ESR for healthy adult men, age in years is divided by 2, and for women, age in years plus 10, divided by 2. Clinical considerations for using ESR have been defined (Brigden, 1998; Sox and Liang, 1986). It should not be used as a screening test for disease in asymptomatic persons. As a single test after a normal history and physical examination in asymptomatic persons, ESR contributes to disease detection of a serious illness in less than 6 of 10,000 persons. The underlying cause of an elevated ESR is usually apparent by the history and physical examination, especially for extreme elevations of about 100 mm/hr. Many cases of unexplained elevated ESR are transient and not associated with serious disease. If no obvious cause is seen for elevated ESR, repeating the test in several months is recommended, rather than searching for occult disease.

Fecal Occult Blood Test

The fecal occult blood test (FOBT) is used to detect blood loss in the stool that is not clinically apparent. Patients who report rectal bleeding or those with frank blood by rectal examination should undergo further diagnostic evaluation and do not need an FOBT. Although mainly used to screen for colorectal cancer, the FOBT is not specific for colorectal cancer. The two main FOBTs commercially available are the *guaiac-based tests*, which detect pseudoperoxidase in the heme portion of hemoglobin, and the more expensive *immunochemical tests*, which detect the globulin portion of human hemoglobin. Most RCTs using the FOBT as a screening test

for colorectal cancer used guaiac testing. Newer methods using immunochemical testing are also used in clinical practice. Stool assays that identify colon neoplasia are still being developed and tested. Guaiac FOBT kits include Hemoccult and Hemoccult II SENSE; Hemoccult II has been widely used in clinical practice as well as RCTs.

The basis of the guaiac test is that the pseudoperoxidase of hemoglobin oxidizes guaiac to form a blue-colored quinone compound, after the addition of a hydrogen peroxide developer. The likelihood of a positive guaiac test is related to the amount of blood present in the stool. Normally, about 0.5 to 1.5 mL of blood is lost daily into the GI tract. The FOBT test requires approximately 2 mL/day of blood to be positive; to be consistently positive requires more. Several factors have an impact on FOBT performance characteristics. Bleeding from proximal gastrointestinal lesions, including the right colon, may allow for degradation of the heme, which will then not catalyze the guaiac reaction. The myoglobin or hemoglobin in red meat can give a false-positive reaction, although ingesting 8 oz of cooked red meat daily has only a 5% probability of giving a positive test result. Peroxidase-rich raw vegetables and fruits (turnips, parsnips, horseradish, artichokes, mushrooms, radishes, broccoli, cauliflower, beets, apples, oranges, bananas, melons, grapes, pears, plums, cantaloupe) may give a false-positive result if fecal specimens are tested immediately after collection. However, plant peroxidases are unstable with time; therefore, if a specimen is developed several days after collection, the likelihood of a false-positive test result because of plant peroxidases is reduced.

Gastric irritants such as aspirin, NSAIDs, and excessive alcohol consumption may also produce positive results. Oral iron supplements and acetaminophen do not affect the guaiac test. Ascorbic acid (vitamin C) in excess of 250 mg/day or multivitamins with vitamin C may cause a false-negative result because ascorbic acid is a reducing agent and interferes with the oxidation of guaiac. Other antioxidants should also be avoided. Antacids may also cause false-negative results.

The processes of collecting and processing FOBTs are important in the evaluation of the results. Delaying the processing of the slides allows for dehydration of the specimen, which allows degradation of peroxidase activity and will decrease the sensitivity of testing. The delay between preparation and laboratory testing should not exceed 6 days. The issue of rehydration of dried slides with water is controversial. Rehydration of slides increases sensitivity and decreases specificity (false-positive rate increases). Rehydration increases the positivity rate of Hemoccult II fourfold, from 2% to 3% to 8% to 16% (10% average), but this rate can be minimized if the patient adheres to a low-peroxidase diet. Proper patient instruction and preparation are essential during collection of specimens (Bresalier, 2002). Patients should not collect specimens until 3 days after menses have stopped or if obvious rectal bleeding or hematuria is noted. For 3 days before testing, patients should avoid ingesting red meat, vegetables with high amounts of peroxidase (broccoli, turnip, cantaloupe, cauliflower, radishes), aspirin, NSAIDs, and vitamin C. The detection of the blue color of a positive test may be affected by other factors, including a thick stool smear, exposure to high ambient temperatures, and black stools from iron ingestion.

As a screening test for colorectal cancer, FOBT has low sensitivity and specificity. Other GI lesions, including hemorrhoids, angiodysplasia, diverticular disease, and upper GI lesions, can lead to increased blood in the stool. Bleeding from colon cancers can be intermittent or undetectable, and other factors can give false-positive or false-negative readings. About 2% to 6% of asymptomatic adults have a positive FOBT test, 10% of whom have cancer and 20% to 30% adenomas. The rest have upper GI sources of bleeding, non-neoplastic lower GI sources of bleeding (e.g., hemorrhoids), or no identified source of bleeding. The sensitivity of the FOBT in patients with colon cancer is approximately 30%.

With home-based testing, FOBT has best been studied using a regimen of three stools. Because only one specimen is obtained during a digital rectal examination (DRE), office collection is less sensitive than three at-home determinations. A study compared FOBT during DRE (without rehydration) in the office and home-based six-sample FOBT (with rehydration) to colonoscopy. The digital FOBT was positive in 6.4% of patients with adenomas with high-grade dysplasia and 9.5% of patients with cancer, whereas the home-based FOBTs were positive in 29.8% of patients with adenomas with high-grade dysplasia and in 42.9% of patients with cancer (Collins et al., 2005). A single digital FOBT has poor sensitivity and therefore cannot be recommended as the sole test for screening for colon cancer.

Because of the concerns about sensitivity and specificity with the FOBT, new tests have been developed. With a change in the developer fluid, the Hemoccult SENSE is more sensitive than Hemoccult or Hemoccult II but less specific. Newer fecal immunochemical tests (FITs; Hema Select, FlexSure, Insure) have been developed to increase the sensitivity and specificity over FOBT. These tests are based on an antigen-antibody reaction that is specific for human hemoglobin. They do not react with animal hemoglobin or peroxide-containing foods. Moreover, the FIT is not affected by ingestion of vitamin C, iron, or rehydration, and testing can be delayed for up to 30 days. Therefore, dietary restrictions and specimen handling are not critical issues. The FIT can detect stool hemoglobin at one-tenth the concentration of the FOBT. Some brands (e.g., Insure) detect the globulin portion of hemoglobin, which is degraded in the upper GI tract. Therefore, these tests are more specific for identifying bleeding from the colon.

Glucose

The reference range for a fasting plasma glucose level is between 70 and 99 mg/dL. *Hypoglycemia* is best documented by a plasma venous glucose level less than 50 mg/dL, although there is considerable variability in the level of hypoglycemia that causes symptoms. Asymptomatic hypoglycemia in a patient not taking insulin or oral hypoglycemic agents may be a laboratory artifact caused by ongoing metabolism of glucose in the specimen, especially if a delay has occurred in processing the specimen. The diagnosis of hypoglycemia is best made with typical symptoms associated with a laboratory confirmation of venous hypoglycemia, followed by relief of symptoms after ingesting glucose. The glucose tolerance test (GTT) can produce hypoglycemia in normal persons and should not be routinely ordered in the evaluation of hypoglycemia.

Hypoglycemia can be defined as iatrogenic, postprandial, or fasting. *Postprandial* hypoglycemia occurs after meals and is usually mild and self-limiting. *Alimentary* hypoglycemia occurs when patients have rapid gastric emptying. Insulin levels rise rapidly after a meal and fall more slowly than glucose levels, which results in hypoglycemia. *Fasting* hypoglycemia is seen much less often than reactive hypoglycemia and may be a harbinger of more severe disease, including insulin-producing pancreatic tumors and hepatic, adrenal, or renal insufficiency, or it may be the result of excess insulin or sulfonylurea administration. True fasting hypoglycemia needs to be confirmed by a prolonged fast, with simultaneous measurement of glucose and insulin. This technique can help determine whether the hypoglycemia is associated with excess insulin.

Diabetes mellitus is characterized by *hyperglycemia*. The American Diabetes Association has defined *normal* fasting plasma glucose as less than 100 mg/dL (5.6 mmol/L), *pre-diabetes* as 100 to 125 mg/dL (5.6-6.9 mmol/L), and diabetes mellitus as 126 mg/dL (7.0 mmol/L) or greater.

Glycosylated Hemoglobin (Hemoglobin A_{1c})

The hemoglobin A_{1c} (HbA_{1c}) fraction measures nonenzymatic glycosylation of hemoglobin, which is related to level of glucose concentration over the life span of the erythrocyte. The HbA_{1c} fraction can be used to estimate glucose control in the previous 3 months. In persons with normal erythrocyte survival, the glucose levels in the last 30 days contribute to 50% of the HbA_{1c}, whereas the glucose levels in the preceding 90 to 120 days contribute only 10% to the HbA_{1c} measurement. Although previously laboratories varied considerably in the reporting of HbA_{1c} results, virtually all U.S. laboratories now have adopted the National Glycohemoglobin Standardization Program (NGSP) methods. Recent standards propose reporting HbA_{1c} in the familiar percentage and in international units (mmol/mol), combined with the HbA_{1c}-derived average glucose (ADAG) (Saudek et al., 2008). Using NHANES III data that the population average for HbA_{1c} was 5.17 with standard deviation (SD) of 0.45, the International Expert Committee (2009) selected an HbA_{1c} of 6.5% (~3 SD above average) as the cutoff point to diagnose diabetes mellitus, with confirmation by a fasting glucose greater than 126 mg/dL or oral GTT greater than 200 mg/dL, or a repeat HbA_{1c} greater than 6.5%. Goals for achieving optimal control of diabetes are controversial, but a reasonable goal in most persons is an HbA_{1c} less than 7%. Conditions that shorten erythrocyte survival, such as hemolysis or recent bleeding, give a lower HbA_{1c} level.

Helicobacter pylori

A spiral, urease-producing bacterium, *Helicobacter pylori* is associated with almost 90% of duodenal ulcers. Testing is indicated in patients with either active or previously documented peptic ulcer disease, in the evaluation of dyspepsia who have no "alarm features," and for patients with a history of gastric MALT (mucosa-associated lymphoid tissue) lymphoma (MALToma) (Chey and Wong, 2007). Several tests can be performed during endoscopy. Rapid urease testing of a biopsy specimen has sensitivity over 90% and specificity over 95%, with results available within 1 to 24 hours. The sensitivity of rapid urease tests is reduced by drugs that treat

H. pylori, including bismuth, antibiotics, and proton pump inhibitors (PPIs). Histologic examination of gastric biopsies can also detect *H. pylori*. Culturing *H. pylori* has a lower yield, is more expensive, and is not widely done.

Serologic tests for immunoglobulin G (IgG) antibody to *H. pylori* are helpful in determining previous infection and have sensitivity of approximately 88% but specificity of only 70% to 80%. Even though titers may decline slowly after eradication of the organism with antibiotics, these tests have limited use in evaluation of the effectiveness of antibiotic therapy and cannot reliably distinguish current from past infection. The value of *H. pylori* antibody testing in the evaluation of uninvestigated dyspepsia depends on the prevalence of *H. pylori* infection. In areas of high prevalence (>20%), serologic testing may be cost-effective for a test-and-treat strategy. Antibody testing is inexpensive and has a very good negative predictive value.

Urease breath tests using carbon 13 (¹³C)-urea or ¹⁴C-urea can detect ongoing replication of *H. pylori*. These tests are most helpful in determining whether *H. pylori* has been successfully eradicated after a course of treatment, but they can also confirm active infection in the presence of positive serologic findings. After the ingestion of labeled urea, urease-producing *H. pylori* organisms break down the urea and produce labeled CO₂, which is absorbed into the circulation and exhaled, and can be measured by collecting an exhaled breath sample in a bag. False-negative breath tests may occur with the recent use of antibiotics, bismuth, or PPIs. Most studies find the sensitivity and specificity of the urease breath test to be greater than 95%.

Testing for *H. pylori* antigen in the stool by ELISA assays has been found to have sensitivity over 90% and specificity approaching 100%, thereby making it an accurate non-invasive method to diagnose active *H. pylori* infection in untreated patients. As in urease breath testing, recent antibiotics, PPIs, and bismuth can cause false-negative results. Stool tests can also be used to confirm eradication, but no sooner than 4 weeks after completion of therapy.

Hepatitis Serology

Hepatitis A virus (HAV), hepatitis B virus (HBV), and less often hepatitis C virus (HCV) are the usual causes of acute viral hepatitis. A person with symptoms of acute hepatitis should have these four hepatitis serologies performed: immunoglobulin M (IgM) anti-HAV, hepatitis B surface antigen (HBsAg), IgM anti-HBc, and anti-HCV. At present, stool and blood assays for HAV antigen are not available. The diagnosis of hepatitis A is made by the detection of IgM anti-HAV during acute illness. A positive anti-HAV with only IgG anti-HAV indicates previous infection.

In hepatitis B, HBsAg is the earliest serologic marker of infection and is present before elevation of the aminotransferases. If HBsAg is present for more than 6 months, the patient should be considered chronically infected (carrier). Antibodies to HBsAg (anti-HBs) indicate immunity to hepatitis B and appear several weeks to months after HBsAg disappears. The gap between the presence of HBsAg and anti-HBs is a window period; during this time antibody to hepatitis core antigen (anti-HBc) can be detected in the blood. Anti-HBc can be differentiated into an IgM anti-HBc, which indicates recent infection, and an IgG anti-HBc, which indicates

previous infection. HBeAg, a subparticle of core antigen, is present only when HBsAg is present and is a marker for infectiousness. Anti-HBe appears after HBeAg disappears, indicates decreasing infectivity, a good prognosis, and remains detectable for years. HBV DNA testing can be used to follow titers in patients receiving antiviral therapy for chronic hepatitis B infection. *Hepatitis delta virus* (HDV) infection coexists with hepatitis B in about 4% of hepatitis B infections and carries an increased mortality rate. HDV depends on the presence of HBV for expression and replication and can cause acute or chronic infection. Previous vaccination for hepatitis B should produce a positive titer only for anti-HBs.

Hepatitis C occasionally presents as acute hepatitis, but more frequently is detected in the evaluation of patients with elevated aminotransferases or chronic liver disease. With chronic hepatitis, aminotransferases are often only mildly elevated and occasionally, normal. The diagnosis is made by detecting antibody to hepatitis C (anti-HCV). Anti-HCV does not differentiate acute from chronic infection and does not indicate immunity. In acute hepatitis C the antibody may not be detected initially, and the test may need to be repeated later to confirm infection. In a patient with abnormal liver enzymes and a risk factor for hepatitis C (e.g., injection drug use, hemophilia, history of blood transfusions before 1985), a positive anti-HCV is sufficient to make the diagnosis.

A quantitative HCV-RNA assay can be used for diagnosis of acute infection as early as 1 to 2 weeks after exposure, and before anti-HCV appears. Quantification of viral ribonucleic acid (RNA) by the reverse-transcriptase polymerase chain reaction (RT-PCR) also can confirm hepatitis C infection, as well as measure viral load. These tests are particularly useful in the absence of risk factors or abnormal liver enzymes, when antibody testing is indeterminate, or with immunodeficiency. In addition, quantification of viral RNA can assess response to treatment.

Human Immunodeficiency Virus

The diagnosis of HIV infection usually depends on the detection of antibodies to the virus. The recommended screening test for HIV infection is an initial enzyme immunoassay, the ELISA test, which can detect the presence of antibody to HIV 2 to 8 weeks after infection. HIV ELISA testing studies in blood donors have found specificities of 99.7% and 99.99% (Chou et al., 2005). An initially positive ELISA should be repeated, and repeatedly positive ELISAs need to be confirmed by a more specific test, most often the Western blot. A positive ELISA combined with a negative Western blot should be considered a false-positive HIV test and indicates that HIV infection is not present. A positive ELISA and an indeterminate Western blot result can be a marker for early HIV infection or advanced acquired immunodeficiency syndrome (AIDS), or it can be a false-positive test result. The predictive value of a positive HIV test depends on the prevalence in the population being tested.

Rapid HIV tests are currently available that check saliva, whole blood, and plasma. The whole-blood tests measure capillary blood with a finger stick and do not require centrifugation. These tests are interpreted visually, do not require instrumentation, and provide test results in minutes. Rapid tests may be preferred for testing in patients who are not likely to return for results of standard testing, for pregnant women at delivery with

no HIV testing during their pregnancy, and for testing during occupational exposure. Rapid tests for HIV have similar sensitivity and specificity to the standard ELISA tests. Clusters of false-positive oral rapid tests have been reported, emphasizing the need for confirmatory testing of positive rapid tests.

Tests to measure HIV directly include quantitative HIV RNA testing by PCR, which measures viral load or actual viral replication. Quantitative HIV RNA measurements are useful in evaluating indeterminate Western blot results and acute HIV infection, when the patient presents before seroconversion. Because neonates born to HIV-infected mothers often have maternal antibodies for months, early testing with HIV-1 DNA PCR can identify infants with HIV infection. In 2006 the U.S. Centers for Disease Control and Prevention (CDC) recommended routine, voluntary HIV screening for all patients age 13 to 64 in any health care setting.

Iron Studies

Iron deficiency is the most common type of anemia worldwide and therefore a significant cause of human morbidity. Other than menstrual blood losses, negligible iron is lost in a healthy person. Normally, regulation of iron absorption in the proximal small intestine controls iron balance. Iron deficiency results from increased need (growth of infancy or childhood, pregnancy), excessive loss (menstruation, hemorrhage, GI loss), inadequate intake (iron-deficient diet), or defective absorption (gastrectomy or sprue). In adult men or postmenopausal women with adequate iron stores, it takes 3 to 4 years for these stores to be depleted once negative iron balance starts.

During early *iron deficiency anemia*, the erythrocytes may be normochromic normocytic, and later the peripheral blood smear may show microcytosis, anisocytosis, poikilocytosis, and hypochromia. The reticulocyte count is low, and RDW is high (>16). Bone marrow stores of iron are decreased or absent. Serum iron has marked diurnal variation (higher in morning, lower later in day) and is increased transiently after meals. Because morning levels determine the reference range, iron levels should be performed on a fasting morning specimen. Obtaining a serum iron level without determining the level of transferrin (*total iron-binding capacity*, TIBC) is of limited value. Serum iron is decreased with inflammation, infection, and ascorbate deficiency and increased with iron ingestion, transfusions, liver disease, aplastic anemia, and ineffective erythropoiesis. TIBC is an approximation of transferrin and can be calculated when the transferrin is known, as follows:

$$\text{TIBC (g/dL)} = \text{Transferrin (mg/dL)} \times 1.25$$

The total iron-binding capacity or transferrin is not subject to diurnal fluctuation, but it is reduced in chronic inflammation and malnutrition. Iron deficiency is the only microcytic hypochromic anemia associated with absent iron stores (Brittenham, 2005). The serum ferritin is the best indirect marker for the assessment of iron stores. However, serum ferritin is an acute-phase reactant and can be elevated in some patients with liver disease, malignancy, or inflammatory or infectious diseases. Therefore, although a low ferritin (<12 µg/L) is highly specific for iron deficiency, elevated ferritin levels do not rule out iron deficiency. Hemolysis may cause falsely high levels of serum iron. Table 15-17 lists results of iron studies in common anemias.

Lipid Profile

Lipid levels are often obtained to evaluate cardiovascular risk. There are four major classes of lipoproteins: chylomicrons, very-low-density lipoprotein (VLDL) cholesterol (VLDL-C), low-density lipoprotein (LDL) cholesterol (LDL-C), and high-density lipoprotein (HDL) cholesterol (HDL-C). Approximately 60% to 70% of plasma cholesterol is carried as LDL-C. A direct association is seen between increased LDL-C and the risk of CHD. HDL-C functions in the reverse transport of cholesterol to the liver and carries apolipoprotein A-1. HDL-C accounts for about 20% to 30% of total cholesterol. HDL-C and CHD have a strong independent inverse relationship; for every 1-mg/dL decrease in HDL, the risk of coronary artery disease (CAD) increases 2% to 3%. The Adult Treatment Panel (ATP III) of the National Cholesterol Education Program (2001) has recommended lipid screening as a tool to promote cardiovascular disease risk reduction. The standard lipid profile, as recommended by the ATP III, consists of direct measurement of total cholesterol, HDL-C, and triglycerides, with a calculated LDL-C, obtained after a 9-hour fast. The basis for the LDL calculation is the recognition of the following:

$$\text{Total cholesterol} = \text{HDL} - \text{C} + \text{LDL} - \text{C} + \text{VLDL} - \text{C} + \text{Chylomicrons}$$

In the fasting state, chylomicrons approximate zero and drop out of the equation. The VLDL is estimated as the triglycerides (mg/dL)/5. The Friedewald formula for calculating LDL follows:

$$\text{LDL} = \text{Total cholesterol} - \text{HDL} - (\text{Triglycerides} / 5)$$

The Friedewald formula for estimating LDL is not valid in the following three conditions: when there are chylomicrons present, when the triglycerides are over 400 mg/dL, and when there is dysbetalipoproteinemia (type III hyperlipidemia). Hypertriglyceridemia and dysbetalipoproteinemia lead to underestimations of the LDL. Using the Friedewald formula, some non-LDL lipoproteins—intermediate-density lipoprotein (IDL) and lipoprotein (a)—are included in the LDL calculation. Measurements of direct LDL, although more costly, give more accurate values than calculations using this formula in patients with hypertriglyceridemia. Recent analysis

suggests that using nonfasting total cholesterol and HDL measurements give reliable assessment of CHD risk without the need to measure triglycerides (Di Angelantonio, 2009).

There are a number of sources of physiologic and analytic variation in lipid measurements. The physiologic variation is the amount that results can vary in one person, even under ideal testing circumstances, because of different physiologic states. The analytic variation is the variation in a measurement from the same sample using the same assay. Physiologic variations can result in lipid measurements 13% above or below a person's mean levels and are greater than analytic variations. The following conditions can affect the physiologic variation and should be considered when interpreting a lipid profile. Chylomicrons should be eliminated after a 12-hour fast; however, almost all the chylomicrons are removed after 9 hours. Failure to fast before the test elevates the triglycerides and leads to an underestimation of the LDL. The total cholesterol and HDL are not significantly different in the fasting or postprandial state. Testing should be done with standardization of body position. Lying down leads to dilution of the plasma, with an approximate 10% reduction in total cholesterol, LDL, and HDL and a 15% reduction in triglycerides. Most guidelines suggest performing the test 5 minutes after sitting. In addition, prolonged application of the tourniquet during venipuncture can cause elevation of the cholesterol; 2% to 5% increases in cholesterol have been noted after 2 minutes of tourniquet application. Dietary changes begin to become apparent in lipid measurements in approximately 1 to 2 weeks; therefore, patients should have a stable diet for 3 weeks before testing. Morning specimens are preferred because triglycerides have diurnal variation—lowest in the morning, highest in the afternoon. In addition, lipids are 8% higher in the winter than summer. Recent illness or surgery, including myocardial infarction, stroke, or cardiac catheterization, can lower lipid measurements for several weeks. For major illness or injury, it may be necessary to wait 2 to 3 months before measurement. Cholesterol levels decrease 24 hours after myocardial infarction and remain depressed for up to 12 weeks. The plasma cholesterol level is about 3% lower than the serum level. Lipid values may fluctuate by 3% to 9% with use of the same sample and assay. Table 15-18 lists drugs that can affect the lipid components. Major causes of secondary dyslipidemia include diabetes mellitus, hypothyroidism, nephrotic syndrome, and obstructive liver disease.

Table 15-17 Iron-Related Laboratory Measurements in Common Anemias

| Type of Anemia | Serum Iron | Total Iron-Binding Capacity | Transferrin Saturation | Serum Ferritin | Serum Transferrin Receptor |
|---------------------------|------------|-----------------------------|------------------------|----------------|----------------------------|
| Iron deficiency anemia | Low | High | Low | Low | High |
| Anemia of chronic disease | Low | Low | Low | High* | Low |
| Thalassemia | High | Low | High | High | High |
| Megaloblastic anemia | High | Low | High | High | High |
| Hemolytic anemia | High* | Low* | High* | High* | High |

*May fall within normal range.

Magnesium

Magnesium levels are not routinely included in standard chemistry panels, so abnormalities of magnesium frequently go unrecognized. The reference range of serum magnesium concentration is 1.7 to 2.2 mg/dL (1.5-1.7 mEq/L, or 0.75-0.95 mmol/L). The most common cause of *hypermagnesemia* is excess magnesium intake in a patient with chronic kidney disease (Table 15-19). Mild hypermagnesemia can also be seen in Addison's disease, hypothyroidism, and lithium intoxication. Symptoms of hypermagnesemia are seen with levels greater than 4 to 6 mg/dL.

Hypomagnesemia is more common than hypermagnesemia. The three mechanisms causing hypomagnesemia are reduced intestinal absorption from malnutrition or malabsorption, increased urinary losses, and intracellular shifts. Hypomagnesemia is typically associated with alcohol abuse, hypokalemia, hypocalcemia, chronic diarrhea, and ventricular arrhythmias. Symptoms occur with serum concentrations less than 1 mEq/L. Clinically, hypomagnesemia is associated with neuromuscular hyperirritability, including tremors, tetany, and rarely, seizures. In distinguishing renal wasting from extrarenal losses as the cause of hypomagnesemia, a 24-hour urine excretion of greater than 24 mg or a spot urine fractional excretion of magnesium greater than 2% suggests that the cause of hypomagnesemia is excessive renal losses. Drugs that cause hypomagnesemia include loop and thiazide diuretics (but not potassium-sparing diuretics), cisplatin, aminoglycosides, pentamidine, and cyclosporine.

Mononucleosis (Epstein-Barr Virus Infection)

Mononucleosis is a common viral infection, particularly in adolescents and young adults, and has an incubation period of 30 to 45 days and a prodrome of 7 to 14 days.

Typically, mononucleosis is associated with an infection by the Epstein-Barr virus (EBV), which is a herpesvirus. Laboratory findings include leukocytosis, with more than half the leukocytes being lymphocytes. Approximately 10% to 15% of the mononuclear cells are atypical lymphocytes. Thrombocytopenia may develop with infectious mononucleosis. Almost 90% of patients with mononucleosis have abnormal liver enzymes. Mononucleosis is typically diagnosed by detecting a *heterophile antibody*, which is a nonspecific response to EBV infection. The heterophile antibody response is an IgM antibody that will agglutinate with the surface antigen of sheep and horse RBCs, but not with guinea pig kidney cells. Monospot tests are done with rapid slide agglutination procedures and horse RBCs to detect the heterophile antibody. Clinically, about 40% of patients have a positive heterophile antibody response at week 1, 60% at week 2, and 80% to 90% by week 3. The heterophile antibody usually persists for 3 to 6 months after an acute infection, less frequently up to 1 year. The heterophile antibody has an overall false-negative rate of 10% to 15%. However, in children under age 4 years, the heterophile antibody is falsely negative in 70% to 80% of cases. False-positive heterophile antibodies can occur with rubella, hepatitis, other viral infections, and lymphoma.

When the heterophile antibody is negative or the features of infectious mononucleosis are atypical, the disease can be confirmed with specific Epstein-Barr antibodies. Acute or recent infection is thought to be present if four serologic criteria are found: positive IgM to viral capsid antigen (VCA); high titers (>1:320) of IgG to VCA; positive early antigen antibody (anti-EA); and initial absence of antibody to Epstein-Barr nuclear antigens (EBNAs). The most useful EBV-specific antibody to diagnose acute mononucleosis is the IgM VCA, which appears soon after the onset of symptoms and has sensitivity of 91% to 98%

Table 15-18 Effects of Drugs on Lipid Values

| Drug | Total Cholesterol | LDL Cholesterol | HDL Cholesterol | Triglycerides |
|--------------------|-------------------|-----------------|-----------------|---------------|
| Androgens | — | ↑ | ↓ | — |
| Antiepileptics | — | ↑ | ↑ | ↑ |
| Thiazide diuretics | ↑/— | ↑ | — | ↑ |
| Beta blockers | — | — | ↓ | ↑ |
| Alpha blockers | ↓/— | ↓/— | ↑ | ↓ |
| Corticosteroids | ↑ | ↑ | ↑ | ↑ |
| Cyclosporine | ↑ | ↑ | — | — |

| Cyclosporine |
| Cisplatin |
| Aminoglycosides |
| Carbenicillin |
| Amphotericin B |

and specificity of 99%. Convalescent testing should document the appearance of IgG EBNA and disappearance of IgM VCA and anti-EA.

Syndromes mimicking infectious mononucleosis, but with negative heterophile antibodies, are considered *heterophile-negative* infectious mononucleosis. The most common syndromes are related to cytomegalovirus infection and toxoplasmosis. Occasionally, viral hepatitis, rubella, lymphoma, leukemia, and the drugs isoniazid and phenytoin can cause a mononucleosis-like syndrome. Because heterophile antibodies are not uniformly positive early in the disease, serial tests may often be needed weekly to confirm mononucleosis. Specific serologic tests for EBV are relatively expensive and take longer to obtain results, so they are generally reserved for unclear cases and are not necessary in most patients with infectious mononucleosis. In an adolescent or young adult with appropriate clinical symptoms, heterophile antibodies are 95% sensitive and specific.

Natriuretic Peptides (BNP and N-terminal pro-BNP)

Blood levels of natriuretic peptides are used in the evaluation of *heart failure*. Cardiac cells release natriuretic peptides, in response to stretch and wall tension. Ventricular myocytes release a pro-B-type natriuretic peptide (pro-BNP), which is cleaved into the active B-type natriuretic peptide (BNP) and the inactive N-terminal pro-BNP (NT-pro-BNP). Levels of both BNP and NT-pro-BNP increase with age and in renal insufficiency and are reduced in women and obese patients. Some medications, including spironolactone, ACE inhibitors, and angiotensin receptor blockers, lower BNP/NT-pro-BNP levels. Other conditions that increase natriuretic peptides include myocardial ischemia, atrial fibrillation, pulmonary embolus, pulmonary hypertension, chronic kidney disease, and sepsis.

The major established use of BNP testing is evaluating *acute dyspnea*, when the cause is uncertain, to differentiate whether the etiology is from heart failure versus another cause. A normal level in a patient with acute dyspnea has a high negative predictive value and suggests that heart failure is unlikely the etiology. Elevated levels of BNP and NT-pro-BNP also are predictive of death or increased cardiovascular events. The optimal cutoffs for BNP/NT-pro-BNP vary with age. BNP less than 100 pg/mL or NT-pro-BNP less than 400 pg/mL makes the diagnosis of heart failure unlikely. Levels of BNP greater than 400 pg/mL or NT-pro-BNP greater than 2000 suggest heart failure (Dickstein et al., 2008). Using BNP measures to guide therapy in patients with established heart failure did not improve overall survival, quality of life, or total hospitalization but did reduce hospitalizations for heart failure in patients less than 75 years old (Pfisterer et al., 2009).

Phosphorus

The usual serum phosphorus level is approximately 2.5 to 4.8 mg/dL in adults and 4.0 to 6.0 mg/dL in children. Disorders of phosphorus metabolism are caused by variations in dietary intake, phosphorus excretion, and transcellular shifts. Because postprandial phosphorylation of glucose can decrease serum phosphorus levels, fasting specimens are more accurate. *Hyperphosphatemia* most often occurs in the setting of reduced renal excretion from renal insufficiency. Other causes of hyperphosphatemia include excess phosphate ingestion, either orally or with phosphate-containing enemas, hypoparathyroidism, and spurious causes such as thrombocytosis. Less common causes include acromegaly, hyperthyroidism, acidosis, and massive cell lysis from hemolysis, rhabdomyolysis, and tumor lysis after chemotherapy.

Hypophosphatemia is defined as a serum phosphorus level below 2.5 mg/dL. Clinically significant hypophosphatemia occurs at levels less than 1.5 mg/dL. The three major mechanisms associated with hypophosphatemia are decreased intestinal absorption, increased phosphate loss from the kidney, and increased phosphorus shift into the bones. Decreased absorption occurs most often with antacid use. Persistent hypophosphatemia most frequently results from disorders causing increased phosphate loss in the kidney, including hyperparathyroidism, renal tubular disease, and chronic acidosis. Intracellular shifts into cells and bones,

during acute respiratory alkalosis, hyperalimentation, intravenous carbohydrate administration, rapid tumor growth, or treatment of respiratory failure or diabetic ketoacidosis, can cause hypophosphatemia.

Potassium

Potassium is the most abundant *cation* in the body and has a much higher concentration in the intracellular space than in extracellular fluids. Normal potassium levels are maintained despite fluctuating potassium intake by adjustments in renal secretion of potassium. *Hyperkalemia* is defined as a serum potassium level greater than 5.1 mmol/L. Occasionally, hyperkalemia can be an artifact (pseudohyperkalemia) of phlebotomy, associated with thrombocytosis, leukocytosis, or hemolysis during phlebotomy. In a patient with hyperkalemia of no apparent cause, a plasma potassium level can eliminate these effects on the potassium measurement. Because the normal response to increased potassium intake is to increase excretion, hyperkalemia is not likely to be attributed to increased intake unless there is a deficiency in potassium excretion. Shifts of potassium from intracellular to extracellular fluids, such as with acute metabolic acidosis, crush injury, burns, insulin deficiency, beta-adrenergic blockade, and hemolysis, can be associated with a transient hyperkalemia. Persistent hyperkalemia is usually associated with decreased potassium excretion. Potassium excretion by the kidney is flow dependent; therefore, oliguria and anuria are important causes of hyperkalemia. Because aldosterone deficiency is an important cause of decreased potassium excretion, hyperkalemia is seen with hyporeninism, hypoaldosteronism, type 4 renal tubular acidosis, and drugs that inhibit aldosterone (Table 15-20).

Hypokalemia is associated with a serum potassium level of less than 3.5 mmol/L. Symptoms are nonspecific and include muscular weakness. Occasionally, hypokalemia is associated with sustained inadequate potassium intake, particularly in patients with alcohol abuse. Transient episodes of hypokalemia are associated with increased extracellular to intracellular potassium shifts and occur with catecholamine increase, hyperinsulinemia, and adrenergic drugs such as bronchodilators. More frequently, hypokalemia is a result of GI loss of potassium, such as with protracted vomiting, diarrhea, and laxative abuse. Other causes of hypokalemia include drugs, metabolic alkalosis, skin losses, and increased urinary losses. Hypomagnesemia is an important cause of refractory hypokalemia.

Pregnancy Tests

Current pregnancy tests use immunoassays with monoclonal antibodies to measure the beta subunit of human chorionic gonadotropin (hCG). Serum assays and sensitive urine assays can now detect pregnancy approximately 1 week after conception. Home pregnancy tests are generally sensitive enough to diagnose pregnancy accurately when done on the first day of the missed period. The most common reason for a false-negative pregnancy test is incorrect timing, such as performing the test too soon.

In the first 4 to 8 weeks of pregnancy, hCG levels double approximately every 2 days. Failure to double in 48 to 72 hours suggests an ectopic pregnancy or abnormal intrauterine

pregnancy. For the first 2 weeks after conception, serum levels of hCG are higher than those in urine. However, beginning at approximately 3 weeks and for the remainder of the pregnancy, urine levels are higher than serum levels. Levels of hCG return to normal approximately 2 weeks after delivery. After an abortion, levels return to normal in approximately 3 to 8 weeks. Other conditions that can raise hCG levels include gestational trophoblastic neoplasms, such as hydatidiform mole and choriocarcinoma.

Prostate-Specific Antigen

Prostate-specific antigen (PSA) is a glycoprotein protease enzyme produced by the epithelial cells of the prostate. This protein circulates in the serum and can become elevated because of benign and malignant conditions of the prostate. From 50% to 90% of PSA is protein bound and the remainder is free. PSA is used as a tumor marker for the screening, diagnosis, and management of prostate cancer. PSA lacks specificity for cancer, however, because it can be elevated in benign conditions such as benign prostatic hypertrophy (BPH). Estimates suggest that a PSA higher than 4 ng/mL has sensitivity of 70% to 80% and specificity of 60% to 70% for prostate cancer. Factors other than prostate cancer can affect the PSA level (Table 15-21). Controversy surrounds the effect of the digital rectal examination (DRE) on PSA. Theoretically, digitally palpating the prostate gland should elevate the serum PSA. However, it appears that PSA elevations after DRE are probably not significant, so there is no recommendation to withhold PSA testing immediately after DRE.

Although elevations of the PSA are associated with increased risk of prostate cancer, the upper limit of normal of 4 ng/mL may be somewhat arbitrary. During an initial screening examination, prostate cancer was found in 27% of men with PSA levels of 4.1 to 9.9 ng/mL and 59% with PSA over 10 ng/mL (Hernandez and Thompson, 2004). However, prostate cancer is found in 23.9% of men with PSA of 2.1 to 3.0 ng/mL and 26.9% with PSA of 3.1 to 4.0 ng/mL (Thompson et al., 2004).

The positive predictive value (PPV) of the PSA is improved if used complementary to DRE (Table 15-22). The PPV is doubled if the patient also has an abnormal DRE. A normal PSA does not exclude cancer; 20% to 40% of men with organ-confined prostate cancer will have PSA within the reference range. One report of men with confirmed, untreated, clinically significant prostate cancer found these PSA values: less than 4 ng/mL (27%), 4 to 10 ng/mL (21%), 10 to 20 ng/mL (16%), and greater than 20 ng/mL (36%).

The use of PSA for screening for prostate cancer remains controversial. Although it is clear that PSA testing can lead to earlier detection of prostate cancer, it is not clear that early diagnosis and treatment offers significant reduction in prostate cancer mortality. Given that the lifetime risk of death from prostate cancer is only 3% in U.S. men, a large portion of men detected by screening may not have clinically significant disease.

In addition to screening, PSA is used to monitor the response to treatment for localized prostate cancer. After radical prostatectomy, PSA levels should become undetectable. Any detectable levels suggest residual or recurrent tumor and may occur months or years before it becomes clinically apparent. PSA levels fall after radiation therapy, although usually do not become

Table 15-20 Causes of Abnormal Potassium Levels

| | |
|--|---|
| Hyperkalemia | Renal losses |
| Pseudohyperkalemia | Diuresis |
| Thrombocytosis | Renal tubular acidosis (proximal, distal) |
| Leukocytosis | Hypomagnesemia |
| Prolonged tourniquet use during venipuncture | Hyperaldosteronism |
| Hemolysis | Cushing's syndrome |
| Reduced excretion | Nonrenal losses |
| Oliguria | Diarrhea |
| Renal failure | Vomiting |
| Hyporeninemic hypoaldosteronism | Periodic paralysis |
| Adrenal insufficiency | Burns |
| Type IV renal tubular acidosis | Cellular shifts |
| Cellular shifts | Alkalosis |
| Acute acidosis | Beta-adrenergic therapy |

undetectable. A PSA recurrence has been defined as three successive increases in the PSA level after radiation therapy.

Total Protein

Total protein includes albumin and globulin. The factors that affect the total protein level include changes in fluid status, the balance of protein synthesis and catabolism, and protein

losses. While dehydration can cause a relative increase in serum protein concentration, volume expansion causes a relative decrease in protein concentration. Elevated protein levels in the absence of dehydration are usually related to increased globulin levels. As previously discussed, acute-phase reactants are proteins that are increased in inflammatory conditions and include C-reactive protein, haptoglobin, fibrinogen, ceruloplasmin, and α_1 -antitrypsin.

Table 15-21 Noncancer Factors that May Influence Prostate-Specific Antigen

| Factor | Change |
|--------------------------------------|----------------------------------|
| Acute urinary retention | Increase |
| Androgens | Increase |
| Antiandrogens | Decrease |
| Bed rest | Decrease |
| Benign prostatic hypertrophy | Increase |
| Cirrhosis | Increase |
| Cystoscopy | Increase |
| Digital rectal examination | Not significant |
| Diurnal variation | No change |
| Ejaculation | Increase |
| Extensive exercise | Increase |
| Finasteride | Decrease |
| Physiologic variation | May fluctuate by 30% |
| Prostate needle biopsy | Increase |
| Prostatic massage | Increase |
| Prostatitis | Increase |
| Radial prostatectomy | Decrease |
| Radiation therapy | Increase initially then decrease |
| Transurethral resection of prostate | Increase |
| Transurethral ultrasound of prostate | No change |
| Urethral instrumentation | Increase |

Serum protein *electrophoresis* separates proteins based on their mobility in an electric field and can provide a visual estimate of albumin and globulin levels. The five bands on the electrophoresis column include albumin, α_1 -globulin, α_2 -globulin, β -globulin, and γ -globulin. The main component of the α_1 band is α_1 -antitrypsin, which may increase with pregnancy, estrogen therapy, and inflammation. α_2 -Globulin is composed of haptoglobin, ceruloplasmin, and α_2 -macroglobulin. The main component of β -globulin is transferrin, which functions to transport iron. Transferrin levels are reduced in liver disease, nephrotic syndrome, protein-losing enteropathy, and starvation. Levels of transferrin are helpful in monitoring nutritional status in hospitalized patients. Elevations may be seen in iron deficiency anemia, pregnancy, and estrogen use. The β -lipoprotein band can be found in the α_2 -globulin or β -globulin zone. The immunoglobulins are found primarily in the γ region. Diffuse elevations in the γ region can occur with chronic infections, liver disease, autoimmune disorders, and granulomatous diseases. A monoclonal spike in the γ region indicates proliferation of a single immunoglobulin, as

Table 15-22 Positive Predictive Value (PPV) of Total Prostate-Specific Antigen (PSA) for Prostate Cancer

| Digital Rectal Examination | PSA Value | | |
|----------------------------|---------------|--------------|-----------|
| | 0.0-4.0 ng/mL | 4.1-10 ng/mL | >10 ng/mL |
| Negative | 9% | 20% | 31% |
| Positive | 17% | 45% | 77% |

Data from Oesterling JE. Prostate-specific antigen: a valuable clinical tool. *Oncology* 1991;5:112.

seen in myeloma or a monoclonal gammopathy of uncertain significance. Immunoglobulin abnormalities noted on protein electrophoresis can be further characterized by *immuno-electrophoresis*.

Rheumatoid Factor and Anti-Cyclic Citrullinated Peptide Antibodies

The diagnosis of rheumatoid arthritis (RA) is usually made based on clinical findings, supported by laboratory testing. The mainstay of testing has been the IgM rheumatoid factor (RF), which is an autoantibody directed against the Fc portion of the IgG molecule. The sensitivity of RF is approximately 54% to 88% and the specificity 48% to 92%, depending on the method used (Lee and Schur, 2003). RF is not specific for RA and may be detected in the serum of persons with other rheumatoid conditions, chronic infections, or inflammatory conditions, as well as in healthy older adults.

Results are usually reported as a titer determined by using a tube dilution method. A significant titer is 1:80 or greater. In RA, titers are often 1:640 to 1:520 but can even be found up to 1:320,000. Very high titers more likely indicate severe disease or systemic involvement. Increasing serial titer elevations can be used to monitor RA disease progression, but not response to therapy. RF titers may decrease during remission, but only rarely do they become undetectable. The ESR is a better index of disease activity.

Anti-cyclic citrullinated peptide (anti-CCP) antibodies show promise in the diagnosis of RA. Citrulline is an amino acid produced by modification of arginine and is found in filaggrin, a component of keratin. Recently, sensitivity and specificity of anti-CCP antibodies was reported as 67% and 95%, respectively. The advantage of anti-CCP over RF is that it is much more specific for RA. Its optimal use is uncertain, but anti-CCP testing shows greatest benefit with false-positive RF, such as in hepatitis C with cryoglobulinemia. In patients with a moderate pretest probability of RA, positive anti-CCP significantly increases the likelihood of RA (Shmerling, 2009).

Sodium

Abnormal serum sodium levels are markers for impaired water balance. The reference range for serum sodium concentration is 135 to 145 mmol/L. In the evaluation of abnormal

Table 15-23 Classification of Hyponatremia

| Clinical Findings | Causes |
|---|--|
| <i>Volume depletion</i> Tachycardia Hypotension Urine sodium <10 mEq/L Increased urine osmolality <i>Volume overload</i> Edema Urine sodium <10 mEq/L Urine osmolality high | Gastrointestinal losses: vomiting, diarrhea Renal losses: diuretics, chronic renal failure, salt-wasting nephropathies Skin losses: burns Third-space losses: pancreatitis Congestive heart failure, nephrotic syndrome, cirrhosis |
| Euvolemic | SIADH |
| No edema No evidence of dehydration Urine sodium >20mEq/L (unless Na-restricted diet) Urine osmolality > serum osmolality Normal thyroid and adrenal function | CNS disorders: infection, mass lesion, head trauma, acute intermittent porphyria Pulmonary: lung cancer, infection Drugs: chlorpropamide, opiates, nicotine, diuretics, phenothiazines, vincristine, carbamazepine, SSRIs |

| CNS, Central nervous system; SSRIs, selective serotonin reuptake inhibitors. | |

Table 15-24 Classification of Hypernatremia

| Total Body Sodium (Na) | Causes | Urine Measurements |
|---|---|---|
| Reduced total body sodium (both Na and water losses, but relatively more loss of water) | Gastrointestinal losses: diarrhea, lactulose Skin losses: excess sweating Renal losses: loop diuretics, osmotic diuretics | Urine Na <10 mEq/L Hypertonic urine Urine Na \geq 20 mEq/L Hypotonic or isotonic urine |
| Normal total body Na (loss of water) | Renal losses: central or nephrogenic diabetes insipidus, lithium, demeclocycline, hypercalcemia, hypokalemia Nonrenal losses: insensible losses from skin or respiratory tract | Variable urine Na Variable urine tonicity Urine Na variable Hypertonic urine |
| Increased total body Na (addition of sodium) | Hypertonic intravenous fluids Hypertonic dialysate Saltwater drownings | Urine Na >20 mEq/L Hypertonic or isotonic urine |

Modified from Schrier RW. Renal and Electrolyte Disorders, 4th ed. Boston, Little, Brown, 1992, p 43.

sodium levels, it is helpful to measure or calculate the plasma osmolality, which typically has a range of 280 to 295 mOsm/kg H₂O.

$$\text{Calculated osmolality} = (2 \times \text{Na}) + (\text{BUN} / 2.8) + (\text{Glucose} / 18)$$

In most cases, *hyponatremia* is associated with hypo-osmolality. Pseudohyponatremia can occur in the presence of other osmotically active substances, such as ethanol, methanol, mannitol, and glucose. Pseudohyponatremia is associated with an osmolar gap, which means the laboratory's measured osmolality is greater than the calculated osmolality by 10. In the setting of hyperglycemia, every 100-mg/dL rise in glucose lowers serum sodium by 1.6 mmol/L.

In hyponatremia associated with hypo-osmolality, the determination of the patient's volume status is essential to determine the cause of hyponatremia (Verbalis, 2007).

Hyponatremia can occur in states of volume deficiency, euvolemic states, or hypervolemic conditions (Table 15-23). The clinical significance of hyponatremia depends on the severity and rate of development. In general, symptoms are seen when sodium levels are less than 120 mmol/L.

Hypovolemic hyponatremia is associated with low total-body sodium. The most common sources of sodium loss are the GI tract or kidney and, less often, third-space losses. With nonrenal losses, the kidney responds by reducing sodium and water excretion in the urine. In the absence of diuretic therapy, the urine sodium concentration is usually less than 30 mmol/L, and urine osmolality is high. Hypovolemic hyponatremia responds readily to isotonic fluid replacement.

Hypervolemic hyponatremia can occur with advanced congestive heart failure, cirrhosis, nephrotic syndrome, and renal failure in the presence of total-body sodium overload and edema. In these disorders, effective renal blood flow is reduced, thus stimulating the release of antidiuretic hormone

*Normal range: 3.5 to 5.1 mmol/L.

(ADH), which reduces renal excretion of water. Both sodium and water are increased, but water is increased proportionally more than sodium. In the absence of diuretic therapy, urine sodium is generally less than 30 mmol/L, and urine osmolarity is increased.

The most common cause of *euvolemic hyponatremia* is the syndrome of inappropriate ADH secretion (SIADH), which occurs when the stimulus for ADH secretion is not related to osmolarity or reduced renal blood flow. No edema is present, although mild volume expansion and a modest increase in weight are seen. Continued release of ADH occurs despite low plasma osmolarity. SIADH should be considered a cause of hyponatremia in the absence of evidence of volume loss, edema, and adrenal insufficiency or hypothyroidism. The major laboratory finding, in addition to hyponatremia, is urine that is not maximally dilute (i.e., urine osmolarity >100 mOsm/kg H₂O). The urine sodium level is greater than 30 mmol/L, assuming adequate sodium intake. Other clinical findings that suggest SIADH include a uric acid level less than 3 mEq/dL and BUN less than 10 mg/dL. Serum ADH

levels are not helpful because most causes of hyponatremia are associated with elevated ADH levels. The major causes of SIADH are drugs and pulmonary and central nervous system diseases. SIADH can respond to fluid restriction or correction of the underlying disorder. Another cause of euvolemic hyponatremia is called *primary polydipsia*, which occurs in people who consume massive amounts of water and have very large volumes of urine. In general, plasma osmolarity is mildly decreased. These individuals have low urine sodium and dilute urine. The hyponatremia readily responds to a reduction in fluid intake.

Hypernatremia is a serious electrolyte abnormality, but it generally occurs in the setting of a significant underlying medical illness (Table 15-24). Determination of the patient's volume status is also critical in the evaluation of hypernatremia (Schrier, 1992). Hypernatremia can occur in the setting of reduced total-body sodium, normal total-body sodium, and increased total-body sodium. Hypernatremia is seen with reduced total-body sodium when sodium and water losses occur but more water than sodium is lost. For example, when a patient has significant diarrhea, hypernatremia can develop when the patient cannot ingest enough water to compensate for the loss. Clinical evidence of dehydration is noted, urine osmolarity is high, and the urine sodium level is low.

Water loss not connected with sodium loss is associated with hypernatremia and normal total-body sodium. Inadequate ADH secretion (central diabetes insipidus) or renal tubules unresponsive to ADH (nephrogenic diabetes insipidus) can lead to hypernatremia because of an inability to concentrate the urine. Uncommon disorders of the hypothalamus and pituitary can cause a high-set osmoreceptor in which osmotic, but not volume, regulation is impaired. The trigger for the release of ADH may be closer to 300 instead of the normal 285 mOsm/kg.

Less frequently, hypernatremia can occur in a setting of increased total-body sodium from an excessive exogenous sodium load. Hypertonic intravenous fluids, saltwater near-drowning, and hypertonic dialysis can cause hypernatremia.

Streptococcal Testing

"Pharyngitis" is a frequent office diagnosis, but the only common form of pharyngitis that requires antibiotic treatment is that caused by *group A beta-hemolytic streptococci* (GABHS). Approximately 15% to 30% of children and 5% to 10% of adults with sore throat have streptococcal pharyngitis. Suggestive clinical features include fever, no cough or rhinorrhea, tonsillar exudates or beefy-red pharynx, and tender anterior cervical lymphadenopathy.

For an acutely ill patient, the *rapid antigen detection test* (RADT) and traditional bacterial throat culture are available to identify GABHS. In the setting of pharyngitis and a typical syndrome, a positive culture or RADT is sufficient to begin treatment. The sensitivity of both is affected by throat swab technique. Using Dacron or rayon rather than cotton swabs will enhance the chances of detection. Testing should be done of both tonsils or tonsillar pillars and the posterior pharynx. Antigen or bacterial recovery from the throat is increased by rigorous swabbing. Avoid swabbing just the soft palate, tongue, buccal mucosa, or lips. The RADT has the advantage of giving immediate results, which allows for

early antibiotic therapy and thus decreases the duration of illness, complications, and contagiousness. Current RADTs use immunoassay or nucleic acid testing to detect the group A streptococcal carbohydrate. This antigen disappears rapidly after antibiotic therapy, so a history of recent antibiotic use may give a false-negative result. The major limitation of rapid streptococcal tests is low sensitivity (75%-80% on average), but specificity is high (95%-98%). Therefore, a positive test can be accepted as evidence of disease and therapy begun without further testing. However, a negative result does not exclude the possibility of GABHS as the source of the pharyngitis. Children and adolescents with a negative RADT should have a throat culture for confirmation. Because of the low incidence of streptococcal pharyngitis and the extremely low risk of rheumatic fever in adults, the American Society of Infectious Diseases supports the use of RADT alone in adults, without confirmation by cultures (Bisno et al., 2002).

The throat culture is performed on sheep blood agar plate under aerobic conditions. If proper collection and plating technique are used, throat culture sensitivity is 95% to 96% and specificity 99.5%. With poor technique, sensitivity can be as low as 30%. To differentiate group A from other streptococci, a bacitracin disk is placed on this agar. Hemolysis is inhibited in over 95% of group A streptococci by bacitracin, whereas only 10% to 20% of groups C and G and a small percentage of group B are inhibited by bacitracin. Previous antibiotic use may diminish the colony count. If clinical conditions suggest the presence of other pharyngeal pathogens, such as *Candida albicans*, *Corynebacterium diphtheriae*, or *Neisseria gonorrhoeae*, the laboratory test should be altered because different collection and plating techniques are required. Throat culture results are generally reported 24 to 28 hours after plating. Antibiotic sensitivities are not routinely reported because GABHS is uniformly sensitive to penicillin.

Syphilis Testing

The sexually transmitted disease (STD) syphilis is usually diagnosed with serologic testing. Although darkfield microscopy can identify spirochetes in fluid obtained from lesions of primary syphilis, the test has many false-negative readings, and many physicians are not trained to perform these tests. PCR for *Treponema pallidum* DNA is now commercially available for diagnosing early syphilis, with early reports showing good sensitivity and specificity. The major serologic tests for syphilis are the nonspecific nontreponemal Venereal Disease Research Laboratories (VDRL) and rapid plasma reagin (RPR) tests, which measure antibody production to a cardiolipin-cholesterol-lecithin antigen, and the specific treponemal antibody tests, which measure antibodies against the spirochete *T. pallidum*. The usual screening for syphilis is a two-step process, beginning with the RPR or VDRL test, followed by treponemal antibody testing for confirmation.

The RPR or VDRL is reported as a titer of the highest dilution giving a positive test. The VDRL usually becomes positive approximately 1 to 4 weeks after the development of a chancre. The highest titers of nontreponemal tests are seen in secondary syphilis. The sensitivity of the RPR or VDRL is 78% to 86% in primary syphilis, 100% in secondary syphilis, and 95% to 98% in latent syphilis. Titers of VDRL or RPR parallel disease activity. After appropriate treatment of primary or secondary syphilis, titers decline and usually

become negative within 1 year. A fourfold decline in titer 6 months after treatment suggests an adequate response to treatment of primary or secondary syphilis. A fourfold rise in titers after treatment suggests reinfection. Low titers may persist after treatment of late and latent syphilis. Approximately 20% of nontreponemal screening tests are false positive; false-positive tests usually have titers less than 1:8. Causes of false-positive nontreponemal tests include autoimmune disorders, HIV infection, infectious mononucleosis, endocarditis, and lymphoma.

The treponemal tests, such as the fluorescent treponemal antibody absorption (FTA-ABS) test or *T. pallidum* enzyme immunoassay (EIA), are used to confirm infection in a patient with a positive nontreponemal test. The FTA has a sensitivity of 84% in primary syphilis and almost 100% in other stages of syphilis. The specificity is 96%; approximately 1% of the population has a false-positive treponemal antibody, and it is not routinely used for screening. The treponemal tests are reported as positive or negative. Treponemal tests remain positive in 95% of patients, even after treatment, and are not used to monitor treatment response.

In neurosyphilis, cerebrospinal fluid (CSF) abnormalities include elevated protein, a lymphocytic pleocytosis, and a positive VDRL. The CSF VDRL is the preferred test because it is more specific than the CSF FTA. However, the sensitivity is low enough that a negative CSF VDRL does not rule out neurosyphilis. In congenital syphilis, the diagnosis can be difficult because both FTA and VDRL antibodies can be transferred passively to newborns, and their identification at birth in the baby does not necessarily indicate infection. Passively transmitted antibodies generally decline in the first 2 months of life. If titers rise after birth, congenital syphilis is likely. Testing using specific *T. pallidum* EIA IgM may allow earlier diagnosis of congenital syphilis.

Thyroid Testing

Currently available tests for assessing thyroid function measure functional activity of the thyroid, the hypothalamic-pituitary-thyroid axis, or thyroid hormone levels. The third-generation thyroid-stimulating hormone (TSH) test is the best method to confirm or exclude thyroid disease in an ambulatory population. TSH is produced by the pituitary and is inhibited by circulating thyroxine (T_4) and triiodothyronine (T_3). In general, a normal TSH level is approximately 0.5 to 5 mIU/L and excludes hyperthyroidism or primary hypothyroidism. Supersensitive tests measure TSH at levels at least as low as 0.01 mIU/L. TSH levels less than 0.1 mIU/L suggest hyperthyroidism. Levels of 0.1 to 0.5 mIU/L may represent subclinical hyperthyroidism or excess thyroid hormone administration. Levels of 6 to 10 mIU/L are often considered subclinical hypothyroidism, are usually associated with normal free T_4 levels, and are not usually associated with symptoms. In patients with subclinical hypothyroidism, the presence of thyroid antibodies suggests a risk of conversion to frank hypothyroidism of about 5% per year. Symptomatic hypothyroidism occurs with TSH levels greater than 10 mIU/L. The TSH test is also the best way to monitor the results of replacement or suppressive therapy. Although the TSH level is an excellent screen for thyroid function in ambulatory patients, it must be interpreted with caution in acutely ill patients. TSH levels should be used to diagnose

thyroid disorders in acutely ill hospitalized patients only when less than 0.1 mIU/L or greater than 20 mIU/L.

Measurements of circulating thyroid hormone should be obtained to confirm abnormal TSH levels. Measurement of free T₄ levels measure the total amount of hormone in blood, free and protein bound. Total T₄ or T₃ levels can be misleading in the setting of protein-binding abnormalities, such as estrogen therapy and liver disease. An approximate reference range in the adult for free T₄ is 0.7 to 2.5 ng/dL and for free T₃ 0.2 to 0.5 ng/dL. Free T₃ testing is usually not necessary. One exception is in early hyperthyroidism, when the TSH is suppressed, free T₄ is normal, and free T₃ is elevated.

Primary hypothyroidism accounts for more than 95% of cases of hypothyroidism and is associated with an elevated TSH and reduced free T₄. *Central hypothyroidism* (secondary or tertiary) is associated with low free T₄ and normal to low TSH. Primary hyperthyroidism is associated with a suppressed TSH and elevated free T₄. Subclinical hyperthyroidism is associated with a reduced TSH, but normal free T₄ and T₃ levels.

The radioactive iodine uptake scan measures 24-hour thyroid uptake of a labeled quantity of radioactive iodine. In normal persons, uptake is 8% to 30%. Lower limits of normal cannot be reliably differentiated from hypothyroidism in the radioactive iodine uptake scan. Its major value is to help identify causes of thyrotoxicosis associated with low levels of iodine uptake, such as thyroiditis and fictitious hyperthyroidism from overingestion of thyroid hormones. Other causes of reduced thyroid hormone uptake include recent iodine contrast administration and amiodarone.

Uric Acid

Uric acid is produced in the liver as a byproduct of purine metabolism. Measurement of uric acid is useful in the evaluation of *gout* and monitoring of certain types of chemotherapy. Uric acid levels are increased in situations with increased dietary purine intake, reduced excretion, or increased production. In addition, volume status affects uric acid secretion. With a decrease in extracellular volume, uric acid excretion declines, and serum uric acid levels increase. Conversely, volume expansion increases uric acid excretion and leads to *hypouricemia*. Several drugs inhibit the reabsorption of uric acid in the kidney and therefore lead to *uricosuria* (Table 15-25).

Progressively higher levels of *hyperuricemia* predict the likelihood of gout; however, most authorities believe that asymptomatic hyperuricemia should not be treated. At 37°C, saturation in plasma occurs when uric acid levels are greater than 6.8 mg/dL. Most patients with gout have uric acid levels greater than 7 mg/dL at some time, but they can have normal serum uric acid levels at the time of an acute gouty attack. Although a biologically significant uric acid level is greater than 6.8 mg/dL, the upper limits of "normal" based on population studies are 7.7 mg/dL for men and 6.8 mg/dL for women. The incidence of gout is approximately 5% per year in men with uric acid levels greater than 9 mg/dL, but only 0.5% per year with uric acid levels of 7.0 to 8.9 mg/dL.

A distinction between production of uric acid and reduced uric acid excretion as a cause of hyperuricemia may be helpful in evaluating patients with gout. This can

be accomplished by measurement of 24-hour urinary uric acid and creatinine excretion. "Underexcretion" is identified when the *fractional excretion* (excretion of uric acid/excretion of creatinine) is less than 6%. When a person is consuming a regular diet, excretion of uric acid greater than 800 mg/day is considered *hyperuricosuria*. Follow-up testing for patients with hyperuricosuria can be repeated on a low-purine diet, with 24-hour excretion of uric acid greater than 600 mg indicating uric acid overproduction. Of patients with gout, an estimated 90% have reduced uric acid excretion, and less than 10% have overproduction of uric acid as the cause. Drugs that lower serum uric acid include losartan, amlodipine, fenofibrate, and atorvastatin.

Urine Drug Screens

The standard urine drug screen in a clinical setting is a panel of immunoassays designed to detect common drugs of abuse. The panel can include the five drugs required by federal workplace testing: amphetamines, cocaine, opiates, marijuana, and PCP. Other drugs that are prevalent in the community can be added to the panel, including benzodiazepines and barbiturates. Point-of-care testing kits can be ordered for office use that are individualized to the need of the practice. These point-of-care tests provide results in minutes and have generally good sensitivity. The manufacturers recommend follow-up testing with a different laboratory technique to confirm positive tests.

The guidelines that mandate testing procedures for federal workplace testing do not apply in clinical settings. For example, there are no required chain-of-custody policies to safeguard the processing of specimens in clinical settings. Clinical laboratories are not required to perform tests to ensure that the urine sample provided has not been diluted or adulterated. The cutoff points designated to define a positive and negative test are somewhat arbitrary, are chosen mainly to maximize sensitivity and specificity, and do not correlate with the degree of impairment or toxicity. Urine that contains a drug concentration below the cutoff will be reported as negative, even though the drug is present. With standard drug screens, the immunoassays can produce false-positive results. In workplace settings, positive screening tests are followed by more specific tests, such as gas chromatography/mass spectroscopy (GC/MS), and a specimen is not reported as positive unless the GC/MS is also positive. In clinical settings, confirmatory tests are not routinely available and are rarely ordered. Therefore, urine drug screens are designed to help the physician take care of the patient; they are not intended to be used for forensic or legal purposes.

Generally, drugs and their metabolites are detectable in urine tests for about 3 days after use. A notable exception is marijuana, which can be present in the urine for weeks after heavy use. Urine drug screens have significant limitations, which are not always recognized. For example, most immunoassays for "opiates" are designed to detect heroin and measure codeine, which is a byproduct of heroin and morphine metabolism. However, synthetic opioids such as fentanyl or methadone do not cross-react with codeine immunoassays and will produce a negative result. A negative urine drug screen for opiates might falsely lead the physician to believe that the person does not use any opioids. To help determine the sensitivity and the known false-positive results associated

with a urine drug screen, the physician should review the package inserts (Warner and Sharma, 2009).

Vitamin D

Vitamin D is now recognized not only for its importance in preventing rickets, but also in preventing osteopenia, osteoporosis, muscle weakness, and falls. Testing levels of vitamin D can be considered in patients at increased risk of vitamin D deficiency, including elderly patients and those with osteoporosis, osteopenia, fat malabsorption, chronic kidney disease, and increased skin pigmentation. The term "vitamin D" includes vitamin D₂ and vitamin D₃. Vitamin D₂ (calciferol) is manufactured from the plant sterols in yeast, and vitamin D₃ (cholecalciferol) is manufactured from lanolin. Vitamin D is hydroxylated by the liver into 25-hydroxyvitamin D [25(OH)D], the major circulating form of vitamin D in the body. The kidney converts 25(OH)D into 1,25-dihydroxyvitamin D [1,25(OH)₂D], which is the active form of vitamin D.

The laboratory diagnosis of vitamin D deficiency relies on measuring the levels of 25(OH)D. Measuring 1,25(OH)₂D is not recommended in clinical practice because it is not a reliable indicator of vitamin D status. 1,25(OH)₂D has a half-life of only 4 hours, whereas 25(OH)D has a half-life of about 3 weeks. In addition, vitamin 1,25(OH)₂D levels can actually increase with vitamin D deficiency, because increasing PTH levels result in increasing levels of 1,25(OH)₂D.

The 25(OH)D is a measurement of vitamin D intake and that made in the body after sun exposure. Although some laboratories may report 25(OH)D₂ and 25(OH)D₃ levels, it is the total level that is used clinically to monitor vitamin D status. PTH rises when the 25(OH)D levels are less than 30 ng/mL. Although labs may list 20 to 100 ng/mL as the reference range for 25(OH)D, most experts define a preferred level of 25(OH)D as 30 to 60 ng/mL, with deficiency defined as less than 20 ng/mL and insufficiency as 20 to 20 ng/mL. Currently, a 25(OH)D greater than 30 ng/mL is considered the preferred level for both adults and children.

BRONCHITIS

David R. McBride

Key Points

- Acute bronchitis is part of the continuum of “acute respiratory tract infection” most often caused by viruses.
- Antibiotics are not routinely recommended for the treatment of bronchitis.
- The cough of bronchitis may last up to 4 weeks.
- Beta-adrenergic agonists are not helpful unless patients have signs of bronchospasm associated with the infection.
- Acute exacerbations of chronic bronchitis with increased sputum production should be treated with antibiotics to decrease mortality.

Infections of the upper respiratory tract accounted for more than 36 million ambulatory medical visits in 2005, according to the National Ambulatory Medical Care Survey (Cherry et al., 2007). Although a large percentage of these infections are viral in origin, antibiotics are still prescribed for more than 50% of patients with *acute respiratory tract infection* (ARTI). *Acute bronchitis*, in the ARTI category, is defined as a respiratory infection in which cough is the predominant symptom and there is no evidence of pneumonia. Antibiotics are often prescribed despite limited evidence that they shorten the duration of acute bronchitis. With increasing incidence of antibiotic resistance, bronchitis allows physicians to practice “prescriptive restraint” and to provide supportive therapy. Consider using the phrase “chest cold” to help patients understand the viral and benign nature of this infection.

Chronic bronchitis is one of the manifestations of *chronic obstructive pulmonary disease* (COPD) and is defined clinically as cough and sputum production on most days for 3 months annually for 2 years. Chronic bronchitis is thought to be primarily inflammatory in origin, although infection may be associated with acute exacerbations; with increased sputum production and worsening dyspnea, antibiotics have proved effective in acute episodes. However, systemic corticosteroids are the mainstay of COPD exacerbation management.

The patient with acute bronchitis presents with cough, often productive. Patients may report clear or colored mucus in association with the presumed diagnosis of acute bronchitis. Despite what many patients believe, the color of sputum, even purulent sputum, is not predictive of bacterial infection. The cough of bronchitis can last up to 4 weeks, sometimes even longer. Typically, acute bronchitis is associated with other manifestations of infection, such as malaise and fever.

Respiratory viruses are thought to cause the majority of cases of acute bronchitis. Influenza A and B, parainfluenza, respiratory syncytial virus (RSV), coronavirus, adenovirus, and rhinovirus are common pathogens in the viral category. Clues to a specific virus may be found in the patient history; for example, RSV might be considered when there is household exposure to infected children. Influenza typically presents with sudden onset of symptoms, including fever, myalgias, cough, and sore throat.

Neuraminidase inhibitors are modestly effective in shortening the duration of influenza in ambulatory and healthy

patients (by about 1 day), if initiated in the first 48 hours of illness. The resistance patterns of influenza A and B have shifted in the last several years and may vary based on yearly viral strains. Influenza B has remained, as of 2010, sensitive to zanamivir (Relenza) and oseltamivir (Tamiflu). Currently circulating strains of influenza A, both H1N1 and H3N2, and influenza B have generally remained sensitive to both oseltamivir and zanamivir (Fiore et al., 2011). Family physicians are advised to consider restraint in the prescribing of these agents, since resistance is of great concern. Yearly influenza immunization and cough etiquette and hygiene are likely the most useful techniques for influenza management.

Studies have identified other pathogens, such as *Mycoplasma pneumoniae* and *Chlamydia pneumoniae*, in a small minority of cases of clinical acute upper respiratory illness with cough as the predominant symptom. No significant benefit has been found in treating these infections with antibiotics. An exception in the treatment of acute bronchitis-like illness with antibiotics is when confirmed or probable *Bordetella pertussis* is present. Early treatment with a macrolide antibiotic and patient isolation will likely decrease coughing paroxysms and limit spread of disease (Braman, 2006). Although common upper respiratory bacterial pathogens, such as *Moraxella (Branhamella) catarrhalis*, *Streptococcus pneumoniae*, and *Haemophilus influenzae*, may be isolated from patients with acute bronchitis, their relevance is questionable because these bacteria can be present in the respiratory tract of healthy individuals. Obtaining sputum for culture when bronchitis is the diagnosis generally is not useful.

Antibiotics may offer a modest benefit in the treatment of acute bronchitis, with many studies showing no statistical significance in the outcome of treated versus not-treated groups. Measures of function, such as duration of illness, loss of work, and limitation of activity, have not shown clinically significant improvement in those with acute bronchitis taking antibiotics. Coupled with cost and the potential for side effects, the use of antibiotics for acute bronchitis is not recommended. If a provider decides to use an antibiotic in a specific patient situation, narrow-spectrum respiratory agents are preferred, such as a first-generation macrolide or doxycycline.

Treating the symptom of cough in acute bronchitis is an important concern for patients. In adults with acute bronchitis with signs of airway obstruction, evidenced by wheezing on examination or decreased peak expiratory flow rate, beta-2 agonists may be helpful in alleviating cough. These agents are not helpful for children with acute cough or adults with cough and no evidence of airway obstruction. Side effects of tremor and an anxious feeling must be weighed against this benefit.

Patients often are primarily interested in alleviating symptoms caused by respiratory illness. Unfortunately, there is mixed evidence for the use of over-the-counter (OTC) and prescription cough medications. Dextromethorphan and codeine may be somewhat effective, although they have not been evaluated in randomized, double-blinded, placebo-controlled trials for acute bronchitis. Combination first-generation antihistamine-decongestant products may be effective for the cough associated with colds. Naproxen showed efficacy against cough in one upper respiratory model study (Sperber et al., 1992). Guaifenesin acts as an expectorant and may have some effect on cough by its mucus-thinning properties.

Chronic Bronchitis: Acute Exacerbation

Acute exacerbations of chronic bronchitis may be triggered by bacterial or viral infection or may be noninfectious. *H. influenzae* accounts for 50% of bacterial exacerbations with *S. pneumoniae* and *M. catarrhalis* causing an additional third (Moussaoui et al., 2008). For acute exacerbation of COPD associated with purulent sputum and increased shortness of breath, antibiotic therapy decreases mortality by 77% and treatment failure by 53% (Ram et al., 2009). This finding was true regardless of the antibiotic choice, although coverage for the organisms just noted seems rationale. Consideration of the frequency of beta-lactamase production within these organisms in a community is important. More recent meta-analysis shows that a shorter course, no longer than 5 days, is as effective as longer treatment with antibiotic (Moussaoui et al., 2008).

Other features of the management of acute exacerbation of chronic bronchitis include systemic corticosteroids, inhaled beta agonists and anticholinergics (e.g., ipratropium), and support for oxygenation status and ventilation. Patients with chronic bronchitis may have multiple hospital admissions and may remain colonized with both community-acquired and hospital-acquired organisms. It is advisable to reserve the use of antibiotics, unless absolutely necessary to prevent the development of resistant organisms.

KEY TREATMENT

Antibiotics for the treatment of bronchitis is not recommended because of the cost, potential for side effects, and lack of clinical benefit (Braman, 2006; Smith et al., 2009) (SOR: A).
 In the treatment of *Bordetella pertussis*, early administration of a macrolide antibiotic and patient isolation will likely decrease coughing paroxysms and limit spread of disease (Braman, 2006) (SOR: A).
 In adults with acute bronchitis with signs of airway obstruction, as evidenced by wheezing on examination or decreased peak expiratory flow rate, beta-2 agonists may be helpful in alleviating cough (Braman, 2006) (SOR: B).
 For acute exacerbation of COPD associated with purulent sputum and increased shortness of breath, treatment with antibiotics decreases mortality by 77% and treatment failure by 53% (Ram et al., 2009) (SOR: A).

PNEUMONIA

Anthony Zeimet

Key Points

- Assessment tools for pneumonia severity (e.g., CURB-65) can help determine the treatment approach.
- The therapy of pneumonia is often empiric because the infecting organism is not readily isolated in more than 50% of cases.
- Chest radiography is one of the most useful diagnostic tools in pneumonia.

Community-acquired pneumonia (CAP) is defined as an acute infection of the pulmonary parenchyma and, along with influenza, is the seventh leading cause of death in the United States. Fever, cough, sputum production, pleuritic chest

pain, and dyspnea are common symptoms of CAP. Nausea, vomiting, and diarrhea also may occur, and in elderly patients, CAP may present with mental status changes. Although its absence usually makes pneumonia less likely, fever can be absent in the elderly patient. Other physical examination findings include an elevated respiratory rate, conversational dyspnea, tachycardia, and rales. Egophony and dullness to percussion may be noted with focal consolidation. Typical laboratory findings include leukocytosis. The diagnosis of pneumonia is based on the presence of symptoms and the presence of an infiltrate on chest radiograph. If infiltrate is not present, consider obtaining a chest tomography scan (which has higher sensitivity) to rule in or rule out CAP. If negative, other diagnoses should be considered.

The most common microbiologic agent of pneumonia is often not isolated (Table 16-1). Furthermore, studies have shown that bacteriologic causes of pneumonia cannot be determined by radiographic appearance (i.e., “typical” vs. “atypical”). In the proper clinical setting, certain clinical microbes should be considered because they can affect treatment considerations and epidemiologic studies. These include *Legionella* spp., influenza A and B, and community-acquired methicillin-resistant *Staphylococcus aureus* (MRSA).

Certain diagnostic tests are performed based on clinical setting. Blood cultures are not routinely done in the outpatient setting but should always be done if the patient is being admitted to the hospital, ideally before antibiotics are given. The use of Gram stain and sputum culture remains controversial but can provide more evidence of a bacterial cause (e.g., many PMNs). If sputum cultures are being obtained, it is recommended that the physician have the patient expectorate directly into a specimen cup and have it sent immediately for processing. This can increase the yield of isolating *Streptococcus pneumoniae* among

Table 16-1 Most Common Etiologies of Community-Acquired Pneumonia

| Patient Type | Etiology |
|---------------------|--|
| Outpatient | <i>Streptococcus pneumoniae</i> <i>Mycoplasma pneumoniae</i> <i>Haemophilus influenzae</i> <i>Chlamydophila pneumoniae</i> Respiratory viruses* |
| Inpatient (non-ICU) | <i>S. pneumoniae</i> <i>M. pneumoniae</i> <i>C. pneumoniae</i> <i>H. influenzae</i> <i>Legionella</i> spp. Aspiration Respiratory viruses* |
| Inpatient (ICU) | <i>S. pneumoniae</i> <i>Staphylococcus aureus</i> <i>Legionella</i> spp. Gram-negative bacilli <i>H. influenzae</i> |

Modified from Mandell LA, Wunderink RG, Anzueto A, et al. Infectious Diseases Society–American Thoracic Society Consensus Guidelines on Management of Community-Acquired Pneumonia in Adults. *Clin Infect Dis* 2007;44:S27-S72.

ICU, Intensive care unit.

*Influenza A and B, adenovirus, respiratory syncytial virus, and parainfluenza.

other respiratory pathogens. Other tests include urine antigen tests for *S. pneumoniae*, *Legionella pneumophila* serogroup 1, and nasal swab for influenza A and B. In young children, RSV, adenovirus, and parainfluenza in addition to influenza are common causes. Nasal swab for RSV and influenza can be rapidly done, but the other causes can be determined with viral cultures, serology, enzyme-linked immunosorbent assay (ELISA), and polymerase chain reaction (PCR), although results usually are received after resolution of the acute symptoms.

Perhaps the most important decision for clinicians is to determine the location of treatment. The American Thoracic Society (ATS) and the Infectious Diseases Society of America (IDSA) recommend use of the *pneumonia severity index* (PSI), which uses 20 variables to risk-stratify the patient into five mortality classes, or the CURB-65, which measures five clinical variables in this decision making. The CURB-65 may be the easiest and most convenient to use at the site of decision making. A score of 0 or 1 indicates treatment as an outpatient; a score of 2 requires hospital admission to the general medical ward; and a score of 3 or more indicates admission to an intensive care unit (ICU) (Box 16-1).

Treatment of CAP should be targeted toward the most likely etiology (Table 16-2). Outpatient therapy for patients who have no comorbidities and have not received antibiotics within the last 3 months includes doxycycline or a macrolide antibiotic. Use of a fluoroquinolone antibiotic (levofloxacin or moxifloxacin) should be reserved for patients with more complicated pneumonia and those requiring hospitalization. Patients who have comorbid conditions or recent antibiotic exposure, or who will be hospitalized, should receive a respiratory fluoroquinolone or combination therapy with a beta-lactam drug plus a macrolide, for 48 to 72 hours after fever abates (usually 5-7 days' total therapy). If an organism is isolated, therapy may be narrowed to cover the causative agent. The clinician should consider longer therapy and appropriate antibiotics to cover for infection by less common organisms such as *Staphylococcus aureus* or *Pseudomonas aeruginosa*. If the patient has no more than one abnormal value (temperature $<37.8^{\circ}\text{C}$, heart rate <100 , respiratory rate <24 , SBP >90 , O_2 saturation $>90\%$, $\text{Po}_2 >60$ on room air) and the patient is able to maintain oral intake and has a normal mental status, the clinician can safely switch to oral therapy and discharge the patient from the hospital. Unless the etiology of the pneumonia is known, the physician should switch to oral antibiotics in the same class as the intravenous antibiotics used.

Box 16-1 CURB-65 Criteria

Assign a value of 1 for each variable:

- Confusion: Is the patient disoriented to person, place, or time?
- BUN >20 mg/dl
- Respiratory rate > 30 breaths/min
- Blood pressure: systolic <90 or diastolic <60 mm Hg
- Age >65 years

Interpretation

- Score 0 or 1: outpatient treatment
- Score 2 : inpatient treatment on a general medical floor
- Score >3 : inpatient treatment in an intensive care unit

BUN, Blood urea nitrogen.

The U.S. Preventive Services Task Force (USPSTF) along with IDSA and ATS recommend annual influenza vaccinations to those over 50 years of age, those who are (or who reside with those who are) at high risk for influenza complications, and all health care workers. Furthermore, the pneumococcal vaccine should be given to all those over age 65. Smoking cessation is also important and should be discussed at each clinic visit.

KEY TREATMENT

Locally adapted guidelines should be implemented to improve the processing of care variables and relevant clinical outcomes in pneumonia (Mandell et al., 2007) (SOR: B).

Objective criteria or scores should always be supplemented with physician determination of subjective factors, including the patient's ability to take oral medication safely and reliably and the availability of outpatient support resources (Mandell et al., 2007) (SOR: B).

For patients with CURB-65 score of 2 or higher, more intensive treatment (i.e., hospitalization or, where appropriate and available, intensive in-home health care services) is usually warranted (Mandell et al., 2007) (SOR: C).

INFLUENZA

Anthony Zeimet

Key Points

- Concerns about development of resistant seasonal and H1N1 swine-derived influenza virus should be considered in the decision to administer antiviral medications to healthy patients with these infections.
- The abrupt onset of fever with chills, headache, malaise, myalgias, arthralgias, and rigors during "flu season" is sufficient to diagnose influenza.
- Prevention of influenza is generally with vaccination.

Influenza deserves special mention because it is an important cause of pneumonitis and can precede a bacterial pneumonia. Influenza viruses are medium-sized enveloped ribonucleic acid (RNA) viruses that consist of a lipid bilayer with matrix proteins with spiked surface projections of glycoproteins (hemagglutinins, neuraminidase) on the outer surface (Figure 16-1). Both influenza A and influenza B have eight segmented pieces of single-stranded RNA. The only difference between influenza A and B is that B does not have an M2 ion channel. *Hemagglutinins*, three types of which typically infect humans (H1, H2, H3), bind to respiratory epithelial cells and allow fusion with the host cell. *Neuraminidase*, consisting of two types (N1, N2), allows release of virus from the infected cells.

A unique aspect of influenza is that antigenic variation occurs annually. Antigenic shift is caused by a genetic reassortment between animal and human influenza strains, producing a novel virus that generally causes the worldwide pandemics. Influenza viruses circulate mostly among humans, birds, and swine. Sometimes; a human strain and an animal strain can intermingle and create a new, unique virus. This is what happened during spring 2009, heralding the most recent pandemic and creating "Novel H1N1 Influenza" (swine influenza). Genotype analysis

Table 16-2 Guide to Empiric Choice of Antimicrobial Agent for Treating Patients with Community-Acquired Pneumonia (CAP)

| Patient Characteristics | Preferred Treatment Options | Patient Characteristics | Preferred Treatment Options |
|---|---|---|--|
| Outpatient | | Intensive Care Unit (ICU) | |
| Previously Healthy | | <i>Pseudomonas</i> infection is not an issue | |
| No recent antibiotic therapy | Oral-based β -lactam, macrolide,* or doxycycline | <i>Pseudomonas</i> infection is not an issue but patient has a β -lactam allergy | A β -lactam ^{††} plus either an advanced macrolide or a respiratory fluoroquinolone |
| Recent antibiotic therapy [†] | A respiratory fluoroquinolone [‡] alone, an advanced macrolide* plus high-dose amoxicillin, [§] or an advanced macrolide plus high-dose amoxicillin-clavulanate. [¶] | <i>Pseudomonas</i> infection is an issue ^{‡‡} (cystic fibrosis, impaired host defenses) | A respiratory fluoroquinolone, with or without clindamycin |
| Comorbidities (COPD, diabetes, renal failure or congestive heart failure, or malignancy) | | <i>Pseudomonas</i> infection is an issue but the patient has a β -lactam allergy. Health care-associated exposure | |
| No recent antibiotic therapy | An advanced macrolide* plus β -lactam or a respiratory fluoroquinolone | Either (1) an antipseudomonal β -lactam ^{§§} plus ciprofloxacin, or (2) an antipseudomonal agent plus an aminoglycoside ^{##} plus a respiratory fluoroquinolone or a macrolide | |
| Recent antibiotic therapy | A respiratory fluoroquinolone [‡] alone or an advanced macrolide plus a β -lactam ^{**} | Aztreonam plus aminoglycoside plus levofloxacin ^{¶¶} or other respiratory quinolone | |
| Suspected aspiration with infection | Amoxicillin-clavulanate or clindamycin | Anti- <i>Pseudomonas</i> cephalosporin, carbapenem (not ertapenem) or β -lactam/ β -lactamase inhibitor with anti- <i>Pseudomonas</i> activity plus vancomycin (for MRSA coverage) \pm quinolone or aminoglycoside | |
| Influenza with bacterial superinfection | Vancomycin, linezolid, or other coverage for MRSA or community-acquired MRSA | Nursing Home | |
| Inpatient | | Receiving treatment in nursing home | |
| Medical Ward | | Hospitalized | |
| No recent antibiotic therapy | A respiratory fluoroquinolone alone or an advanced macrolide plus a β -lactam ^{††} | A respiratory fluoroquinolone alone or vancomycin (for <i>S. aureus</i> including MRSA) plus a β -lactam (cefepime or piperacillin/tazobactam if <i>Pseudomonas</i> is suspected; ceftriaxone if <i>Pseudomonas</i> is not suspected) | |
| Recent antibiotic therapy | An advanced macrolide plus a β -lactam, or a respiratory fluoroquinolone alone (regimen selected will depend on nature of recent antibiotic therapy) | Same as for medical ward and ICU | |

Data from Mandell LA, Wunderink RG, Anzueto A, et al. Infectious Diseases Society of America/American Thoracic Society consensus guidelines of community-acquired pneumonia in adults. Clin Infect Dis. 2007;44:S27-S72.

COPD, Chronic obstructive pulmonary disease; MRSA, methicillin-resistant *Staphylococcus aureus*.

*Azithromycin or clarithromycin.

[†]That is, the patient was given a course of antibiotic(s) for treatment of any infection within the past 3 months, excluding the current episode of infection. Such treatment is a risk factor for drug-resistant *Streptococcus pneumoniae* and possibly for infection with gram-negative bacilli. Depending on the class of antibiotics recently given, one or another of the suggested options may be selected. Recent use of a fluoroquinolone should dictate selection of a nonfluoroquinolone regimen, and vice versa.

[‡]Moxifloxacin, levofloxacin, or gemifloxacin.

[§]Dosage: 1 g orally (PO) three times daily (tid).

[¶]Dosage: 2 g PO twice daily (bid).

^{**}High-dose amoxicillin (1 g tid), high-dose amoxicillin-clavulanate (2 g bid), cefpodoxime, cefprozil, or cefuroxime.

^{††}Cefotaxime, ceftriaxone, ampicillin-sulbactam, or ertapenem.

^{‡‡}The antipseudomonal agents chosen reflect this concern. Risk factors for *Pseudomonas* infection include severe structural lung disease (e.g., bronchiectasis) and recent antibiotic therapy, health care-associated exposures or stay in hospital (especially in the ICU). For patients with CAP in the ICU, coverage for *S. pneumoniae* and *Legionella* species must always be considered. Piperacillin-tazobactam, imipenem, meropenem, and cefepime are excellent β -lactams and are adequate for most *S. pneumoniae* and *H. influenzae* infections. They may be preferred when there is concern for relatively unusual CAP pathogens, such as *P. aeruginosa*, *Klebsiella* spp., and other gram-negative bacteria.

^{§§}Piperacillin, piperacillin-tazobactam, imipenem, meropenem, or cefepime.

^{##}Data suggest that older adults receiving aminoglycosides have worse outcomes.

^{¶¶}Dosage for hospitalized patients, 750 mg/day.

of this strain determined that components came from an influenza virus circulating among swine herds in North America that combined with a virus circulating among ill swine in Eurasia, creating a new influenza strain capable of causing disease in humans. Because this virus had not previously infected humans, it had the potential to cause

widespread morbidity and mortality worldwide. During pandemics, the U.S. Centers for Disease Control and Prevention (CDC) estimates an additional 10,000 to 40,000 deaths caused by influenza. Although higher than in non-pandemic years, mortality was significantly less than initially predicted in 2009.

Figure 16-1 Schematic model of influenza A virus.

(From Treanor JJ: Influenza viruses, including avian influenza and swine influenza. In Mandell GL, Bennett JE, Dolin RD (eds). *Mandell, Douglas, and Bennett's Principles and Practices of Infectious Diseases*, 7th ed. Philadelphia, Churchill Livingstone, 2010, p 2266.)

The abrupt onset of fever, along with chills, headache, malaise, myalgias, arthralgias, and rigors during “flu season,” is sufficient to diagnose influenza. As the fever resolves, a dry cough and nasal discharge predominate. A rapid nasal swab or viral cultures can be used to confirm the diagnosis of influenza but is rarely needed. In fact, the sensitivity of these rapid tests can range from 50% to 70%, so a negative test does not rule out influenza. The primary care physician needs to determine if the patient has influenza or the common cold, because symptoms of both illnesses generally overlap (Table 16-3).

Treatment of influenza is generally not necessary because it is usually a self-limiting condition. Treatment should be reserved for those with comorbidities who present within 48 hours of symptom onset. Neuraminidase inhibitors (zanamivir and oseltamivir) prevent the release of virus from the respiratory epithelium and are approved for both influenza A and influenza B. The M2 inhibitors (amantadine and rimantadine) are approved by the U.S. Food and Drug Administration (FDA) for the treatment of influenza A because these drugs block the M2 ion protein channel, preventing fusion of the virus to host cell membrane (influenza B has no M2 ion channel). The use of M2 inhibitors is limited because of increasing resistance among influenza A viruses, as well as causing central nervous system (CNS) problems that are usually exacerbated in elderly persons, who are more likely to seek treatment for influenza (Table 16-4).

The major complication of influenza is a secondary bacterial pneumonia or exacerbation of underlying COPD. Initial improvement in clinical symptoms followed by deterioration usually suggests a secondary bacterial pneumonia, which can usually be confirmed with a chest radiograph showing an infiltrate. Other, less common complications of influenza

Table 16-3 Common Cold versus Influenza Symptoms

| Symptom | Common Cold | Influenza |
|------------------|---------------------------|--------------------------|
| Fever | Rare | Abrupt onset |
| Cough | Frequent, usually hacking | Frequent, usually severe |
| Sore throat | Frequent | Rare |
| Nasal congestion | Frequent | Rare |
| Sneezing | Frequent | Rare |
| Myalgia | Rare | Frequent |
| Headache | Rare | Frequent |
| Fatigue | Mild | Severe |

include myositis, myocarditis, pericarditis, transverse myelitis, encephalitis, and Guillain-Barré syndrome.

Prevention of influenza is generally with vaccination. Box 16-2 outlines patients at risk for influenza complications who should be vaccinated yearly. Although anyone wanting an influenza vaccine should be vaccinated, during periods of vaccine shortage, high-risk groups have priority. A well-matched vaccine can prevent influenza among 70% to 90% of adults and decrease work absenteeism. Conversely, a poorly matched vaccine only prevents influenza in 50% of healthy adults. Proper hand hygiene and covering one's cough are two additional important components in preventing the spread of influenza virus.

KEY TREATMENT

Early treatment (within 48 hours of onset of symptoms) with oseltamivir or zanamivir is recommended for influenza A (Jefferson et al., 2006) (SOR: A).

Use of oseltamivir and zanamivir is not recommended for patients with uncomplicated influenza with symptoms for more than 48 hours (Kaiser and Hayden, 1999) (SOR: A).

Oseltamivir and zanamivir may be used to reduce viral shedding in hospitalized patients or to treat influenza pneumonia (Mandell et al., 2007) (SOR: C).

SYSTEMIC VIRAL INFECTIONS

Anthony Zeimet

Key Points

- Population-based vaccination programs have been highly effective in decreasing the incidence of many viral infections.
- Acyclovir can be used in adults and children with varicella to decrease symptoms if given in the first 48 hours after rash onset, but its benefit must be weighed against its cost and the possibility of development of viral resistance.
- Antiviral medications should be considered to decrease the incidence of postherpetic neuralgia, particularly in older patients.

Table 16-4 Treatment and Chemoprophylaxis Recommendations for Influenza

| Agent/ Group | Treatment | Chemoprophylaxis |
|---------------------------------------|--|--|
| Neuraminidase Inhibitors | | |
| Oseltamivir | | |
| Adults | 75-mg capsule twice daily (bid) for 5 days | 75-mg capsule once daily (qd) |
| Children (age >12 mo) | | |
| <15 kg | 60 mg/day divided into 2 doses | 30 mg qd |
| 15-23 kg | 90 mg/day in 2 doses | 45 mg qd |
| 24-40 kg | 120 mg/day in 2 doses | 60 mg qd |
| >40 kg | 160 mg/day in 2 doses | 75 mg qd |
| Zanamivir | | |
| Adults | Two 5-mg inhalations (10 mg bid) | Two 5-mg inhalations (10 mg qd) |
| Children | Two 5-mg inhalations (10 mg bid)(age >7 yr) | Two 5-mg inhalations (10 mg qd)(age >5 yr) |
| M2 Inhibitors (Adamantadines)* | | |
| Rimantadine[†] | | |
| Adults | 200 mg/day as either a single daily dose or divided into 2 doses | 200 mg/day as either a single daily dose or divided into 2 doses |
| Children | | |
| 1-9 yr | 6.6 mg/kg/day (max, 150 mg/day) divided in 2 doses | 5 mg/kg qd, not to exceed 150 mg |
| >10 yr | 200 mg/day as either a single daily dose or divided into 2 doses | 200 mg/day as either a single daily dose or divided into 2 doses |
| Amantadine | | |
| Adults | 200 mg/day as either a single daily dose or divided into 2 doses | 200 mg/day as either a single daily dose or divided into 2 doses |
| Children | | |
| 1-9 yr | 5-8 mg/kg/day divided into 2 doses or as a single daily dose (max, 150 mg/day) | 5-8 mg/kg/day divided into 2 doses or as a single daily dose (max, 150 mg/day) |
| 9-12 yr | 200 mg/day divided into 2 doses | 200 mg/day divided into 2 doses |

Modified from Harper SA, Bradley JS, Englund JA, et al. Seasonal influenza in adults and children: diagnosis, treatment, chemoprophylaxis, and institutional outbreak management. Clinical Practice Guidelines of the Infectious Diseases Society of America. Clin Infect Dis 2009;48:1003-1032.

*The adamantines should be used only when influenza A (H1N1) infection or exposure is suspected. The adamantines should not be used for infection or exposure to influenza A (H2N3) or influenza B.

[†]Rimantadine has not been approved by the U.S. Food and Drug Administration for treatment of children, although published data exist on safety and efficacy in the pediatric population.

Box 16-2 Groups at risk for Influenza Complications*

Unvaccinated infants age 12 to 24 months

Persons with asthma or other chronic pulmonary disease, such as cystic fibrosis in children or chronic obstructive pulmonary disease in adults

Patients with hemodynamically significant cardiac disease

Patients with immunosuppressive disorders or receiving immunosuppressive therapy

Patient with human immunodeficiency virus (HIV) infection

Patients with sickle cell anemia and other hemoglobinopathies

Patients with disease requiring long-term aspirin therapy (e.g., rheumatoid arthritis, Kawasaki disease)

Patients with chronic renal obstruction

Patients with cancer

Patients with chronic metabolic disease, such as diabetes mellitus

Patient with neuromuscular disorders, seizure disorders, or cognitive dysfunction that may compromise the handling of respiratory secretions

Adults older than 66 years

Residents of any age of nursing homes or other long-term care facilities

Modified from Harper SA, Bradley JS, Englund JA, et al. Seasonal influenza in adults and children: diagnosis, treatment, chemoprophylaxis, and institutional outbreak management. Clinical Practice Guidelines of the Infectious Diseases Society of America. Clin Infect Dis 2009;48:1003-1032.

*Data suggest that the highest risk of both mortality and serious morbidity (e.g., hospitalization) occurs in severely immunocompromised patients (e.g., hematopoietic stem cell transplant patients) and very elderly (>85 years) residents of nursing homes; infants under age 24 months also have high hospitalization rates but lower case-fatality rates than the other two groups.

- Measles has had a resurgence in recent years and should be suspected when a patient presents with cough, coryza, conjunctivitis, and head-to-toe rash.
- Epstein-Barr virus and cytomegalovirus infections are generally not clinically distinguishable, and their treatment is primarily supportive.

Vaccinations have dramatically decreased the incidence of a number of historically common viral infections; smallpox has been eradicated through widespread vaccination. However, recent outbreaks of measles and mumps on college campuses underscore the need to remain vigilant in administering vaccines at the population level, even though no vaccine is available for many common viruses.

Varicella and Herpes Zoster

Varicella is one of the classic viral exanthems of childhood. Before routine vaccination, having chickenpox was one of childhood's "rites of passage." The virus, a herpesvirus (human herpesvirus 3), is effectively transmitted, causing outbreaks in schools and households.

Patients with primary varicella present with fever, headache, and sore throat. Generally within 1 to 2 days of onset of symptoms, a papulovesicular rash erupts diffusely. The classic description of the chickenpox lesion is "a dewdrop on a rose petal," suggesting a central vesicle on an erythematous base. Lesions continue to appear for 5 to 7 days. All lesions going from papule to vesicle to crusted lesion takes about

2 weeks. Patients are considered to be infectious, primarily through respiratory secretions, during the 2 days before symptoms appear and until all lesions are crusted.

Treatment of varicella is generally supportive. Control of spread may be a concern in group-living environments such as schools or residence halls. Isolation of the infected patient away from those susceptible to varicella infection is standard practice. Acyclovir can be started within the first 24 hours after rash eruption to achieve an attenuation of the infectious course. In children, this means a decrease in the duration of fever by about 1 day and a decrease in the number of lesions (Swingler, 2010). In adults, acyclovir decreases rash duration and the number of lesions, although the results are less significant than for children. Adult dosing of acyclovir for varicella is 800 mg five times daily. The marginal benefit must be weighed against the possible development of resistance at a population level and the cost of the medication. Complications of varicella can include secondary infection of skin lesions, pneumonitis, encephalitis, and dehydration from vomiting and diarrhea.

Varicella is prevented primarily through administration of vaccine. The vaccine is highly effective in children, with recommended dosing at 12 to 15 months with a second dose at 4 to 6 years. Varicella is now included in a measles-mumps-rubella (MMR) vaccine, which can be given between 12 months and 12 years of age. The varicella vaccine is a live, attenuated virus and should not be given to certain immunocompromised patients. The vaccine can also be administered to exposed immunocompetent contacts, although the benefit is clearer for children than adults. Severely immunocompromised patients exposed to varicella (particularly those with advanced HIV disease) may be given high-dose acyclovir to prevent development of disease.

Herpes zoster is a reactivation of the neurotropic varicella virus, typically in a dermatomal distribution. This is more common in elderly or immunocompromised patients but can occur in healthy people as well. Patients with zoster may note generalized malaise, hyperesthesia, numbness, tingling, and pain in the skin before development of a rash. The appearance of the rash is the same as for chickenpox, although most often isolated to a unilateral dermatome. The diagnosis of herpes zoster is clinical based on the history and the classic appearance of the rash. In immunocompromised patients, however, the rash may not be dermatomally isolated. When the diagnosis is unclear, viral culture can be obtained from the base of a lesion.

Antiviral medications are likely to decrease the incidence of *postherpetic neuralgia* and are recommended, particularly in elderly patients (Wareham, 2010). Valacyclovir (1 g three times daily) or famciclovir (500 mg every 8 hours) for 7 days is likely more effective than acyclovir in achieving this result. Either drug should be started as soon after the diagnosis as possible, preferably within 48 to 72 hours of rash onset. When patients have established postherpetic neuralgia, gabapentin and tricyclic antidepressants are helpful in alleviating the pain.

The rash of zoster is infectious to the touch. Patients should be advised to keep the rash covered until all the lesions have crusted. Zoster of the trigeminal nerve can extend to the eye and warrants immediate ophthalmologic intervention.

A vaccine to prevent herpes zoster in adults was released in 2006. The zoster vaccine differs from the varicella vaccine in

that the amount of attenuated virus is 14 times higher in the zoster vaccine. The vaccine decreases the incidence of zoster by 50%. It is recommended for administration by the American Academy of Family Physicians (AAFP) to adults over age 60, regardless of prior varicella or zoster history. Although generally well tolerated, the vaccine is somewhat costly.

Measles

In 2008, more measles cases were reported than in any other year since 1997 (CDC, 2010). Measles is the “first disease” of childhood from the history of medicine. In adults, measles infection may be acquired in the face of waning immunity from remote immunization. A booster dose of MMR vaccine is recommended before college entry.

Clinically, measles presents with cough, coryza (nasal irritation and congestion), and conjunctivitis. Fever is common several days before the onset of the rash. The rash of measles typically spreads from head to toe and has an erythematous, papular appearance with a “sandpaper” feeling. Koplik’s spots are erythematous papules with a bluish center on the oral mucosa and appear early in measles. Measles is highly contagious through droplets.

Lymphopenia and neutropenia are common laboratory findings with measles infection. Complications of measles include primary infections such as pneumonia, gastroenteritis, encephalitis, and the rare subacute sclerosing panencephalitis. Secondary infections such as otitis media, pneumonia, and adenitis may also occur.

Treatment is supportive, and the implications of measles infection are primarily in the public health realm. Patients with measles should be isolated for at least 4 days after the appearance of the rash. It is important to recognize that patients are contagious for 2 days before the development of symptoms. Careful verification of immunization status for close contacts is essential.

Epstein-Barr Virus and Cytomegalovirus

Clinical *infectious mononucleosis* is a common infection in adolescents and early adults. The clinical syndrome is most often caused by Epstein-Barr virus (EBV), although cytomegalovirus (CMV) may also be the source in this clinical syndrome, which includes fever, exudative tonsillitis, adenopathy (often including posterior cervical or occipital nodes), and fatigue. EBV is transmitted in oral secretions and may be transmitted sexually as well. B cells are infected with EBV either directly or after contact with epithelial cells, resulting in diffuse lymphoid enlargement.

The diagnosis of infectious mononucleosis is made by recognizing the clinical symptoms of fever, pharyngitis, and adenopathy along with the laboratory findings of greater than 50% lymphocytes with 10% or more atypical lymphocytes (Hoagland, 1952). Also, a positive serologic test for heterophile antibody assists the family physician in the diagnosis. To differentiate EBV from CMV mononucleosis, serology (IgG and IgM) may be obtained. Results of these tests are generally not available in time to have a significant benefit clinically.

Splenic enlargement as part of this lymphoid hypertrophy can lead to splenic rupture (0.1% risk) (Dommerby

et al., 1986). Athletes with infectious mononucleosis must be managed carefully to avoid their participation in sports that could result in abdominal trauma. Other risks associated with infectious mononucleosis include upper airway obstruction, asymptomatic transaminase elevation, thrombocytopenia, and rash after the administration of ampicillin or amoxicillin. Routinely obtaining transaminase levels in patients without clinical hepatitis is of little value and can increase the overall cost of management.

Treatment of infectious mononucleosis is largely supportive. Patients should be instructed to treat fever with antipyretics, rest, and expect symptom duration of 2 to 4 weeks, although symptoms can last for several months. The use of steroids, such as prednisone, has shown limited benefit. Data suggest an initial benefit 12 hours after steroid administration, although this is lost within several days (Candy and Hotopf, 2006). Combination of steroid and an antiviral (valacyclovir) may have some positive effect on fatigue.

KEY TREATMENT

Acyclovir started within the first 24 hours after varicella rash eruption can attenuate the infectious course, decreasing duration of fever by 1 day and reducing the number of lesions (SOR: A). Administration of varicella vaccine to a susceptible child within 3 days of exposure will likely modify or prevent disease (Macartney and McIntyre, 2008) (SOR: A). Antiviral medications decrease the incidence of postherpetic neuralgia (Wareham, 2010) (SOR: B).

TUBERCULOSIS

David McCrary

Key Points

- The most common presentation of tuberculosis is pulmonary disease.
- Tuberculosis is diagnosed by acid-fast bacilli smears and cultures.
- Standard first-line agents to treat TB are isoniazid, rifampin, pyrazinamide, and ethambutol.
- High-risk patients with a positive purified protein derivative skin test or Quantiferon-TB Gold test should be treated for latent TB infection.
- The current recommendation for first-line treatment for latent TB is 9 months of oral isoniazid.

Tuberculosis skin testing should be interpreted without regard to bacille Calmette-Guérin (BCG) history, because BCG is administered in areas where TB is endemic and BCG does not provide complete protection from TB infection.

Tuberculosis (TB) is a disease that has plagued humans since antiquity, with evidence of spinal TB in neolithic and early Egyptian remains. At present, TB affects approximately one third of the world's population. TB is the world's second most common cause of death from infectious disease after human immunodeficiency virus or acquired immunodeficiency syndrome (HIV/AIDS). Tuberculosis is caused by *Mycobacterium tuberculosis*, an acid-fast bacillus. TB is acquired by inhalation of respiratory droplets. These respiratory

droplets are spread by coughing. Brief contact carries little risk for acquiring TB, and infection generally does not occur in open air; open-air sanatoriums were the cornerstone of TB treatment before antimicrobial therapy.

Epidemiology

In the United States, TB incidence rates have been on the decline since 1992, coinciding with the control of HIV-induced AIDS by antiretroviral therapy. However, TB remains prevalent in certain high-risk groups (i.e. immigrants, IV drug use, homeless persons). Most cases of TB are in people age 15 to 49 years. TB in elderly persons is generally caused by a reactivation of latent infection acquired in the remote past, whereas TB in young children indicates ongoing active transmission in the community. Infection in children is more likely to progress to active TB and disseminated disease. Persons with HIV infection have a disproportionately higher risk for acquiring TB than the general population.

Presentation

Tuberculosis is most frequently manifested clinically as pulmonary disease, but it can involve any organ. Extrapulmonary TB accounts for about 20% of disease in HIV-seronegative persons but is more common in HIV-seropositive persons. Pulmonary TB typically manifest with fever, night sweats, chronic cough, sputum production, hemoptysis, anorexia, and weight loss. Chest radiographs in patients with pulmonary TB typically reveal upper-lobe cavitory lesions and can reveal infiltrates or nodular lesions, as well as lymphadenopathy (Figure 16-2). TB in the setting of advanced HIV co-infection does not generally manifest in the typical manner (Table 16-5).

Figure 16-2 Chest radiograph showing right apical infiltrate typical of a patient with primary tuberculosis.

(From Fitzgerald D, Sterling T, Haas D. *Mycobacterium tuberculosis*. In Mandell GL, Bennett JE, Dolin R (eds). *Mandell, Douglas, and Bennett's Principles and Practice of Infectious Diseases*, 7th ed. Philadelphia, Churchill Livingstone, 2010, p 3141.)

Diagnosis

The diagnosis of pulmonary TB is made by the demonstration of acid-fast bacilli (AFB) in sputum and the growth of *M. tuberculosis* in culture. These patients typically have an abnormal chest radiograph, as previously described. *M. tuberculosis* is a slow-growing bacterium, and cultures can take up to 6 weeks to grow. A PCR assay developed for *M. tuberculosis* can be run on AFB smear–positive sputum to hasten the diagnosis of pulmonary TB. A positive PCR on AFB-positive sputum is diagnostic of pulmonary TB, but a negative test does not rule out the diagnosis.

Table 16-5 Clinical Manifestations of Active Tuberculosis in Early versus Late* Human Immunodeficiency Virus Infection

| Sign | Early | Late |
|------------------------|------------------|------------------------|
| Tuberculin test | Usually positive | Usually negative |
| Adenopathy | Unusual | Common |
| Pulmonary distribution | Upper lobe | Lower and middle lobes |
| Cavitation | Often present | Typically absent |
| Extrapulmonary disease | 10%-15% of cases | 50% of cases |

Modified from Murray JF. Cursed duet: HIV infection and tuberculosis. *Respiration* 1990;57:210-220.

*For practical purposes, "early" and "late" may be defined as CD4+ cell counts >300 cells/mm³ and <200 cells/mm³, respectively.

Treatment

Patients with AFB positive smears from sputum samples should be started on anti-TB therapy while awaiting results of PCR and cultures. The treatment of TB always uses multiple agents with anti-TB activity. Single agents should never be used. The standard first-line agents are isoniazid (INH), rifampin (RIF), pyrazinamide (PZA), and ethambutol (EMB) (Figure 16-3 and Table 16-6). If administered, INH should be given with pyridoxine (vitamin B₆; 25-50 mg orally daily) to prevent neuropathy. Treatment of active pulmonary TB is generally for 6 months regardless of HIV status, but treatment may need to be extended in certain situations.

Directly observed therapy (DOT) is the preferred mechanism of administration to ensure compliance. Many local county and state health departments have systems for DOT. Treatment of HIV-seropositive patients with TB who are receiving an antiretroviral (ARV) regimen that contains a protease inhibitor is complicated by the latter's interaction with rifamycins (particularly rifampin). Management of such patients should be coordinated with an infectious diseases specialist, who also should manage drug-resistant TB treatment.

Latent Tuberculosis Infection and Purified Protein Derivative

In the United States, latent tuberculosis infection (LTBI) is the most prevalent form of tuberculosis. LTBI is the term given to patients with a positive purified protein derivative (PPD) skin test without evidence of active TB. PPD has been used for more than 100 years and relies on delayed-type hypersensitivity (DTH) to *M. tuberculosis* cellular proteins.

Figure 16-3 Treatment algorithm for tuberculosis. Patients in whom TB is proved or strongly suspected should have treatment initiated with isoniazid, rifampin, pyrazinamide, and ethambutol for the initial 2 months. A repeat smear and culture should be performed when 2 months of treatment has been completed. If cavities were seen on the initial chest radiograph or the acid-fast smear is positive at completion of 2 months of treatment, the continuation phase of treatment should consist of isoniazid and rifampin daily or twice weekly for 4 months to complete a total of 6 months of treatment. If cavitation was present on the initial chest radiograph and the culture at completion of 2 months' therapy is positive, the continuation phase should be lengthened to 7 months (total of 9 months of treatment). If the patient has HIV infection and the CD4+ cell count is less than 100/mm³, the continuation phase should consist of daily or three-times-weekly isoniazid and rifampin. In HIV-uninfected patients having no cavitation on chest radiograph and negative acid-fast smears at completion of 2 months of treatment, the continuation phase may consist of either once-weekly isoniazid and rifampin, or daily or twice-weekly isoniazid and rifampin, to complete a total of 6 months (*bottom*). Patients receiving isoniazid and rifampin, and whose 2-month cultures are positive, should have treatment extended by an additional 3 months (total of 9 months).

*EMB may be discontinued when results of drug susceptibility testing indicate no drug resistance. †PZA may be discontinued after it has been taken for 2 months (56 doses).

‡RPT should not be used in HIV-infected patients with TB or in patients with extrapulmonary TB. Therapy should be extended to 9 months if 2-month culture is positive. AFB, Acid-fast bacilli; CXR, chest radiograph (x-ray); EMB, ethambutol; INH, isoniazid; PZA, pyrazinamide; RIF, rifampin; RPT, rifampentine.

From Centers for Disease Control and Prevention (CDC). *Treatment of tuberculosis*. American Thoracic Society, CDC, and Infectious Diseases Society of America. *MMWR* 2003;52(RR-11):1-88.

Because PPD relies on DTH, any factor that reduces the DTH affects the host response to PPD. The most common clinical example is use of corticosteroids, which blunt the DTH response and can complicate PPD interpretation. Therefore, PPD testing should not be performed while a patient is taking corticosteroids. Also, TB testing should be targeted to those with higher risk of infection and should not routinely be done in those with low risk (ATS/CDC, 2000).

The PPD can also give false-positive results in patients with previous bacille Calmette-Guérin (BCG) vaccination or with infection by other mycobacterial infections. In the United States, this may cause difficulties in testing immigrants from countries who routinely use BCG vaccination programs. However, previous BCG vaccination should not change the interpretation of the PPD or willingness to treat such individuals accordingly.

Table 16-6 Recommended Treatment Regimens for Pulmonary Tuberculosis

| Initial Phase | | | Continuation Phase | | | Rating* (Evidence) [†] | |
|--------------------------|--|---------|--------------------|---|---|---------------------------------|---------------------|
| Drugs | Interval and doses‡ (minimal duration) | Regimen | Drugs | Interval and doses‡ [§] (minimal duration) | Range of total doses (minimal duration) | HIV Positive | HIV Negative |
| Regimen 1 | | | | | | | |
| INH RIF PZA EMB | 7 days per week for 55 doses (8 wk) or 5 d/wk for 40 doses (8 wk) ^{¶¶} | 1a | INH/RIF | 7 d/wk for 126 doses (18 wk) or 5 d/wk for 90 doses (18 wk) [¶] | 182-130(26 wk) | A (I) | A (II) |
| | | 1b | INH/RIF | Twice weekly for 36 doses(18 wk) | 92-76(26 wk) | A (I) | A (II) [¶] |
| | | 1c** | INH/RPT | Once weekly for 18 doses(18 wk) | 74-58(26 wk) | B (I) | E (I) |
| Regimen 2 | | | | | | | |
| INH RIF PZA EMB | 7 days per week for 14 doses (2 wk), then twice weekly for 12 doses (6 wk) or 5 d/wk for 10 doses (2 wk), [¶] then twice weekly for 12 doses (6 wk) | 2a | INH/RIF | Twice weekly for 36 doses (18 wk) | 62-58(26 wk) | A (II) | B (II) [¶] |
| | | 2b** | INH/RPT | Once weekly for 18 doses(18 wk) | 44-40(26 wk) | B (I) | E(I) |
| Regimen 3 | | | | | | | |
| INH RIF PZA EMB | Three times weekly for 24 doses (8wk) | 3 | INH/RIF | Three times weekly for 54 doses (18wk) | 78 (26 wk) | B (I) | B(II) |
| Regimen 4 | | | | | | | |
| INH RIF EMB | 7 days per week for 56 doses (8wk) or 5d/wk for 40 doses (8wk) [¶] | 4a | INH/RIF | 7 days per week for 217 doses (31wk) or 5d/wk for 155 doses (31 wk) ^{¶¶} | 273-195(39 wk) | C (I) | C (III) |
| | | 4b | INH/RIF | Twice weekly for 62 doses (31wk) | 118-102(39 wk) | C (I) | C (III) |

From American Thoracic Society, CDC, Infectious Diseases Society of America. Treatment of tuberculosis. MMWR 2003;52:1-77.

DOT, Directly observed therapy; EMB, ethambutol, INH, isoniazid; PZA, pyrazinamide; RIF, rifampin; RPT, rifapentine.

*Definitions of evidence ratings: A, preferred; B, acceptable alternative; C, offer when A and B cannot be given; E, should never be given.

[†]Definition of evidence ratings: I, randomized clinical trial; II, data from clinical trials that were not randomized or were conducted in other populations; III, expert opinion.

[‡]When DOT is used, drugs may be given 5 days per week and the necessary number of doses adjusted accordingly. Although there are no studies that compare five with seven daily doses, extensive experience indicates this would be an effective practice.

[§]Patients with cavitation on initial chest radiograph and positive cultures on completion of 2 months of therapy should receive a 7-month (31 weeks, either 217 doses [daily] or 62 doses [twice weekly]) continuation phase.

[¶]Five-days-a-week administration is always given by DOT. Rating for 5 day per week regimens is AllI.

^{¶¶}Not recommended for HIV-infected patients with CD4+ cell counts <100 cells/ μ L.

**Options 1c and 2b should be used only in HIV-negative patients who have negative sputum smears at completion of 2 months of therapy and who do not have cavitation on initial chest radiograph. For patients started on this regimen and found to have a positive culture from the 2-month specimen, treatment should be extended an extra 3 months.

The DTH response can wane over time. To overcome this problem, nonreacting patients may undergo repeat PPD 1 week after their initial PPD. The diagnosis of LTBI is made by interpretation of a PPD and by ascertaining the patient's risk factors for progression to active TB if left untreated (Box 16-3). Interpretation of the PPD should be based on the area of induration and not the area of surrounding erythema. Persons whose PPDs have converted from negative to positive within 2 years are presumed to have been infected recently. The decision to use PPD means treating the patient for LTBI if the PPD test is positive.

Patients at increased risk for progression to active TB include those who have been recently infected (recent PPD converters); patients who are HIV seropositive; patients who have silicosis, diabetes, or chronic renal failure (including those receiving hemodialysis); solid-organ transplant recipients; patients with gastrectomy or jejunioileal bypass or head and neck cancer; injection drug users; patients with chest radiograph evidence of prior TB; and patients who weigh at least 5% less than ideal body weight. Patients taking chronic corticosteroid therapy and those who are to receive tumor necrosis factor alpha (TNF- α) blockers (e.g., infliximab) are also at risk. Patients taking corticosteroids also have higher risk of progression to active TB with larger doses and longer courses of corticosteroids.

Standard therapy for LTBI is INH, 300 mg orally daily for 9 months, regardless of HIV status. Again, INH should always be administered with pyridoxine to prevent neuropathy.

Interferon- γ Release Assays

To overcome the false-positive results and confusion of PPD testing in certain populations, newer interferon-gamma (IFN- γ) release assays such as the Quantiferon-TB Gold (QFT-G) test have been developed to detect latent *M. tuberculosis*.

Box 16-3 Criteria for Tuberculin Positivity by Risk Group

Reaction ≥ 5 mm of Induration

HIV-positive persons
Recent contacts of tuberculosis patients
Fibrotic changes on chest radiography consistent with prior tuberculosis
Patients with organ transplants and other immunosuppressed patients (receiving equivalent of ≥ 15 mg/day of prednisone for at least 1 month)

Reaction ≥ 10 mm of Induration

Recent immigrants (within 5 years) from high-prevalence countries
Injection drug users
Residents and employees of high-risk congregate settings (prisons and jails, nursing homes, hospitals and other health care facilities, residential facilities for patients with AIDS, and homeless shelters)
Children less than 4 years of age, or infants, children, and adolescents exposed to adults at high risk.

Reaction ≥ 15 mm of Induration

Person with no risk factors for tuberculosis

Modified from Centers for Disease Control and Prevention. Targeted tuberculin testing and treatment of latent tuberculosis infection. American Thoracic Society. MMWR 2000;49(RR-6):1-51.

QFT-G quantifies the release of IFN- γ from lymphocytes of the host's blood in response to three *M. tuberculosis* target antigens that are absent from BCG and most other nontuberculous *Mycobacterium* spp. The advantages of using QFT-G include one-time blood testing without the need for follow-up visit, no triggering of anamnestic responses, and possibly more specific response to *M. tuberculosis*. However, QFT-G use in immunocompromised or anergic patients is limited, with indeterminate results. Some studies also show discordant results in individuals tested with both PPD and QFT-G. In general, QFT-G may be used in all circumstances in which the PPD is used. However, whether the QFT-G is truly more specific or sensitive than the PPD in latent or active TB is yet to be determined.

KEY TREATMENT

The treatment of choice for latent TB infection is daily isoniazid (INH) for 9 months (ATS/CDC, 2000) (SOR: A). Short-course rifampin (Rifadin) plus INH (3 months) is equivalent to standard INH therapy and may increase compliance in patients with latent TB infection (Ena and Valls, 2005) (SOR: B). Although uncommon in the United States, drug-resistant TB and multidrug-resistant TB underscore the need for combination drug therapy and directly observed therapy in patients with tuberculosis (CDC, 2007) (SOR: C).

SEXUALLY TRANSMITTED INFECTIONS

David R. McBride

Key Points

- The U.S. Preventive Services Task Force recommends "high-intensity" behavioral counseling to at-risk adults and adolescents to prevent sexually transmitted infections.
- Be specific in addressing patients' sexual practices so as to provide appropriate prevention advice.
- Regular screening for *Chlamydia* infection is recommended for all sexually active women under age 24, all pregnant women under 24, and at-risk pregnant and nonpregnant women over 24.
- The presence of STIs such as gonorrhea, *Chlamydia*, and herpes increases the likelihood of HIV transmission.
- Testing for HIV should be offered on an "opt out" basis in all health care settings.
- The majority of patients with herpes simplex virus infection will not show recognizable symptoms. Screening for HSV immunity is of questionable value.
- Urine is an acceptable specimen to test for gonorrhea and *Chlamydia* in both men and women.
- The human papillomavirus vaccine is effective in reducing incidence of HPV infection, and physicians should discuss the vaccine with young women and men and their families.
- Routine screening for the mere presence of HPV is not recommended outside the context of cervical cancer screening.

The CDC estimates that 19 million new cases of *sexually transmitted infections* (STIs) occur each year. More than half are in young people age 15 to 24 years. The most important

development in the primary prevention of STIs is immunization against human papillomavirus (HPV). The vaccine can prevent infection with certain strains of HPV that cause cervical cancer and genital warts. Trials are ongoing to determine the effectiveness of daily ARV therapy in preventing transmission of HIV. Vaccination investigation is ongoing for herpes simplex, *Chlamydia trachomatis*, and HIV. This breadth of research effort holds promise for the future in the prevention of STIs.

Prevention

The USPSTF recommends “high-intensity” behavioral counseling to at-risk adults and adolescents to prevent STIs. High-intensity counseling involves multiple sessions and often is delivered to groups of patients. Unfortunately, this type of intervention has limitations in its practicality for population-based delivery. No risk of harm was discovered in the delivery of counseling for STI prevention.

Vaccination is the most important form of primary prevention of common infectious diseases. Two vaccines are currently on the market for HPV prevention—one that protects against four viral subtypes (6,11,16,18) and is licensed for use in males and females 9 to 26 years of age, and the other against two subtypes (16,18), licensed for females 10 to 25 years of age. Hepatitis B is a sexually transmitted infection, and immunization is recommended for adolescents who have not been previously inoculated. This is a requirement in many states for school entry. Hepatitis A can be transmitted by oro-anal sexual contact, and vaccination should be offered to patients who are contemplating engaging in this sexual practice.

Recommendations surrounding the use of barrier methods for STI prevention should be tailored to the sex practices of the client. For example, a percentage of women use anal sex as a method of birth control but may not consider the need for condom use with this practice. The question, “Do you regularly use condoms?” has little relevance to infection control for many sexual practices. Evidence supports the advice to use barrier methods of latex or other approved material in a manner that prevents the exchange of blood and body fluids in decreasing STIs. Condoms confer a 30% risk reduction for herpes simplex and up to an 80% risk reduction for HIV, when used correctly (Weller and Davis-Beaty, 2002; Martin et al., 2009).

The secondary prevention of STIs is achieved through direct and nonjudgmental patient assessment and screening and avoiding assumptions about patient sexual practices. Screening is a tool to prevent the inadvertent spread of infection as well as the sequelae of undetected disease. Table 16-7 summarizes USPSTF and CDC recommendations for screening of STIs.

Genital Ulcers

Infectious genital ulcers are associated with herpes simplex virus (HSV), syphilis, chancroid, lymphogranuloma venereum, and granuloma inguinale. HSV is by far the most common, affecting 50 million people in the United States. HSV-1 and HSV-2 are chronic, neurotropic viral infections that enter through epithelium and come to rest in the dorsal root ganglia. Therefore, infection leads to lifetime presence of the virus, but the clinical manifestation of this condition

Table 16-7 Recommendations for the Screening of Sexually Transmitted Infections (STIs)

| STI | Who to Screen? | Recommending Body |
|------------------|--|-------------------|
| <i>Chlamydia</i> | All sexually active women under age 24. Women over 24 at increased risk. All pregnant women under 24 and those over 24 at increased risk. Insufficient evidence for or against screening men. | USPSTF |
| Gonorrhea | All sexually active women at increased risk. Insufficient evidence for screening women not at increased risk. Insufficient evidence for or against screening men at increased risk. | USPSTF |
| Syphilis | Strongly recommended for pregnant women and all patients at increased risk. | USPSTF |
| HIV | All individuals as a routine part of health care in all settings after informing the patient. Pregnant women as standard prenatal testing. | CDC |
| Herpes | Recommendation against screening for asymptomatic individuals. | USPSTF |
| Hepatitis B | Strongly recommended for pregnant women at their first prenatal visit. | USPSTF |

Modified from US Preventive Services Task Force (USPSTF). Guide to Clinical Preventive Services, 2009. <http://www.ahrq.gov/clinic/pocketgd09/pocketgd09.pdf>; and Branson B et al. Revised recommendations for HIV testing of adults, adolescents and pregnant women in health-care settings. MMWR 2006;55(RR-14):1-17.

is variable. A small percentage of those with serologic evidence of HSV-2 (10%-25%) have had symptoms of clinical herpes infection. In addition, patients with HSV infection can shed the virus in the absence of symptoms, creating a prime opportunity for spread.

Herpes Simplex

Herpes simplex outbreak may be followed by a prodrome of malaise, fever, and regional lymphadenopathy before the appearance of grouped vesicles on an erythematous base. The vesicles are typically quickly broken and become ulcerated in appearance, with each vesicle usually less than several millimeters in size. True first-time infections tend to present more severely than secondary presentations of previously infected individuals, with a prodrome present in 80% of cases.

The lesions can be in any location around the genitals or rectum, on the proximal thighs and buttocks, inside the vagina, and in and around the mouth. The lesions are most

often painful, particularly when on mucosal surfaces, or itchy. In women, herpes simplex can present with cervicitis-like symptoms with bleeding and discharge and cervical ulcerations on examination, or simply mucopurulent cervicitis. Herpetic lesions around the urethra tend to be extremely painful and can make urination difficult. Rectal HSV can be confused with irritation, perianal fissure, and even candidiasis because of its often beefy-red appearance and itching.

Vesicles typically appear 6 days after infection and can last up to 2 weeks in an initial infection. Subsequent outbreaks tend to have a shorter duration and to be less uncomfortable for patients. Confirmation of infection is helpful, but the diagnosis can be made primarily on the clinical appearance of the exanthema. Vigorous sample collection from an ulcer (which the patient may not appreciate) to be sent for PCR identification and typing is the most readily available method of laboratory diagnosis. Serum antibody testing is not useful in the initial HSV diagnosis because antibody levels will not be appreciable early in infection. The appearance of convalescent immunoglobulin G (IgG) and IgM levels several weeks after a suspected outbreak might help to support the diagnosis of HSV infection.

The value of screening for HSV immunity is debatable and should generally not be recommended for asymptomatic individuals. In addition, the USPSTF recommends against screening asymptomatic pregnant women for HSV to prevent transmission to the newborn. Given that many patients with HSV infection never manifest symptoms, the value of knowing that one is HSV seropositive is questionable. In addition, HSV-1 and HSV-2, although classically oral and genital, respectively, can “mix and match” based on sexual practices. It is often confusing for asymptomatic individuals to know that they have HSV antibody (Do I have cold sores? Do I have genital herpes? How should this change the way I live my life?). In monogamous couples with one partner known to be HSV positive and the other with unknown status, testing of the latter may indicate suppressive therapy in the seropositive partner if the other is found to be negative.

Regular barrier method use decreases transmission of herpes in both men and women, with patients using condoms 100% of the time having a 30% reduction in HSV acquisition from those who never use condoms (Martin et al., 2009). Serodiscordant couples may also decrease transmission through antiviral suppressive therapy to the HSV-positive partner (Table 16-8).

Syphilis

Syphilis is a spirochetal infection that has resurged since 2001, the nadir year since 1996. Syphilis infection rates are highest in men who have sex with men. Syphilis is much less common than the other STIs, with an infection rate of 5.6 per 100,000 population in the United States (vs. 496 per 100,000 for *Chlamydia*).

Syphilis presents in several stages. The *primary* phase of syphilis is a painless ulcer called a *chancre* (Figure 16-4). The chancre may be visible on the genitals, although it can also be inside the vagina, mouth, or rectum, making it difficult to find. This lesion will appear within 3 weeks of transmission and will last for several weeks untreated. The *secondary* phase of infection is disseminated and involves a diffuse macular rash, typically with palm and sole lesions, generalized lymphadenopathy,

fever, and condyloma latum (smooth, moist lesions on genitals without cauliflower appearance of condyloma acuminatum). *Tertiary* syphilis is often asymptomatic but affects the heart, eyes, and auditory system and can be associated with gumma formation. *Gummas* are soft, granulomatous growths in organs that can cause mechanical obstruction and weakening of blood vessel walls. Latent infection often involves the CNS.

Diagnosis of primary syphilis is challenging. The test of choice is darkfield microscopy, which is not readily available. Direct fluorescent (monoclonal) antibody (DFA) testing may be available. Antibody tests for syphilis, such as the rapid plasma reagin (RPR) and the less frequently used Venereal

Table 16-8 Treatment Guidelines for Herpes Simplex Infection

| Drug | Initial Outbreak | Suppression | Recurrence |
|--------------|--------------------------|---------------------------------------|---|
| Acyclovir | 400 mg tid for 7-10 days | 400 mg bid | 400 mg tid for 5 days 800 mg bid for 5 days 800 mg tid for 2 days |
| Valacyclovir | 1.0 g bid for 7-10 days | 500 mg once daily 1.0 g once daily | 500 mg bid for 3 days 1.0 g once daily for 5 days |
| Famciclovir | 250 mg tid for 7-10 days | 250 mg bid | 125 mg bid for 5 days 1.0 g bid for 1 day |

tid, Three times daily; bid, twice daily.

Figure 16-4 Primary chancre of syphilis.

(From <http://www.stdptc.uc.edu/system/files/images/syphilisprimary%20chancre%20of%20glans.thumbnail.jpg>.)

Disease Research Laboratories (VDRL), are often not positive early in infection and thus cannot be used to rule out primary syphilis based on a single reading. Treponemal antigen testing (EIA) may be available in some laboratories. The fluorescent treponemal antibody absorption (FTA-ABS) test may also be negative in the early infection. Direct PCR for primary syphilis lesions has been tested but is not yet FDA approved. A physician may choose to treat presumptively if a painless chancre and risk factors are present and may then do a convalescent RPR test in 1 to 2 weeks to confirm the infection by the appearance of a positive reaction. One would expect a fourfold change in titer of either test to indicate the presence of disease.

Primary and secondary syphilis are treated with a single injection of penicillin G, 2.5 million units. Other regimens do not have proven effectiveness but can be used in the penicillin-allergic patient, including doxycycline, 100 mg twice daily for 14 days; ceftriaxone, 500 mg to 1 g intramuscularly (IM) daily for 8 to 10 days; or azithromycin, 2 g as a single oral dose, although resistance to azithromycin has been observed. Patients treated for primary syphilis should have periodic clinical follow-up and serologic testing to determine a fourfold decrease in RPR reactivity within 6 months.

Latent syphilis can be either *early*, meaning infection within the last year, or *late*, meaning infection beyond a year. Early latent syphilis is treated with a single injection of penicillin G, 2.4 million units. Syphilis of late latency or unknown duration is treated with three injections of penicillin G, 2.4 million units, in 3 consecutive weeks. For penicillin-allergic patients, doxycycline, 100 mg twice daily for 28 days, is required. Those with latent syphilis should have ophthalmic examination as well as evaluation for vascular gumma formation. Suspected neurologic involvement of latent syphilis must be evaluated with cerebrospinal fluid (CSF) examination and treatment with aqueous penicillin G, 3-4 million units intravenously (IV) every 4 hours for 10 to 14 days.

Partners of patients with newly diagnosed syphilis are at risk for infection. Partners within 90 days of a diagnosis of primary syphilis should be tested, but treated presumptively even if serologic testing is negative. For partners prior to 90 days before diagnosis, serology is generally reliable in detecting presence of infection and may guide treatment. Patients with secondary syphilis should inform partners within 6 months before diagnosis, or 12 months for those diagnosed with tertiary syphilis (Table 16-9).

Table 16-9 Diagnosis and Treatment of Syphilis

| Stage | Clinical Manifestations | Diagnosis (Sensitivity) | Treatment |
|--------------------------|--|---|--|
| Primary syphilis | Chancre | Darkfield microscopy of skin lesion (80%) Nontreponemal tests (78%-86%) Treponemal-specific tests (76%-84%) | Penicillin G benzathine, 2.4 million units IM (single dose) Alternatives in nonpregnant patients with penicillin allergy: doxycycline (Vibramycin), 100 mg PO bid for 2 weeks; tetracycline, 500 mg PO four times daily for 2 weeks; ceftriaxone (Rocephin), 1 g IM or IV once daily for 8-10 days; or azithromycin (Zithromax), 2 g PO (single dose) |
| Secondary syphilis | Skin and mucous membranes: diffuse rash, condyloma latum, other lesions Renal system: glomerulonephritis, nephrotic syndrome Liver: hepatitis CNS: headache, meningismus, cranial neuropathy, iritis, uveitis Constitutional symptoms: fever, malaise, generalized lymphadenopathy, arthralgias, weight loss, others | Darkfield microscopy of skin lesion (80%) Nontreponemal tests (100%) Treponemal-specific tests (100%) | Same treatments as for primary syphilis |
| Latent syphilis | None | Nontreponemal tests (95%-100%) Treponemal-specific tests (97%-100%) | Early latent syphilis: same treatments as for primary and secondary syphilis Late latent syphilis: penicillin G benzathine, 2.4 million units IM once weekly for 3 weeks Alternatives in nonpregnant patients with penicillin allergy: doxycycline, 100 mg PO bid for 4 weeks, or tetracycline, 500 mg PO four times daily for 4 weeks |
| Tertiary (late) syphilis | Gummatous disease, cardiovascular disease | Nontreponemal tests (71%-73%) Treponemal-specific tests (94%-96%) | Same treatment as for late latent syphilis |
| Neurosyphilis | Seizures, ataxia, aphasia, paresis, hyperreflexia, personality changes, cognitive disturbance, visual changes, hearing loss, neuropathy, loss of bowel or bladder function, others | Cerebrospinal fluid examination | Aqueous crystalline penicillin G, 3-4 million units IV q4h for 10-14 days, or penicillin G procaine, 2.4 million units IM once daily, plus probenecid, 500 mg PO four times daily, both drugs given for 10-14 days |

Data from Brown DL, Frank JE. Diagnosis and management of syphilis. *Am Fam Physician*. 2003;68:283-290.
IM, Intramuscularly; IV, intravenously; PO, orally; q4h, every 4 hours; CNS, central nervous system.

Chancroid

Chancroid may occur in regional outbreaks and presents with a painful genital ulcer and suppurative regional adenopathy. Herpes and syphilis should both be ruled out in the patient suspected of having chancroid infection. Chancroid is caused by *Haemophilus ducreyi* and there is currently no FDA approved test to directly detect this organism. Treatment with azithromycin (1 g as single dose), ceftriaxone (250 mg IM as a single dose), ciprofloxacin (500 mg twice daily for 3 days), or erythromycin (500 mg three times daily for 7 days) are all alternatives (Table 16-10). It may be necessary to perform incision and drainage on fluctuant inguinal nodes. Patients should be reexamined in 1 to 2 weeks to ensure healing of the primary ulcer(s) and resolution of the adenopathy. Partners who had contact with the infected patient starting 10 days before development of the patient's symptoms should be treated, regardless of the presence of symptoms.

Table 16-10 Treatment of Chancroid, Lymphogranuloma Venereum, and Granuloma Inguinale

| Infection | Recommended Treatment | Alternate Treatment |
|--------------------------|--|--|
| Chancroid | Azithromycin, 1 g PO × 1 or Ceftriaxone, 250 mg IM single dose or Ciprofloxacin, 500 mg bid for 3 days or Erythromycin base, 500 mg tid for 7 days | — |
| Lymphogranuloma venereum | Doxycycline, 100 mg bid for 21 days | Erythromycin base, 500 mg PO four times daily for 21 days |
| Granuloma inguinale | Doxycycline, 100 mg bid for at least 3 weeks until all lesions have completely healed | Azithromycin, 1 g PO once weekly for 3 weeks until all lesions have completely healed or Ciprofloxacin, 750 mg PO four times daily for at least 3 weeks until all lesions have completely healed or Erythromycin base, 500 mg four times daily for at least 3 weeks until all lesions have completely healed or TMP/SMX, 1 DS bid for at least 3 weeks or until all lesions have completely healed |

PO, Orally; IM, intramuscularly; bid, twice daily; tid, three times daily; qid, four times daily; TMP-SMX, trimethoprim-sulfamethoxazole; DS, double-strength tablet.

Lymphogranuloma Venereum and Granuloma Inguinale

Less common ulcerating STIs include lymphogranuloma venereum (LGV) and granuloma inguinale (Figure 16-5). LGV causes regional adenopathy and often an ulcer at the point of entry. Rectal LGV may cause a proctocolitis with anal pain, discharge, bleeding, and diarrhea. LGV is caused by *Chlamydia trachomatis* serotypes and can be detected by testing swabbed material from open lesions or aspirates from lymph nodes with culture, DFA, or nucleic acid detection. Treatment is noted above (Table 16-10). Granuloma inguinale, caused by *Klebsiella granulomatis*, is rare in the United States and causes progressive ulcerative disease of the genitals.

Urethritis and Cervicitis

A second STI category includes those causing the clinical presentation of vaginal discharge, pelvic pain, dyspareunia, and dysuria in women and penile discharge and dysuria in men, as well as possible rectal pain and discharge in men and women. Of this group, *Chlamydia trachomatis* is the most common, causing 1.2 million infections in the United States in 2008 (CDC, 2009). In fact, *Chlamydia* is the most frequently reported reportable infection.

Chlamydia trachomatis

The majority of women with *Chlamydia* infection are without symptoms. Many men are asymptomatic as well. Regular screening for *Chlamydia*, as recommended by the USPSTF, can significantly reduce the incidence of pelvic inflammatory disease (PID), one of the most serious sequelae of untreated infection. In women with untreated *Chlamydia* infection, in addition to PID, tubo-ovarian abscess, tubal scarring and ectopic pregnancy, and infertility can all result.

As previously mentioned, regular screening is currently recommended for all sexually active women under age 24, all pregnant women under 24, and at-risk pregnant and nonpregnant women over 24. *Chlamydia* testing can be performed on several liquid-based Papanicolaou (Pap) tests.

Figure 16-5 Biopsy of granuloma inguinale lesion revealing “Donovan bodies” consistent with *Klebsiella granulomatis*.

(From Mandell GL, Bennett JE, Dolin R (eds). *Mandell, Douglas, and Bennett's Principles and Practices of Infectious Diseases*, 7th ed. Philadelphia, Churchill Livingstone, 2010.)

Endocervical swabs for nucleic acid amplification are acceptable when a conventional Pap smear is being used. Given the recent liberalization of recommendations about Pap testing for women under 21 years of age, urine nucleic acid amplification is a readily available alternative for *Chlamydia* testing. This can easily be done at a contraceptive counseling clinic. Urine testing is also an acceptable method of testing for men, in addition to a urethral swab. Rectal *Chlamydia* infection can occur in individuals who practice receptive anal intercourse. An FDA-approved method of testing should be used for screening and diagnosis of this infection.

Asymptomatic *Chlamydia* infection is treated with either a single dose of azithromycin, 1 g orally, the drug of choice, or doxycycline, 100 mg twice daily, for 7 days (Table 16-11). Patient-delivered partner therapy (PDPT), the practice of dispensing treatment to diagnosed patients to treat their partner(s), has proved effective in reducing reinfection rates and further spread of infection. EPT is legally allowable in 21 states and potentially allowable in another 21.

Chlamydia infection may present symptomatically in men or women with symptoms of dysuria and with discharge and with pelvic pain and dyspareunia in women. The discharge of *C. trachomatis*, versus that of *Neisseria gonorrhoeae*, is said to be more mucoid than purulent, although this characteristic

is not specific enough to provide diagnostic accuracy. Symptomatic *Chlamydia*, without evidence of PID, is treated the same as asymptomatic infection. Many practitioners will treat presumptively for *Chlamydia* and gonorrhea in patients who present with the symptoms previously mentioned while they wait for confirmatory testing.

Neisseria gonorrhoeae

Neisseria gonorrhoeae infection may be asymptomatic in both men and women. The current USPSTF recommendation is for screening women at risk. Men with penile gonorrhea typically present with purulent penile discharge and dysuria with *N. gonorrhoeae* infection. Mucopurulent discharge, dysuria, pelvic pain, and dyspareunia are typical symptoms in women. In patients who engage in anal intercourse, anal discharge, rectal pain, and bleeding can be presenting symptoms. Gonococcal pharyngitis is within the differential of exudative pharyngitis in sexually active patients. When symptomatic, throat pain, tonsillar exudates, and anterior cervical adenopathy may be present.

Testing for gonorrhea can be done using liquid-based Pap technologies, cervical or urethral swabs, or urine for nucleic acid amplification. In men with visible discharge, a Gram stain with white blood cells (WBCs) and gram-positive intracellular diplococci has a high degree of sensitivity. Culture testing may be preferred for suspected pharyngeal and rectal specimens pending FDA approval of other methods.

Again, physicians may opt to treat patients with mucopurulent cervicitis or urethritis presumptively for gonorrhea and *Chlamydia* while waiting for confirmatory testing. Fluoroquinolone therapy is no longer recommended because of widespread resistance (Table 16-11).

Because reinfection with gonorrhea is common for several months after treatment, it may be advisable to retest patients with confirmed gonorrhea in the 3 months after treatment. Similarly, STIs may be an indicator of risk behavior, and a complete risk history and testing for other STIs is advisable if not completed at the initial visit.

Table 16-11 Treatment of Urethritis and Cervicitis

| Infection | Recommended Treatment | Alternate Treatment |
|--|---|--|
| <i>Chlamydia trachomatis</i> | Azithromycin, 1 g PO \times 1 or Doxycycline, 100 mg bid for 7 days | Erythromycin base, 500 mg PO four times daily for 7 days or Ofloxacin, 300 mg PO bid for 7 days or Levofloxacin, 500 mg PO once daily for 7 days |
| <i>Neisseria gonorrhoeae</i> : urethral, cervical, or rectal | Ceftriaxone, 125 mg IM \times 1 Treat for <i>C. trachomatis</i> concurrently if this has not been ruled out. | Cefixime, 400 mg PO single dose |
| <i>Neisseria gonorrhoeae</i> : pharynx | Ceftriaxone, 125 mg IM \times 1 or Treat for <i>C. trachomatis</i> concurrently if this has not been ruled out. | — |
| Nongonococcal urethritis | Azithromycin, 1 g PO single dose or Doxycycline, 100 mg PO bid for 7 days | Erythromycin base, 500 mg PO qid for 7 days or Ofloxacin, 300 mg PO bid for 7 days or Levofloxacin, 500 mg PO daily for 7 days |
| <i>Trichomonas vaginalis</i> | Metronidazole, 1 g PO \times 1 or Tinidazole, 2 g PO \times 1 | — |

Modified from Centers for Disease Control and Prevention. Sexually transmitted disease treatment guidelines, 2010. MMWR 2010;59(No. RR-12).

Nongonococcal Urethritis

In male patients with symptomatic urethritis, a causative agent may not be identified, a situation often referred to as nongonococcal urethritis (NGU). Technically, *Chlamydia* is included in this category. Organisms such as *Ureaplasma urealyticum* and *Mycoplasma genitalium* may be the cause and may be difficult to detect. Treatment for these infections is the same as for symptomatic *Chlamydia*, with azithromycin or doxycycline (Table 16-11). It is recommended that partners of patients with NGU should be evaluated and treated. In some cases, testing of partners may detect a specific organism as the cause of infection (e.g., *Chlamydia*).

Trichomonas vaginalis

Trichomonas vaginalis causes vaginitis in women, who may have a stereotypic frothy, green, and foul-smelling discharge. Many women are asymptomatic with trichomoniasis. In addition to causing asymptomatic infection in men, *T. vaginalis* may cause urethritis. This organism may be suspected in men when patients have repeated treatment failures and

no other explanation for symptoms. Microscopic examination of vaginal discharge is 60% to 70% sensitive in women. A first voided urine specimen or urethral swab for microscopic exam may be helpful in identifying the protozoa. Culture for *Trichomonas*, which requires a special medium, may be necessary to identify this infection accurately in men. *Trichomonas* is effectively treated with a single 2-g dose of metronidazole (Table 16-11).

For non-STI causes of vaginal discharge, see the online discussion at www.expertconsult.com.

Pelvic Inflammatory Disease

Pelvic inflammatory disease can be caused by a number of organisms, including *Chlamydia*, and presents with pelvic pain and discharge. Findings that contribute to the diagnosis of PID include fever greater than 101° F, cervical or vaginal mucopurulent discharge, abundant WBCs on saline preparation of vaginal discharge, elevated erythrocyte sedimentation rate (ESR), elevated C-reactive protein (CRP), and evidence of *N. gonorrhoeae* or *C. trachomatis* infection. Hospitalization with parenteral antibiotics may be necessary in pregnant patients, patients in whom surgical emergency cannot be ruled out, those who do not respond to oral treatment, those who cannot tolerate oral treatment, and patients who have severe illness or tubo-ovarian abscess. When treating PID parenterally, improvement of symptoms for 24 hours may prompt a change to oral therapy (Table 16-12). Conversely, if oral therapy is not producing significant improvement within 2 to 3 days, admission for parenteral therapy may be necessary.

Human Papillomavirus

Patient awareness of human papillomavirus infection has greatly increased in recent years, in large part related to the patient-directed advertising of the HPV vaccine. HPV is likely the most common STI. Thirty types of HPV can infect the genital area, some causing genital warts, some causing malignancies of the genital organs, and most being asymptomatic. The gross categories most often used are “high risk” (most often types 16 and 18) and “low risk” (types 6 and 11) HPV infection, the former more often associated with genital cancer.

Prevention of HPV infection and cervical cancer was revolutionized with the release of the HPV vaccine, which is effective in reducing the incidence of HPV-associated disease. Currently, two vaccines are licensed in the United States. Gardasil (Merck), released in 2006, includes protection against viral types 6, 11, 16, and 18. It is approved for the prevention of vulvar and vaginal cancer and for the prevention of cervical cancer, cervical dysplasia, and genital warts in females age 9 to 26. The vaccine was recently approved for males of the same age range for the prevention of genital warts. More recently, Cervarix (GlaxoSmithKline) was approved for the prevention of cervical cancer and cervical dysplasia from HPV types 16 and 18 in women age 10 to 25. Ideally, the vaccine should be administered before initiation of sexual activity to prevent initial acquisition of these HPV types. Patients who are already sexually active may also receive the vaccine.

The transmission of HPV to men decreases with consistent condom use, from 53.9% in men who never use condoms to

37.9% in men who “always” use them. Unfortunately, HPV can infect skin that is not covered by the use of traditional barrier methods (Nielson et al., 2010). Male circumcision may decrease the transmission of HPV.

Patients have many questions about HPV, in particular about screening for asymptomatic infection. HPV infection occurs with high frequency in the sexually active population; up to 50% or more of sexually active individuals have HPV at some point in their life. In addition, HPV is effectively transmitted, even if contact does not involve genital-to-genital touching (i.e., manual stimulation can transmit the virus). Again, most HPV infections are without symptoms and resolve spontaneously through eradication by the intact immune system. For all these reasons, screening for the mere presence of HPV infection has minimal utility. There is no treatment for asymptomatic HPV infection.

The most common presentation of HPV infection is in the context of an abnormal Pap smear. HPV is directly linked to cervical dysplasia. For women over age 21 and under 35, HPV testing with high-risk viral detection is common. The presence of high-risk HPV informs further management of the Pap result. It is currently recommended that women over 35 be automatically tested for high-risk HPV infection at the Pap smear.

Patients may present with visible warts, or these may be detected at routine or STI screening. Genital warts are often cosmetically unacceptable to patients, even though they are infrequently functionally problematic. In some circumstances, wart burden can be high enough to cause physical discomfort or relative obstruction of the vagina or rectum.

Table 16-12 Treatment of Pelvic Inflammatory Disease (PID)

| Route | Recommended Treatment | Alternate Treatment |
|---------------|--|--|
| Parenteral | Cefotetan, 2 g IV q12h <i>or</i> Cefoxitin 2 g IV q6h <i>plus</i> Doxycycline, 100 mg PO <i>or</i> IV q12h <i>or</i> Clindamycin, 900 mg IV q8h <i>plus</i> Gentamicin loading dose IV <i>or</i> IM (2 mg/kg) followed by maintenance dose (1.5 mg/kg) q8h; may use once-daily gentamicin dosing. | Ampicillin/sulbactam, 3 g IV q6h <i>plus</i> Doxycycline, 100 mg PO <i>or</i> IV q12h |
| Intramuscular | Ceftriaxone, 250 mg IM single dose, <i>plus</i> doxycycline, 100 mg bid for 14 days, with <i>or</i> without metronidazole, 500 mg bid for 14 days | Cefoxitin 2 g IM single dose <i>plus</i> probenecid 1 g orally concurrently administered <i>plus</i> doxycycline 100 mg bid for 14 days with <i>or</i> without metronidazole 500 mg bid for 14 days. |

Data from Centers for Disease Control and Prevention. Sexually transmitted disease treatment guidelines, 2010. MMWR 2010;59(No. RR-12).

IV, Intravenously; PO, orally; IM, intramuscularly; q6h, q8h, q12h, every 6, 8, or 12 hours; bid, twice daily.

The treatment of warts is destructive and may serve to stimulate an immune response to the HPV-infected cells, which are typically “above” the surveillance mechanisms of the immune system in the epidermis. Office methods of treatment include cryotherapy and trichloroacetic acid or podophyllin resin application. Patients may apply podofilox 0.5% solution or gel or imiquimod 5% cream (Table 16-13). For more extensive cases of warts or intra-anal or intravaginal infections that are difficult to treat using the previous methods, surgical techniques may be necessary to achieve resolution. Untreated, warts may resolve spontaneously, remain the same, or worsen.

Ectoparasites

Patients with *pediculosis pubis*, or pubic lice, most often present with pruritus or with visible nits. Pubic lice are visible on inspection of the pubic area, as are nits, which are adherent to the hair shaft. Partners of patients with pubic lice should also be treated to prevent reinfection. Linens and clothing should be laundered or dry-cleaned or kept in a closed plastic container or bag for 72 hours.

Table 16-13 Treatment of Genital Warts

| Provider applied |
|---|
| Cryotherapy Trichloroacetic acid (TCA): small amount applied until wart whitens Podophyllin resin, 10% to 25% All these may be repeated every 1 to 2 weeks until warts are resolved. |
| Patient applied |
| Podofilox 0.5% solution or gel applied twice daily for 3 days, followed by 4 days of no therapy. Imiquimod 5% cream applied once daily at bedtime three times a week for up to 16 weeks; washed off 6 to 10 hours after application. |

Table 16-14 Treatment for Ectoparasites

| Infestation | Recommended Treatment | Alternate Treatment |
|-------------------|--|--|
| Pediculosis pubis | Permethrin 1% cream applied to affected area and washed off after 10 minutes <i>or</i> Pyrethrins with piperonyl butoxide applied to affected area and washed off after 10 minutes | Malathion 0.5% lotion applied for 8-12 hours and washed off <i>or</i> Ivermectin, 250 µg/kg orally once, repeated in 2 weeks |
| Scabies | Permethrin cream 5% applied to whole body, neck to soles of feet, and washed off in 8-14 hours, <i>or</i> Ivermectin, 200 µg/kg orally once, repeated in 2 weeks | Lindane 1% applied to whole body, neck to soles of feet, and washed off in 8 hours |

Data from Workowski KA, Berman SM. Sexually transmitted disease treatment guidelines. MMWR 2006;55(RR-11).

Scabies diagnosis can be challenging. Again, patients present with itching that can be anywhere on the body, although often in the genital area or on the buttocks when infection is sexual in origin. The pruritus associated with *Sarcoptes scabiei* is a result of sensitization to the mite droppings underneath the skin as the mite burrows. The classic “burrow” or linear papular eruption is not always present. Scraping of lesions with microscopic examination may be performed to identify the mite. As with pediculosis, close contacts should be treated. Linens and clothing should be laundered or dry-cleaned or isolated in plastic containers for 72 hours. The pruritus-associated with scabies can take several weeks to resolve after treatment. Patients living in group settings (dormitories or apartments) may reinfect one another as a result of inadequate primary treatment of all contacts (Table 16-14).

KEY TREATMENT

Regular barrier method use decreases transmission of herpes simplex virus in both men and women, with patients using condoms 100% of the time having a 30% reduction in HSV acquisition compared with those who never use condoms (Martin et al., 2009) (SOR: A).
For STIs other than syphilis, expedited partner therapy, the practice of administering medication to diagnosed patients to treat their partner(s), has proved effective in reducing reinfection rates and further spread of infection (CDC, 2006) (SOR: B).
Human papillomavirus vaccine is effective in reducing the incidence of HPV infection (Sundar et al., 2010) (SOR: A).
Imiquimod 1% or 5% increases wart clearance compared with placebo in people without HIV infection (Buck, 2010) (SOR: A).
Podofilox (Condylox) is more effective than placebo at clearing genital warts after 16 weeks (SOR: A).
The most common outpatient treatment for PID is ceftriaxone (250 mg IM) plus doxycycline (100 mg) twice daily for 14 days.

GENITOURINARY INFECTIONS

William E. Roland

Key Points

- Symptomatic urinary tract infections (UTIs) should be treated.
- Uncomplicated cystitis in women can be treated safely and effectively through telephone treatment protocols.
- Asymptomatic UTIs should be treated in pregnant women and in men about to undergo urologic surgery.
- Young children with UTIs might benefit from an etiologic workup (renal ultrasound, voiding cystourethrogram) if they are:
 - Boys of any age
 - Children of any age with a febrile UTI
 - Girls younger than 3 years with first UTI (difficulty verbalizing symptoms)
 - Children with recurrent UTI who have not been imaged previously
 - First UTI in children with a family history or with renal disease, abnormal voiding, poor growth, urinary tract abnormalities, or hypertension
- Acute prostatitis is usually caused by *Escherichia coli*.

Urinary tract infection (UTI) is defined as significant bacteriuria in the presence of symptoms. UTI accounts for a significant number of emergency department visits; an estimated 20% of women experience a UTI in their lifetime. The urinary tract is normally sterile. *Uncomplicated* UTI involves the urinary bladder in a host without underlying renal or neurologic disease. The bladder mucosa is invaded, most often by enteric coliform bacteria (e.g., *E. coli*) that ascend into the bladder via the urethra. Sexual intercourse can promote this migration, and cystitis is common in otherwise healthy young women. Frequent and complete voiding has been associated with a reduction in the incidence of UTI. *Complicated* UTI occurs in the setting of underlying structural, medical, or neurologic disease.

Signs and symptoms of a UTI include dysuria, frequency, urgency, nocturia, enuresis, incontinence, urethral pain, suprapubic pain, low back pain, and hematuria. Fever is unusual. Up to 30% of patients with symptoms of cystitis have a smoldering *pyelonephritis*, especially when symptoms have been present for more than 1 week. A patient with *pyelonephritis* usually appears ill, with fever, sweating, and prostration, along with costovertebral angle (flank) tenderness in most cases. The differential diagnosis of uncomplicated UTI includes use of diuretics or caffeine, interstitial cystitis, vaginitis, pregnancy, pelvic mass, PID, and benign prostatic hypertrophy (BPH).

If a UTI is suspected, the initial test of choice is urinalysis, although with classic signs and symptoms of infection in women, this test is not always necessary. Pyuria, as indicated by a positive result on the leukocyte esterase dip test, is found in the majority of patients with UTI. The presence of urinary nitrites is fairly specific for UTI. The combination of positive leukocyte esterase and nitrites improves sensitivity. On urine microscopy, levels of pyuria as low as two to five leukocytes per high-power field (2-5 WBCs/hpf) in a centrifuged specimen are significant in the female patient with appropriate symptoms, as is the presence of bacteriuria. Urine culture and sensitivity are not needed in simple UTIs. Cultures should be done in patients with recurrent UTIs, patients with *pyelonephritis*, and pregnant patients.

Antibiotic therapy can be given in a 3-day regimen for young, sexually active women. A 7- to 10-day course of antibiotics should be used in pregnant patients and patients with complicated UTIs. All the drugs listed in Table 16-15 can be used in a 3-day or 7- to 10-day course. Clinical practice guidelines that include telephone assessment and treatment have shown a decrease in unnecessary laboratory utilization while maintaining quality of care (Saint et al., 1999). Trimethoprim-sulfamethoxazole (TMP-SMX) has been a mainstay of UTI therapy, but in some localities, resistance of *E. coli* to TMP-SMX is 20% (Mehnert-Kay, 2005).

If a urine culture is done and the organism is resistant to the drug prescribed, a change in antibiotics is indicated only if the patient is still symptomatic. For symptomatic treatment, a bladder anesthetic can be used, such as phenazopyridine (Pyridium), 200 mg three times daily for 2 days. Patients should be warned that this produces an orange tinge in tears and urine. Patients should also be instructed to increase fluid intake.

Pyelonephritis is suggested by a failure of a short course of antibiotics. Signs and symptoms of *pyelonephritis* include shaking chills and fever higher than 38.5° C (101.3° F), flank pain, malaise, urinary frequency and burning, and costover-

Table 16-15 Treatment Regimens for Acute Uncomplicated Cystitis*

Otherwise Healthy Women†

3-Day Regimens

TMP-SMX, 160/800 mg q12h
Trimethoprim, 100 mg q12h
Fluoroquinolones‡
Ciprofloxacin, 100-250 mg q12h
Ciprofloxacin XR, 500 mg qd
Gatifloxacin, 200 mg qd
Levofloxacin, 250 mg qd

5-Day to 7-Day Regimens

Nitrofurantoin monohydrate/macrocrystals, 100 mg q12h
Nitrofurantoin macrocrystals, 50-100 mg qid
Amoxicillin, 250 mg q8h or 500 mg q12h
Cephalexin, 250 mg q6h, or other cephalosporin
Consider 7-day regimen.

Pregnant Women

Amoxicillin, 250 mg q8h or 500 mg q12h
Nitrofurantoin monohydrate/macrocrystals, 100 mg q12h
Nitrofurantoin macrocrystals, 50-100 mg qid
Cephalexin, 250 mg q6h, or other cephalosporin
TMP-SMX, 160/800 mg q12h

Other Patients

Male gender, diabetes, symptoms for 7 days, recent antimicrobial use, age > 65
TMP-SMX,§ 160/800 mg q12h
Fluoroquinolones, as per 3-day regimens
Cephalexin, 250 mg q6h, or other cephalosporin
Consider 7-day regimen.

From Hooton TM, Stamm WE. Diagnosis and treatment of uncomplicated urinary tract infection. *Infect Dis North Am* 1997;11:551.

TMP-SMX, Trimethoprim-sulfamethoxazole; qd, every day; q12h, every 12 hours; q6h, every 6 hours; q8h, every 8 hours; qid, four times daily.

*Treatments listed to be prescribed before etiologic agent is known (Gram stain may help); therapy can be modified when cause is identified.

†Characteristic pathogens are *Escherichia coli* (85%-90%) and *Staphylococcus saprophyticus* (5%-15%); other organisms account for less than 5% of cases and include *Proteus mirabilis*, *Klebsiella pneumoniae*, and *Enterococcus* spp.

‡Fluoroquinolones should not be used in pregnancy.

§Although classified as pregnancy category C, TMP-SMX is widely used; however, avoid its use in the first and second trimesters.

tebral angle tenderness. The infection can produce septic shock. A patient who is unable to tolerate oral intake should be hospitalized and given empiric IV antibiotics aimed at broad-spectrum gram-negative coverage, such as third-generation cephalosporins, fluoroquinolones, or aminoglycosides, while awaiting results of blood and urine cultures. A 14-day course of antibiotic therapy (IV or PO) is recommended.

Urinary Tract Infection in Pregnancy

Although the most common bacterial infection during pregnancy, the incidence of UTI in pregnancy is similar to that reported in sexually active nonpregnant women of childbearing age. Up to 40% of pregnant women with

untreated bacteriuria in the first trimester develop acute pyelonephritis later in pregnancy. Premature births and perinatal mortality are increased in pregnancies complicated by UTI. Therefore, in pregnant women, asymptomatic bacteriuria should be actively sought and aggressively treated with at least one urinalysis, preferably toward the end of the first trimester.

Nitrofurantoin, ampicillin, and the cephalosporins have been used most extensively in pregnancy and are the regimens of choice for treating asymptomatic or minimally symptomatic UTI. TMP-SMX should be avoided in the first trimester because of possible teratogenic effects and should be avoided near term because of a possible role in the development of kernicterus. Fluoroquinolones are avoided because of possible adverse effects on fetal cartilage development. For pregnant women with overt pyelonephritis, admission to the hospital for parenteral therapy should be the standard of care; beta-lactam agents with or without aminoglycosides are the cornerstone of therapy. Prevention of UTI, including pyelonephritis, can be accomplished during pregnancy with nitrofurantoin or cephalexin taken prophylactically after coitus or at bedtime without relation to coitus. Such prophylaxis should be considered for patients who have had acute pyelonephritis during pregnancy, patients with bacteriuria during pregnancy who have had a recurrence after a course of treatment, and patients who had recurrent UTI before pregnancy that required prophylaxis.

Catheter-Associated Urinary Tract Infection

Catheter-associated UTIs are associated with increased mortality and costs. Risk factors for catheter-associated UTIs include the duration of catheterization, lack of systemic antibiotic therapy, female gender, age older than 50 years, and azotemia. To help prevent infection, urinary catheters should be avoided when possible and used only as long as needed. The catheter should be inserted with strict aseptic technique by trained persons, and a closed system should be used at all times. Treatment of catheter-associated UTI depends on the clinical circumstances. Symptomatic patients (e.g., those with fever, chills, dyspnea, and hypotension) require immediate antibiotic therapy along with removal and replacement of the urinary catheter if it has been in place for a week or longer. In an asymptomatic patient, therapy should be postponed until the catheter can be removed. Patients with long-term indwelling catheters seldom become symptomatic unless the catheter is obstructed or is eroding through the bladder mucosa. In patients who do become symptomatic, appropriate antibiotics should be administered and the catheter changed. Therapy for asymptomatic catheterized patients leads to the selection of increasingly antibiotic-resistant bacteria.

Recurrent Urinary Tract Infection

Recurrence of uncomplicated cystitis in reproductive-age women is common, and some form of preventive strategy is indicated if three or more symptomatic episodes occur in 1 year. However, risk factors specific to women with recurrent cystitis have received little study (Sen, 2008). Several antimicrobial strategies are available, but before initiating therapy, the patient should try such simple interventions as voiding

immediately after sexual intercourse and using a contraceptive method other than a diaphragm and spermicide. Ingestion of cranberry juice has been shown to be effective in decreasing bacteriuria with pyuria, but not bacteriuria alone or symptomatic UTI, in an elderly population. Cranberry juice may be effective for preventing UTI in young, otherwise healthy women.

If simple nondrug measures are ineffective, continuous or postcoital—if the infections are temporally related to intercourse—low-dose antimicrobial prophylaxis with TMP-SMX, a fluoroquinolone, or nitrofurantoin should be considered. Typically, a prophylactic regimen is initially prescribed for 6 months and then discontinued. If the infections recur, the prophylactic program can be instituted for a longer period. An alternative approach to antimicrobial prophylaxis for women with less frequent recurrences (<4 a year) is to supply TMP-SMX or a fluoroquinolone and allow the patient to self-medicate with short-course therapy at the first symptoms of infection.

A minority of patients have *relapsing* UTI, as evidenced by finding the same bacterial strain within 2 weeks after completion of antimicrobial therapy. Two factors can contribute to the pathogenesis of relapsing infection in women: (1) deep tissue infection of the kidney that is suppressed but not eradicated by a 14-day course of antibiotics and (2) structural abnormality of the urinary tract, particularly calculi. Patients with true relapsing UTIs should undergo renal ultrasound, intravenous pyelogram (IVP), or voiding cystourethrogram, and longer-term therapy should be considered.

Urinary Tract Infections in Children

Urinary tract infection is one of the most common infections of childhood. Factors predisposing to UTI include taking broad-spectrum antibiotics (e.g., amoxicillin, cephalexin), which are likely to alter gastrointestinal and periurethral flora; incomplete bladder emptying or infrequent voiding; voiding dysfunction; and constipation. UTI in young children serves as a marker for abnormalities of the urinary tract. Imaging of the urinary tract is recommended in every febrile infant or young child with a first UTI to identify children with abnormalities that predispose to renal damage. Imaging should consist of urinary tract ultrasonography to detect dilation of the renal parenchyma. Voiding cystourethrography is often ordered but does not appear to improve clinical outcomes in uncomplicated UTIs (Alper and Curry, 2005).

Prostatitis

A common complication of UTI in men is prostatitis. Bacterial prostatitis is usually caused by the same gram-negative bacilli that cause UTI in female patients; 80% or more of such infections are caused by *Escherichia coli*. The pathogenesis of this condition is poorly understood. Antibacterial substances in prostatic secretions probably protect against such infections. A National Institutes of Health (NIH) expert consensus panel has recommended classifying prostatitis into three syndromes: acute bacterial prostatitis, chronic bacterial prostatitis, and *chronic pelvic pain syndrome* (CPPS). *Acute bacterial prostatitis* is a febrile illness characterized by chills, dysuria,

urinary frequency and urgency, and pain in the perineum, back, or pelvis. The bladder outlet can be obstructed. On physical examination, the prostate is found to be enlarged, tender, and indurated. Pyuria is present, and urine cultures generally grow *E. coli* or another typical uropathogen.

Chronic bacterial prostatitis is a clinically more occult disease and may be manifested only as recurrent bacteriuria or variable low-grade fever with back or pelvic discomfort. Urinary symptoms usually relate to the reintroduction of infection into the bladder, with both pyuria and bacteriuria. A chronic prostatic focus is the most common cause of recurrent UTI in men. CPPS is the diagnosis for the large group of men who present with minimal signs on physical examination but have a variety of irritative or obstructive voiding symptoms; perineal, pelvic, or back pain; and sexual dysfunction. These men can be divided into those with and those without inflammation (defined as >10 WBCs/hpf in expressed prostatic secretions). The etiology and appropriate management in these patients, regardless of inflammatory status, is unknown.

KEY TREATMENT

Pregnant women should be screened for asymptomatic bacteriuria in the first trimester of pregnancy (Wadland and Plante, 1989) (SOR: A).

Pregnant women who have asymptomatic bacteriuria should be treated with antimicrobial therapy for 3 to 7 days (Nicolle et al., 2005) (SOR: B).

Pyuria accompanying asymptomatic bacteriuria should not be treated with antimicrobial therapy (Nicolle, 2003) (SOR: C1).

A 3-day course of TMP-SMX (Bactrim, Septra) is recommended as empiric therapy of uncomplicated UTIs in women, in regions where the rate of resistant *E. coli* is less than 20% (Warren et al., 1999) (SOR: C).

Fluoroquinolones are not recommended as first-line treatment of uncomplicated UTIs, to preserve their effectiveness for complicated UTIs (Warren et al., 1999) (SOR: C).

A randomized, placebo-controlled trial of 150 women over 12 months found that cranberry juice and cranberry extract tablets significantly decreased the number of patients having at least one symptomatic UTI per year (Stothers, 2002) (SOR: B).

TICK-BORNE INFECTIONS

William E. Roland

Key Points

- Laboratory findings in acute tick-borne infection often include a normal or low WBC count, thrombocytopenia, hyponatremia, and elevated liver enzymes.
- Doxycycline is the drug of choice for patients with RMSF.
- Appropriate antibiotic treatment should be initiated immediately with strong suspicion of ehrlichiosis.
- If left untreated, Lyme disease can progress to cognitive disorders, sleep disturbance, fatigue, and personality changes.

In the United States, more vector-borne diseases are transmitted by ticks than by any other agent. Tick-borne diseases can result from infection with pathogens that include bacteria, rickettsiae, viruses, and protozoa. Most tick-borne diseases are transmitted during the spring and summer

months when ticks are active. A knowledge of which species of tick is endemic in an area can help narrow the diagnosis (Table 16-16).

Rocky Mountain Spotted Fever

Rocky Mountain spotted fever (RMSF) is the most severe and most often reported rickettsial illness in the United States. It is caused by *Rickettsia rickettsii*, a species of bacteria that is spread to humans by ixodid (hard) ticks (Figure 16-6).

Initial signs and symptoms include sudden onset of fever, headache, and muscle pain, followed by development of rash. The disease can be difficult to diagnose in the early stage. RMSF is most common among males and children. Risk factors are frequent exposure to dogs and living near wooded areas or areas with high grass. The presentation of RMSF is nonspecific, following an incubation of about 5 to 10 days after a tick bite. Initial symptoms can include fever, nausea, vomiting, severe headache, muscle pain, and lack of appetite. Later signs and symptoms include rash, abdominal pain, joint pain, and diarrhea. The rash first appears 2 to 5 days after the onset of fever. Most often it begins as small, flat, pink, nonitchy spots on the wrists, forearms, and ankles. The characteristic red spotted rash of RMSF is usually not seen until the sixth day or later after onset of symptoms. As many as 10% to 15% of patients never develop a rash (Figure 16-7). No widely available laboratory assay provides rapid confirmation of early RMSF, although commercial PCR testing is available. Therefore, treatment decisions should be based on epidemiologic and clinical clues. Treatment should never be delayed while waiting for confirmation by laboratory results. Routine clinical laboratory findings suggestive of RMSF include normal WBC count, thrombocytopenia, hyponatremia, and elevated liver enzyme levels. Serologic assays are the most often used methods for confirming cases of RMSF.

Doxycycline is the drug of choice for patients with RMSF. Therapy is continued for at least 3 days after fever subsides and until there is unequivocal evidence of clinical improvement, generally for a minimum total course of 5 to 10 days. Tetracyclines are usually not the preferred drug for use in pregnant women. Whereas chloramphenicol is typically the preferred treatment for RMSF during pregnancy, care must be used when administering chloramphenicol late during the third trimester of pregnancy because of risks associated with gray baby syndrome.

Ehrlichiosis

Three species of *Ehrlichia* in the United States are known to cause disease in humans. *Ehrlichia chaffeensis*, the cause of human monocytic ehrlichiosis, occurs primarily in southeastern and south-central regions and is primarily transmitted by the lone star tick, *Amblyomma americanum* (Figure 16-8). Human granulocytic ehrlichiosis is caused by *Anaplasma phagocytophila* or *Anaplasma equi* and is transmitted by *Ixodes* ticks. *Ehrlichia ewingii* is the most recently recognized human pathogen, with cases reported in immunocompromised patients in Missouri, Oklahoma, and Tennessee.

After an incubation period of about 5 to 10 days following the tick bite, initial symptoms generally include fever,

Table 16-16 Features of Common Tick-Borne Diseases in the United States*

| Disease (Causative Agent) | Primary Vector(s) | Approx. Distribution | Incubation Period (Days) | Common Initial Signs and Symptoms | Common Laboratory Abnormalities | Rash | Fatality Rate (%) |
|--|--|---|--------------------------|--|--|---|-------------------|
| Rocky Mountain Spotted fever (<i>Rickettsia rickettsii</i>) | American dog tick (<i>Dermacentor variabilis</i>), Rocky Mountain wood tick (<i>D. andersoni</i>); brown dog tick (<i>Rhipicephalus sanguineus</i>) in Arizona | Widespread in United States, especially in south Atlantic and south-central states | 2 to 14 | Fever, nausea, vomiting, myalgia, anorexia, headache | Thrombocytopenia, mild hyponatremia, mildly elevated hepatic transaminase levels | Maculopapular rash ; appears about 2 to 4 days after fever onset in 50% to 80% of adults and more than 90% of children; may involve palms and soles | 5 to 10 |
| Human monocytic ehrlichiosis (<i>Ehrlichia chaffeensis</i>) | Lone star tick (<i>Amblyomma americanum</i>) | Southern, south-central, mid-Atlantic, and northern states; isolated areas of New England | 5 to 14 | Fever, headache, malaise, myalgia | Leukopenia, thrombocytopenia, elevated serum transaminase levels | Rash appears in more than 30% of adults and in about 60% of children | 2 to 3 |
| Human granulocytic anaplasmosis (<i>Anaplasma phagocytophilum</i>) | Black-legged tick (<i>Ixodes scapularis</i> and <i>I. pacificus</i>) in United States | North central and Pacific states; New England | 5 to 21 | Fever, headache, malaise, nausea, vomiting | Leukopenia, thrombocytopenia, elevated serum transaminase levels | Rare | <1 |
| <i>Ehrlichia ewingii</i> infection | Lone star tick | South Atlantic and south-central states; isolated areas of New England | 5 to 14 | Fever, headache, myalgia, nausea, vomiting | Leukopenia, thrombocytopenia, elevated serum transaminase levels | Rare | None documented |

Modified from Chapman AS, Bakken JS, Folk SM, et al. Diagnosis and management of tick-borne rickettsial diseases: Rocky Mountain spotted fever, ehrlichioses, and anaplasmosis—United States. A practical guide for physicians and other health-care and public health professionals. MMWR 2006;55(RR-4):3.

*Treatment for these diseases is the same: adults should receive 100 mg of doxycycline (Vibramycin) orally or intravenously twice a day, and children who weigh less than 100 lb (45.4 kg) should receive 2.2 mg/kg of doxycycline orally or intravenously twice a day.

**Figure 16-6** Ixodid tick**Figure 16-7** Image of a patient with Rocky Mountain spotted fever; note late rash on trunk.

(From Bratton R, Corey G. Tick-borne diseases. *Am Fam Physician* 2005;71:2323-2332.)

Figure 16-8 Lone star tick, *Amblyomma americanum*.
(From <http://www.cdc.gov/ncidod/dvbid/stari/lone-star-tick-image.htm>.)

headache, malaise, and muscle aches. Other signs and symptoms can include nausea, vomiting, diarrhea, cough, joint pains, confusion, and occasionally rash. Laboratory findings indicating ehrlichiosis include leukopenia, thrombocytopenia, and elevated liver enzymes. Ehrlichiosis can be a severe illness, especially if untreated, and as many as half of all patients require hospitalization. Laboratory confirmation of ehrlichiosis requires serologic, molecular (PCR), or culture-based methods.

Appropriate antibiotic treatment should be initiated immediately when there is a strong suspicion of ehrlichiosis on the basis of clinical and epidemiologic findings. The treatment recommendations are the same as for Rocky Mountain spotted fever. Rifampin has been used successfully in a limited number of pregnant women with documented ehrlichiosis.

Babesiosis

Babesiosis is caused by hemoprotzoan parasites of the genus *Babesia*. The white-footed deer mouse is the main reservoir in the United States, and the vector is *Ixodes* ticks. Most infections are probably asymptomatic. Manifestations of disease include fever, chills, sweating, myalgias, fatigue, hepatosplenomegaly, and hemolytic anemia. Symptoms typically occur after an incubation period of 1 to 4 weeks and can last several weeks. The disease is more severe in immunosuppressed, splenectomized, or elderly patients. Diagnosis can be made by microscopic examination of thick and thin blood smears stained with Giemsa, looking for the parasite in red blood cells (RBCs). Options for treatment include clindamycin plus quinine or atovaquone plus azithromycin.

Lyme Disease

Lyme disease is caused by the spirochetal bacterium *Borrelia burgdorferi*. *Ixodes* ticks are responsible for transmitting Lyme disease bacteria to humans. In the United States, Lyme disease

Figure 16-9 Target rash of erythema migrans in Lyme disease.
(From http://phil.cdc.gov/PHIL/Images/9875/9875_lores.jpg.)

is mostly localized to states in the northeastern, mid-Atlantic, and upper north-central regions, as well as northwestern California. Lyme disease most often manifests with a characteristic bull's-eye rash (erythema migrans) accompanied by nonspecific symptoms such as fever, malaise, fatigue, headache, muscle aches, and joint aches (Figure 16-9).

Lyme disease spirochetes disseminate from the site of the tick bite, causing multiple (secondary) erythema migrans lesions. Other manifestations of dissemination include lymphocytic meningitis, cranial neuropathy (especially facial nerve palsy), radiculoneuritis, migratory joint and muscle pains, myocarditis, and transient atrioventricular blocks of varying degree. If left untreated, the disease can progress to intermittent swelling and pain of one or a few joints (usually large weight-bearing joints such as the knee), cognitive disorders, sleep disturbance, fatigue, and personality changes. The diagnosis is based primarily on clinical findings, and it is often appropriate to treat patients with early disease solely on the basis of objective signs and a known exposure. Serologic testing may provide valuable supportive diagnostic information in patients with endemic exposure and objective clinical findings that suggest later-stage disseminated Lyme disease.

Treatment for 3 to 4 weeks with doxycycline or amoxicillin is generally effective in early disease. Cefuroxime axetil or erythromycin can be used for persons allergic to penicillin or who cannot take tetracyclines. Later disease, particularly with objective neurologic manifestations, can require treatment with intravenous ceftriaxone or penicillin for 4 weeks or more, depending on disease severity.

Tularemia

Tularemia is caused by *Francisella tularensis*, one of the most infectious pathogenic bacteria known. Most cases in the United States occur in south-central and western states. Humans can become infected through diverse environmental exposures, including bites by infected arthropods; handling infectious animal tissues or fluids; direct contact with or ingestion of contaminated food, water, or soil; and inhalation of infective aerosols. Inhaled *F. tularensis* causes pleuropneumonitis. Some exposures contaminate the eye, resulting in ocular tularemia; penetrate broken skin, result-

Figure 16-10 *Dermacentor andersoni* tick.
(From http://www.cdc.gov/ticks/images/rocky_mountain_wood_tick.jpg.)

ing in ulceroglandular or glandular disease; or cause oropharyngeal disease with cervical lymphadenitis. Untreated, bacilli inoculated into skin or mucous membranes multiply, spread to regional lymph nodes, multiply further, and then can disseminate to organs throughout the body.

The onset of tularemia is usually abrupt, with fever, headache, chills and rigors, generalized body aches, coryza, and sore throat. A dry or slightly productive cough and substernal pain or tightness often occur with or without objective signs of pneumonia. Nausea, vomiting, and diarrhea can occur. Sweats, fever, chills, progressive weakness, malaise, anorexia, and weight loss characterize continuing illness. Rapid diagnostic testing for tularemia is not widely available. Respiratory secretions and blood for culture should be collected in suspected patients and the laboratory alerted to the need for special diagnostic and safety procedures. Streptomycin (1 g IM bid for 10 days) is the drug of choice, and gentamicin is an acceptable alternative. Tetracyclines and chloramphenicol can also be used.

Colorado Tick Fever

Colorado tick fever is an acute viral infection transmitted by the bite of the *Dermacentor andersoni* tick (Figure 16-10). The disease is limited to the western United States and is most prevalent from March to September. Symptoms start about 3 to 6 days after the tick bite. Fever continues for 3 days, stops, and then recurs 1 to 3 days later for another few days. Other symptoms include excessive sweating, muscle aches, joint stiffness, headache, photophobia, nausea, vomiting, weakness, and an occasional faint rash. Routine blood tests might show a low WBC count, mildly elevated liver function, and mildly elevated creatine phosphokinase (CPK). Diagnosis is confirmed by testing blood for complement fixation immunofluorescent antibody staining to Colorado tick virus. Treatment is removal of the tick and treatment of symptoms.

Prevention of Tick-Borne Disease

Physicians should advise patients who walk or hike in tick-infested areas to tuck long pants into socks to protect the legs and wear shoes and long-sleeved shirts. Ticks show up on white or light colors better than dark colors, making them easier to remove from clothing. If attached, ticks should be

removed immediately by using a tweezers, pulling carefully and steadily. Insect repellents such as DEET, alone or in combination with permethrin, may be helpful.

KEY TREATMENT

Appropriate antibiotic therapy should be initiated immediately when there is suspicion of Rocky Mountain spotted fever, ehrlichiosis, or relapsing fever rather than waiting for laboratory confirmation (Bratton and Corey, 2005; Spach et al., 1993) (SOR: C). Treatment with doxycycline (Vibramycin) or tetracycline is recommended for RMSF, Lyme disease, ehrlichiosis, and relapsing fever (Bratton and Corey, 2005; Spach et al., 1993) (SOR: C). Recommended actions to prevent tick-borne disease include avoidance of tick-infested areas; wearing long pants and tucking the pant legs into socks; applying diethyltoluamide (DEET) insect repellents; using bed nets when camping; and carefully inspecting oneself frequently while in an at-risk area (Bratton and Corey, 2005; Spach et al., 1993) (SOR: C). Antibiotic prophylaxis is not routinely recommended for a tick bite to prevent Lyme disease, unless the risk of infection is high (Wormser et al., 2006) (SOR: B). Recommended treatment for suspected tularemia is streptomycin or gentamicin given empirically before evidence of laboratory confirmation (Bratton and Corey, 2005; Spach et al., 1993) (SOR: C).

CELLULITIS

William E. Roland

Key Points

- Most cases of cellulitis are caused by staphylococci or streptococci, but other causes should be considered by clinical situation.
- Physicians must rule out more ominous causes of skin inflammation, such as necrotizing fasciitis and pyomyositis, when considering cellulitis.
- Edema-associated cellulitis is best treated by mobilizing edema fluid.

Cellulitis is an acute, spreading inflammation of the derma and subcutaneous issue. Patients complain of tenderness, warmth, swelling, and spreading erythema. In contrast to *erysipelas*, cellulitis usually lacks sharp demarcation at the border. Factors that predispose to cellulitis include trauma, an underlying skin lesion (furuncle, ulcer), or a complication arising from a wound, ulcer, or dermatosis. Occasionally, cellulitis results from a blood-borne infection that metastasizes to the skin.

Pain and erythema usually develop within several days and are often associated with malaise, fever, and chills. The area involved is often extensive, red, hot, and swollen. Patchy involvement with skip lesions can be seen. Regional lymphadenopathy is common, and bacteremia can occur. Several clinical entities resemble cellulitis, including pyoderma gangrenosum, gout, and insect bites. Necrotizing fasciitis and gas gangrene are surgical emergencies. Given that the predominant organism involved in most cases of cellulitis is a gram-positive coccus, clinical history and morphology on physical examination usually suffice in the diagnosis and treatment of cellulitis. A history of freshwater exposure may implicate *Aeromonas hydrophila* as the causative organism; saltwater

exposure suggests *Vibrio* spp. Cellulitis in a patient with liver disease and shellfish ingestion moves *Vibrio vulnificans* to the top of the differential.

Patients with soft tissue infection should have blood drawn for laboratory testing if signs and symptoms of systemic toxicity are present (e.g., fever or hypothermia, tachycardia, hypotension). Laboratory testing should include blood culture and drug susceptibility tests; WBC count with differential; and measurement of creatinine, bicarbonate, CPK, and CRP levels. Hospitalization should be considered for patients with hypotension or an elevated creatinine level, low serum bicarbonate level, elevated CPK level (i.e., 2-3 times upper limit of normal), marked left shift, or CRP level greater than 13 mg/L (123.8 nmol/L). Gram stain with culture and culture of needle aspiration or punch biopsy specimens should be performed to determine a definitive etiology, and a surgical consult should be considered for inspection, exploration, and drainage. Findings that may signal potentially severe, deep, soft tissue infection and that may require emergent surgical evaluation include cutaneous hemorrhage, gas in the tissue, pain disproportionate to physical findings, rapid progression, skin anesthesia, skin sloughing, and violaceous bullae.

Radiologic studies may be helpful if abscess or osteomyelitis is a possibility. Ultrasonography is helpful in detecting a subcutaneous collection of fluid. Magnetic resonance imaging (MRI) is also useful in differentiating cellulitis from necrotizing fasciitis. The diagnosis of necrotizing cellulitis is by direct surgical examination or by frozen pathology sections.

Empiric antibiotics for immunocompetent patients with cellulitis should be targeted toward gram-positive cocci (Table 16-17). Broader coverage should be initiated for diabetic patients to include gram-positive aerobes, gram-negative aerobes, and anaerobes. Patients who present with severe infection or whose infection is progressing despite empiric antibiotic therapy should be treated more aggressively; the treatment strategy should be based on results of appropriate Gram stain, culture, and drug susceptibility analysis. In the case of *Staphylococcus aureus*, the physician should assume that the organism is resistant, and agents effective against MRSA, such as vancomycin, linezolid (Zyvox), or daptomycin (Cubicin), should be used.

The antibiotic may be switched from an intravenous drug to an oral drug when fever has subsided and the skin lesion begins to resolve, usually in 3 to 5 days. The total duration of therapy should be 7 to 14 days. Longer duration may be required if the response is slow or is associated with abscess, tissue necrosis, or underlying skin processes (infected ulcers or wounds). Treatment of cellulitis should include elevation and immobilization to decrease swelling. Patients with interdigital dermatophytic infections should be treated with a concomitant topical antifungal applied once or twice daily. Topical antifungals can also help reduce the risk of recurrence of the cellulitis. Support stockings, good skin hygiene, and prompt treatment of tinea pedis helps with prevention of cellulitis in patients with peripheral edema, who are predisposed to recurrence. In patients who continue to have frequent episodes of cellulitis or erysipelas, prophylactic treatment with penicillin V, 250 mg or 500 mg orally twice daily, or erythromycin, 250 mg once or twice daily (for penicillin-allergic patients), may be indicated.

KEY TREATMENT

Penicillin, given parenterally or orally depending on clinical severity, is the treatment of choice for erysipelas (Stevens et al., 2005) (SOR: A). For cellulitis, a penicillinase-resistant semisynthetic penicillin (amoxicillin/clavulanate) or a first-generation cephalosporin should be selected, unless streptococci or staphylococci resistant to these agents are common in the community (Stevens et al., 2005) (SOR: A). For suspected MRSA skin infections, oral treatment options include trimethoprim-sulfamethoxazole, clindamycin, and doxycycline (Stevens et al., 2005) (SOR: C).

FURUNCLES AND CARBUNCLES

David R. McBride

KEY POINTS

- The majority of furuncles and carbuncles are caused by *Staphylococcus* spp., increasingly, community-acquired methicillin-resistant *S. aureus*.
- Drainage of pus is of primary importance in treating skin and soft tissue infections.
- Culture of SSTIs is important in guiding antibiotic treatment when initial measures of drainage are not effective.
- For recurrent boils, consider referral to infectious disease specialist, possibly to eradicate carriage state.

Furuncles, or boils, are infections of the skin and soft tissue usually associated with a hair follicle. *Carbuncles* are an extension of this skin and soft tissue infection continuum and involve more of the surrounding and subcutaneous tissue. The broad category *skin and soft tissue infections* (SSTIs) is used to describe this continuum that includes furuncles and carbuncles. SSTIs are common in both healthy and immunocompromised patients and likely initiate with some breach of the skin integrity, such as irritation of hair follicles from friction or microscopic trauma to the skin.

Up to 74% of furuncles and carbuncles are caused by community-acquired methicillin-resistant *Staphylococcus aureus* (CA-MRSA) (CDC, 2010). Other potential causative organisms include nonresistant *Staphylococcus* spp. and *Streptococcus* spp. It has become increasingly important to obtain culture of a lesion to direct antibiotic coverage given the increase in CA-MRSA.

There is no reliable historical or examination element that will distinguish a CA-MRSA from a methicillin-sensitive staphylococcal skin lesion. Stereotypically, patients report CA-MRSA lesions starting like a spider bite. Furuncles and carbuncles can occur anywhere on the body, although the axillae, groin, and buttocks are particularly common sites. In addition, practices that cause skin trauma (e.g., shaving, waxing) are often noted in patients with these SSTIs. Fever and malaise are uncommon with milder lesions but become more frequent with the increasing scope of localized infection.

Of primary importance in the management of carbuncles and furuncles is facilitation of drainage of any purulent material. With smaller lesions, this may be accomplished by heat application by the patient at home. As lesions increase in size and fluctuance, surgical drainage is essential to facilitate resolution of an SSTI. It is important to consider culture

Table 16-17 Antimicrobial Therapy for Impetigo and for Skin and Soft Tissue Infections (SSTIs)

| Dosage | | | |
|-----------------------------|--|--|--|
| Antibiotic | Adults | Children* | Comments |
| Impetigo[†] | | | |
| Dicloxacillin | 250 mg qid PO | 12 mg/kg/day in 4 divided doses PO | — |
| Cephalexin | 250 mg qid PO | 25 mg/kg/day in 4 divided doses PO | — |
| Erythromycin | 250 mg qid PO‡ | 40 mg/kg/day in 4 divided doses PO | Some strains of <i>Staphylococcus aureus</i> and <i>Streptococcus pyogenes</i> may be resistant. |
| Clindamycin | 300-400 mg tid PO | 10-20 mg/kg/day in 3 divided doses PO | — |
| Amoxicillin/ clavulanate | 975/125 mg bid PO | 25 mg/kg/day of amoxicillin component in 2 divided doses PO | — |
| Mupirocin ointment | Apply to lesions tid. | Apply to lesions tid. | For patients with limited lesions |
| MSSA SSTIs | | | |
| Nafcillin or oxacillin | 1-2 g q4h IV | 100-150 mg/kg/day in 4 divided dose | Parenteral drug of choice; inactive against MRSA |
| Cefazolin | 1 g q8h IV | 50 mg/kg/day in 3 divided doses | For penicillin-allergic patients, except those with immediate hypersensitivity reactions |
| Clindamycin | 600 mg/kg q8h IV or 300-450 mg tid PO | 25-40 mg/kg/day in 3 divided doses IV or 10-20 mg/kg/day in 3 divided doses PO | Bacteriostatic; potential for cross-resistance and emergence of resistance in erythromycin-resistant strains; inducible resistance in MRSA |
| Dicloxacillin | 500 mg qid PO | 25 mg/kg/day in 4 divided doses PO | Oral agent of choice for methicillin-susceptible strains |
| Cephalexin | 500 mg qid PO | 25 mg/kg/day in 4 divided doses PO | For penicillin-allergic patients, except those with immediate hypersensitivity reactions |
| Doxycycline, minocycline | 100 mg bid PO | Not recommended for children <8 yr | Bacteriostatic; limited clinical experience |
| TMP-SMZ | 1 or 2 double-strength tablets bid PO | 9-12 mg/kg (based on TMP component) in either 4 divided doses IV or 2 divided doses PO | Bacteriostatic; efficacy poorly documented |
| MRSA SSTIs | | | |
| Vancomycin | 30 mg/kg/day in 2 divided doses IV | 40 mg/kg/day in 4 divided doses IV | For penicillin-allergic patients; parenteral drug of choice for MRSA infections |
| Linezolid | 600 mg q12h IV or 600 mg bid PO | 10 mg/kg q12h IV or PO | Bacteriostatic; limited clinical experience; no cross-resistance with other antibiotic classes; expensive; may replace other second-line agents as preferred oral drug for MRSA infections |
| Clindamycin | 600 mg/kg q8h IV or 300-450 mg tid PO | 25-40 mg/kg/day in 2 divided doses IV or 10-20 mg/kg/day in 3 divided doses PO | Bacteriostatic; potential for cross-resistance and emergence of resistance in erythromycin-resistant strains; inducible resistance in MRSA |
| Daptomycin | 4 mg/kg every 24 hours IV | Not applicable | Bactericidal; possible myopathy |
| Doxycycline, minocycline | 100 mg bid PO | Not recommended for children <8 yr | Bacteriostatic; limited clinical experience |
| TMP-SMZ | 1 or 2 double-strength tablets bid PO | 9-12 mg/kg (based on TMP component) in either 4 divided doses IV or 2 divided doses PO | Bactericidal; limited efficacy data |

Modified from Stevens D et al. Practice guidelines for the diagnosis and management of skin and soft-tissue infections. Clin Infect Dis 2005;41:1373-1406.

MSSA, Methicillin-susceptible *Staphylococcus aureus*; MRSA, methicillin-resistant *S. aureus*; TMP-SMZ, trimethoprim-sulfamethoxazole; PO, orally; IV, intravenously; qid, four times daily; tid, three times daily; bid, twice daily; q4h, every 4 hours; q8h, every 8 hours; q12h, every 12 hours.

*Doses listed not appropriate for neonates.

[†]Infection caused by *Staphylococcus* and *Streptococcus* spp. Duration of therapy is about 7 days, depending on clinical response.

‡Adult dosage of erythromycin ethylsuccinate is 400 mg qid PO.

of purulent material when performing incision and drainage in the event that the patient fails to improve and antibiotic coverage becomes necessary. Cure rates of lesions with drainage alone exceed 90%. Careful follow-up after drainage is essential to ensure clinical improvement; daily dressing changes in the office after surgical drainage is effective. The addition of postdrainage antibiotics has not shown much added benefit.

To prevent the spread of infection to others who come into contact with the patient recovering from an SSTI, an occlusive dressing to prevent leakage of lesion fluid and careful hygiene are indicated. There is no evidence that extensive cleaning of common spaces (e.g., locker rooms) prevents the spread of SSTI-causing bacteria more than routine cleaning measures. Towels and soiled clothing should be laundered in hot water, and any common equipment should be cleaned per manufacturer recommendations.

When lesions do not respond to heat, or when lesions are larger yet not amenable to drainage, antibiotics may be used. Reasonable first-line antibiotic coverage for non-fluctuant lesions may include dicloxacillin, first- or second-generation cephalosporins, macrolides, or clindamycin. In patients with suspected CA-MRSA, better choices include TMP-SMX, tetracycline, or clindamycin. It is important to note that up to 50% of CA-MRSA species will be resistant to clindamycin, particularly if the patient has been treated with other antibiotics in the previous weeks to months (Stevens et al., 2005). Oral administration of these antibiotics is acceptable in the nontoxic patient. Patient signs and symptoms that would warrant hospital admission include fever or hypothermia, tachycardia, or hypotension as signs of sepsis and lesions greater than 5 cm in size (Table 16-18).

For patients with recurrent SSTIs, evaluation for the presence of nasal carriage with a nasal culture is indicated. The value of eradication of bacterial carriage is unclear. Referral for infectious disease specialist evaluation may be indicated to guide decision making in the patient with recurrent furuncles and carbuncles.

KEY TREATMENT

Cure rates of fluctuant skin lesions with drainage alone is over 90%. Postdrainage antibiotics do not significantly improve outcomes (Stevens et al., 2005; Rajendran et al., 2007) (SOR: A). Trimethoprim-sulfamethoxazole (TMP-SMX), clindamycin, and tetracycline are first-choice antibiotics when CA-MRSA is suspected. Up to 50% of CA-MRSA species will be resistant to clindamycin, particularly in the patient previously treated with other antibiotics (Stevens et al., 2005) (SOR: C).

DIABETIC ULCERS

William E. Roland

Key Points

- The existence, severity, and extent of infection, as well as vascular status, neuropathy, and glycemic control, should be assessed in patients with a diabetic foot infection.

Table 16-18 Proposed Strategy for Management of Patients with Skin and Soft Tissue Infection (SSTI)

| Class | Patient Criteria | Management | Antibiotic |
|-------|---|---|--|
| 1 | Afebrile and healthy, other than cellulitis | Treat with common first-line antibiotics for SSTI if no drainable abscess. Surgical drainage with or without antibiotics. | Semisynthetic penicillin, Oral 1st/2nd-generation cephalosporin, macrolide, or clindamycin |
| 2 | Febrile and ill appearing, but no unstable comorbidities; lesion <5 cm | Surgical drainage of abscess if possible. Treat presumptively for MRSA and monitor closely for response. Inpatient management may be indicated. | Trimethoprim-sulfamethoxazole (TMP-SMX), tetracycline (TTC), or clindamycin |
| 3 | Toxic appearance or at least one unstable comorbidity or a limb-threatening infection | Hospital admission with broad-spectrum antibiotics with MRSA coverage; infectious disease (ID) consultation. | Broad-spectrum coverage, including vancomycin |
| 4 | Sepsis syndrome or life-threatening infection (necrotizing fasciitis) | Same as above, plus aggressive surgical debridement. | Same as above, with ID specialist guidance |

Modified from McBride D. CA-MRSA lesions: what works, what doesn't. *J Fam Pract* 2008;57:588-592.

- Visible bone and palpable bone on probing suggest underlying osteomyelitis in patients with a diabetic foot infection.
- Before an infected wound of a diabetic foot infection is cultured, any overlying necrotic debris should be removed to eliminate surface contamination and to provide more accurate results.

Patients with diabetes are prone to skin ulcers caused by neuropathy, vascular insufficiency, and diminished neutrophil function. Minor wounds can be secondarily infected, leading to ulcer formation. These ulcers often have extensive undermining with necrotic tissues and are often close to the anus, thus promoting an environment suitable for multiple species of microorganisms, including anaerobes. Diabetic foot infections range in severity from superficial paronychia to deep infection involving bone. Non-limb-threatening infections involve superficial ulcers with minimal cellulitis (<2 cm from portal of entry), no signs of systemic toxicity, and no significant ischemia in the limb.

Common causes of infections are aerobic gram-positive bacteria, particularly *Staphylococcus aureus* and beta-hemolytic streptococci. Limb-threatening infections have extensive cellulitis, lymphangitis, ulcers extending to the

subcutaneous tissues, and prominent ischemia. Infection in patients who have recently received antibiotics or who have deep, limb-threatening infection or chronic wounds are usually caused by a mixture of aerobic gram-positive, aerobic gram-negative (e.g., *Escherichia coli*, *Proteus* spp., *Klebsiella* spp.), and anaerobic organisms (e.g., *Bacteroides*, *Clostridium*, *Peptococcus*, and *Peptostreptococcus* spp.). Surgery is necessary to unroof encrusted areas, and the wounds need to be examined and probed to determine the extent of the infection and check for bone involvement (Dinh et al., 2008). Debridement or drainage should be promptly performed. Deep wound cultures should be obtained if possible. If deep culture is not feasible, Gram stain and culture from the curettage of the base of the ulcer or from purulent exudates may be needed to guide antibiotic therapy (Figure 16-11).

Plain radiography of the foot is indicated for detection of osteomyelitis, foreign bodies, and soft tissue gas. When plain radiography is negative but osteomyelitis is clinically suspected, radionuclide scan or MRI should be performed. MRI provides more accurate information regarding the extent of the infectious process. The presence of peripheral artery disease and neuropathy should be assessed.

The antibiotic regimen should be based on meaningful bacteriologic data. However, the initial regimen for a previously untreated patient with non-limb-threatening infection should focus on *S. aureus* and streptococci. Mild infections may be treated with dicloxacillin or cephalexin for 2 weeks. Amoxicillin/clavulanate may be used if polymicrobial infection is suspected. If MSRA is suspected, oral treatment options include TMP-SMX or doxycycline. For limb-threatening infections, broad-spectrum antibiotics are recommended for coverage of group B streptococci, other streptococci, Enterobacteriaceae, anaerobic gram-positive cocci, and *Bacteroides* spp. Treatment regimens include ampicillin-sulbactam or ertapenem (Invanz), clindamycin plus a third-generation cephalosporin, and clindamycin plus ciprofloxacin. Intravenous vancomycin should be added if MRSA infection is suspected. Ciprofloxacin as a single agent is not recommended.

In addition to antibiotic treatment, good glycemic control should be obtained and open wounds gently packed with sterile gauze moistened with ¼-strength povidone-iodine (Betadine) solution. Edema should be reduced by bed rest, elevation, and diuretic therapy as indicated. For prevention of diabetic foot ulcers, all patients with diabetes should have an annual foot examination that includes assessment for anatomic deformities, skin breaks, nail disorders, loss of protection sensation, diminished arterial supply, and inappropriate footwear.

KEY TREATMENT

Routine wound swabs and cultures of material from sinus tracts are unreliable and strongly discouraged in the management of diabetic foot infection (Pellizzer et al., 2001; Senneville et al., 2006) (SOR: B).

The empiric antibiotic regimen for diabetic foot infection should always include an agent active against *Staphylococcus aureus*, including MRSA if necessary, and streptococci (Abdulrazak et al., 2005; Lipsky et al., 2004). (SOR: A)

BITE INFECTIONS

David McCrary

Key Points

- The use of prophylactic antibiotics may be necessary in the initial management of bite wounds, particularly if the bite is on the hand or face or from a cat.
- First-generation cephalosporins (e.g., cephalexin) are not effective as monotherapy for bite wounds because of resistance issues.
- Avoid primary wound closure in the management of bite wounds.

It is estimated that bites account for 800,000 medical visits annually in the United States, making up 1% of emergency department visits. Bite wounds consist of lacerations, evulsions, punctures, and scratches. The microbiology of bite wounds is generally polymicrobial, with an array of potential bacteria from the environment, the victim's skin flora, and the biter's oral flora.

Animal Bites

Dog bites account for approximately 80% of all animal bites requiring medical attention, in which 85% are provoked attacks. Most dog bites occur on the distal extremities, but children tend to sustain facial bites. Patients who present for medical attention are often concerned about the care of disfiguring wounds or the need for appropriate vaccination (i.e., tetanus, rabies). However, up to 30% of medically treated wounds may become infected. These wounds are often contaminated with multiple strains of aerobic and anaerobic bacteria. Local signs of infection with erythema, edema, pain, and purulent drainage are common with animal bite wounds.

Although the most frequently isolated pathogen related to dog and cat bite wounds is *Pasteurella multocida*, the array of potential organisms is much greater. Anaerobes such as *Bacteroides tectum*, *Prevotella* spp., fusobacteria, and peptostreptococci can be isolated from animal bite wounds 75% of the time, mostly from wounds with abscess formation. *Capnocytophaga canimorsus* has also been associated with fatal infection from fulminant sepsis in asplenic patients. Wounds inflicted by cats are often scratches or tiny punctures located on the extremity and are likely to become infected and lead to abscess formation.

In the United States, venomous snakes bite approximately 8000 people yearly. Envenomation in such snakebites account for the majority of morbidity and mortality associated with such bites. However, infection of soft tissue structures may also occur as a result of oral flora from the snake, which tends to be fecal in nature because live prey usually defecate in the snake's mouth with their ingestion.

Human Bites

Human bites are not uncommon, especially in children. Human bites have a higher complication and infection rate than do animal bites. Human bite wounds most often affect the hand and fingers and in some cases may present as "love

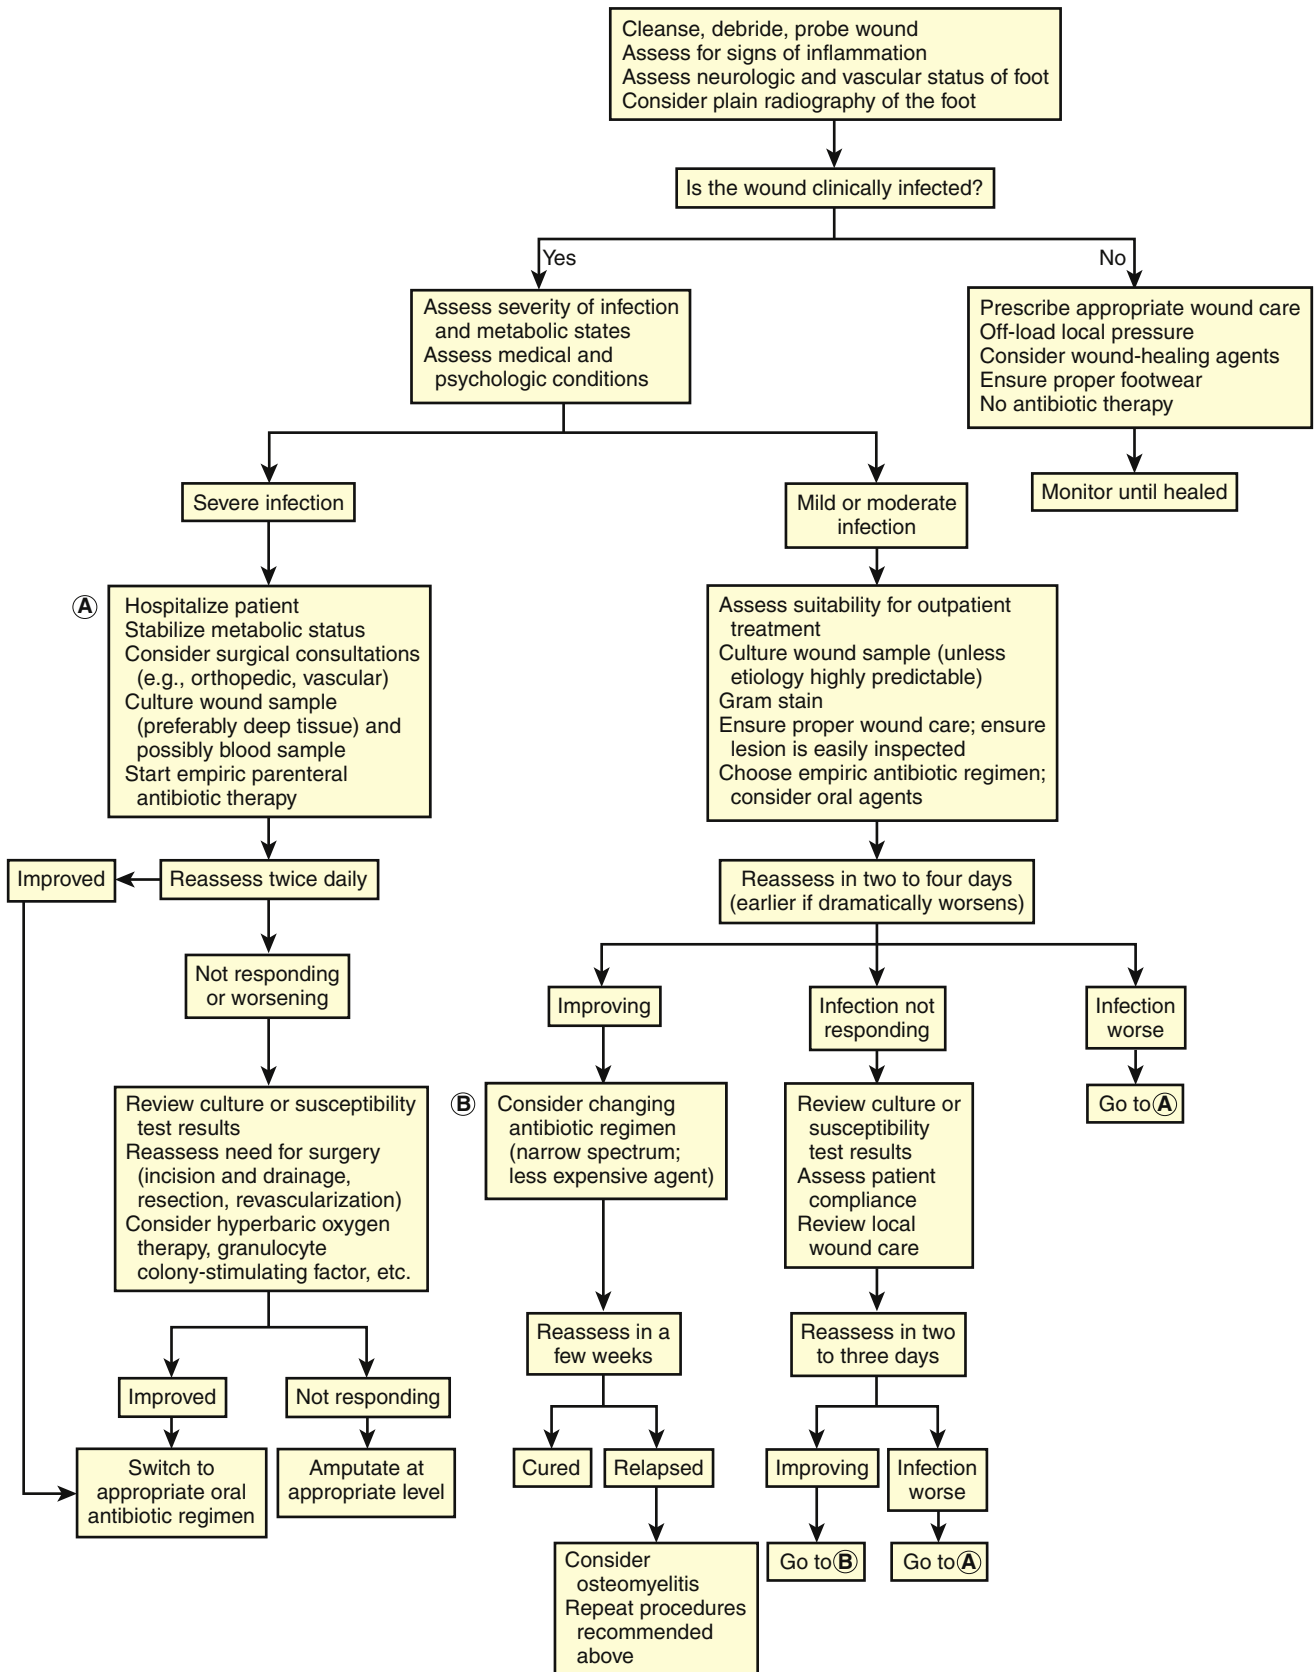

Figure 16-11 Algorithm for the evaluation and treatment of diabetic foot infection.
(Modified from Lipsky BA. Medical treatment of diabetic foot infections. Clin Infect Dis 2004;39(suppl 2):S110.

nips” to the breast and genital areas. Self-inflicted bites often include wounds of the lip and tissues surrounding the nail, such as paronychia. Also included in this are clenched-fist injuries or “fight bites,” which result in small lacerations to the knuckles when striking a person in the mouth. Normal human oral flora, rather than skin flora, is the source of most bacteria isolated from human bite wound cultures (viridans streptococci, *Eikenella corrodens*).

Treatment

Management of bite wounds is the same as for any other wound: good wound care in the form of adequate irrigation and debridement of nonviable tissue as needed (Table 16-19). Bite wounds in general do not require primary closure, but after adequate irrigation and debridement, wounds may be approximated and closed by delayed primary or secondary intention. An exception to this rule may include bite wounds to the face. General wound management measures such as tetanus toxoid administration should also be employed. Bite wounds involving the hands should be evaluated by a hand surgeon, given the risk of adjacent tendon sheath, bone, or joint involvement and the dire consequences if such structures are involved.

The transmission of *rabies* through the bites of domestic pets in the United States and developed countries is rare. In fact, the dog strain of rabies is considered eliminated in the U.S. dog population, and cat bites are often managed through observation of the animal, without the immediate need for rabies *postexposure treatment* (PET). However, wild mammal exposure, especially bat, skunk, or raccoon, often warrants PET, which involves thorough cleaning of the bite wound, ideally with povidone-iodine solution, along with rabies immune globulin given at the wound site and rabies vaccine given on days 0, 3, 7, and 14.

Bite wounds should be considered contaminated wounds from presentation, given the oral microbial flora of humans and animals, and most patients should probably receive antibiotics early. Empiric antibiotics are used to eradicate oral flora inoculated from the mouth of the biter, whether human or animal, into the wound. All moderate to severe animal bite wounds, or wounds that have an associated crush injury or that are close to a bone or joint, should be considered contaminated with potential pathogens, and these patients should receive 3 to 5 days of “prophylactic” antimicrobial therapy. Gram stains with culture of bite wounds are specific but not sensitive indicators of bacterial growth. Nonetheless, Gram stain can be used to help guide initial empiric antibiotic therapy.

Amoxicillin-clavulanic acid (amoxicillin-clavulanate; Augmentin) or penicillin plus a penicillinase-resistant penicillin are normally first-line agents for empiric therapy directed at bite wounds. First-generation cephalosporins (e.g., cephalexin) are not effective as monotherapy because of resistance of some anaerobic bacteria and *E. corrodens*. A 5- to 10-day course of antibiotics is usually adequate for infections limited to the soft tissue, and a minimum of 3 weeks of therapy is required for infections involving joints or bones. Close follow-up is required in all bites to ensure adequate healing.

Of special consideration in human bite wounds is the potential for spread of viral pathogens, most notably *hepatitis*

B virus (HBV) and HIV, if the source person is positive. HBV exposure in this setting should be handled in the same manner as other exposures, with administration of HBIG and HBV vaccination. With regard to HIV, CDC guidelines for managing nonoccupational HIV exposure recommend handling each case individually in consultation with an infectious diseases specialist.

KEY TREATMENT

Use of antibiotic prophylactic after bites of the hand reduces the incidence of infection (Medeiros and Saconato, 2005) (SOR: B).
Antibiotic prophylaxis after bites by humans reduces incidence of infection (SOR: C).

BONE AND JOINT INFECTIONS

Anthony Zeimet

Key Points

- The diagnosis of osteomyelitis is based on radiographic findings (plain radiograph or MRI) showing bony destruction along with histologic analysis and culture results.
- Chronic osteomyelitis is not an emergency, and antibiotics can be safely withheld until an etiologic diagnosis is established.
- Diabetic foot infections require a careful evaluation to assess perfusion and vascular supply, and corrective measures should be undertaken to reestablish adequate perfusion if necessary.
- In diabetic foot ulcers, if one can probe to bone, the patient most likely has osteomyelitis.
- Orthopedic hardware infections are best managed in conjunction with an infectious diseases specialist and orthopedic surgeon.

Osteomyelitis

Osteomyelitis is defined as progressive, inflammation leading to destruction of the bone, usually secondary to an infectious agent. Bacteria can enter bone through hematogenous seeding or a contiguous focus after trauma, implantation of a foreign device, or a local soft tissue infection. Acute osteomyelitis is defined as infection that evolves over a few weeks. Chronic osteomyelitis implies persistent infection of several weeks to months.

Hematogenous osteomyelitis occurs primarily in children within the metaphyses of long bones (tibia and femur) and vertebrae in adults. In addition to local signs of inflammation and infection, patients generally have various systemic signs, including fever, irritability, and lethargy. Physical findings include tenderness over involved area and decreased range of motion in adjacent joints. Chronic osteomyelitis usually occurs in adults, caused by an open injury to bone and surrounding soft tissue. Erythema, drainage around area, and bone pain are usually present on physical examination. Systemic symptoms occur less frequently.

The diagnosis of osteomyelitis is based on the clinical picture and supporting laboratory and radiologic findings. Leukocytosis and elevations in CRP and ESR may

Table 16-19 Management of Bite Wounds

| History |
|--|
| <p><i>Animal bite:</i> Ascertain the type of animal, whether the bite was provoked or unprovoked, and the situation/environment in which the bite occurred. If the species can be rabid, locate the animal for 10 days' observation or sacrifice.</p> <p><i>Patient:</i> Obtain information on antimicrobial allergies, current medications, splenectomy, mastectomy, liver disease, and immunosuppression.</p> |
| Physical Examination |
| Record a diagram of the wound with the location, type, and depth of injury; range of motion; possibility of joint penetration; presence of edema or crush injury; nerve and tendon function; signs of infection; and odor of exudate. |
| Culture |
| Infected wounds should be cultured and a Gram stain performed. Anaerobic cultures should be obtained in the presence of abscesses, sepsis, serious cellulitis, devitalized tissue, or foul odor of the exudate. Small tears and infected punctures should be cultured with a minitipped (nasopharyngeal) swab. |
| Irrigation |
| Copious amounts of normal saline should be used for irrigation. Puncture wounds should be irrigated with a "high-pressure jet" from a 20-mL syringe and an 18-gauge needle or catheter tip. |
| Debridement |
| Devitalized or necrotic tissue should be cautiously debrided. Debris and foreign bodies should be removed. |
| Radiographs |
| Radiographs should be obtained if fracture or bone penetration is possible to provide a baseline for future osteomyelitis. |
| Wound Closure |
| Wound closure may be necessary for selected, fresh, uninfected wounds, especially facial wounds, but primary wound closure is not usually indicated. Wound edges should be approximated with adhesive strips in selected cases. |
| Antimicrobial Therapy |
| <p><i>Prophylaxis:</i> Consider prophylaxis (1) for moderate to severe injury less than 8 hours old, especially if edema or crush injury is present; (2) if bone or joint penetration is possible; (3) for hand wounds; (4) for immunocompromised patients (including those with mastectomy, liver disease, or steroid therapy); (5) if the wound is adjacent to prosthetic joint; and (6) if the wound is in the genital area. Coverage should include <i>Pasteurella multocida</i>, <i>Staphylococcus aureus</i>, and anaerobes.</p> <p><i>Treatment:</i> Cover <i>P. multocida</i>, <i>S. aureus</i>, and anaerobes. Use oral medication if the patient is seen early after a bite and only mild to moderate signs of infection are present. The following can be considered for cat or dog bites in adults:</p> <ul style="list-style-type: none"> • <i>First choice:</i> Amoxicillin/clavulanic acid, 875/125 mg bid or 500/125 mg tid with food. • <i>Penicillin allergy:</i> No alternative treatment for animal bites has been established for penicillin-allergic patients. The following regimens can be considered for adults: <ol style="list-style-type: none"> 1. Clindamycin (300 mg PO qid) plus either levofloxacin (500 mg PO daily) or trimethoprim-sulfamethoxazole (2 double-strength tablets PO bid). 2. Doxycycline, 100 mg PO bid. 3. Moxifloxacin, 400 mg PO daily. 4. In the highly penicillin-allergic pregnant patient, macrolides have been used, but the wounds must be watched carefully. <p>On emergency department discharge, a single starting dose of parenteral antibiotic, such as ertapenem (1 g), may be useful in selected cases. If hospitalization or closely monitored outpatient follow-up is required, intravenous agents should be used. Current choices include ampicillin/sulbactam and ceftioxin. The rising incidence of community-acquired <i>S. aureus</i> isolates that are methicillin resistant and therefore resistant to the drugs recommended here emphasizes the importance of susceptibility-testing any <i>S. aureus</i> isolates.</p> |
| Hospitalization |
| Indications include fever, sepsis, spread of cellulitis, significant edema or crush injury, loss of function, a compromised host, and patient noncompliance. |
| Immunizations |
| <p>Give tetanus booster (Td; tetanus and diphtheria toxoids for adults) if original three-dose series has been given but none in the past 5 years. Adults who have not received acellular pertussis vaccine (Tdap), should be given this instead of Td. Give a primary series and tetanus immune globulin if the patient was never immunized.</p> <p>Rabies vaccine (on days 0, 3, 7, 14, and 28) with hyperimmune globulin may be required, depending on the type of animal, ability to observe the animal, and locality.</p> |
| Elevation |
| Elevation may be required if any edema is present. Lack of elevation is a common cause of therapeutic failure. |

Table 16-19 Management of Bite Wounds—cont'd

| |
|--|
| Immobilization |
| Immobilize the extremity, especially hands, with a splint. |
| Follow-up |
| Follow-up should occur at 24 hours and perhaps 48 hours for outpatients. |
| Reporting |
| Reporting the incident to a local health department may be required. |
| From Goldstein EJC. Bites. In Mandell GL, Bennett JE, Dolin RD (eds). Mandell, Douglas, and Bennett's Principles and Practice of Infectious Diseases, 7th ed. Philadelphia, Churchill Livingstone— Elsevier, 2010. PO, Orally; <i>bid</i> , twice daily; <i>tid</i> , three times daily; <i>qid</i> , four times daily. |

be seen but can also be normal. Blood cultures may be positive in up to half of children with acute osteomyelitis. If plain radiographs show bone destruction and inflammation; the diagnosis of osteomyelitis is confirmed. Typical findings on plain-radiographs will include osteolysis, periosteal reaction, and sequestra (segments of necrotic bone separated from living bone by granulation tissue). Findings seen on plain radiographs usually denote a process that has been ongoing for at least 2 weeks. Bone scintigraphy (bone scan) is often performed on patients with suspected osteomyelitis; however, sensitivity is quite low, and a negative result can offer false reassurance to the physician, so its routine use is not recommended. If the plain-radiographs are negative but the suspicion for osteomyelitis is still high, an MRI scan should be considered.

Once the diagnosis of osteomyelitis has been made, the next step is to obtain an etiologic diagnosis. Histopathologic and microbiologic examination of bone is the “gold standard.” Cultures of sinus tracts are not reliable for identifying the causative organism. Common causative bacteriologic organisms in neonates include *Staphylococcus aureus*, group B streptococci, and *Escherichia coli*. Later in life, *S. aureus* is most common, and in elderly persons, gram-negative organisms such as *Pseudomonas aeruginosa* and *Serratia* spp. have increased incidence.

Empiric antibiotics are rarely required for chronic disease but are often necessary for acute osteomyelitis. Ideally, surgical debridement of all necrotic tissue and inflammatory debris (pus) should be undertaken and multiple surgical cultures with bone histology samples obtained. Antimicrobial therapy will be dictated by test results. Generally, treatment is for 4 to 6 weeks. With the exception of the fluoroquinolone class of antibiotics, which achieve high serum levels with oral administration, bone antibiotic levels cannot exceed the minimum inhibitory concentration (MIC) for the infecting organism; therefore, antibiotics must be given intravenously. This underscores the importance in obtaining a bacterial diagnosis so that the appropriate antibiotic can be used for the duration of treatment. Acute osteomyelitis is usually readily curable; however, chronic osteomyelitis is generally more refractory to therapy and requires repeat debridement and antibiotic courses.

Diabetic Foot Osteomyelitis

Patients with uncontrolled diabetes are at increased risk for development of osteomyelitis, especially in the presence of neuropathy or venous or arterial insufficiency. *S. aureus* and beta-hemolytic streptococci are the predominant organisms, although other gram-positive or gram-negative aerobic or anaerobic bacteria may also be seen. Plain radiographs should be the initial test to evaluate for the presence of osteomyelitis, followed by MRI if negative. If there is a draining sinus, the “probe to bone” test should be performed with a sterile probe; if bone is palpated, the diagnosis of osteomyelitis is highly likely. Further evaluation of the diabetic patient should be to assess for vascular insufficiency with the use of ankle-brachial indices and transcutaneous oximetry. If significant compromise is found, arteriography followed by revascularization should be undertaken. Surgical debridement is again the cornerstone of treatment, along with antibiotics directed toward the causative microorganism.

Orthopedic Hardware Infections

Infections secondary to orthopedic hardware devices have become common problems with the increasing incidence of hip, knee, and shoulder replacement surgeries. Also, patients with traumatic injury resulting in a fracture often have hardware implanted to stabilize the bone. These patients present in one of the three following ways:

1. **Early:** Symptoms develop less than 3 months after surgery and have an acute presentation with pain, erythema, and warmth, usually caused by *S. aureus* and gram-negative bacilli.
2. **Delayed:** Symptoms develop 3 to 24 months after surgery, generally with subtle signs of infection, including implant loosening and persistent pain, and usually caused by less virulent organisms such as coagulase-negative staphylococci and *Propionibacterium acnes*.
3. **Late:** Symptoms develop 24 months after surgery and are usually caused by hematogenous seeding from skin, dental, respiratory, and urinary infections.

Treatment requires debridement of the surrounding tissue and hardware removal, although this cannot always be done in patients with bone instability. It is recommended that treatment

of these infections be done in conjunction with an infectious diseases specialist working with the orthopedic surgeon.

Septic Arthritis

Septic arthritis is defined as infection within the joint space of two bones. The major causative organisms include *S. aureus* and in the sexually promiscuous individual, *Neisseria gonorrhoeae*. Intravenous drug users are likely to develop septic arthritis within unusual joints (e.g., sternoclavicular, sacroiliac). Rheumatoid arthritis, presence of joint prostheses, and steroid use are predisposing factors for development of septic arthritis.

Diagnosis is usually based on clinical presentation of a warm, swollen joint with limitation in range of motion. A joint aspiration should be completed and the synovial fluid sent for Gram stain with culture, WBC count with differential, and crystal analysis to rule out gout and pseudogout. Blood cultures should also be drawn before initiation of antibiotics.

Gonococcal arthritis usually presents as an acute arthritis involving one or more joints in a sexually active individual. Two thirds of patients have dermatitis with one or multiple, usually asymptomatic, lesions that progress from macular to papular and finally vesicular or pustular. Joint fluid, urethral, and rectal cultures should also be obtained. Treatment is generally with a third-generation cephalosporin intravenously until improvement, followed by oral therapy to complete a 1-week course of therapy.

Treatment of nongonococcal arthritis requires proper draining of the infected joint. This is often done surgically, although repeat needle drainage may also be successful if the joint is easily accessible. Treatment generally depends on the Gram stain and includes a third-generation cephalosporin, with the addition of vancomycin if gram-positive cocci in clusters are seen. Duration of therapy is 3 to 4 weeks.

KEY TREATMENT

Treatment of osteomyelitis requires surgical debridement followed by a 4- to 6-week course of intravenous antibiotic therapy (SOR: C). Septic arthritis is usually caused by a gonococcus in a sexually active adult, and use of a third-generation cephalosporin is the mainstay of therapy (Workowski and Berman, 2006) (SOR: A). Nongonococcal arthritis should be treated with surgical debridement or repeated needle aspirations, with a third-generation cephalosporin and vancomycin if gram-positive cocci are seen (Goldenberg, 1998) (SOR: B).

FEVER OF UNKNOWN ORIGIN

Anthony Zeimet

Key Points

- A comprehensive history and physical examination with laboratory and radiologic evaluation are important in the workup for fever of unknown origin (FUO).
- If routine information is unrevealing, more specific testing for FUO is undertaken based on the patient's age, travel history, and disease process to develop a differential diagnosis.

- The serum ferritin level (often elevated with malignancy) and naproxen test (reduces fever with malignancy) may be helpful in determining an underlying malignant process.
- Initiation of empiric antibiotics should be done only in specific FUO situations to prevent skewing culture results, thus maximizing isolation of the causative organism.

Patients who have a persistent fever despite workup are generally classified as having a "fever of unknown origin" (FUO). In 1961, Petersdorf and Beeson described 100 patients with persistent fever, otherwise known as fever of unknown origin. They introduced the standard, classic definition of FUO: fever higher than 38.3° C (101° F) on several occasions, persisting without diagnosis for at least 3 weeks, with 1 week of investigational study in the hospital setting. With advancing technology, this definition has been revised to allow for more than two outpatient visits, or 3 days if investigation is in the hospital setting. Most patients with FUO have chronic or subacute symptoms and can be safely evaluated in the outpatient setting, with a median time to diagnosis of 40 days.

The differential diagnosis of FUO is quite broad and extensive. Determining an etiologic diagnosis of an FUO depends on generating a differential diagnosis compatible with the patient's history and physical examination. The principal disease categories for FUO include infection (30% overall), neoplasms (18%), collagen vascular diseases (12%), and miscellaneous (14%) (Box 16-5). Because of this broad differential, a newer classification system divides FUO into four groups: classic, nosocomial, neutropenic, and HIV associated, which helps narrow the differential diagnosis. Furthermore, classic FUO can be broken down into three subgroups: infants and children, elderly, and travelers. Despite an extensive workup, the etiologic diagnosis usually remains elusive in 7% to 30% of patients (Box 16-4).

The diagnostic workup of FUO should begin with a thorough history and physical examination, including documentation of the fever. The patient may provide a diary noting the date and time of fever. Routine noninvasive investigations are recommended in all patients before diagnosing FUO (Box 16-6). Acute febrile illness is never called an FUO. The patient's medication profile is reviewed because numerous drugs can be the cause. If unrevealing, a workup is initiated based on the differential diagnosis for the patient's age, travel history, geographic location, and disease process. Dukes criteria for infective endocarditis have 99% specificity in patients with FUO. When the initial investigations are not helpful in identifying a cause, imaging should be considered, such as computed tomography (CT) scans of the chest, abdomen, and pelvis; CT may reveal an abscess or suggest an underlying malignancy. An elevated serum ferritin level can suggest a neoplasm or myeloproliferative disorder and, if normal, greatly decreases the chance that the patient has an underlying malignancy. Lower-extremity Doppler ultrasound should be considered in the sedentary or obese patient to rule out deep venous thrombosis. A temporal artery biopsy should be considered in the elderly patient to rule out temporal arteritis. Liver biopsy has a high diagnostic yield with minimal toxicity, whereas bone marrow cultures usually have a low yield and should be considered only in special situations.

Empiric therapy with antibiotics is rarely appropriate for the patient with FUO. A diagnosis is essential to guide

Box 16-4 Differential Diagnosis for Fever of Unknown Origin (FUO)**Classic**

Infections: Abscesses, endocarditis, tuberculosis (TB), complicated urinary tract infection (UTI).

Geographic location: Leishmaniasis (Spain), melioidosis (Southeast Asia, Australia), Kikuchi-Fujimoto disease (form of necrotizing lymphadenitis, Japan).

Connective tissue diseases: Juvenile rheumatoid arthritis (JRA, Still's disease), rheumatoid arthritis (RA), systemic lupus erythematosus (SLE), temporal arteritis, polymyalgia rheumatica (PMR).

Neoplasms: malignant neoplasm, lymphoma, leukemia.

Other: Familial Mediterranean fever in Ashkenazi Jews.

Infants and Children

Respiratory infections predominate if <12 years.

Kawasaki disease if <5 years.

JRA, (Still's disease) in the older child/young adult.

Elderly

Connective tissue diseases are more prominent.

Travelers

Infections: Malaria, hepatitis, pneumonia/bronchitis, UTI/pyelonephritis, dysentery, dengue fever, enteric fever, TB, rickettsial infection, acute human immunodeficiency virus (HIV) infection, amebic liver abscess.

Nosocomial

Postoperative urinary and respiratory tract instrumentation; use of intravascular devices; drug therapy; immobilization.

Septic thrombophlebitis, pulmonary embolus, *Clostridium difficile* colitis, drug fever.

Neutropenic

Fungal: 40% susceptible to empiric antifungals, 5% will be resistant to empiric therapy.

Bacterial: 10% not responding to empiric antimicrobial therapy and usually with cryptic focus.

Unusual pathogens: 5% will be toxoplasmosis (*Toxoplasma gondii*) reactivation, atypical mycobacterial, TB, fastidious pathogens (*Legionella*, *Mycoplasma*, *Chlamydia*).

Viral: 5% of causes (HSV, CMV, EBV, HHV-6, VZV, RSV, influenza, parainfluenza).

Other: 10% will be transplant related (e.g., GVHD) following stem cell transplant, 25% will be undefined.

HIV Associated

Infections: *Mycobacterium avium* complex (MAC), *Pneumocystis carinii* pneumonia (PCP), cytomegalovirus (CMV), histoplasmosis, viral (HCV, HBV, adenovirus, HSV esophagitis, VZV encephalitis), TB, other fungi, cerebral toxoplasmosis, disseminated cryptosporidiosis.

Neoplasms: Lymphoma, Kaposi's sarcoma.

Other: Drug fever, Castleman's disease.

HSV, Herpes simplex virus; **EBV,** Epstein-Barr virus; **HHV,** human herpesvirus; **VZV,** varicella-zoster virus; **RSV,** respiratory syncytial virus; **GVHD,** graft-versus-host disease; **HCV,** hepatitis C virus; **HBV,** hepatitis B virus.

Box 16-5 Causes of Fever of Unknown Origin**Infections**

Abscesses: Hepatic, subhepatic, gallbladder, subphrenic, splenic, peri-appendiceal, perinephric, pelvic, and other sites.

Granulomatous: Extrapulmonary and miliary tuberculosis, atypical mycobacterial infection, fungal infection.

Intravascular: Catheter-related endocarditis, meningococemia, gonococemia, *Listeria*, *Brucella*, rat-bite fever, relapsing fever.

Viral, rickettsial, and chlamydial: Infectious mononucleosis, cytomegalovirus, human immunodeficiency virus, hepatitis, Q fever, psittacosis.

Parasitic: Extraintestinal amebiasis, malaria, toxoplasmosis.

Noninfectious Inflammatory Disorders

Collagen vascular diseases: Rheumatic fever, systemic lupus erythematosus, rheumatoid arthritis (particularly Still's disease), vasculitis (all types).

Granulomatous: Sarcoidosis, granulomatous hepatitis, Crohn's disease.

Tissue injury: Pulmonary emboli, sickle cell disease, hemolytic anemia.

Neoplastic Diseases

Lymphoma/leukemia: Hodgkin's and non-Hodgkin's lymphoma, acute leukemia, myelodysplastic syndrome

Carcinoma: Kidney, pancreas, liver, gastrointestinal tract, lung, especially when metastatic

Atrial myxomas

Central nervous system tumors

Drugs

Sulfonamides

Penicillins

Thiouracils

Barbiturates

Quinidine

Laxatives (especially with phenolphthalein)

Factitious Illnesses

Injections of toxic material

Manipulation or exchange of thermometers

Other Causes

Familial Mediterranean fever

Fabry's disease

Cyclic neutropenia

From Dale DC. The febrile patient. In Goldman L, Ausiello D (eds). Cecil Textbook of Medicine, 22nd ed. Philadelphia, Saunders, 2004, p 1730.

treatment, and use of antibiotics may delay determining a causative infectious agent. The naproxen test (Naprosyn; 375 mg PO every 12 hours for 3 days) is helpful in determining if the fever is secondary to infection or malignancy. A dramatic decrease in the patient's temperature during the test generally indicates a malignant focus, whereas minimal or no response indicates an infectious etiology.

The prognosis of FUO depends on the etiologic category. Undiagnosed FUO has a very favorable outcome. Patients in whom diagnostic investigations fail to identify an etiology should be followed clinically with serial history reviews and physical examinations until the fever resolves or new diagnostic clues are found.

KEY TREATMENT

Diagnosis of FUO may be assisted by the Dukes criteria for endocarditis, CT scan of the abdomen, nuclear scanning with a technetium-based isotope, and liver biopsy (Mourad et al., 2003) (SOR: B). Routine bone marrow cultures are not recommended in the FUO workup (Mourad et al., 2003) (SOR: B). Empiric antibiotics should be initiated only in specific situations, to avoid skewing culture results and thus maximizing potential isolation of the causative organism (Mourad et al., 2003) (SOR: B).

COMPLICATED INTRA-ABDOMINAL INFECTIONS

Richard Basilan

Intra-abdominal infections may either be *uncomplicated* (limited to the gut lumen, such as gastroenteritis or colitis) or *complicated* (extending through to the peritoneum) (Solomkin et al., 2010). The clinical presentation of complicated intra-abdominal infections can range from mild symptoms such as nausea, mild abdominal pain, and cramping to life-threatening septic shock.

Clinical findings result from local or diffuse inflammation with or without abscess formation. Fever and abdominal pain are typically present, with additional symptoms depending on the organ involved. Elderly and immunocompromised patients present with atypical, usually milder symptoms. Imaging studies form an important adjunct to diagnosis. Management involves empiric antibiotic coverage for bowel flora—mainly streptococci, enterococci, enteric gram-negative rods, and anaerobes—as well as controlling the source of infection, usually through surgery.

SPONTANEOUS BACTERIAL PERITONITIS

Richard Basilan

Key Points

- Spontaneous bacterial peritonitis usually occurs in the setting of ascites and chronic liver disease.
- Spontaneous bacterial peritonitis is a diagnosis of exclusion.
- Ascitic fluid culture yield improves with inoculation into blood culture bottles at bedside.

Spontaneous bacterial peritonitis (SBP) is a form of infectious peritonitis without a surgically correctable cause and is therefore a diagnosis of exclusion. The route of infection in SBP is usually not apparent and is often presumed to be hematogenous, lymphogenous, by transmural migration through an intact gut wall from the intestinal lumen, or in women, from the vagina via the fallopian tubes (Levison and Bush, 2010). SBP occurs in the setting of ascites in most cases, and it is particularly common in patients with cirrhosis. In pediatric populations, those with postnecrotic cirrhosis or nephrotic syndrome are more often affected. In adults, almost 70% of patients who develop SBP have Child-Pugh class C liver disease, and 10% to 30% of hospitalized patients with cirrhosis and ascites have SBP (Mowat and Stanley, 2001). SBP is almost always caused by a single organism, typically enteric gram-negative rods, most often *E. coli*, followed by *Klebsiella pneumoniae*. Gram-positive cocci account for about 25% of

Box 16-6 Minimal Diagnostic Workup to Qualify as Fever of Unknown Origin

Comprehensive history
Physical examination
Complete blood cell count plus differential
Blood film reviewed by hematopathologist
Routine blood chemistry (including lactate dehydrogenase, bilirubin, and liver enzymes)
Urinalysis and microscopy
Blood (×3) and urine cultures
Antinuclear antibodies, rheumatoid factor
Human immunodeficiency virus antibody
Cytomegalovirus IgM antibodies; heterophil antibody test (if consistent with mononucleosis-like syndrome)
Q-fever serology (if exposure risk factors exist)
Chest radiography
Hepatitis serology (if abnormal liver enzyme test result)

From Mourad O, Palda V, Detsky A. A comprehensive evidence-based approach to fever of unknown origin. *Arch Intern Med* 2003;163:545-551.

episodes of SBP, and streptococci are isolated most often. SBP caused by anaerobes is rare. Growth of more than one organism should raise the suspicion of secondary peritonitis.

Signs and symptoms of SBP are subtle and require a high index of suspicion. Fever greater than 100° F (38° C) is the most common presenting sign, occurring in 50% to 80% of cases. Abdominal pain, nausea, vomiting, and diarrhea are usually present. Peritoneal signs (abdominal tenderness or rebound tenderness) are common but may be absent in patients with ascites. In adults, mental status changes may also occur. SBP is often confused with acute appendicitis in children. In adults, SBP should be suspected in any patient with previously stable chronic liver disease who undergoes acute decompensation in clinical status.

Spontaneous bacterial peritonitis is diagnosed by analysis of ascitic fluid obtained by abdominal paracentesis. Infection has been typically defined as an ascitic fluid WBC count higher than 250 cells/mm³, which is considered diagnostic even when the culture of the ascitic fluid is negative. In cases where bloody fluid is obtained (“traumatic paracentesis”), the WBC count should be corrected by 1 WBC per 250 RBCs/mm³. The use of bedside dipstick for leukocyte esterase has a high false-negative rate and is not recommended (Nguyen-Khac et al., 2008). Ascitic fluid culture yield can be increased by inoculating blood culture bottles with 10 mL of ascitic fluid at the bedside. Blood cultures should also be obtained as part of the workup.

After the diagnosis of peritonitis is established, secondary peritonitis should be ruled out. CT of the abdomen with oral and intravenous contrast can help direct the surgeon to a particular source of infection, as opposed to doing a full exploratory laparotomy. A high ascitic fluid total protein (>1 g/dL) or amylase level is suggestive of secondary peritonitis. The treatment of choice is generally a third-generation cephalosporin such as cefotaxime (2 g IV every 8-12 hours) or ceftriaxone (2 g IV once daily). Patients who have an ascitic fluid WBC count higher than 250 cells/mm³ should be given empiric intravenous antibiotics without delay. Oral amoxicillin-clavulanic acid can be used for mild, uncomplicated cases (Navasa et al., 1996). Duration of treatment varies

from 5 to 14 days depending on clinical response. Patients usually respond to appropriate antibiotic therapy within 48 to 72 hours; otherwise, a repeat paracentesis should be performed. If the ascitic fluid WBC count does not decrease by more than 25%, alternative diagnoses should be considered. Prophylaxis with a fluoroquinolone or trimethoprim-sulfamethoxazole should be considered, particularly in high-risk patients (Garcia-Tsao and Lim, 2009).

KEY TREATMENT

Spontaneous bacterial peritonitis is treated with third-generation cephalosporins (cefotaxime or ceftriaxone), with ampicillin-sulbactam, fluoroquinolones, or carbapenems as alternative agents (Solomkin et al., 2010) (SOR: B).

Patients with diffuse peritonitis should undergo an emergency surgical procedure as soon as possible, even if ongoing measures to restore physiologic stability need to be continued during the procedure (Solomkin et al., 2010) (SOR: B).

Discussions of the following infections can be found online at www.expertconsult.com:

- Secondary bacterial peritonitis and intra-abdominal abscesses
- Cholecystitis
- Cholangitis
- Appendicitis
- Diverticulitis

CENTRAL NERVOUS SYSTEM INFECTIONS

Richard Basilan

Key Points

- Bacterial meningitis is life threatening and requires urgent medical attention and treatment.
- Viral encephalitis should be treated with acyclovir until herpes simplex virus is ruled out.
- Most brain abscesses are caused by streptococci and *Staphylococcus aureus*.
- The CNS infections most likely to be encountered in clinical practice include meningitis, encephalitis, and abscess.
- All CNS infections can be difficult to diagnose, and a high index of suspicion by the health care provider is sometimes indicated to ensure patient survival.
- MRI is the most sensitive neuroimaging test for encephalitis.
- Acyclovir should be started immediately and continued until HSV PCR testing is obtained.

Bacterial Meningitis

Meningitis can be acute, subacute, or chronic. In otherwise healthy children, the three most common organisms causing acute bacterial meningitis are *Streptococcus pneumoniae*, *Neisseria meningitidis*, and *Haemophilus influenzae* type b (Hib). Isolation of an organism other than these three organisms from the CSF of a child older than 2 months always requires an explanation or evaluation for unusual host susceptibility. Children with cochlear implants, asplenia, HIV infection, or CSF leak

from basilar skull or cribriform fracture are at greater risk for pneumococcal meningitis. Deficiencies in terminal components of complement lead to greater risk for meningococcal infection (Saez-Llorens and McCracken, 2008). In adults, the common etiologic agents of acute meningitis include *S. pneumoniae*, *N. meningitidis*, and *Listeria monocytogenes*.

Patients with acute meningitis most often present with fever, headache, meningismus, and altered mental status. Infants can present with nonspecific symptoms such as inconsolable crying, irritability, nausea, vomiting, and diarrhea. Lethargy, anorexia, and grunting respirations indicate a critically ill infant. Older children may complain of headache, vomiting, back pain, myalgia, and photophobia; may be confused or disoriented; and may verbalize specifically that the neck is stiff or sore. Seizures are noted in up to 20% to 30% of children before hospital admission or early in the course of the illness.

In contrast, patients with subacute or chronic meningitis may have the same symptoms with a much more gradual onset, lower fever, and associated lethargy and disability. *Mycobacterium tuberculosis*, *Treponema pallidum* (syphilis), *Borrelia burgdorferi* (Lyme disease), and fungi (e.g., *Cryptococcus neoformans*, *Coccidioides* spp.) are the most common agents (Tunkel et al., 2010).

Physical examination should look for papilledema, middle ear and sinus infections, petechiae (common with *N. meningitidis*), nuchal rigidity, and in infants, a bulging fontanel. Blood cultures should be taken. A lumbar puncture (LP) for CSF analysis should be done as soon as possible. A brain CT scan before LP is not necessary if the patient has no evidence of immunocompromise, CNS disease, new seizure, papilledema, altered consciousness, or focal neurologic deficit, and if a subarachnoid hemorrhage is not suspected. If neuroimaging is necessary, blood cultures should be taken and antibiotics given before the study; a delay in administration of antibiotics leads to a worse outcome. CSF should be sent for cell count, WBC differential, glucose, protein, and Gram stain with culture. Acid-fast bacilli stain and cryptococcal antigen may be obtained when indicated.

Empiric antibiotics for the initial treatment of bacterial meningitis are listed in Table 16-20, but these should be tailored to the isolated organisms whenever possible. Adjunctive dexamethasone is recommended for children and infants with Hib meningitis, but not if they have already received antibiotics. In adults, adjunctive dexamethasone is recommended for pneumococcal meningitis (Tunkel et al., 2004). Close contacts of patients with *N. meningitidis* should receive rifampin, 20 mg/kg (not to exceed 600 mg) twice daily for 2 days, or ciprofloxacin, 500 mg as a single dose, or ceftriaxone, 250 mg IM as a single dose. Unimmunized persons exposed to *H. influenzae* meningitis should receive rifampin (Tunkel et al., 2010). Pregnant women should not receive rifampin or doxycycline.

A repeat LP should be done if no clinical response is seen after 48 hours of appropriate antibiotic therapy, particularly for patients with resistant pneumococcal disease and those who received dexamethasone. Neonates with gram-negative bacilli and patients with ventriculoperitoneal (VP) shunts require documentation of CSF sterility. The duration of antimicrobial therapy is 7 days for patients with *N. meningitidis* or Hib, 10 to 14 days for pneumococcal meningitis, and 14 to 21 days for *Streptococcus agalactiae*.

Table 16-20 Empiric Antibiotics for Initial Treatment of Bacterial Meningitis

| Age/Risk Factors | Empiric Antibiotic Therapy |
|---------------------------------|---|
| <1 month | Ampicillin + cefotaxime or amp + aminoglycoside |
| 1 month to 2 years | Vancomycin + ceftriaxone or cefotaxime* |
| 2 to 50 years | Vancomycin + ceftriaxone or cefotaxime* |
| >50 years | Ampicillin + vancomycin + ceftriaxone or cefotaxime* |
| Basilar skull fracture | Vancomycin + ceftriaxone or cefotaxime |
| Penetrating head trauma | Vancomycin + ceftazidime, cefepime, or meropenem [†] |
| Postneurosurgery status | Vancomycin + ceftazidime, cefepime, or meropenem |
| Cerebrospinal fluid (CSF) shunt | Vancomycin + ceftazidime, cefepime, or meropenem |

Modified from Practice Guidelines for Bacterial Meningitis, CID 2004:39.
 *Consider adding rifampin if dexamethasone is also given.
[†]Imipenem should be avoided because it increases the risk of seizures.

KEY TREATMENT

Adjunctive dexamethasone is recommended for children and infants with *H. influenzae* type b meningitis, but not if they have already received antibiotics (Tunkel et al., 2004) (SOR: A). In adults, adjunctive dexamethasone is recommended for pneumococcal meningitis (Tunkel et al., 2004) (SOR: B).

Viral Meningitis Viral meningitis manifests similar to bacterial meningitis, although its course is rarely aggressive. The diagnostic process and examination are similar to those for bacterial meningitis. Viral meningitis is usually caused by enteroviruses, HSV, mumps virus, and HIV. Along with the signs of meningitis, signs that suggest a viral etiology include genital lesions (HSV-2), diarrhea, or a maculopapular rash (enteroviruses). Diagnosis is made by the history, examination, and CSF results. Early in the course, the CSF might show predominantly neutrophils that can resemble bacterial meningitis. Treatment is symptomatic. Suppressing therapy should be offered to patients with recurrent HSV meningitis.

Viral Encephalitis

Although encephalitis can also be caused by bacteria and fungi, the great majority of cases are caused by viruses. Herpes simplex accounts for 10% of cases. Patients present with fever, acute decreased level of consciousness, and occasionally, seizures and language, memory, or behavior disturbances. MRI is the most sensitive neuroimaging test for encephalitis and might show temporal lobe inflammation in early HSV encephalitis. CSF studies and electroencephalography (EEG) are also recommended for all patients with encephalitis. Herpes simplex PCR should be done, and acyclovir should be given immediately until HSV encephalitis

is ruled out. During late summer and early fall, doxycycline should be considered to cover for tick-borne illnesses, and testing should include the mosquito-borne encephalitides such as West Nile, St. Louis, Eastern equine, and Western equine. Treatment depends on the suspected etiologic agent but is generally supportive (Tunkel et al., 2008).

Brain Abscess

A brain abscess is a focal, intracerebral infection that develops into a collection of pus surrounded by a well-vascularized capsule. Although fungi and protozoa (particularly *Toxoplasma*) can also cause brain abscesses, bacterial causes are much more common. Streptococci are found in 70% of bacterial abscesses and are usually from oropharyngeal infection or infective endocarditis, whereas *Staphylococcus aureus* accounts for 10% to 20% of isolates and is more often found after trauma. Community-associated MRSA strains have been increasing. Enteric gram-negative bacilli (e.g., *E. coli*; *Proteus*, *Klebsiella*, and *Pseudomonas* spp.) are isolated in 23% to 33% of patients, often in patients with ear infection, septicemia, or immunocompromise and those who have had neurosurgical procedures.

Most clinical symptoms are caused by the size and location of the abscess rather than the systemic signs of an infection. Headache is the most common complaint and may be accompanied by fever, mental status changes, evidence of increased intracranial pressure (nausea, vomiting, papilledema), or focal neurologic deficits. Diagnosis is usually made by CT scan with IV contrast showing the characteristic hypodense center with a peripheral uniform ring enhancement, with or without a surrounding area of brain edema. MRI is becoming the preferred imaging modality because of increased sensitivity, particularly for detecting satellite lesions. Additional testing depends on risk factors and the likely underlying source of infection and may include blood cultures, chest imaging, testing for HIV and antibodies to *Toxoplasma*, and transesophageal echogram. Empiric therapy typically involves vancomycin, ceftriaxone, and metronidazole. Optimal management also includes surgical drainage for most abscesses, both to find an etiologic microorganism and to improve chances of cure (Turkel, 2010).

INFECTIOUS DIARRHEA

Hoonmo Koo

Key Point

- Most acute diarrheal illness is viral and can be managed symptomatically and with appropriate attention to hydration.
- Travelers' diarrhea is usually caused by diarrheogenic *Escherichia coli*.
- The infection in travelers' diarrhea is usually self-limited.
- Antibiotics may shorten the duration of diarrhea by 1 to 3 days.
- The most common cause of antibiotic-associated diarrhea is *Clostridium difficile*.
- Treatment of antibiotic-associated diarrhea involves discontinuing the offending agent, if possible.

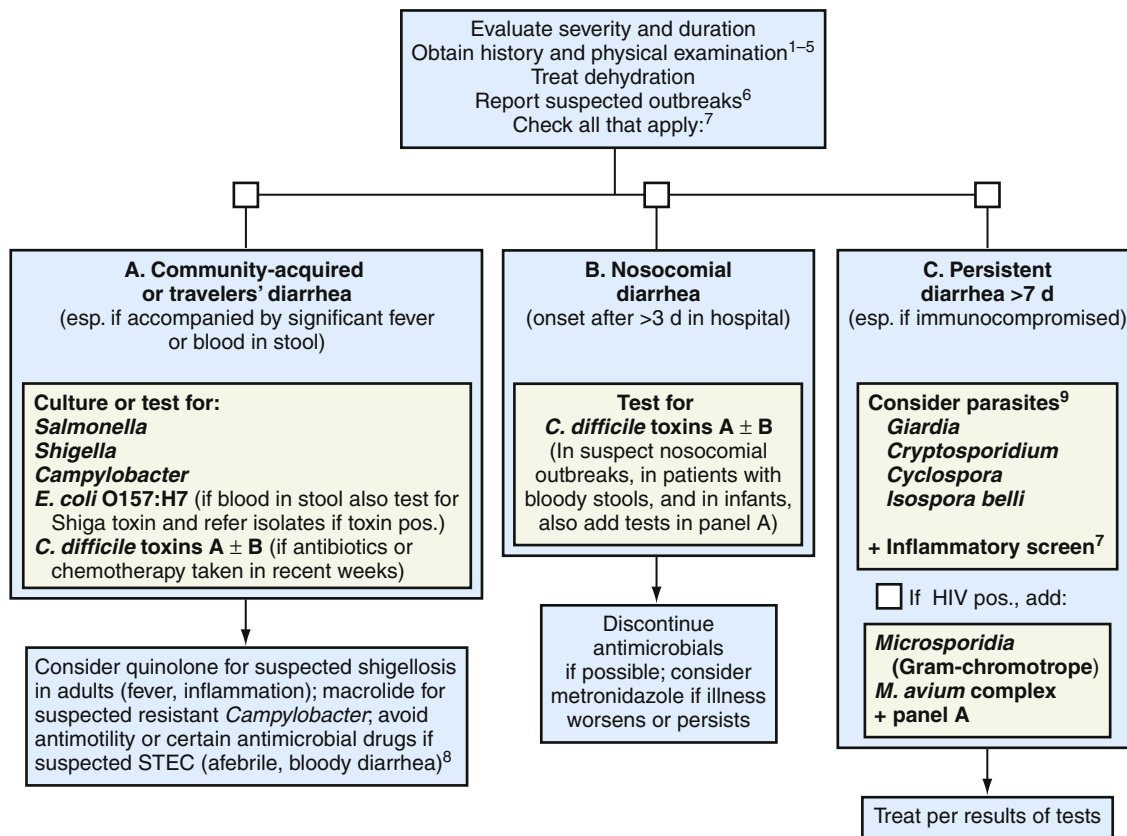

Figure 16-12 Recommendations for diagnosis and management of diarrheal illnesses. *HIV*, Human immunodeficiency virus; *Pos.*, positive. ¹Seafood or seacoast exposure should prompt culture for *Vibrio* spp. ²Travelers' diarrhea that has not responded to empiric therapy with rifaximin, a quinolone, or azithromycin should be managed with the above approach. ³Persistent abdominal pain and fever should prompt culture for *Yersinia enterocolitica* and cold enrichment. Right-side abdominal pain without high fever but with bloody or nonbloody diarrhea should prompt culture for Shiga toxin producing *E. coli* (STEC) O157. ⁴Proctitis in symptomatic homosexual men can be diagnosed with sigmoidoscopy. Involvement in only the distal 15 cm suggests herpesvirus, gonococcal, chlamydial, or syphilitic infection; colitis extending more proximally suggests *Campylobacter*, *Shigella*, *Clostridium difficile*, or chlamydial (LGV serotype) infection, and noninflammatory diarrhea suggests giardiasis. ⁵Postdiarrheal hemolytic uremic syndrome (HUS) should prompt testing of stools for STEC O157 and for Shiga toxin (send isolates to reference laboratory if toxin-positive but STEC-negative). ⁶Outbreaks should prompt reporting to the health department. Consider saving culture plates and isolates and freeze whole stools or swabs at -70°C . ⁷Fecal lactoferrin testing or microscopy for leukocytes can help document inflammation, which may be present in invasive colitis with *Salmonella*, *Shigella*, *Campylobacter*, or *C. difficile* colitis, and with inflammatory bowel disease. ⁸Some experts recommend avoiding administration of antimicrobial agents to persons in the United States who have bloody diarrhea. ⁹Commonly used tests for parasitic causes of diarrhea include fluorescence and EIA for *Giardia* and *Cryptosporidium*; acid-fast stains for *Cryptosporidium*, *Cyclospora*, *Isospora*, or *Mycobacterium* spp. (as well as culture for *Mycobacterium avium* complex); and special chromatrope or other stains for *Microsporidia*.

From Guerrant RL, Van Gilder T, Steiner TS, et al. Practice guidelines for the management of infectious diarrhea. *Clin Infect Dis* 2001;32:334.

Diarrhea is a common presenting complaint in the primary care physician's office. Not all causes of diarrhea are infectious, and not all infectious causes of diarrhea require specific antibiotic therapy. Diarrhea remains a major cause of morbidity and mortality, particularly for children in the developing world. Diarrhea is an alteration of normal bowel function, characterized by an increase in the water content, volume, or frequency of stools. *Acute* diarrhea is typically defined as present less than 14 days, and diarrhea is considered *chronic* when symptoms persist longer than 30 days (Figure 16-12).

Viral Gastroenteritis

Infectious diarrhea seen in the primary care physician's office is most frequently caused by viruses. A number of viral agents can cause diarrheal illness (Box 16-7). Rotaviruses are the principal enteric pathogens in children less than 5 years of age and the most important cause of hospitalization and infant mortality related to diarrheal illnesses. Noroviruses

Box 16-7 Viral Pathogens Causing Gastroenteritis

Established Pathogens

From Guerrant RL, Bobak DA. Nausea, vomiting, and noninflammatory diarrhea. In Mandell GL, Bennett JE, Dolin R (eds). Principles and Practice of Infectious Diseases, 6th ed. Philadelphia, Churchill Livingstone, 2005, pp 1236-1249.

are the most common cause of food-borne disease worldwide.

Viral gastroenteritis is usually an acute self-limited illness, referred to as the “stomach flu.” Enteric viruses are easily spread by fecal-oral transmission, through contamination of food and water, fomites, and person-to-person spread. Secondary attack rates can be high. Nausea and vomiting are the most prominent symptoms of viral gastroenteritis. Diarrhea, fever, headache, and constitutional symptoms may also be experienced. These viral infections can occur at any time during the year, but tend to occur more often in the winter. There is no specific therapy. Treatment is supportive, with particular emphasis on adequate replacement of fluids and electrolytes. If rehydration can be accomplished enterally, it is preferred.

Both the pentavalent bovine-human reassortment (RV5) and the oral, live-attenuated monovalent (RV1) rotavirus vaccines are effective for prevention of severe gastroenteritis. The RV5 vaccine series is recommended for children at ages 2, 4, and 6 months, whereas the RV1 vaccine should be administered to children 2 and 4 months of age.

Travelers’ Diarrhea

Approximately 40% of travelers to developing regions of the world will develop diarrhea. Bacteria are responsible for approximately 80% of diarrhea acquired by travelers. Other important causes include viruses and parasites. The onset of the majority of cases of travelers’ diarrhea is usually within 5 to 15 days after arrival. The presentation is typically a noninflammatory, nonbloody diarrhea associated with abdominal discomfort, fever, nausea, or vomiting. The duration is usually 1 to 5 days.

Enterotoxigenic *E. coli* is responsible for approximately 30% of travelers’ diarrhea. Enteroaggregative *E. coli* is the second most common bacterial agent and causes 20% of cases. *Salmonella*, *Shigella*, and *Campylobacter* spp. are less often detected but are important causes of dysentery, particularly in Asia and Africa. *Dysentery* is severe inflammatory diarrhea manifested by fever and bloody stools. Most cases of travelers’ diarrhea are self-limited, but chronic postinfectious irritable bowel syndrome may occur in up to 10% of those who experience diarrhea.

Prevention of travelers’ diarrhea is an important component of pretravel counseling for high-risk countries. Food should be boiled, cooked, or peeled and water boiled to avoid consumption of fecal contamination. If a person develops travelers’ diarrhea, a short course of antibiotics with rifaximin, ciprofloxacin, or azithromycin can shorten the duration of illness by 1 to 3 days. Antibiotic therapy is recommended for persons with bloody diarrhea or fever. Rifaximin, a nonabsorbed antibiotic, is not effective against invasive pathogens

and should not be administered for dysentery. Ciprofloxacin or azithromycin should be used for dysenteric symptoms based on local antimicrobial susceptibilities.

Antibiotic-Associated Diarrhea

Antibiotics are frequently prescribed in the primary care physician’s office for a variety of infections. Unfortunately, antibiotics can alter the normal host microflora that can be protective against other infections. Antibiotic effects on the normal gastrointestinal tract microbiome can lead to antibiotic-associated diarrhea, which causes significant morbidity and mortality. Administration of antibiotics usually precedes symptoms of antibiotic-associated diarrhea by about 1 week but can be as distant as 2 or 3 months. Strong associations with clindamycin (Cleocin), cephalosporins, penicillins, and fluoroquinolones have been demonstrated, but any antibiotic can lead to antibiotic-associated diarrhea.

The most important cause of antibiotic-associated diarrhea is *Clostridium difficile*, an anaerobic, gram-positive, spore-forming rod. *C. difficile* is implicated as the cause in up to 25% of antibiotic-associated diarrhea cases, in 50% to 75% of antibiotic-associated colitis cases, and in more than 90% of antibiotic-associated pseudomembranous colitis cases. Risk factors for *C. difficile* diarrhea include antibiotics, health care exposure (recent stay in hospitals or long-term care facilities), older age (>60), and comorbid conditions.

The clinical presentation of *C. difficile* colitis is usually diarrhea, abdominal pain or cramping, and fever in a patient who recently received antibiotics. Leukocytosis is common and may be profound; levels can be consistent with leukemoid reaction. A rare but potentially fatal complication is toxic megacolon. *Toxic megacolon* manifests as acute colonic dilation to a diameter greater than 6 cm, associated with systemic toxicity and the absence of mechanical obstruction. With its high associated mortality, any patient who develops toxic megacolon requires immediate surgical evaluation for possible colectomy.

Diagnosis of *C. difficile* diarrhea is achieved by demonstration of *C. difficile* toxin A or B in the stool by enzyme immunoassay (EIA) or cell culture cytotoxicity assay in a symptomatic patient with a previous history of antibiotic use. Asymptomatic patients should not be tested. With the improved sensitivities of these diagnostic assays, one stool sample is usually sufficient to test for *C. difficile*, unless symptoms recur. Test of cure after therapy with repeat stool for *C. difficile* toxin is not recommended because stools may remain positive for *C. difficile* toxin despite clinical resolution. Endoscopy can demonstrate pseudomembranes in the colon. Pseudomembranes are diagnostic of *C. difficile* infection, but are often not present. Endoscopy may only reveal the presence of nonspecific colitis.

Clostridium difficile colitis is treated by discontinuing the offending agent(s) if possible and initiating antibiotic therapy (Box 16-8). Antimotility agents should be avoided. Oral metronidazole (Flagyl), 500 mg three times daily for 10 to 14 days, is recommended for mild-moderate *C. difficile* diarrhea. Severe diarrhea should be treated with oral vancomycin. Oral vancomycin is currently not recommended for all patients with *C. difficile* diarrhea because of concerns for the promotion of vancomycin-resistant enterococci (VRE) and its expense. About 10% to 20% of patients experience relapse

KEY TREATMENT

In travelers’ diarrhea, in which enterotoxigenic *E. coli* or other bacterial pathogens are likely causes, prompt treatment with a fluoroquinolone, azithromycin, or rifaximin or, in children, azithromycin 10 mg/kg/day once daily can reduce the duration of an illness from 3 to 5 days to 1 to 2 days (DuPont, 2010) (SOR: A).

Box 16-8 Classification of *Clostridium difficile* Disease Severity and Treatment Recommendations**Severity Scoring****1 point**

Requiring care in the ICU
 $T_{\max} > 38.3^{\circ}\text{C}$ (100.9°F)
 Albumin < 2.5 mg/dL
 WBC $> 15,000$ cells/mm³
 Age > 60 years

2 points

Endoscopic or CT evidence of pseudomembranous colitis

Recommendations

For mild-moderate *C. difficile* diarrhea (≤ 1 point), treat with metronidazole (Flagyl) PO 500 mg tid.

For severe disease (≥ 2 points), use vancomycin 125 mg PO qid.

For patients who cannot receive oral medications, IV metronidazole 500 mg qid and vancomycin by nasogastric tube \pm rectal enema should be administered.

ICU, Intensive care unit; CT, computed tomography; PO, by mouth; IV, intravenous; qid, four times daily; tid, three times daily; WBCs, white blood cells.

Modified from Zar FA, Bakkanagari FR, KMLST, et al. A comparison of vancomycin and metronidazole for the treatment of *Clostridium difficile*-associated diarrhea, stratified by disease severity. Clin Infect Dis 2007;45:302-307.

KEY TREATMENT

Treat mild-moderate *C. difficile* diarrhea with metronidazole (Zar et al., 2007) (SOR: B).

Vancomycin should be administered for severe *C. difficile* diarrhea (Zar et al., 2007) (SOR: B).

after therapy. For relapse, a repeat course of the original *C. difficile* treatment should be administered. Patients who have mild to moderate cases without volume depletion or systemic toxicity can be treated as outpatients.

Discussions of the following infections can be found online at www.expertconsult.com:

- Infectious viral hepatitis
- Endocarditis

Key Points

- A behaviorally based, sexually transmitted infection, HIV affects multiple organ systems.
- No longer uniformly fatal, HIV disease is becoming a chronic condition that requires regular monitoring.
- Family physicians can expect to play a pivotal role in diagnosing HIV infection and monitoring age-related illnesses and medication side effects.

Know Syphilis in all its manifestations and relations, and all other things clinical will be added unto you.

WB Bean (1968)

Human immunodeficiency virus (HIV) infection may reasonably be called the “Syphilis” of the modern age. Both diseases are behaviorally based and sexually transmitted; both affect multiple organ systems; and both pose special clinical and public health challenges. This chapter discusses issues in the care of HIV-positive patients important to family medicine residents and physicians. Primary care physicians and trainees have treated HIV-positive patients since HIV was identified as the virus that causes acquired immunodeficiency syndrome (AIDS) and can expect to play a central role in coordinating the care of HIV-positive patients for the following reasons:

1. The Centers for Disease Control and Prevention (CDC) recommends universal voluntary testing of patients age 13 to 64 in all health care settings as of September 2006. This helps make HIV testing a routine part of medical care, decreases anxiety and stigma, encourages safer behaviors, and extends life. An additional benefit is reduced HIV transmission. Regular primary

care physician visits present a unique opportunity for the patient to be tested and for the physician to assume responsibility for HIV testing.

2. As patients with HIV/AIDS age, they can expect to develop age-related illnesses that family medicine physicians are qualified and trained to monitor and treat.
3. Highly active antiretroviral therapy (HAART) prolongs lives but causes metabolic, cardiovascular, renal, hepatic, neuropsychiatric, and rheumatologic side effects that require monitoring and management.
4. HIV infection is transforming from a uniformly fatal illness to a chronic condition, with increasing numbers of people living with, and not dying from, HIV/AIDS. The care of patients living with HIV illness must now focus on common elements of chronic disease management.

Box 17-1 presents a timeline on HIV/AIDS and antiretroviral therapy.

Epidemiology

Key Points

- Of the 33 million persons living with HIV infection worldwide, 1 million live in the United States.
- Incidence of HIV infection in the United States has increased by 15%, whereas mortality has declined by 17% (2004–2007).
- Minorities and women are disproportionately affected by HIV infection.

About 33 million people worldwide are living with HIV/AIDS in 2007. Of these, 2.7 million have been newly infected, and 2 million people have died of HIV/AIDS. Developing

Box 17-1 Key Events in HIV/AIDS Crisis and Development of Therapy

| | |
|------|--|
| 1959 | African man dies of a mysterious viral illness, now recognized as the ancestor of HIV. |
| 1981 | CDC reports “gay-related immune deficiency” (GRID) as the cause of outbreaks of deaths of gay men in California and New York. Cases soon appear among heterosexuals, intravenous drug users, and recipients of blood transfusions |
| 1983 | Montagnier and Gallo isolate retrovirus later named HIV. CDC warns about possible problems with the blood supply. |
| 1985 | HIV test is patented by Gallo’s laboratory. Rock Hudson dies; Ryan White refused admission to school. |
| 1987 | Advent of zidovudine (AZT or ZDV) as first treatment for HIV infection. |
| 1992 | Combination therapy with zalcitabine (ddC) approved. |
| 1993 | Definition of AIDS revised by CDC. Concorde trials from Britain show that patients develop AIDS despite treatment with ZDV. |
| 1996 | Advent of protease inhibitors and “triple therapy” regimens. Viral reservoirs persist while viral loads remain undetectable. |
| 1997 | ACTG 076 shows AZT in pregnancy and during delivery reduces vertical transmission from 25% to 3%. CDC reports drop in annual AIDS deaths. |
| 1998 | First human trials of a vaccine begin. Generic HIV medications become available in Europe. |
| 2001 | First-entry inhibitor, enfuvirtide (Fuzeon), is developed. |
| 2004 | First generic antiretroviral approved by FDA. Combination drugs Truvada (emtricitabine and tenofovir) and Epzicom (abacavir and lamivudine) and new protease inhibitors Reyataz and Lexiva become available. |
| 2005 | As side effects of chronic HAART identified, experts recommend delay of HAART initiation. |
| 2006 | Current scientific opinion holds origin of HIV in the meat and bites of African monkeys. |
| 2009 | HIV genome is decoded. |

countries account for more than 95% of these infections (UN AIDS, 2007). Since 1981, an estimated 1.7 million people have been infected; more than 1 million people in the United States are currently living with HIV/AIDS; and 565,927 have died of AIDS. The number of deaths has declined by 17% between 2003 and 2007. From 2004 to 2007, there has been an increase of 15% in the incidence of HIV/AIDS cases in the United States. This increase occurred mainly in persons age 40 to 44, who accounted for 15% of all HIV/AIDS cases, likely caused by both changes in reporting systems and increased HIV testing.

A disproportionate number of minorities and women are affected by HIV. Although the U.S. population is 13% black, blacks constituted 45% of newly diagnosed cases in 2006, with a rate of infection of 83.7 per 100,000. Of these, 60% are women. Blacks living with HIV/AIDS constitute about 60% of the adult HIV-positive population in 2007, with a rate of 76.7 per 100,000. Similarly, Hispanics, although constituting 12% of the population, reflect 17% of those persons newly infected with HIV in 2006 and 20% of those living with HIV/AIDS in 2007, with rates of 29.3 and 20 per 100,000, respectively. Year-end prevalence rates in 2007 were 185.1 per 100,000 population, with a range

between 2.2 in Samoa and 1750 per 100,000 in the District of Columbia.

Acquired immunodeficiency syndrome was diagnosed within 12 months of diagnosis of HIV infection for a larger percentage of Hispanics and male intravenous drug users (IVDUs) and men with high-risk heterosexual contact. Survival after AIDS diagnosis has increased in those who were diagnosed between 1998 and 2000, among men who have sex with men (MSM), and those who have acquired HIV perinatally. More whites survive 48 months after a diagnosis of AIDS than minorities. Survival has declined in IVDUs and with each year of age at diagnosis after age 35 (HIV/AIDS Surveillance Report, 2007).

Modes of Transmission and Relative Risk

Key Points

- Human immunodeficiency virus is transmitted through mucous membranes during anal, vaginal, and oral intercourse.
- Transmission of HIV also occurs through sharing injection equipment and needles. Vertical transmission occurs from mother to child.
- Blood, semen, vaginal fluid, breast milk, cerebrospinal fluid, amniotic fluid, and serosanguineous fluid can transmit HIV; saliva, tears, and sweat do not.
- The virus cannot survive outside the host, and 90% to 99% of infective HIV on dry surfaces is eliminated within hours. Insect bites and casual contact carry no risk.

As epidemic and scientific approaches to HIV infection evolved, the focus shifted from “risk groups” to “risky behaviors.” This distinction is important, because risk groups can give a false sense of security by implying that certain groups of individuals are less vulnerable to infection. *Risky behaviors* is a more useful term, falling along a spectrum of “no risk” (e.g., complete sexual abstinence), “very low risk” (e.g., 100% use of latex condoms), to “very high risk” (e.g., unprotected receptive anal intercourse with ejaculation), with other behaviors in midspectrum. The physician serves as a source of accurate information to be provided in simple, nonjudgmental terms because ultimately the patient will decide the acceptable degree of risk.

The three main modes of transmission of HIV are as follows:

1. Through the mucous membranes during anal, vaginal, or oral sexual intercourse with an HIV-infected person. Average risk of transmission in heterosexual exposure is 1 in 1000 and increases with commercial sex workers to about 5 to 10 in 100. Co-infection with other sexually transmitted diseases (STDs), rough sex, and higher viral load increase risk, whereas condom use and male circumcision reduce risk. Uncircumcised men run risk similar to a woman, and circumcised men may transmit the virus to female partners four times as efficiently as uncircumcised men. Postmenopausal women are more susceptible because of thinning of the vaginal mucosa. Risk of infection per act has been suggested from cohort studies, so physicians should avoid discussing risks in numeric terms.

- Through the veins while sharing needles or injection paraphernalia with an HIV-infected person.
- Vertically from an HIV-infected mother to an infant during pregnancy, delivery, or through breastfeeding. High viral load, prolonged time after rupture of membranes, and chorioamnionitis increase risk of transmission, and peripartum prophylactic antiretroviral therapy decreases risk. Overall risk of transmission by breastfeeding is about 15% to 25% in 18- to 24-month-old infants.

Occupational exposure occurs by needle stick injuries (risk, 3:1000), infected blood or fluid splashing into the mouth or nose, or exposure to infected blood through a cut or an open wound. Mucous membrane exposure carries a risk of infection of about 9 in 10,000. Transmission of HIV through infected blood is extremely rare after routine screening of the blood supply was initiated in 1985. With risk of transmission as low as 2 per million, 16 annual infections are accounted for by infectious donations. Neither insect bites nor casual contact carry any risk.

Human immunodeficiency virus can be transmitted by blood, semen, vaginal fluid, breast milk, and serosanguineous body fluids. Contact with cerebrospinal fluid (CSF), amniotic fluid, and synovial fluid can be a risk factor for HIV transmission. Importantly, although HIV can be present in small quantities in saliva, sweat and tears, contact with these fluids does not transmit HIV. The virus cannot survive outside the host, and the amount of infective virus dried on surfaces is reduced by 90%-99% in a few hours.

Pathophysiology

Key Points

- Human immunodeficiency virus belongs to the viral group of Retroviridae, named for its capacity to synthesize DNA using RNA as a template. The subgroup is Lentivirinae, characterized by a long incubation period.
- HIV-1 is found globally, whereas HIV-2 is found mainly in western Africa, although cases of HIV-2 are being seen more frequently in the United States.
- HIV-1 is further subdivided into group M, O, and N, with group M (subdivided into 10 clades) causing most infections worldwide.
- Billions of virions are turned over daily in the virus, leading to frequent mutations and genetic variations.

Human immunodeficiency virus belongs to the group of viruses called *retroviruses*, so named because of their capacity to synthesize deoxyribonucleic acid (DNA) using ribonucleic acid (RNA) as a template, facilitated by the enzyme *reverse transcriptase*. Within the retrovirus class, HIV belongs to the lentivirus subgroup; lentiviruses are characterized by a long incubation period, allowing the infected person to spread the infection because they may remain unaware of their own HIV status (Chiu et al., 1985).

Of the two genetically distinct viral types of HIV, type 1 (HIV-1) is associated with global disease, whereas type 2

(HIV-2) is found mainly in western Africa, although cases of HIV-2 have started to appear in the United States. HIV-1 variants are further divided into group M (main), group O (outlier), and group N (non-M/non-O). As suggested by the name, group M causes most of the infections worldwide and is further subdivided into 10 subtypes, or *clades* (A-K). Clade C is the most common worldwide, and clade B is most frequently seen in North America and Europe. More than 20 sub-subtypes and *circulating recombinant forms* (CRFs) are seen in group M alone. AE is a recombinant subtype transmitted most effectively by heterosexual contact and most prevalent in Southeast Asia (Buonaguro et al., 2007). As billions of virions are turned over in the virus on a daily basis, mutations and genetic variations are quite common, a fact that becomes relevant when treatment is considered.

Life Cycle of HIV and Relevance to Treatment

Key Points

- Infection with HIV proceeds in a series of steps, the first step being virion binding to the host cell and releasing the viral RNA. Fusion inhibitors can interrupt this step.
- In step 2, HIV uses reverse transcriptase to convert viral RNA to DNA. RT inhibitors can prevent this step.
- The HIV DNA is then incorporated into the host genome to form the provirus, facilitated by integrase. The virus may remain latent until the CD4+ cell is immune activated, making viral proteins. Integrase Inhibitors interfere with this step.
- Transcription of DNA to RNA occurs in the nucleus. During translation, mRNA takes over the protein-making mechanism to form viral proteins as well as viral RNA. The products are then divided into functional units using viral protease. Protease inhibitors interrupt this step.
- The final step consists of assembly, budding, and pinching off of the viral proteins, RNA, and enzymes inside the host membrane to form the complete virion.

Human immunodeficiency virus gains access to CD4+ cells in stages (Berger et al., 1999; Smith and Daniel, 2006; Zheng et al., 2005). CD4+ cells are the main mediators of cellular immune response, helping T lymphocytes and B lymphocytes to perform their functions. The 800 to 1200 cells/mm³ of blood in healthy people are usually decimated by HIV. Minor infections, such as herpes simplex virus, thrush, and vaginal candidiasis may occur as the CD4+ count falls below 500, when 50% of the immune reserve is depleted. With a worsening disease process and decreasing CD4+ count (<200), risk of life-threatening opportunistic infections and cancer increases. Research has focused on medications that can interrupt the life cycle and slow the infection of cells.

Step 1

The HIV adheres to and sequentially binds with the host CD4+ cell receptor and a co-receptor (CCR5 or CXCR4). Most wild-type viruses have the CCR5 co-receptor, but with prolonged infection, more and more CXCR4 appears.

Binding with the host CD4+ cell allows the virion to enter the cell and, aided by the co-receptor, to release the two copies of the viral RNA. Drugs called *fusion inhibitors* interrupt this step.

Step 2

Using the viral RNA as a template, HIV reverse transcriptase (RT) converts viral RNA to DNA in the cytoplasm. Smaller functional pieces of the HIV DNA split from the full copy of the DNA. *Reverse transcriptase inhibitors* (RTIs) are used to interrupt this step in the HIV life cycle. Nucleoside RTIs bind competitively and nonnucleoside RTIs (NNRTIs) bind noncompetitively with RT. NNRTIs are specific for HIV-1 and show no activity against HIV-2.

Step 3

The HIV DNA enters the cell nucleus and is incorporated into the host's DNA by the enzyme *integrase* to form the provirus. The virus may remain in a dormant state for many years if the cell is not activated. Once activated, the cell makes many thousands of virions, either for weeks or in a single burst that destroys the cell. *Integrase inhibitors* can prevent the incorporation of viral DNA into the host DNA.

Step 4

Activated CD4+ cells make more viral proteins by copying the DNA back to RNA. This step is called *transcription* and is controlled by both viral and host cell factors. This messenger RNA (mRNA) is transported back to the cytoplasm to be used as a template to make more viral proteins. This step is called *translation*. At this point the protein sequence of mRNA is changed back into the molecules that form envelope and core proteins. The enzyme that splices these large proteins into smaller functional proteins is called *protease*. This step can be prevented by *protease inhibitors* (PIs). HIV-2 carries many of the mutations that confer PI resistance, thus limiting PI activity.

Step 5

The core proteins, RNA, and enzymes just inside the cell membrane are combined with the viral envelope proteins within the host cell membrane. The virus then pinches off, and the process is repeated many times. The complete virus is thus a combination of viral as well as host cell components.

Classification and Staging of HIV/AIDS

Key Points

- The CDC classification uses CD4+ counts and specific HIV-related conditions to stage HIV illness. WHO guidelines use clinical observations.
- The CDC lists AIDS categories as A3, B3, C1, C2, and C3, with 23 AIDS-defining conditions. WHO includes primary HIV infection and four clinical stages.

The two classification systems currently in use to monitor the severity of HIV illness and assist with its management have been developed by the CDC (Table 17-1) and the World Health Organization (WHO) (Box 17-2). The CDC classification, last modified in 1993, uses CD4+ counts and specific HIV-related conditions, whereas the WHO classification, developed in 1990 and revised in 2007, is guided by clinical observations and can be used in settings where access to CD4+ tests is unavailable.

Category B: Symptomatic Conditions

These conditions must indicate defective cell-mediated immunity caused by HIV infection, or their clinical course and management must be complicated by HIV. Category B conditions include the following:

- Constitutional symptoms (fever >38.5° C or diarrhea) lasting more than 1 month
- Candidiasis: oropharyngeal or persistent or recurrent vulvovaginal
- Pelvic inflammatory disease
- Moderate or severe cervical dysplasia or carcinoma in situ
- Oral hairy leukoplakia
- Idiopathic thrombocytopenic purpura
- Peripheral neuropathy
- More than two episodes of multidermatomal herpes zoster
- Bacillary angiomatosis

Category C: AIDS-Defining Illnesses

Category C conditions include bacterial, viral, fungal infections, parasitic infestations, and some cancers.

Bacterial

- *Mycobacterium tuberculosis* infection at any site, pulmonary or extrapulmonary
- *Mycobacterium avium* complex disease; infection with *M. kansasii* or other species, disseminated or extrapulmonary
- *Mycobacterium*, any species disseminated or extrapulmonary
- Bacterial pneumonia, recurrent (>2 episodes in 12 months)
- Nontyphoid *Salmonella* septicemia, recurrent

Viral

- Cytomegalovirus disease (other than liver, spleen, or nodes) and retinitis with vision loss
- Herpes simplex virus (chronic ulcer persisting >1 month, bronchitis, pneumonitis, esophagitis)
- Progressive multifocal leukoencephalopathy

Fungal

- Candidiasis of the esophagus, bronchi, trachea, or lungs
- Coccidioidomycosis, disseminated or extrapulmonary
- Cryptococcosis, extrapulmonary
- Histoplasmosis, disseminated or extrapulmonary

Table 17-1 CDC Classification System of HIV/AIDS

| CD4 Cell Count | Clinical Categories | | |
|-------------------------------|------------------------------------|--|--------------------------------|
| | A Asymptomatic Acute HIV or PGL | B Symptomatic state Neither A nor C | C AIDS Indicator Conditions |
| ≥500 cells/mm ³ | A1 | B1 | C1 |
| 200-499 cells/mm ³ | A2 | B2 | C2 |
| <200 cells/mm ³ | A3 | B3 | C3 |

Data from US Centers for Disease Control and Prevention. 1993 Revised classification system for HIV infection and expanded surveillance case definition for AIDS among adolescents and adults. MMWR 1992;41(RR-17):1-19.

- Isosporiasis, chronic intestinal (persisting for >1 month)
- Pneumonia, recurrent (*Pneumocystis jiroveci*)

Parasitic

- Cryptosporidiosis, chronic intestinal (persisting for >1 month)
- Toxoplasmosis of brain
- Isosporiasis, chronic intestinal (persisting for >1 month)

HIV-Related Conditions

- Encephalopathy, HIV related
- Wasting syndrome, HIV related (weight loss >10% body weight with either chronic diarrhea of >2 stools/day × 1 month or chronic weakness and documented fever >1 month)

Cancers

- Cervical cancer, invasive
- Kaposi's sarcoma
- Lymphoma (Burkitt's, immunoblastic, or primary lymphoma of brain)

Cancers and chronic renal failure associated with AIDS and lipodystrophy, insulin resistance, osteoporosis, and cardiovascular complications of HAART are being increasingly recognized and addressed.

Natural History and Clinical Course

Key Points

- About 20% of HIV-infected persons are unaware of their status because they look and feel healthy.
- Primary HIV infection manifests as a flulike syndrome 1 to 6 weeks after exposure.
- Symptoms include fever, pharyngitis, rash, myalgias, and meningismus; viral load is very high.
- The asymptomatic phase (8-12 weeks later) can persist for many years.
- The lower the viral set point, the better is the long-term prognosis.

More than one fifth of people infected with HIV are unaware of the infection because they look and feel healthy. Family physicians are likely to be the first health

Box 17-2 WHO Clinical Staging of HIV/AIDS

Primary HIV infection

Asymptomatic
Acute retroviral syndrome

Clinical Stage 1

Asymptomatic
Persistent generalized lymphadenopathy

Clinical Stage 3

Moderate unexplained weight loss (<10% body weight)
Recurrent respiratory infections (sinusitis, tonsillitis, otitis media, pharyngitis)
Herpes zoster
Angular cheilitis
Recurrent oral ulceration
Papular pruritic eruptions
Seborrheic dermatitis
Fungal nail infections

Clinical Stage 3

Severe, unexplained weight loss (>10% body weight)
Unexplained diarrhea longer than 1 month
Unexplained, persistent, constant or intermittent fever longer than 1 month (>37.6° C)
Persistent oral candidiasis
Oral hairy leukoplakia
Pulmonary tuberculosis
Severe presumed bacterial infections (pneumonia, empyema, pyomyositis, bone and joint infections, meningitis, bacteremia)
Acute necrotizing gingivitis, stomatitis, periodontitis
Unexplained anemia (hemoglobin <8 g/dL)
Neutropenia (<500 cells/mm³)
Chronic thrombocytopenia (<50,000 cells/mm³)

Clinical Stage 4

All the AIDS indicator conditions as defined by the CDC classification *and*
Atypical disseminated leishmaniasis
Symptomatic HIV-associated nephropathy
Symptomatic HIV-associated cardiomyopathy
Reactivation of American trypanosomiasis (meningoencephalitis or myocarditis)

Modified from World Health Organization. Case definitions of HIV for surveillance and revised clinical staging and immunological classification of HIV related disease in adults and children. Geneva, WHO, 2007. www.who.int/hiv/pub/guidelines/HIV.

professional contact for patients with primary HIV infection. Symptoms resemble a flu or mononucleosis syndrome. A high index of suspicion for HIV infection must be maintained in sexually active, injection drug-using patients or those with known HIV exposure. The incubation period from exposure to the development of the acute clinical illness, known as acute HIV syndrome, is usually 2 to 4 weeks (range, 1-6 weeks).

Common symptoms of primary infection, including fever, lymphadenopathy, pharyngitis, and a maculopapular rash, may occur in 50% to 70% of infected persons. Other symptoms include myalgias and arthralgias, headache, and diarrhea. HIV viral load reaches levels as high as several million RNA copies per milliliter during primary infection. During this period, HIV has seeded lymphoid tissues and various other body organs. Physical examination shows a rash that can involve the face, soles, palms, and trunk; malaise; fever of 40° C (104° F); lymphadenopathy; pharyngitis; oral, vaginal, or anal ulcers; and signs of meningismus. Oral or vaginal thrush may also occur. Cohort studies enrolling seroconverting patients have consistently shown that both the number and the duration of acute retroviral symptoms each independently increase the likelihood of later disease progression (Borrow et al., 1994; Douek, 2003; Koup et al., 1994; Zaunders et al., 2001, 2003). One study found a 78% likelihood of progression to AIDS within 3 years in patients with an acute viral syndrome lasting 14 days or more, whereas the chance of progression dropped to 10% in asymptomatic seroconverters (Lindback et al., 1994).

Patients enter an asymptomatic phase within 8 to 12 weeks after infection. This phase can persist for many years. At this stage, viral RNA is reduced (5000-15,000 copies/mL), even to an undetectable level. The balance between viremia and host response leads to the viral load being set at a relatively low, stable level called the *viral set point*. The lower the viral set point, the better is the long-term prognosis for the infected person (Mellors et al., 1996).

Depending on a variety of viral and host factors, viral replication overcomes immune response, and the viral load increases with an associated decrease in CD4+ lymphocytes (Figure 17-1). At counts less than 350 cells/mm³, thrush, herpes zoster, recurrent dermatoses, and other mucosal infections signify impaired immune function. Once the CD4+ count drops below 200 cells/mm³, the risk of developing life-threatening opportunistic infections increases greatly. This process can take years to develop, and long-term “non-progressors” have been identified. Proposed mechanisms causing CD4+ cell loss include direct infection by HIV, bone marrow toxicity leading to impaired lymphocytic regeneration, apoptosis from chronic immune activation, CTL activity against normal CD4+ cells, and ADCC killing of CD4+ cells carrying viral protein gp120 (Levy, 2006).

The final stage of HIV infection is the development of the CDC classification of AIDS. Median survival time after an AIDS-defining illness was about 12 months in the pre-HAART era (1981–1995), increasing to 60 months by 1995. An estimated 85% to 90% of patients will survive more than 6 years after a diagnosis of AIDS (CDC, 2006).

Diagnosis

Key Points

- Early HIV diagnosis increases access to care and decreases transmission.
- Approximately half of patients are diagnosed with AIDS within the first year of HIV diagnosis.
- Routine HIV testing using blood (or less often saliva or urine) helps reduce stigma and decrease anxiety.
- Infection is diagnosed by detection of HIV antigen in a two-step process, a preliminary EIA and a confirmatory Western blot.
- Rapid HIV testing removes the barrier of a return visit because results are available in 20 minutes.

Figure 17-1 Typical course of HIV infection showing the relationship between the levels of HIV (viral load) and CD4+ T-cell counts over the average course of untreated HIV infection. NIAID publication showing clinical progression of HIV.

(Modified from Fauci AS et al. Immunopathogenic mechanisms of HIV infection. *Ann Intern Med* 1996;124:654-663.)

- The Oraquick and Multispot tests detect both HIV-1 and HIV-2; Reveal and Uni-Gold Recombigen tests detect HIV-1 only.
- As of September 2006, the CDC recommends voluntary testing in all health care settings after informing patients and allowing them to “opt out” if they choose.

Early diagnosis increases access to treatment and helps reduce HIV transmission, but it remains a challenge. Approximately half of HIV-positive patients are diagnosed with AIDS within the first year of HIV diagnosis (Klein et al., 2003; Samet et al., 2001). Many patients ignore the obvious link between sexual and drug use behavior. Taking a careful drug use and sexual history helps identify patients at high risk for HIV infection, and routine HIV testing helps remove the stigma of such identification (Box 17-3). Although blood tests are most common, tests using saliva or urine are also available.

Laboratory diagnosis of HIV that depends on the presence and detection of antibodies to HIV antigen is a two-step process. A specific test for the p24 antigen or HIV-1 RNA is also available but is not widely used. The highly sensitive enzyme immunoassay (EIA) constitutes the first step of the process; further testing is necessary only if the EIA is positive. If exposure occurred less than 3 months earlier and the test is negative, it is repeated in 3 months. EIA is repeated in duplicate if positive or indeterminate. A confirmatory Western blot test is done if the results of repeat testing are again positive or indeterminate. A positive Western blot is conclusive evidence for seropositivity. Indeterminate tests are repeated in a month. A Western blot discordant with EIA raises the possibility of HIV-2 infection.

The CDC estimates that 31% of people tested for HIV did not return for results in 2001 (CDC, 2003). Rapid HIV testing further removes the often-neglected barrier of repeat visits because results are available in about 20 minutes.

Box 17-3 Recommendations for HIV Screening

Patients in All Health Care Settings

Patients must be notified and then screened for HIV unless they decline (opt-out screening).

High-risk subpopulations should be screened for HIV at least annually.

Persons at high risk for HIV infection should have at least annual screening.

Using the general consent for medical care should be enough for HIV testing.

Prevention counseling should not be required with HIV diagnostic testing or screening.

Pregnant Women

All pregnant women must be routinely screened for HIV infection.

Patients must be notified and then screened for HIV unless they decline (opt-out screening).

Separate written consent for HIV testing should not be required if the patient has already signed a general consent for medical care.

Repeat screening in the third trimester is recommended in certain jurisdictions with elevated rates of HIV infection among pregnant women.

Modified from Centers for Disease Control and Prevention. Revised recommendations for HIV testing of adults, adolescents and pregnant women in healthcare settings. *MMWR* 2006;55(RR-14):1-17.

The U.S. Food and Drug Administration (FDA) has approved four rapid HIV screening tests: Oraquick (and Oraquick Advance), Reveal (and Reveal G2), Uni-Gold Recombigen HIV1/HIV2 Rapid Test, and Multispot HIV1/HIV2 Rapid Test. Oraquick and Multispot can detect both HIV-1 and HIV-2. If HIV antibodies are present, they bind to the HIV antigens affixed to the test strip membrane. This complex in turn binds to the colorimetric agent of the test kit and can be seen for a positive test. All these tests require confirmation if reactive. They are highly sensitive and specific, are interpreted visually, and require no instrumentation, making them highly convenient for office use. Oraquick and Uni-Gold are CLIA waived.

Approach to the Patient

Key Points

- Managing HIV/AIDS in the primary care setting helps decrease stigma and patient anxiety.
- Health promotion and disease prevention are becoming as important as managing chronic symptoms.
- A nonjudgmental attitude and strict confidentiality promote trust in the physician-patient relationship.
- Different aspects of the history and physical examination may need to be stressed with certain patients, including safer sex practices.
- HIV-specific history, physical examination, and laboratory tests must be obtained as indicated at each visit.

Family physicians are often the portal of entry into medical care, so they can be instrumental in assessing behaviors that put patients at risk for infection, diagnosing infection, and monitoring and treating the infected patient, even if the patient is referred to a specialist. Although controlling chronic symptoms and treating acute infectious episodes remain vital components of HIV care, health promotion and disease prevention are gaining equal prominence, now that novel and effective treatments are available, making the process of HIV care delivery analogous to that of such chronic illnesses as diabetes and hypertension. Also, managing HIV infection in the primary care setting serves to reduce social stigma and reduce patient anxiety.

The essential components of a successful long-term physician-patient relationship are trust that the physician will act in the patient's best interests, respect their wishes, be nonjudgmental about their lifestyle and behaviors, and maintain the highest degree of confidentiality. The physician or other health care professional is responsible for providing a safe space for the patient to discuss sensitive information. Patients may avoid disclosing behaviors they think may be viewed disapprovingly by the professional. It is vitally important that patients are assured of confidentiality and questioned nonjudgmentally and respectfully. Culturally sensitive literature addressing the needs of local populations must be readily available, with pictures and posters showing familiar faces.

The first visit is crucial to establishing the tone of subsequent encounters. Aspects of the history that must be stressed may depend on time since diagnosis and the presence of symptoms. Recently diagnosed and asymptomatic patients need reassurance and accurate knowledge about the availability of current treatments. Life-threatening opportunistic infections

Table 17-2 HIV-Specific Patient History

| Area of Questioning | Relevance |
|--|---|
| Date of diagnosis and mode of transmission Prior HIV-related illnesses and ART treatment history (reasons for discontinuation, side effects experienced) CD4+ counts and viral loads at diagnosis, nadir point, and most recently HIV-associated symptoms such as fever, night sweats, unintentional weight loss, generalized lymphadenopathy, diarrhea, and oral candidiasis History of travel to areas endemic for histoplasmosis, blastomycosis, and coccidioidomycosis | Assessing risk for other STDs, staging of illness, determination of HAART treatment options; assessing risk of immune suppression and disease progression Documentation and assessment of need for further testing and treatment |
| Detailed drug abuse history History of hepatitis and tuberculosis, including duration and adherence to chemoprophylaxis | Assessment of ability to adhere to treatment |
| Documentation of herbal and complementary medications | Determination of potential interactions with HAART |
| Number of pregnancies and HIV status during pregnancy | Determination of children at risk |
| Status of immunizations | Risk of infection in an immunocompromised patient |
| Psychiatric diagnoses | Ability to adhere to medication regimen |
| Living situation, employment, social support, pets, and daily diet | Ability to afford medications, risk of infections, nutritional status |
| Number of sexual partners and condom use, method of contraception, survival sex, persons to whom the patient has disclosed HIV status | Behaviors likely to increase reinfection and put partners at risk |
| <i>ART, Antiretroviral therapy; HAART, highly active ART; STDs, sexually transmitted diseases.</i> | |

(OIs) must be ruled out in symptomatic patients. A detailed treatment history, side effects experienced, and reasons for discontinuation of medications must be obtained from treatment-experienced patients. Screening for substance abuse and STDs must be addressed routinely. Behaviors that put others at risk for infection must be assessed (Table 17-2).

The physical examination must focus on organ systems most likely to be affected by HIV-related OIs and cancers. The examination may also reveal clues to potential complications and aid in staging the illness. Vital signs, including the presence of pain, are documented at every visit (Table 17-3).

Laboratory testing is important to monitor disease progress and the effects of HAART and to delineate treatment side effects, such as lipid, glucose, and renal abnormalities (Table 17-4).

Clinically stable patients need only be seen every 3 to 4 months. Recently diagnosed patients, those with acute illnesses, and those who are failing or have recently changed antiretroviral therapy may need to be seen more frequently. The 2009 guidelines allow follow-up visits to be extended to every 6 months, if the patient is virologically suppressed for more than 2 to 3 years (level 2).

Because 95% adherence maximizes the potential for long-term viral load suppression, adherence to therapy must be confirmed. Asking about doses missed in the prior 48 hours or 2 weeks may yield more accurate answers than inquiring in general about whether or not the patient is taking medications. Younger age, lack of social support, and chronic symptoms, including depression, are negative predictors of adherence. Race, ethnicity, gender, and inactive substance abuse do not predict adherence. Statistical risk factors for poor adherence should not lead to the decision to withhold

treatment. Instead, the clinician must explore ways to counter the effects of these predictors.

Safer sex practices and specific instances of unprotected sex must be discussed. Interim problems and the status of previously discussed problems are also monitored.

Use of Antiretroviral Agents

Key Points

- Primary care physicians with appropriate experience and expertise can provide high-quality care to HIV-infected patients.
- U.S. DHHS guidelines are frequently updated and provide useful direction in treatment of HIV/AIDS patients.
- A few medication combinations should be avoided and certain drugs used with caution in special patient populations.
- Widespread use of HAART has decreased the prevalence of opportunistic infections in HIV/AIDS patients, but prophylaxis is generally advised for specific OIs.
- Once initiated, HAART must be continued indefinitely and lifelong.

The U.S. Department of Health and Human Services (DHHS) guidelines on the use of antiretroviral agents for HIV-infected adults (December 2009) provide guidance to HIV care practitioners on the optimal use of antiretroviral agents for the treatment of HIV infection in adults and adolescents in the United States. The recommendations are mostly based on studies in peer-reviewed journals (Guidelines Working Group, 2008).

Table 17-3 HIV-Specific Physical Examination

| Component of Examination | Area of Relevance |
|--|---|
| Head, Eyes, Ears, Nose and Throat | |
| Oropharyngeal and gingival exam | Candidiasis and Kaposi's sarcoma |
| Funduscopy | Cytomegalovirus retinitis |
| Palpation of thyroid | Risk of anxiety or depression, which can interfere with adherence |
| Chest | |
| Auscultation for abnormal sounds or for absence of air movement | Pleural effusions, pneumonia, pneumothorax |
| Abdomen | |
| Hepatomegaly and splenomegaly | Evidence of hepatitis and cause of anemia |
| Anogenital exam and anal Pap test | Herpes simplex virus, human papillomavirus, or other STDs |
| Pelvic exam at first visit, in 6 months, and annually thereafter | Cancer, STDs, pelvic inflammatory disease |
| Baseline Neurologic Examination | |
| Dissociated sensory loss | Peripheral neuropathy |
| Fine motor skills | Dementia |
| Muscle strength | Myopathy, neuropathy |
| Psychiatric | |
| Mental status exam to rule out HIV-associated depression, anxiety, and psychosis | Impact on adherence to medications and appointments |
| Suicidal thoughts | Need for inpatient care |
| Behavioral changes | Intracranial pathology, side effects of medications, and laboratory abnormalities |
| STDs, Sexually transmitted diseases. | |

Despite the complexity of managing HIV-infected patients, an observational cohort study suggests that family physicians with appropriate experience and expertise in HIV care can provide high-quality care to patients with this complex chronic illness (Landon et al., 2005). Primary care providers without HIV experience, such as those who provide service in rural or underserved areas, should identify experts in the region who will provide consultation when needed. The following goals of therapy have broadened along with knowledge of HIV/AIDS and the epidemiology and long-term consequences of chronic infection:

1. To suppress HIV RNA (viral load) as low as possible (<48 copies/mL), for as long as possible.
2. To preserve or enhance immune function.
3. To delay clinical progression to AIDS.
4. To decrease risk of HIV transmission.
5. To decrease risk of nonopportunistic conditions.
6. To delay the selection of drug-resistant mutations by decreasing the rate of viral replication.

Achieving these goals has resulted in substantial reductions in HIV-related morbidity and mortality and has reduced vertical transmission (Mocroft et al., 1998; Mofenson et al., 1999; Palella et al., 1998; Vittinghoff et al., 1999).

The DHHS guidelines for initiating antiretroviral therapy (ART) include strength of evidence level for each recommendation (Table 17-5). There is strong evidence that patients

with CD4+ count less than 200 cells/mm³ and those with a history of opportunistic illness will benefit the most from early ART. It is currently recommended that ART be initiated in patients with CD4+ count of 200 to 350 cells/mm³ (level 1) and 350 to 500 cells/mm³ (level 1/2) (Box 17-4).

Recent data from the ART Cohort Collaboration and North American AIDS Cohort Collaboration on Research and Design (NA ACCORD) suggest that deferring HAART at CD4+ count greater than 500 cells/mm³ was associated with increased risk of mortality. Following this research finding, current guidelines (level 2) recommend initiation of HAART at CD4+ counts of greater than 500. Half the panel members supported this course of action (1) because of the association between non-AIDS-defining illnesses, such as malignancies and liver and kidney disease, and (2) because currently available medications are much better tolerated for longer periods. Drawbacks to this recommendation are (1) the panel did not reach consensus; (2) the benefits of HAART initiation are still unclear; and (3) the results are from observational analyses.

Current antiretroviral medicines include nucleoside/nucleotide reverse-transcriptase inhibitors (NRTIs), nonnucleoside reverse-transcriptase inhibitors (NNRTIs), protease inhibitors (PIs), fusion inhibitors (FIs), CCR5 inhibitors, and integrase strand transfer inhibitors (INSTIs) (Table 17-6). All these groups except one is FDA approved and indicated in

Table 17-4 Routine Laboratory Testing for HIV-Infected Patients

| Laboratory Investigation | Comments |
|--|--|
| Confirmation of HIV seropositivity | Baseline assessment |
| CD4+ cell count Quantitative HIV RNA | Test every 3 months and after 2 weeks of changes in treatment |
| Antiretroviral resistance testing | With virologic failure |
| Complete and differential blood count Chemistry panel with liver enzymes Urinalysis Lipid profile Glucose-6-phosphate dehydrogenase (G6PD) Hepatitis B surface antigen (HBsAg); surface and core antibody Hepatitis C antibody | Anemia with zidovudine Glucose and lipids with protease inhibitors (PIs) Nephrotoxicity with indinavir Baseline testing as clinically indicated |
| Electroencephalogram Chest radiograph | As clinically indicated |
| Serologic test for syphilis <i>Toxoplasma gondii</i> antibody | As often as clinically indicated |
| Pap smear: cervical and anal for women and anal for men | Annual test indicated |

antiretroviral-naïve patients. FIs are only indicated in antiretroviral-experienced patients. The latest guidelines provided significant changes from the previous version, especially on what combinations regimen to start in antiretroviral-naïve subjects. Current standards of care in antiretroviral-naïve patients recommend using three medications (three active agents), combining an NNRTI, a PI, or an INSTI with two NRTIs. This combination of “highly active antiretroviral therapy” has been labeled HAART.

Maraviroc was the only agent excluded by the 2009 guidelines as either a preferred or an alternative agent in antiretroviral-naïve individuals. Maraviroc is a CCR5 inhibitor, comparable to efavirenz in terms of virologic response. Maraviroc blocks the CCR5 co-receptor but not the CXCR4 co-receptor. At this time, utility of maraviroc is limited because the Trofile test is required to screen for co-receptor use. Maraviroc will likely be recommended in future guidelines.

The number of preferred PIs was reduced to two: ritonavir-boosted darunavir and ritonavir-boosted atazanavir. Both of these are once-daily options, requiring only 1 capsule of 100 mg of ritonavir to enhance their pharmacokinetics. All other PIs were kept as alternative options for various reasons, including tolerability, toxicity, and efficacy. The dose of ritonavir used to boost PIs exerts negligible antiviral activity. However, it serves the important function of acting as a pharmacokinetic enhancer, increasing drug exposure and prolonging plasma half-life of the combined PI.

In terms of alternative options, it is important to keep in mind that most of these agents are occasionally preferred medications in different settings. A good example is the use of ritonavir-boosted lopinavir in pregnancy. In general, PIs remain valid options to initiate therapy. The PIs as a drug class have been associated with higher rates of adverse gastrointestinal events and potentially cardiovascular events, especially in populations with high cardiovascular risk.

Table 17-5 Recommendations for Initiating Antiretroviral Therapy in Treatment-Naïve Adults with Chronic HIV Infection

| Measure | Antiretroviral Therapy Recommended (Rating)* |
|---|--|
| Patients with history of AIDS-defining illness | A |
| Patients with Asymptomatic HIV Disease: | |
| CD4+ cell count $\leq 200/\mu\text{L}$ | A |
| CD4+ cell count $< 350/\mu\text{L}$ but $> 200/\mu\text{L}$ | A |
| CD4+ cell count $< 500/\mu\text{L}$ but $> 350/\mu\text{L}$ | A/B |
| CD4+ cell count $> 500/\mu\text{L}$ | B |
| Other Patients (regardless of CD4+ T-cell count) | |
| Pregnant women | A |
| Patients with HIV-associated nephropathy | A |
| Patients co-infected with hepatitis B virus (HBV) when treatment is indicated | B |

*Strength of recommendation: A, based on consistent and good-quality patient oriented evidence; B, based on inconsistent or limited-quality patient-oriented evidence; C, based on consensus, usual practice, opinion, and disease-oriented evidence.

Box 17-4 Antiretroviral Regimens for Treatment-Naïve Patients**Preferred Regimens: Level 1**

Ritonavir-boosted darunavir + tenofovir + emtricitabine
Ritonavir-boosted atazanavir + tenofovir + emtricitabine
Efavirenz + tenofovir + emtricitabine
Raltegravir + tenofovir + emtricitabine

Alternative Regimens: Level 2

Efavirenz + (abacavir or zidovudine)/lamivudine
Nevirapine + zidovudine/lamivudine
Atazanavir/ritonavir + (abacavir or zidovudine)/lamivudine
FPV/r* (once or twice daily) + either [(abacavir or zidovudine)/lamivudine] or tenofovir/emtricitabine
LPV/r† (once or twice daily) + either [(abacavir or zidovudine)/lamivudine] or tenofovir/emtricitabine
Saquinavir/ritonavir + tenofovir/emtricitabine

*Fosamprenavir calcium and ritonavir.

†Lopinavir and ritonavir (Kaletra).

The preferred NNRTI continues to be efavirenz, with nevirapine (Viramune) remaining an alternative option. Efavirenz now comes coformulated with two other NRTIs, emtricitabine and tenofovir, in a single pill (Atripla) to be taken once daily as a complete antiretroviral regimen, which has increased prescriptions for Atripla. Atripla is not recommended for pregnant women because of potential CNS malformations; Physicians

Table 17-6 Antiretroviral Medicines

| Generic (Brand) | Abbreviation | Generic (Brand) | Abbreviation |
|---|--------------|---|-----------------|
| Nucleoside/Nucleotide Reverse-Transcriptase Inhibitors (NRTIs) | | Protease Inhibitors (PIs) | |
| Abacavir (Ziagen) | ABC | Nevirapine (Viramune) | NVP |
| Emtricitabine (Emtriva) | FTC | Efavirenz, emtricitabine, and tenofovir (Atripla) | EFV + FTC + TDF |
| Didanosine (Videx) | ddI | Fusion Inhibitor | |
| Lamivudine (Epivir) | 3TC | Atazanavir (Reyataz) | ATZ |
| Stavudine (Zerit) | d4T | Darunavir (Prezista) | TMC-114 |
| Tenofovir (Viread) | TDF | Fosamprenavir calcium (Lexiva) | FPV |
| Zalcitabine (Hivid) | ddC | Indinavir sulfate (Crixivan) | IDV |
| Zidovudine (Retrovir) | ZDV | Lopinavir and ritonavir (Kaletra) | LPV/r |
| Abacavir and lamivudine (Epzicom) | ABC + 3TC | Nelfinavir mesylate (Viracept) | NFV |
| Emtricitabine and tenofovir (Truvada) | FTC + TDF | Ritonavir (Norvir) | RTV |
| Lamivudine and zidovudine (Combivir) | 3TC + ZDV | Saquinavir mesylate (Invirase) | SQV |
| Nonnucleoside Reverse-Transcriptase Inhibitors (NNRTIs) | | Tipranavir (Aptivus) | TPV |
| Delavirdine mesylate (Rescriptor) | DLV | CCR5 Inhibitor | |
| Efavirenz (EFV) | EFV | Enfuvirtide (Fuzeon) | T-20 |
| Etravirine (Intelence) | TMC-125 | Integrase Strand Transfer Inhibitor | |
| | | Raltegravir (Isentress) | |

Table 17-7 Antiretroviral Combinations to Avoid

| Combination | Rationale for Avoidance |
|--|--|
| Atazanavir with proton pump inhibitors | Decrease in atazanavir absorption |
| Unboosted PIs with rifampin | Significant decrease in PI blood levels |
| Nevirapine in women with CD4+ >250 cells/mm ³ or men with CD4+ >400 cells/mm ³ | Risk of serious and life-threatening hepatic events. Switching to nevirapine is possible once CD4+ count has increased beyond these levels with ART. |
| Efavirenz with itraconazole | Decrease in efavirenz blood levels |
| Abacavir in patients who are HLA 5701 positive | High potential for serious "abacavir hypersensitivity reaction" |
| Maraviroc in patients with dual/mixed or CXR4-utilizing virus | Because maraviroc is a CCR5 inhibitor, CXCR4-utilizing viruses respond inadequately or negligibly to treatment. |

PIs, Protease inhibitors; ART, antiretroviral therapy.

must be cautious when prescribing efavirenz in fertile women because risk is highest during the first trimester. Nevirapine is not recommended in women with pretreatment CD4+ counts greater than 250 cells/mm³ or in men with CD4+ counts greater than 400 (level 2) because of a higher risk of serious hepatic events in these two groups (Table 17-7).

Both patient characteristics and physician preferences must necessarily be weighed when choosing between efavi-

renz and PIs. The preferred NRTI is emtricitabine coformulated with tenofovir, a one-pill-once-daily medication that has been compared with the other two coformulated NRTIs, lamivudine/zidovudine, and abacavir/lamivudine, because the former showed a better safety profile and virologic efficacy.

Once the antiretroviral regimen is selected, medication compliance becomes the most important factor in treatment success.

Table 17-8 Recommendations for Initiation and Discontinuation of Primary Prophylaxis of Most Common Opportunistic Infections (OIs)

| OI | Initiation | Discontinuation | Drug of choice |
|---|--|--|--|
| PCP | CD4+ cell count <200 cells/mm ³ | CD4+ cell count >200 cells/mm ³ | TMP-SMX (Bactrim) |
| <i>Toxoplasma gondii</i> encephalitis | Seropositive for <i>T. gondii</i> and CD4+ cell count <100 cells/mm ³ | CD4+ cell count >200 cells/mm ³ | TMP-SMX (Bactrim) for PCP serves as primary prophylaxis. Suppressive regimen of choice for secondary prophylaxis is sulfadiazine plus pyrimethamine and leucovorin |
| MAC | CD4+ cell count <50 cells/mm ³ | CD4+ cell count >100 cells/mm ³ | Zithromycin, azithromycin |
| CMV retinitis | Primary prophylaxis is not routinely recommended; discontinuation of secondary prophylaxis can be considered in patients with a sustained response to HAART, defined as a CD4+ cell count greater than 100 to 150 cells/mm ³ for at least 6 months. | | |
| <i>Cryptococcus neoformans</i> meningitis | Primary prophylaxis is not routinely recommended; discontinuation of secondary prophylaxis can be considered in patients with a sustained response to HAART, defined as a CD4+ cell count greater than 150 to 200 cells/mm ³ for at least 6 months. | | |

TMP-SMX, Trimethoprim-sulfamethoxazole; *PCP*, *Pneumocystis jirovecii* (carinii) pneumonia; *MAC*, *Mycobacterium avium* complex; *CMV*, cytomegalovirus.

An adequate response is expected between weeks 16 and 24 after initiation of ART. Other important factors for physicians treating HIV disease include close follow-up and monitoring of drug toxicities. Treatment success is defined as virologic suppression to undetectable HIV RNA (viral load) to the lowest detectable testing available (<48 copies/mL).

The wide use of HAART has helped decrease OI-related mortality in HIV-positive patients. OIs continue to cause morbidity and mortality for the following reasons:

1. Opportunistic infections are the main indicator of disease that drives many people who may be unaware of their HIV status to seek medical attention.
2. Highly active retroviral therapy may not be available to many patients for a variety of psychological and socioeconomic reasons.
3. Certain patients who are prescribed HAART may not experience virologic or immunologic response because of suboptimal adherence, pharmacokinetics, or unknown biologic issues.

Some OIs may cause a transient increase in viral load that may promote HIV disease progression and increase transmission. HAART becomes especially important to combat OIs for which specific treatments are unavailable.

Recommendations for the initiation and discontinuation of primary prophylactic medications are summarized in Table 17-8. Criteria to initiate or discontinue primary prophylaxis include the following:

1. Adequate CD4+ (immunologic) response.
2. The degree of virulence of the opportunistic agent. Thus the CD4+ cell count to minimize the risk of acquiring a specific illness will vary.

3. Other factors to consider in discontinuation of prophylaxis are the reduction of drug resistance, polypharmacy, drug to drug interactions, and cost.

Postexposure prophylaxis (PEP) of HIV infection in exposed individuals must be initiated within hours of exposure, if possible. The route of exposure may well be from mucous membranes, broken skin, or percutaneous route. The decision to initiate prophylaxis must be considered carefully because it is associated with potential morbidity and side effects. HIV testing must be performed at the time of exposure, at 6 and 12 weeks, and then 6 months later. Two-NRTI or three-drug (+ PI) regimens are recommended, depending on the severity of exposure.

Summary

Family physicians have treated HIV-positive patients ever since HIV was identified as the virus that causes AIDS in 1981 and continue to play a central role from the time of routine screening and diagnosis to the point where the disease stabilizes and becomes chronic. While consultation with a specialist may be needed for difficult-to-manage patients, family physicians can successfully care for HIV-positive patients. Acute retroviral infection may be difficult to differentiate from common community-acquired viruses. The approach to a patient must be respectful, nonjudgmental, and confidential. DHHS guidelines provide useful information about treatment of HIV with HAART. Treatment with HAART extends life and improves quality of life but is associated with significant morbidity and side effects.

KEY TREATMENT

Patients with a history of OI's and a CD4+ count less than 200 are likely to benefit most from HAART, but current recommendations suggest that HAART be initiated in those with count of 350 to 500 or even higher.

Current standards of care recommend using three medications (active agents), combining an NNRTI, a PI, or an INSTI with two NRTIs. Most antiretrovirals occasionally are preferred agents in different settings.

Darunavir or atazanavir boosted with ritonavir are the only two PIs preferred. The preferred NNRTI remains efavirenz.

Efavirenz now comes coformulated with emtricitabine (a preferred NRTI) and tenofovir in a once-daily pill (Atripla).

Adherence to the regimen becomes the most important factor once a regimen is selected.

Adequate response is expected at 16 to 24 months. Success is defined as suppression of viral load to 48 copies/mL.

Postexposure prophylaxis involves administration of two NRTIs with or without a PI.

Lung Disease in Primary Care

Breathing and heartbeat draw the line between life and death. Pulmonary disease, respiratory symptoms, and respiratory failure are common, high-impact conditions. For example, asthma is the most common chronic disease of childhood, respiratory failure causes many admissions to our nation's intensive care units (ICUs), and lung cancer is now the leading cause of cancer death for both men and women in America. Lung cancer accounts for 31% of cancer deaths in men and 25% of cancer deaths in women (American Cancer Society, 2002). In part because of the global spread of tobacco, the World Health Organization (WHO) estimates that chronic obstructive pulmonary disease will move from

being the 12th leading cause of disease burden, as measured by lost disability-adjusted life-years (DALY), to being the fifth leading cause by 2020 (Murray and Lopez, 1996).

Roses are red, violets are blue;

Without your lungs, you would be too!

Smoking and Other Risk Factors for Lung Disease

The Centers for Disease Control and Prevention (CDC) describe smoking as the single most preventable cause of premature death in the United States, contributing to more

than 400,000 deaths per year, or one in every five deaths. People who smoke suffer more than a 20-fold increase in risk of death from lung cancer and a 10-fold increase in risk of death resulting from bronchitis or emphysema (CDC, 1993). For women in the United States, there are more deaths caused by lung cancer than by breast cancer. Worldwide there were 5 million deaths attributable to smoking in 2000, almost 2 million of which were related to lung cancer and other lung diseases. WHO projects a doubling of smoking-related deaths by 2020 (Ezzati, 2003).

Smoking cessation is the most important factor in preventing lung and cardiovascular disease and all-cause mortality. Avoidance of secondary exposure to smoke, especially in the household, is also important in preventing childhood asthma and infections as well as adult cancers (DHHS, 2006).

Even simple physician advice to quit smoking provides a marginal benefit of 2.5% of patients quitting successfully (Lancaster and Stead, 2004). Interventions that combine counseling plus education or group strategies plus pharmacologic treatment with nicotine replacement or specific medications can achieve sustained quit rates of 25% to 30% (Hughes et al., 2004; Solomon et al., 2005; Stead and Lancaster, 2005). The Agency for Healthcare Research and Quality (AHRQ, 2008) has provided a comprehensive update to previous clinical guidelines for smoking cessation and treating tobacco dependence. Counseling is most effective when it includes both practical problem solving and social support. Pharmacologic treatment, such as nicotine replacement, bupropion, and varenicline, has proved effective but is most effective when combined with counseling or group programs. The Legacy Foundation reports that ex-smokers have an average of eight quit attempts before ultimately sustaining a tobacco-free lifestyle. **Box 18-1** defines a strategy for helping patients to quit smoking by a simple mnemonic of “five As” (ask, advise, assess, assist, arrange).

Box 18-1 The Five As: Strategies to Help Patients Quit Smoking

Ask: Systematically identify all tobacco users at every visit.

Implement an office-wide system that ensures that, for every patient at every clinic visit, tobacco use status is queried and documented.

Advise: Strongly urge all tobacco users to quit.

In a clear, strong, and personalized manner, urge every tobacco user to quit.

Assess: Determine willingness to make a quit attempt.

Ask every tobacco user if he or she is willing to make a quit attempt at this time (e.g., within the next 30 days).

Assist: Aid the patient in quitting.

Help the patient with a quit plan; provide practical counseling; provide intra-treatment social support; help the patient obtain extra-treatment social support; recommend use of approved pharmacotherapy except in special circumstances; provide supplementary materials.

Arrange: Schedule follow-up contact.

Schedule follow-up contact, either in person or via telephone.

From Global Initiative for Chronic Obstructive Lung Disease: Executive Summary: Global Strategy for the Diagnosis, Management, and Prevention of COPD. Updated 2008. <http://www.goldcopd.com/download.asp?intld=504>.

Diagnostic Tools in Pulmonary Medicine

History and Physical Examination

Diagnosis starts with the patient history and physical examination. Pulmonary symptoms may be evaluated by traditional history-of-present-illness questions, such as character and quality of the symptoms, duration, onset, timing, exacerbating and alleviating factors, efforts at self-treatment, and the patient's own understanding of what is causing the symptoms. For example, the symptoms of asthma may be variously described by patients as shortness of breath, wheezing, whistling, “wheezling,” chest tightness, tight breathing, or poor exercise tolerance. In addition, patients often self-medicate with over-the-counter (OTC) and prescription medications, as well as use herbal and nonmedicinal alternative therapies, which they typically do not report to their personal physician unless specifically asked (Braganza et al., 2003).

In addition to general history-taking, a detailed history of respiratory exposures and risk factors is essential. Smoking is perhaps the most important pulmonary risk factor. A detailed smoking history includes age of first smoking, quantity smoked, number of years as a smoker, other tobacco use, previous attempts to quit, and an assessment of the level of nicotine addiction. Family history can reveal relatives with immunoglobulin E (IgE)-mediated allergy or *atopy* (allergic rhinitis, asthma, eczema, nasal polyps, or aspirin hypersensitivity) or even more serious genetic risk factors, such as cystic fibrosis or α_1 -antitrypsin deficiency. Perinatal history of premature birth, neonatal respiratory failure, and ventilator care can lead to bronchopulmonary dysplasia and chronic lung disease in children who survive neonatal intensive care.

Taking a good occupational history is also essential, asking the specific type of work the patient performs, as well as past jobs. In addition, the clinician should ask two key questions: “Have you ever been exposed to fumes, gases, or dusts?” and “Do your symptoms get better when you are away from work, during weekends and vacations?”

Physical examination begins with vital signs. For example, tachypnea out of proportion to fever may be the first presenting sign of childhood pneumonia. The degree of respiratory difficulty may also be observed in the form of obvious shortness of breath, the work of breathing, the use of accessory respiratory muscles, and the patient's need to take a breath in midsentence (described as *three-to-four-word dyspnea*). General examination can also reveal either peripheral or central cyanosis. Clubbing of the nails can indicate chronic lung disease. Morbid obesity may be associated with obstructive sleep apnea or right-sided heart failure (*cor pulmonale*), or both.

Examination of the chest begins with inspection and progresses to percussion, palpation, and auscultation. Inspection can reveal chest deformities (pectus excavatum or flail chest) or spinal deformities (kyphosis or scoliosis) that interfere with breathing, or an enlarged anteroposterior (AP) diameter in adults with chronically hyperexpanded lungs. Adults with morbid obesity or prior chest trauma that restricts chest wall motion can have pulmonary function tests consistent with restrictive lung disease of extrapulmonary origin. Infants and children in respiratory distress can have retractions.

Palpation can identify thoracic wall abnormalities, mass lesions, or tenderness and show asymmetry of chest wall expansion. Percussion of lung fields should normally be

resonant. Dullness to percussion can indicate fluid in the pleural space or consolidation of the lung itself, with fluid filling the normally air-filled alveolar spaces. Both these conditions also produce decreased breath sounds over the affected area. Hyperresonant lung fields on percussion can indicate the hyperexpansion of obstructive lung disease or even pneumothorax.

Auscultation should include listening over upper, middle, and lower lung fields of each lung posteriorly, as well as over the apices and mid-lung fields anteriorly. The right middle lobe of the lung and the lingula of the left lung can only be heard anteriorly. In addition to identifying areas of decreased breath sounds, the quality of lung sounds on auscultation can further differentiate underlying lung pathology. Normal (vesicular) lung sounds are continuous. Other continuous breath sounds include wheezing (sibilant or musical rhonchi) and bronchial (tubular) breath sounds (“Darth Vader” or snorkel breathing), which occur normally over the trachea or upper anterior chest wall. Discontinuous breath sounds include the sound of small alveolar sacs popping open in fluid-based lung consolidation, which are heard as adventitious lung sounds such as fine rales or crackles. This can occur in both bases, as in congestive heart failure, or in a more localized area, as in a lobar pneumonia. The sound has been described as similar to tufts of hair being rubbed together close to the ear.

Because decreased breath sounds and dullness to percussion can represent either fluid in the pleural space or consolidation of the lungs themselves, additional physical findings can help differentiate the two conditions. Vocal fremitus and tactile fremitus are increased in lung consolidation but decreased in pleural effusion. Localized *egophony* (“e-to-a” changes) indicates consolidation of that segment or lobe of the lung; it is not present in pleural effusion except in a small band just above the upper edge of the effusion.

Signs of bronchial inflammation, mucus, and obstruction in the bronchial tree include coarse crackles and wheezes (sonorous or musical rhonchi). Additionally, in normal vesicular breathing, the duration of the inspiratory phase is longer than the expiratory phase—typically 90% of the expired air is exhaled in the first second. Prolongation of

the expiratory phase is an early sign of obstruction, even before wheezing develops. The diagnostic implications of these physical examination findings are summarized in Table 18-1.

Pulmonary Function Testing

Key Points

- Obstructive lung disease is diagnosed by demonstrating a ratio of forced expiratory volume at 1 second (FEV₁) to forced vital capacity (FVC) (or FEV₁/FEV₆ ratio) of less than 70%.
- Improvement in FEV₁ of at least 12% and at least 200 mL from prebronchodilator to postbronchodilator is considered evidence of reversibility of airway obstruction.
- Restrictive lung disease can be diagnosed using office spirometry if the FVC is reduced to less than 80% of predicted, in the presence of a normal FEV₁/FVC ratio (i.e., no obstruction).

Pulmonary function testing is essential for detecting lung disease and for differentiating obstructive from restrictive lung disease. Pulmonary function tests (PFTs) may be done in a hospital-based pulmonary function laboratory or, more often, in the outpatient setting using office spirometry. The simplest PFT is the *peak expiratory flow rate* (PEFR), measured by hand-held mechanical peak-flow meters given to patients for self-management and used in office settings and emergency departments (EDs) for quick assessment during acute exacerbations of asthma. PEFR is the maximum flow generated during expiration performed with maximal force (“Take a deep breath and blow out as hard and as fast as you can”).

Previous office spirometry units were bulky and required frequent recalibration, but modern units are small, computerized, and often self-calibrating. Quality of testing is important. The patient should be seated comfortably and instructed appropriately. An adequate PFT must include three valid measures (quick start, good effort, maintenance of forced expiration for at least 6 seconds with no cough) and three relatively similar results (FVC varying by <200 mL).

Table 18-1 Physical Findings in Common Pulmonary Disorders

| Disorder | Inspection | Palpation | Percussion | Auscultation |
|---------------------------------|--|---|-------------------------------|---|
| Bronchial asthma (acute attack) | Hyperinflation; use of accessory muscles | Impaired expansion; decreased fremitus | Hyperresonance; low diaphragm | Prolonged expiration; inspiratory and expiratory wheezes |
| Pneumothorax (complete) | Lag on affected side | Absent fremitus | Hyperresonant or tympanic | Absent breath sounds |
| Pleural effusion (large) | Lag on affected side | Decreased fremitus; trachea and heart shifted away from affected side | Dullness or flatness | Absent breath sounds |
| Atelectasis (lobar obstruction) | Lag on affected side | Decreased fremitus; trachea and heart shifted toward affected side | Dullness or flatness | Absent breath sounds |
| Consolidation (pneumonia) | Possible lag or splinting on affected side | Increased fremitus | Dullness | Bronchial breath sounds; bronchophony; pectoriloquy; crackles |

Modified from Hinshaw HC, Murray JF. *Diseases of the Chest*, 4th ed. Philadelphia, Saunders, 1980, p 23.

Results of office spirometry are presented both graphically and numerically, with actual values compared to values predicted by the patient's age, height, and gender. Figure 18-1 shows the points at which two critical values, *forced expiratory volume at 1 second* (FEV_1) and *forced vital capacity* (FVC), are measured on the time-volume curve. Figure 18-2 shows a typical flow-volume loop for patients that compares normal PFTs with obstructive lung disease and restrictive lung disease (Zoorob et al., 2002). Increasingly, the 6-second end point, or FEV_6 , is being used as a reliable and reproducible surrogate measure that can replace FVC for patients unable to complete forced expiration beyond 6 seconds.

The key parameters of office spirometry are the FEV_1 , the FVC, and the FEV_1/FVC ratio (percentage of exhaled volume blown out in first second of exhalation). The diagnosis of obstructive lung disease is made by demonstrating an FEV_1/FVC ratio (or FEV_1/FEV_6) of less than 70%. This means that the patient has exhaled less than 70% of FVC (full volume of air exhaled) in the first second of exhalation. Other tests of airway obstruction are the *mid-maximal expiratory flow rate* (MMEF, or FEF_{25-75}), which is the average expiratory flow over the middle half of expiration, that is, flow rate during the

Figure 18-1 Time-volume spirometry curve showing measurement of FEV_1 , FVC, and FEV_6 and curves for obstructive versus restrictive lung disease.

time when 25% to 75% of the FVC is exhaled. This measure has been described as representing small airway obstruction, but it is less reproducible and has not been included in clinical guidelines for managing patients with obstructive lung disease. However, MMEF can be an early indicator of lung damage caused by smoking or occupational pneumoconioses. The FEF_{25} and FEF_{75} are moment-in-time measures of expiratory airflow and are therefore subject to significant patient-to-patient variability unrelated to clinical factors.

One other dimension of office spirometry in diagnosing and managing obstructive lung disease is to measure these parameters before and after a dose of inhaled beta-2 (β_2)-adrenergic agonist is given. Improvement in FEV_1 of at least 12% and at least 200 mL from prebronchodilator to postbronchodilator measurement is considered evidence of reversibility of airway obstruction. Complete reversibility helps establish the diagnosis of asthma, and it is also useful in guiding therapy by establishing the potential efficacy of medications. For example, some patients with chronic obstructive pulmonary disease (COPD) are more responsive to anticholinergic medications such as inhaled ipratropium, whereas others are more responsive to inhaled β_2 -agonists such as albuterol.

For restrictive lung disease, the "gold-standard" test is the *total lung capacity* (TLC), which is a measure of maximal exhaled air (FVC) plus residual capacity (RC). However, this can only be tested in pulmonary function laboratories that can test the patient in a sealed chamber. For practical purposes in the primary care setting, restrictive lung disease can be diagnosed using office spirometry if the FVC is reduced to less than 80% of predicted in the presence of a normal FEV_1/FVC ratio (i.e., no obstruction). One other test that is available in pulmonary function labs but not in office spirometry is the *diffusion capacity* (DL_{CO}), which is a measure of the diffusion of carbon monoxide across the alveolar-capillary membrane. Clinical reductions in DL_{CO} can occur with thickening of the alveolocapillary membrane, which can be a sign of interstitial fibrosis.

Chest Radiography and Other Diagnostic Imaging

Despite major advances in imaging technology, the chest x-ray film (CXR) is still an important diagnostic modality that can clearly reveal signs of pneumonia, COPD, heart

Figure 18-2 Flow-volume loop showing curves for normal (A), obstructive (B), and restrictive (C) lung disease.

failure, tuberculosis, lung masses, and pleural effusion. **Figure 18-3** shows a chest radiograph with right middle lobe pneumonia. Although the posteroanterior (PA) film shows some consolidation, it is attenuated by the overlying projection of a normal lower lobe. The lateral film, however, shows the classic wedge-shaped profile of a consolidated right middle lobe.

Chest radiography is also widely used in evaluating patients with suspected exposure to tuberculosis (TB), either because of symptoms, personal contact, or a positive intradermal

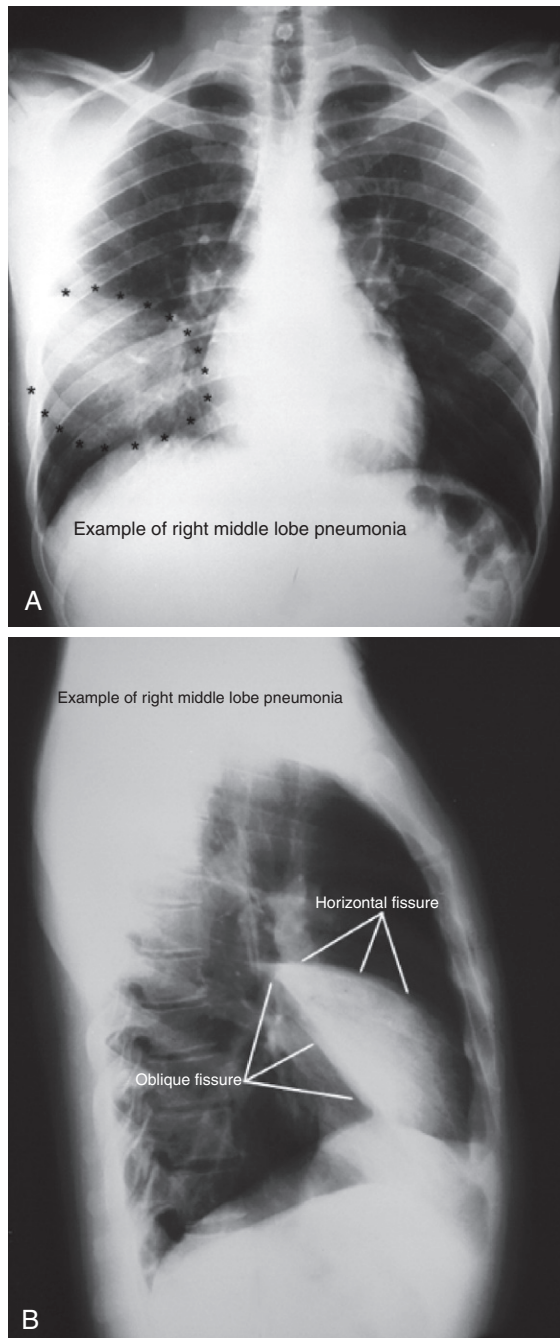

Figure 18-3 Posteroanterior (A) and lateral (B) chest radiographs showing right middle lobe pneumonia. (From Department of Neurobiology and Developmental Sciences, University of Arkansas for Medical Sciences, Little Rock. http://anatomy.uams.edu/anatomyhtml/xrays/xra_atlas39.html and http://anatomy.uams.edu/anatomyhtml/xrays/xra_atlas5.html)

purified protein derivative (PPD) test. **Figure 18-4** shows the patchy infiltrates and hilar adenopathy typical of pulmonary TB, although TB can have a variety of presentations on chest x-ray films, including adenopathy, pleural scarring, infiltrates, cavitary lesions, and miliary TB.

Chest radiography can also be helpful in diagnosing non-pulmonary causes of shortness of breath, as in the case of congestive heart failure, with enlarged heart, bibasilar consolidation, small pleural effusions, and prominent pulmonary vasculature. In other conditions such as asthma, chest x-ray films can be quite normal despite significant respiratory compromise.

Increasingly, chest computed tomography (CT) scan plays an important role in diagnosing lung disease. High-resolution CT (HRCT) can identify pulmonary nodules and hilar lymph nodes at much smaller sizes than can chest radiography, and it is therefore important in diagnosing and staging lung cancers. CT can also detect lung abscess, vascular lesions, and pleural scarring or masses. Whereas early COPD or emphysematous changes can be difficult to detect with even HRCT, additional techniques such as minimum-intensity projection (MIP) can aggregate data from adjacent slices and, by subtracting vascular and other tissue densities not consistent with lung parenchyma and air, demonstrate small air pockets consistent with early emphysema.

Imaging modalities such as spiral CT have been demonstrated to be effective in detecting early lung cancer in patients with high-risk smoking histories, but as yet they have not demonstrated improvements in mortality that would justify this as a universal screening test for smokers in primary care practice. When small, noncalcified pulmonary nodules are detected by CT, the likelihood of malignancy is influenced by nodule size, density, number of nodules, and growth over time, combined with patient factors such as age, smoking history, gender, spirometry, occupational history, and endemic granulomatous disease (Libby et al., 2004).

Positron emission tomography scans using ^{18}F -fluorodeoxyglucose (FDG-PET) are becoming increasingly useful in evaluating lung cancers and lymphomas. The ability to define anatomy and metabolism, that is, glucose uptake within the

Figure 18-4 Chest radiograph showing tuberculosis, with upper lobe fibrotic patchy infiltrates and hilar adenopathy. (From Centers for Disease Control and Prevention, Public Health Image Library, Image 2543. <http://phil.cdc.gov/phil/home.asp>)

tumor, makes the PET scan useful for staging, detecting node involvement, and defining resectability, tumor response to therapy, and tumor recurrence (Avril and Weber, 2005). Diagnosing solitary pulmonary nodules is a common challenge in primary care. A meta-analysis of studies comparing dynamic CT, magnetic resonance imaging (MRI), FDG-PET, and single-photon emission computed tomography (SPECT) scans based on positive and negative likelihood ratios for identifying malignant versus nonmalignant solitary nodules found that all four were similarly accurate (Cronin et al., 2008). Nuclear medicine studies such as gallium scans are also used extensively in evaluating pulmonary symptoms in patients with human immunodeficiency virus (HIV) infection or acquired immunodeficiency syndrome (AIDS) and are discussed in the section on HIV-related pulmonary infections in more detail.

Other imaging studies have more specific indications. One nuclear medicine study long used in primary care is the ventilation-perfusion (V/Q) scan. This is specifically performed to rule out pulmonary embolism, revealed by focal perfusion defects in adequately ventilated areas. This V/Q mismatch, in the absence of underlying lung pathology, is consistent with a high probability of pulmonary embolism. Unfortunately, patients can also demonstrate matching V/Q defects, which can occur when blood flow is shunted away from an under-ventilated area of the lung. Scans with no perfusion defect reflect a low probability for significant pulmonary embolism. Other tests are increasingly taking the place of the V/Q scan (see later discussion).

Bronchoscopy

Fiberoptic bronchoscopy allows direct visualization of the bronchial tree. It is useful for diagnosing conditions that require culture of a lower respiratory tract infection by bronchoalveolar lavage (BAL), or conditions such as bronchogenic carcinoma, that require tissue diagnosis by transbronchial biopsy. Sometimes these techniques are combined, as in the diagnosis of *Pneumocystis jiroveci* (carinii) pneumonia (PCP), for which the sensitivity of bronchoscopy with BAL is approximately 86% and with transbronchial biopsy is 87% (Broaddus et al., 1985). A comparative assessment of different bronchoscopic techniques in obtaining culture specimens in cases of ventilator-associated pneumonia found no significant difference between blind bronchial brushings and bronchoscope-assisted lavage, bronchoscope-directed brushings, or even blind endotracheal aspirates (Wood et al., 2003). Rates of complications (including hemoptysis and pneumothorax) with traditional bronchoscopy are in the range of 0.5% to 1.0% without biopsy and up to 6.8% with transbronchial biopsy (Pue and Pacht, 1995). In a pulmonary fellowship program, the rate of complications for all bronchoscopies performed (with and without biopsy) was 2.06% (Ouellette, 2006). Therapeutic interventions using bronchoscopy are also increasing, and lesions are treated through the bronchoscope with laser, cryotherapy, electrocautery, and stents (Rafanan and Mehta, 2000).

Newer diagnostic techniques include fluorescent bronchoscopy, which can be more sensitive for detecting early endobronchial tumors (Gilbert et al., 2004; Moghissi et al., 2008), and virtual bronchoscopy, which uses sophisticated

software to reconstruct images from HRCT scan, to create three-dimensional imagery without invasive testing. This technique has been found useful in planning partial lung resection surgery, for example, but it cannot provide bronchoscopy's direct visualization of color, texture, or friability of the bronchial mucosa (Finklestein et al., 2004).

Measurement of Blood Gases

Measurement and monitoring of blood gases can be invasive or noninvasive. Transcutaneous pulse oximetry is the most widely used noninvasive test. It provides a fairly accurate measure of oxygen saturation (SO_2) of hemoglobin at values ranging from 70% to 100% by measuring the difference between oxyhemoglobin and reduced hemoglobin in the absorption of light of specific wavelengths. SO_2 of 98% corresponds to an arterial oxygen partial pressure (PaO_2) of 100 mm Hg, and 95% to a PaO_2 of 80 mm Hg, demonstrating the challenge of interpreting a test with a 95% confidence interval of $\pm 5\%$. An oxygen saturation of less than 89% corresponds to a PaO_2 of less than 60 mm Hg. Decreased tissue perfusion or color changes caused by jaundice or intravascular dyes can degrade accuracy. Arterial oxygen levels can also be measured transcutaneously ($tcPo_2$) with a skin surface oxygen electrode, but its accuracy is also affected by tissue perfusion, skin temperature, and other factors.

Exhaled carbon dioxide can also be measured noninvasively, most often in the ICU for patients on mechanical ventilation or in operating rooms during general anesthesia. Capnography, colorimetric techniques, and CO_2 sensors can detect failure of mechanical ventilation or improper endotracheal tube placement, which generate hypercapnia secondary to hypoventilation.

The invasive technique most often used for measuring oxygen, CO_2 , and acid-base blood chemistries is the arterial blood gas (ABG) measurement. Although it requires an arterial needle puncture and several milliliters of blood, it is highly accurate and reproducible. ABG measurement is indicated in any patient with acute respiratory distress or in managing the patient with respiratory failure. In addition to PaO_2 and arterial carbon dioxide partial pressure ($Paco_2$) measurements, ABG testing also provides a measure of pH, bicarbonate (HCO_3^-), and the anion gap, which can be used to detect respiratory (rather than metabolic) causes of acidosis and alkalosis. Patients with moderate to severe COPD can have chronic hypoxia plus chronic hypercapnia (decreased PaO_2 and increased $Paco_2$). They can also show signs of primary respiratory acidosis (reduced pH with elevated CO_2), and a compensatory metabolic alkalosis (partial normalization of the pH despite elevated $Paco_2$) mediated by renal HCO_3^- retention. Nomograms or software used in personal digital assistants (PDAs) allow simultaneous plotting of pH, CO_2 , and HCO_3^- to facilitate interpretation of mixed respiratory and metabolic acid-base disturbances.

Common Pulmonary Symptoms

Shortness of Breath

A common presenting symptom in pulmonary disease is shortness of breath. The fundamental question in patients presenting with recent-onset or episodic shortness of breath is this: Is it a lung problem, a heart problem, or something

else? The most common pulmonary causes of chronic or repeated episodes of shortness of breath include asthma, smoking-related COPD, chronic lung infections (TB and HIV-related infections), and occupational pneumoconiosis. Acute-onset shortness of breath can be caused by acute exacerbations of any of these chronic conditions, by acute infections such as pneumonia or acute bronchitis, or by spontaneous pneumothorax. Among otherwise healthy children, shortness of breath can be related to asthma, bronchiolitis, pneumonia, or upper-airway problems such as croup or epiglottitis. Chronic shortness of breath in children can be related to poorly controlled asthma, bronchopulmonary dysplasia from infancy, or chronic diseases (e.g., cystic fibrosis).

The cardiovascular system is the other organ system most often linked to shortness of breath. In adults, congestive heart failure (CHF) is a leading cause of recent-onset shortness of breath among middle-aged and older adults. In addition to shortness of breath, patients might report symptoms of wheezing from the pulmonary congestion, often referred to as *cardiac asthma*. Differentiating early CHF from pulmonary causes of dyspnea can be a challenge in middle-aged or older patients who smoke or have other chronic medical conditions. Other cardiac conditions associated with shortness of breath include pericarditis and cardiomyopathy, as well as congenital heart defects in infants presenting with respiratory distress. Vascular conditions include chronic pulmonary hypertension and pulmonary embolism in the setting of acute-onset shortness of breath.

Along with the history and physical examination, testing can help in ruling out pulmonary versus cardiac causes of dyspnea. Physicians often begin diagnostic testing with electrocardiogram (ECG) and even echocardiogram to rule out cardiac causes of shortness of breath, but simple history, auscultation of the heart and lungs, chest radiograph, and office spirometry can also assess for common pulmonary causes of shortness of breath. Improvement on weekends or non-workdays can suggest an occupational exposure, and a prolonged expiratory phase with expiratory wheezing suggests obstructive lung disease. Orthopnea and pedal edema suggest a cardiac cause. Bibasilar rales suggest fluid in the lower lung fields from CHF. ECG can approximate chamber enlargement and identify arrhythmias that might decrease ventricular filling time. Echocardiogram can measure ejection fraction and systolic or diastolic dysfunction indicating heart failure; local wall motion abnormalities suggesting ischemic disease; and valvular abnormalities. Levels of B-natriuretic protein (BNP) have a 90% sensitivity and 76% specificity for CHF; levels less than 100 pg/mL make CHF unlikely as the principal cause of shortness of breath or wheezing (Mueller et al., 2005). Chest radiograph can help rule out pulmonary or other thoracic mass lesions, lung infections, granulomatous or interstitial lung disease, pleural disease, pneumothorax, and cardiomegaly, supplemented with CT as needed. Although young patients with a normal physical examination have a low yield on chest radiography, up to 86% of patients older than 40 years with dyspnea have an abnormal chest x-ray film (Benacerraf et al., 1981). Spirometry showing an FEV₁/FVC ratio less than 70% is diagnostic of obstructive lung disease, and an FVC less than 80% of predicted value in the presence of a normal FEV₁/FVC ratio suggests restrictive lung disease.

Many patients present primarily with dyspnea on exertion. The 6-minute walking exercise test is a valid measure of exercise tolerance (compared with maximal exercise testing) in patients with COPD and other pulmonary conditions, as well as in various stages of CHF. It can be performed in primary care settings to assess functional disability and response to therapy (American Thoracic Society, 2002; Lipkin et al., 1986). In patients with pulmonary hypertension, the distance walked with encouragement in 6 minutes in a controlled environment is also a strong independent predictor of mortality (Miyamoto et al., 2000).

Formal cardiac ECG stress testing by exercise treadmill can quantify the level of exercise tolerance and diagnose cardiac ischemia or angina-equivalent conditions, in which a person has ischemia-induced shortness of breath but no chest pain. However, the test has a sensitivity of only 63% and specificity of 74% (86% specificity in the setting of three-vessel or left main coronary artery disease) (Gibbons et al., 1997). Other types of cardiac stress testing, such as exercise echocardiography or the nuclear medicine thallium treadmill test, can be more specific (see Chapter 27) (Mayo Clinic, 1996). The American College of Cardiology and American Society of Echocardiography published a recent consensus guideline on the appropriate use of stress echocardiography for specific clinical scenarios (Douglas et al., 2008). For patients unable to exercise, increased cardiac work may be induced pharmacologically, but dipyridamole and adenosine can each cause bronchospasm and should be avoided in patients with asthma or any other obstructive lung disease or undiagnosed pulmonary conditions (Tak and Gutierrez, 2004).

The presentation of patients with acute-onset shortness of breath requires more urgent evaluation. In addition to history and physical examination, a peak-flow test, chest x-ray film, ECG, complete blood count, and pulse oximetry or ABG testing may be done in short order. Further testing or treatment is guided by the differential diagnosis generated by this initial evaluation. Cardiac isoenzymes and troponin levels can help rule myocardial infarction in or out. If asthma is suspected, responsiveness to a trial of inhaled bronchodilator is both diagnostic and therapeutic. Antibiotics are initiated in cases of pneumonia or other pulmonary infection, and HIV testing can help in cases of suspected opportunistic infections (e.g., PCP).

Any suspicion of pulmonary embolism (PE) as a cause of acute shortness of breath requires specific diagnostic evaluation to allow quick intervention in this potentially life-threatening condition. Acute-onset shortness of breath coupled with pleuritic chest pain, hemoptysis, wedge-shaped pulmonary infarct lesions on chest radiograph, and an S1Q3 pattern and tachycardia on ECG can all point specifically to a diagnosis of PE, but most patients have a more nonspecific presentation. All patients with acute-onset shortness of breath with no apparent cause should be evaluated for PE. Physical examination for signs of deep venous thrombosis (DVT) (e.g., asymmetry in calf or thigh diameter, calf tenderness, Homans sign) are relatively insensitive and nonspecific, whereas other tests (e.g., D-dimer, CT angiography) can more accurately confirm the presence of significant underlying DVT. Clinical decision rules using objective scoring algorithms help establish pretest probability, which in turn enhances the predictive value of other tests for PE (Wells et al., 2000) (see later discussion).

Cough

Cough is also a common presenting symptom in primary care. Although cough can be part of a constellation of symptoms that leads to a specific diagnosis, it can also be the primary symptom in an undifferentiated patient. In these cases, the diagnosis must be obtained through a combination of careful history, physical examination, limited diagnostic testing, and often a trial of empiric therapy. Several elements of the history guide the initial differential diagnosis, especially a history of smoking, immunocompromise (HIV/AIDS or cancer chemotherapy), chronic pulmonary disease, medication use (ACE inhibitors), specific occupational exposures, or exposure to TB patients or TB-endemic areas.

Acute episodes of cough, defined as less than 3 weeks, are almost always caused by an acute infection (usually viral) or an acute exacerbation of chronic disease such as asthma or COPD, and the first rule should be to “do no harm” (*primum non nocere*) by treating conservatively and using time as a diagnostic test. Most episodes of acute cough caused by infection are viral in origin, mainly viral upper respiratory tract infections or acute bronchitis. Acute bacterial infections include sinusitis as well as bacterial overgrowth in exacerbations of chronic bronchitis or COPD. Fever, hemoptysis, or significant shortness of breath in association with cough indicates a chest radiograph or other immediate diagnostic evaluation. Frank hemoptysis can require urgent bronchoscopy for diagnosis and potentially for treatment (electrocoagulation of bleeding site). Without evidence of bacterial infection (clear evidence of sinusitis or pneumonia), previously healthy patients should generally be treated symptomatically without antibiotics, unless symptoms persist for more than 3 weeks.

Foreign body aspiration is a diagnostic consideration in children with either acute or chronic cough. Exacerbations of asthma, as well as infections by *Bordetella pertussis* (whooping cough) or *Bordetella parapertussis*, can lead to a persistent cough for as long as 3 to 8 weeks. Cough might indeed be the only symptom experienced by some patients with asthma (cough-variant asthma). In patients with underlying chronic bronchitis or COPD, antibiotics may be indicated during episodes of increased shortness of breath, wheezing, hypoxia, or limitations of activity if accompanied by a sudden change in sputum from thin and clear to thick or copious or yellow-green. Other subacute or chronic infections include bronchiectasis, which can manifest with a cough productive of mucopurulent, blood-tinged, or foul-smelling sputum. In children with chronic productive cough or recurrent pulmonary infections, cystic fibrosis must be considered. Survivors of premature birth with mechanical ventilation in neonatal intensive care may have chronic lung disease with acute exacerbations.

In adults, the most common causes of chronic cough in nonsmokers are postnasal drip, asthma, gastroesophageal reflux disease (GERD), and angiotensin-converting enzyme (ACE) inhibitors (Holmes and Fadden, 2004). Among smokers, chronic bronchitis, bronchiectasis, and bronchogenic carcinoma (lung cancer) must also be considered. Additional elements of the history can suggest other diagnoses. For example, occupational exposures can suggest specific diagnoses such as coal miner’s lung or farmer’s lung. Immigration from or travel to TB-endemic areas could suggest tuberculosis.

After the history and physical examination, a chest radiograph is the most valuable diagnostic test in evaluating the

patient with chronic cough. Chest x-ray films can reveal infections (atypical pneumonia or TB), mass lesions (carcinoma), granulomatous disease (sarcoidosis), or evidence of occupational lung disease. Radiography can also reveal non-pulmonary causes of chronic cough, such as early CHF or pleural lesions. Office spirometry may also be performed to rule out obstructive lung disease.

In an otherwise healthy nonsmoker with chronic cough and a normal chest x-ray film, a trial of simple measures may be indicated. Persons being treated with an ACE inhibitor should be switched to alternative medication. Patients with occupational exposures should avoid the exposure or use protective equipment and should begin keeping a log to document the association of symptoms with days spent in workplace areas of exposure. Patients with signs of allergic rhinitis or postnasal drip may begin a simple trial of antihistamines. Patients with symptomatic GERD may begin taking a proton pump inhibitor (e.g., omeprazole) or H₂ antagonist. In some cases, chronic cough is the only symptom of GERD, and a successful trial of these agents is diagnostic.

Follow-up is essential, and the primary care practitioner must document instructions to patients that those who do not respond to empiric therapy in 2 to 3 weeks need further diagnostic evaluation. If asthma is suspected and initial office spirometry revealed normal pulmonary function, a simple approach is to ask the patient to keep a log of symptoms and peak flow meter readings, with peak flow tested within 30 minutes of rising each morning. In patients with an abnormal chest radiograph or in smokers with a normal radiograph and a chronic cough that does not respond to empiric therapy, a HRCT scan or even bronchoscopy may be indicated to rule out malignancy. Additional causes of chronic cough that might require further testing include sarcoidosis, TB, and other granulomatous or interstitial lung diseases, as well as pulmonary manifestations of autoimmune disease such as rheumatoid arthritis (RA) or systemic lupus erythematosus (SLE).

Patients with HIV/AIDS or other compromise of the immune system deserve specific evaluation (see Chapter 17). HIV testing may be indicated in patients with any risk factors, because pulmonary symptoms can be the first manifestation of symptomatic HIV disease. In patients known to be HIV positive, tests in addition to chest radiography and HRCT could include gallium scan, PET, bronchoscopy with BAL for stains and cultures, PPD, and sputum testing for PCP.

Obstructive Lung Disease

The most common chronic lung diseases that have a major global impact on disability and health care costs are three obstructive lung diseases: asthma, chronic obstructive pulmonary disease, and chronic bronchitis. Some patients have features of more than one of these conditions, such as the patient with asthma (acute episodes of reversible obstruction) who also has chronic bronchitis (cough productive of phlegm at least 3 months of the year for at least 2 years in a row), or the adult patient with asthma who is developing some level of irreversible decline in pulmonary function. COPD alone can ultimately result in pathologic signs of emphysema, a diagnosis previously made only with tissue pathology or large blebs on x-ray film but increasingly visible with various multislice HRCT techniques.

Asthma

Key Points

- Asthma is defined as an inflammatory, episodic, obstructive lung disease that is completely reversible.
- Self-management is focused on control of environmental triggers, regular peak-flow monitoring, and action plans, which can prevent or abort most flare-ups of asthma.
- All patients with persistent asthma (daytime symptoms more than twice a week or nocturnal symptoms more than twice a month) should be treated with daily long-term control medication, preferably an inhaled corticosteroid.
- Eliminating passive exposure to smokers is the most important intervention in eliminating environmental triggers.

Asthma is a chronic inflammatory airway disease characterized by recurring acute episodes of reversible airway obstruction, with return to normal lung function between episodes. Although bronchospasm is a component of the reversible airway obstruction, recent clinical guidelines have emphasized the inflammatory pathophysiology of asthma (National Heart, Lung and Blood Institute, 2007). Therefore the clinician must treat and prevent the inflammation that leads to mucosal edema, secretions, histologic remodeling of the airways, and bronchospasm of smooth muscle origin.

Epidemiology and Risk Factors

Asthma is the most common chronic disease of childhood and affects many adult patients as well. The prevalence of asthma is increasing rapidly worldwide. It now affects more than 300 million people and causes the loss of more than 15 million disability-adjusted life-years (DALY) each year (Global Initiative for Asthma, 2006). Asthma prevalence is increasing in many countries and is not decreasing globally, despite some indications of decreased emergency care utilization linked to improved care (Anandan et al., 2009). In the United States, National Health Interview Survey (NHIS) data (2002) suggest that 20 million Americans would report currently having asthma (72 per 1000 people). Asthma affects an estimated 6.1 million children nationally (83 per 1000). Across all age groups, asthma led to 1.9 million ED visits (National Hospital Ambulatory Medical Care Survey, 2002) and 4261 deaths in 2002, down from 4487 deaths in 2000 (National Vital Statistics System, 2002a). In 2003, asthma was the primary diagnosis for 469,738 hospitalizations in the United States, with an in-hospital mortality rate of 0.36% (Health Care Utilization Project, 2003). These hospitalizations alone generated charges of over \$5.4 billion.

Asthma is also a high-disparity condition. Low-income, uninsured, and minority patients with asthma consistently receive worse care and have worse outcomes compared with asthma patients in the general population (Lang and Polansky, 1994). Hospitalization rates in the United States are 3.3 times higher for black than for white patients (National Vital Statistics System, 2002b). Publicly insured and uninsured patients are significantly more likely to be hospitalized and to seek ED care during acute exacerbations (Targonski et al., 1995).

The strongest risk factors for developing asthma are exposure to household smokers and a family history of asthma or atopy (asthma, atopic dermatitis, or allergic rhinitis). Family history of nasal polyps or aspirin hypersensitivity can also suggest risk for IgE-mediated atopic disease. Data are mixed on the impact of early childhood infections and bottle feeding versus breastfeeding on the development of asthma, although both are clearly associated with wheezing episodes in the first 3 years of life. Data showing a paradoxical protective effect of early childhood exposure to pets, farm animals, and bacterial antigens are still controversial (Adler et al., 2005; Platts-Mills et al., 2005; Remes et al., 2005; Waser et al., 2005).

Clinical Presentation and Diagnosis

A complete history in patients suspected of having asthma should include the frequency and severity of recent symptoms and should distinguish between daytime and nocturnal symptom frequency, a factor that is also important in staging asthma. A history of past or present smoking (tobacco or other drugs) is essential, as is an inquiry about current passive exposure to smokers in the household or occupational secondary exposure to tobacco smoke (e.g., bartenders, restaurant staff). The clinician should also inquire about activities, acute illnesses, or environmental exposures that trigger episodes, a family history of asthma or atopic disease, and a detailed occupational history. Some patients are also exposed to bronchial irritants through hobbies such as woodworking or oil painting.

Symptomatically, patients can present with complaints of chronic or acute episodic shortness of breath, wheezing, chest tightness, or a chronic cough (often at night). If they already have a diagnosis of asthma, they may report relief with rescue inhalers such as albuterol. Some patients, especially children, only have nocturnal cough, a syndrome known as *cough-variant asthma*, whereas others have symptoms precipitated mostly by exercise or by breathing in cold air.

On physical examination, the patient might have obvious difficulty breathing or audible wheezing during an acute episode. Patients with significant shortness of breath can have difficulty completing a full sentence without taking a breath, which could be described as “three-word dyspnea” (number of words the patient can say without taking a breath). Inspection can reveal nasal flaring, breathing through pursed lips, central or acral cyanosis, hyperexpansion of the chest, or use of accessory respiratory muscles. In more extreme cases, patients appear to have respiratory exhaustion, central or distal cyanosis, or even a blunting of mental status.

On auscultation, the earliest sign of airway obstruction is a prolonged expiratory phase (expiratory phase longer than inspiratory phase). A more obvious sign of asthma is expiratory wheezing. Wheezing can sometimes be brought out by forced expiration, performed by asking the patient to blow out forcefully while the examiner listens over the second intercostal space at the right costal margin. More severe cases of obstruction can result in both inspiratory and expiratory wheezing. In the most severe cases, wheezing might not be audible at all because airflow is minimal. In these cases, wheezing becomes much more prominent as airflow improves. Another sign of severity of an acute episode

is *pulsus paradoxus*, defined as a decrease in systolic blood pressure of more than 20 mm Hg during inspiration.

A more objective measure of pulmonary function during an acute exacerbation of asthma is to measure the peak flow of air during forced expiration using a simple, low-cost peak-flow meter. Airflow is measured in liters per second. The best of three attempts is recorded as the peak-flow measurement. Results can be measured against nomograms based on the patient's age, gender, and height, but a better measurement is to compare the patient's peak flow during the acute episode against their baseline or best performance during a period of complete remission from asthma signs or symptoms.

When patients present with a history of asthma-like symptoms in the primary care setting, the diagnosis can be confirmed with office spirometry, a form of pulmonary function testing. The essential criterion for a diagnosis of airway obstruction is an FEV₁/FVC ratio of less than 70%. To diagnose asthma, the clinician must also demonstrate reversibility with inhaled bronchodilators, either through the patient's history or improvement in the forced expiratory volume of greater than 200 mL or 12%. Because asthma is defined as an obstructive lung disease that is completely reversible between episodes, testing in the office during asymptomatic periods might not demonstrate airway obstruction. In this case, it is helpful for the patient to use a peak-flow meter at home, testing three times each morning and recording the best value, as well as testing during symptom episodes. The record of these values can be reviewed with the family physician to aid in diagnosis, as well as for coaching the patient in self-management and prevention of future episodes.

Chest radiography is not always indicated if the patient has a classic history of episodic airway obstruction, especially if it is reversible with β -agonist rescue inhalers. In infants and children, however, the physician must distinguish upper-airway causes of obstruction from obstructive lung disease. Examples include croup or laryngotracheobronchitis, epiglottitis, and foreign bodies lodged in the upper airway. In infants and in older adults, the clinician must also exclude so-called cardiac asthma, which manifests as wheezing or other signs of airway obstruction related to pulmonary edema or CHF. In these patients, chest radiography is clearly indicated.

Patients older than 40 years who have new-onset asthma should have a complete workup to rule out other causes of airway obstruction. Many clinicians order a chest radiograph in all patients with new asthma, although there is a low rate of finding pathology in otherwise healthy older children and young adults. Chest x-ray films obtained during an acute episode of asthma can give false-positive findings of infiltrates or atelectasis.

Treatment

The National Asthma Education and Prevention Program (NAEPP) guidelines provide a comprehensive and evidence-based approach to the clinical care of asthma (National Heart Lung and Blood Institute, 1997; NAEPP Expert Panel Report 3, 2007). Unfortunately, there is a large gap between best-practice guideline-based care and usual care, as measured by compliance with these national guidelines (Thier et al., 2008) and by the clinical outcomes achievable when these guidelines are followed.

Acute Exacerbations

The mainstay of treatment for acute exacerbations of asthma is inhaled β -agonist medication such as albuterol. Although β -agonist medication is typically administered in the ED or physician's office with a nebulizer machine, a meta-analysis of controlled trials showed that a hand-held metered-dose inhaler (MDI) with a spacer device is at least as effective as a nebulizer in delivering albuterol and achieving a clinical response, as measured by pulmonary function and by clinical outcomes such as hospitalization (Castro-Rodriguez and Rodrigo, 2004). Adding ipratropium bromide to albuterol nebulizer treatments for patients with severe airflow obstruction in the acute ED setting produces additional bronchodilation, resulting in fewer hospital admissions (Plotnick and Ducharme, 2000; Rodrigo and Castro-Rodriguez, 2005).

Additional modalities of treatment include oxygen by nasal cannula or mask, and intravenous (IV) fluids for hydration. Short-term administration of systemic corticosteroids has also been demonstrated to be effective. Corticosteroids may be given intravenously (methylprednisolone), intramuscularly (dexamethasone or equivalent), or orally (prednisone or methylprednisolone). When given for 3 to 5 days as burst or pulse-dose therapy, steroids do not need to be tapered to prevent adrenal suppression. However, patients with chronic or severe exacerbations of asthma can require prolonged tapering to prevent rehospitalization for recurrence of airway obstruction.

Another treatment with evidence for efficacy in treating acute exacerbations of asthma is IV magnesium sulfate. A meta-analysis showed significant benefit in decreasing the rate of hospitalization of ED patients and in improving pulmonary function and clinical symptom scores (Cheuk et al., 2005). The most recent NAEPP Expert Panel Report (EPR-3, 2007) now recommends considering using IV magnesium sulfate or heliox-driven albuterol nebulizer treatments in patients who have failed to respond to 1 hour of conventional asthma therapy. Previous studies simply using heliox in place of oxygen did not prove beneficial (Rodrigo et al., 2003).

The benefit of other treatment options is less well documented. A meta-analysis showed that children treated with theophylline during hospitalizations for acute asthma exacerbations required more albuterol treatments and had longer hospital stays than children not treated with theophylline (Goodman et al., 1996).

Chronic Care and Disease Management

To achieve optimal outcomes, each patient should have a personal asthma care plan, which can be summarized in the mnemonic MAP (Box 18-2). The *management* plan refers to

Box 18-2 MAP for Asthma Care

Management Plan

- What do I do every day to control my asthma?

Action Plan

- What do I do when I have acute symptoms or my peak-flow meter values are dropping?

Prevention Plan

- What can I do to control asthma triggers and prevent acute flare-ups?

daily medications or activities such as measuring peak flow; an *action* plan is needed for specific steps to take in the event of increased symptoms or deteriorating peak-flow values; and a *prevention* plan focuses on understanding personal and environmental triggers, such as avoiding passive exposure to cigarette smoke and eliminating dust mite and cockroach antigens.

Appropriate chronic care requires appropriate staging of the clinical severity of asthma. Stage 1 is intermittent and stages 2, 3, and 4 all represent persistent (mild, moderate, and severe) disease. Criteria for classification of patients into stages 1 to 4 are shown in Figure 18-5 (NHLBI, 1997). This staging of asthma is done based on the level and frequency of symptoms or airflow obstruction before beginning treatment. The patient's step is determined by the *most severe* feature, and classification refers to symptoms *before* starting treatment. Pharmacologic treatment of asthma is linked to this classification, as shown in the treatment algorithm (Fig. 18-6).

A critical decision point is to decide if the patient has *persistent* disease as described by these criteria. Evidence suggests that primary care clinicians routinely underclassify the severity of asthma and thus undertreat with daily anti-inflammatory, long-term control medications. NAEPP guidelines suggest that only patients with truly intermittent disease—that is, patients with normal peak-flow readings, daytime symptoms no more than twice a week, and nighttime symptoms no more than twice a month—should be treated with intermittent medication alone. All other patients—those with mild, moderate, or severe persistent disease—should be treated with daily anti-inflammatory, long-term control medication such as an inhaled corticosteroid. One study has been cited as providing evidence allowing intermittent therapy of patients with mild to moderate persistent asthma, but the study results actually found that daily budesonide therapy produced greater improvements in prebronchodilator FEV₁, bronchial reactivity, sputum eosinophils, exhaled nitric oxide levels, scores for asthma control, and the number of symptom-free days, but not in postbronchodilator FEV₁ or in reported quality of life (Boushey et al., 2005).

A meta-analysis found that inhaled corticosteroids reduced asthma exacerbations by 55% compared with placebo or short-acting β -agonists, and long-acting β -agonists (LABAs) reduced flare-ups by only 26% (Sin et al., 2004). Similarly, a Cochrane Database review found that inhaled steroids at a dose equivalent to 400 μ g/day of beclomethasone are more effective than leukotriene antagonists, and that inhaled corticosteroids should be considered first-line monotherapy for persistent asthma. Another Cochrane review found that patients with mild to moderate disease achieve similar levels of asthma control taking low doses (≤ 200 μ g/day) as high doses (≥ 500 μ g/day) of fluticasone, and that side effects are greater with higher doses. A dose equivalency chart for inhaled steroids is shown in Table 18-2. A new approach to monitoring therapy by measuring the fraction of exhaled nitric oxide (FE_{NO}) can allow better adjustment of inhaled-corticosteroid doses in the future (Smith et al., 2005). High-dose inhaled corticosteroids are useful primarily in weaning patients from oral steroids.

Other second-line long-term control agents include LABAs (salmeterol, formoterol), long-acting anticholinergics

KEY TREATMENT

Daily inhaled corticosteroids significantly reduce exacerbations and hospitalizations in patients with persistent asthma and are significantly more effective as first-line long-term control agents than any alternative agents (Sin et al., 2004) (SOR: A).

Long-acting β -agonists (LABAs) are more effective than leukotriene antagonists as add-on-therapy to inhaled steroids. Because most benefits of inhaled corticosteroid (ICS) are achieved at lower doses, adding a LABA to a low or medium dose of ICS is preferred over using a higher dose of ICS. LABAs should not be used as monotherapy because of higher risk of death (FDA black-box warning) (NAEPP EPR-3; Ram et al., 2005) (SOR: A).

Adding ipratropium bromide to albuterol nebulizer treatments for patients with severe airflow obstruction in the acute ED setting produces additional bronchodilation, resulting in fewer hospital admissions (Plotnick and Ducharme, 2000; Rodrigo and Castro-Rodriguez, 2005) (SOR: A).

Theophylline is an acceptable (but not preferred) alternative to LABA for second-line long-term control treatment in combination with inhaled corticosteroids, but theophylline or aminophylline should not be used in the acute treatment of ED or in-hospital patients (SOR: A).

Teaching patients to engage in effective self-management improves clinical outcomes (Gibson et al., 2002) (SOR: A).

(tiotropium), leukotriene antagonists, inhaled mast cell stabilizers (cromolyn, nedocromil), and theophylline. Although each has demonstrated efficacy, none is as effective as inhaled corticosteroids. When low-dose inhaled corticosteroids are not providing complete remission, the clinician may add a second medication or increase the inhaled steroid dose to moderate levels. In a controlled trial of an inhaled LABA (formoterol) versus theophylline versus a leukotriene antagonist (zafirlukast) as second-line agents added to inhaled corticosteroid therapy, Yurdakul and colleagues (2002) found that the LABA was more effective in preventing exacerbations and had fewer side-effects than the other options. A Cochrane review of 12 controlled trials also found that LABAs were more effective than leukotriene antagonists as add-on therapy to inhaled steroids (Ram et al., 2005). Concern persists, however, that LABAs can increase mortality when used as monotherapy in the absence of inhaled corticosteroids (Abramson et al., 2003b). Randomized controlled trials now show that adding tiotropium bromide to low-dose inhaled corticosteroid (ICS) therapy is superior to doubling the dose of the ICS and equivalent to adding a LABA (Peters, 2010). The leukotriene synthesis inhibitor zileuton appears to improve pulmonary function and decrease need for β -agonist, but causes significant elevations of liver transaminases in 2% to 3% of patients (Nelson et al., 2007).

Immunotherapy also appears to be effective. A Cochrane review found that allergen immunotherapy reduces asthma symptoms and use of asthma medications at a level similar to that of inhaled corticosteroids (Abramson et al., 2003a). A newer third-line therapy is the once- or twice-monthly injection of monoclonal anti-IgE antibodies (omalizumab), an expensive therapy that is associated with a 98% to 99% reduction in free IgE and significantly fewer exacerbations of asthma, even allowing some patients to be weaned from inhaled corticosteroids (Walker et al., 2003).

| Components of Severity | | Classification of Asthma Severity (Youths ≥12 years of age and adults) | | | |
|------------------------|---|---|--|---|---|
| | | Intermittent | Persistent | | |
| | | | Mild | Moderate | Severe |
| Impairment | Symptoms | ≤2 days/week | >2 days/week but not daily | Daily | Throughout the day |
| | Nighttime awakenings | ≤2x/month | 3–4x/month | >1x/week but not nightly | Often 7x/week |
| | Short-acting beta ₂ -agonist use for symptom control (not prevention of EIB) | ≤2 days/week | >2 days/week but not >1x/day | Daily | Several times per day |
| | Interference with normal activity | None | Minor limitation | Some limitation | Extremely limited |
| | Lung function | <ul style="list-style-type: none"> • Normal FEV₁ between exacerbations • FEV₁ >80% predicted • FEV₁/FVC normal | <ul style="list-style-type: none"> • FEV₁ ≥80% predicted • FEV₁/FVC normal | <ul style="list-style-type: none"> • FEV₁ >60% but <80% predicted • FEV₁/FVC reduced 5% | <ul style="list-style-type: none"> • FEV₁ <60% predicted • FEV₁/FVC reduced >5% |
| Risk | Exacerbations requiring oral systemic corticosteroids | 0–1/year (see note) | ≥2/year (see note) → | | |

Prevention

Even though dust mites are usually mentioned as a controllable environmental trigger, a Cochrane review of 49 controlled trials found no evidence that either physical or chemical methods aimed at reducing exposure to house dust mite allergens had any benefit (Gotzsche et al., 2004). On the other hand, a controlled trial of an intervention to reduce cockroach and dust mite allergens and passive exposure to tobacco smoke among urban children with atopic asthma was effective in reducing both allergens in the home and asthma symptom-days (Morgan et al., 2004). Teaching patients to self-monitor and self-manage their asthma using an action plan and ongoing review with their physician is effective in reducing exacerbations and symptoms (Gibson et al., 2002). As with most pulmonary diseases, the most effective preventive strategy is to eliminate smoking as a risk factor from the patient, the household, and the workplace.

Chronic Obstructive Pulmonary Disease and Chronic Bronchitis

Key Points

- Because of the global spread of tobacco addiction, chronic obstructive pulmonary disease (COPD) will become the world's third leading cause of death by 2020.
- Quitting smoking reduces progressive loss of pulmonary function in patients with COPD, even in long-time smokers.
- The 6-minute walk test correlates strongly with quality of life and functional limitations in patients with COPD and other chronic lung diseases.
- Nocturnal home oxygen therapy improves symptoms and survival in patients with hypoxia at rest. Pulmonary rehabilitation improves symptoms but not survival.

- Inhaled corticosteroids, long-acting β_2 -agonists, and long-acting anticholinergics (tiotropium) each decrease exacerbation rates by 20% to 25% in patients with moderate to severe COPD, although patients may differ in their response to each therapy.

Consensus statements from the Global Initiative for Chronic Obstructive Lung Disease (GOLD standards, 2005) define chronic obstructive pulmonary disease as a postbronchodilator FVC of less than 80% of predicted in a patient with evidence of airway obstruction (FEV_1/FVC ratio <70%) that is not completely reversible. Although some patients with asthma, especially those who smoke, can progress to varying degrees of irreversibility consistent with COPD, the underlying pathophysiology and inflammatory mechanisms in asthma are distinct from those found in patients with COPD.

Epidemiology and Risk Factors

In large part because of the global spread of tobacco addiction, WHO estimates that COPD will move from the 12th to fifth leading cause of disability by 2020 (Murray and Lopez, 1996), also becoming the world's third leading cause of death.

Smoking is the most important risk factor for COPD and causes ongoing damage in COPD patients, as measured by an accelerated decline in FEV_1 compared with nonsmokers or ex-smokers. Among COPD patients who have quit smoking, exposure to secondhand smoke can also be a trigger factor for acute exacerbations. Variation in environmental air quality (ozone and small particulates) is also a factor associated with acute exacerbations of COPD. In many countries, air pollution can be a major source of smoking-equivalent damage to the respiratory tract in impoverished settings where daily cooking over indoor fires or charcoal is common. Other trigger factors for acute exacerbations include acute upper respiratory infections, sinusitis, exposure to dust or pet dander, and intercurrent illness. However, once patients reach

a more severe stage of illness in which pulmonary reserves are minimal, almost any small change (e.g., fatigue, stress, change in weather) can trigger an exacerbation.

The other major risk factor for development of COPD is the inherited disorder α_1 -antitrypsin deficiency. The recognition of this disease and its cellular mechanisms of injury to the lung have led to a specific understanding of protease and anti-protease imbalance as one mechanism of disease progression of emphysematous COPD. Any patient who develops COPD without a significant smoking history, any patient with a strong family history of COPD, and any patient developing clinically significant COPD before age 45 should be screened for α_1 -antitrypsin deficiency. A detailed discussion of genetic counseling of patients with α_1 -antitrypsin deficiency or carrier state can be found in the American Thoracic Society and European Respiratory Society (2003) consensus standards.

Clinical Presentation

Chronic obstructive pulmonary disease includes the two overlapping clinical conditions of chronic *bronchitis* and *emphysema*, which can coexist in the same patient. A practical clinical approach is to diagnose COPD by documenting obstruction that is not completely reversible on clinical examination and pulmonary function testing, then assessing whether the patient also has a component of chronic bronchitis, that is, cough productive of phlegm at least 3 months of each year for at least 2 years. Some patients meet this criterion for chronic bronchitis before developing clinical or spirometric evidence of obstructive lung disease. The international GOLD guidelines no longer categorize this as stage 0 COPD, because of insufficient evidence that patients will inevitably progress to obstructive lung disease.

Often, patients who smoke have had a chronic smoker's cough for years and present for medical treatment only when symptoms such as shortness of breath on exertion or at rest begin to appear. The hallmark symptom of symptomatic COPD is progressive and persistent shortness of breath. Because of the built-in reserve of the pulmonary system, such functional disability often is not noticed until there is a substantial decline in pulmonary function and substantial damage to lung parenchyma. Still, the U.S. Preventive Services Task Force (USPSTF) recommends not screening routinely with spirometry for obstructive lung disease or declining lung function.

Comorbidities are often present, and they must be comanaged with COPD if patients are to have optimal clinical outcomes and quality of life. For example, CHF can eventually occur after years of elevated right-sided pulmonary pressure (right-sided failure leading ultimately to biventricular failure), or patients might simply experience smoking-related myocardial infarctions and coronary ischemia in parallel with their COPD. Symptomatic COPD has a powerful adverse effect on quality of life, and a substantial percentage of patients with COPD develop comorbid depression. Chronic hypoxia and air hunger can also generate significant anxiety.

Diagnosis and Staging

By the time many patients present for treatment, the diagnosis of COPD is apparent. In addition to symptoms of dyspnea, chronic productive cough, and functional limitations, patients can show physical findings of lung hyperexpansion

(increased lung span on percussion, increased thoracic AP diameter, and use of accessory muscles of respiration). Extrathoracic signs include peripheral or central cyanosis, nail clubbing, and signs of increased central venous pressure or even right-sided heart failure. **Box 18-3** presents the differential diagnosis and distinguishing features of COPD suggested by the GOLD guidelines. Any patient who develops

Box 18-3 Differential Diagnosis of COPD* (GOLD Guidelines)

COPD

Onset in midlife
Symptoms slowly progressive
Long smoking history
Dyspnea during exercise
Largely irreversible airflow limitation

Asthma

Onset early in life (often childhood)
Symptoms vary from day to day
Symptoms at night and early morning
Allergy, rhinitis, and/or eczema are also present
Family history of asthma
Largely reversible airflow limitation

Congestive Heart Failure (CHF)

Fine basilar crackles on auscultation
Chest radiograph shows dilated heart, pulmonary edema
Pulmonary function tests indicate volume restriction, not airflow limitation

Bronchiectasis

Large volumes of purulent sputum
Often associated with bacterial infection
Coarse crackles/clubbing on auscultation
Chest radiograph or CT shows bronchial dilation or bronchial wall thickening

Tuberculosis (TB)

Onset all ages
Chest radiograph shows lung infiltrate
Microbiologic confirmation
High local prevalence of tuberculosis

Obliterative Bronchiolitis

Onset in younger age, nonsmokers
May have history of rheumatoid arthritis or fume exposure
CT on expiration shows hypodense areas

Diffuse Panbronchiolitis

Most patients are male and nonsmokers.
Almost all have chronic sinusitis.
Chest radiography and HRCT show diffuse small centrilobular nodular opacities and hyperinflation

From Global Initiative for Chronic Obstructive Lung Disease: Executive Summary: Global Strategy for the Diagnosis, Management, and Prevention of COPD, Updated 2008, p 39. <http://www.goldcopd.com/Guidelineitem.asp?1=2&l2=1&intId=996>.

*These features tend to be characteristic of the respective diseases but do not occur in every case. For example, a person who has never smoked may develop COPD, especially in the developing world where other risk factors may be more important than cigarette smoking, and asthma may develop in adult and even elderly patients.

COPD, Chronic obstructive pulmonary disease; CT, computed tomography; HRCT, high-resolution computed tomography.

COPD without a significant smoking history, or any patient developing COPD before age 45, should be screened for α_1 -antitrypsin deficiency. HRCT can help identify granulomatous or interstitial lung diseases or provide evidence of bronchiectasis.

Spirometry is the key to making a formal diagnosis, as well as for staging the severity of illness. COPD may be diagnosed when obstructive lung disease is not fully reversible, defined as a postbronchodilator FVC of less than 80% of predicted in a patient with evidence of airway obstruction (FEV_1/FVC ratio $<70\%$). A pattern of restrictive lung disease (FVC $<80\%$ of predicted in presence of normal FEV_1/FVC ratio) would suggest alternative diagnoses, such as pulmonary fibrosis, sarcoidosis, autoimmune conditions, or primary CHF.

Although there are several classification systems for severity of COPD, the American Thoracic Society (ATS) guidelines and the international GOLD standards are similar (Fig. 18-7). They are based on spirometric criteria—the presence of obstruction and the level of impairment in FEV_1 —and correlate strongly with quality of life and functional limitations. The 6-minute walk test is another way to stage COPD by its impact on daily activities. A distance of less than 149 meters walked in 6 minutes of encouraged walking indicates more severe functional limitation, and a distance farther than 350 m indicates minimal limitation (Celli et al., 2004).

Treatment

Acute Exacerbations

The course of COPD is characterized by patients' daily coping with chronic obstruction, punctuated by episodic exacerbations that can be life threatening and only partially responsive to treatment. Initial evaluation includes the patient's assessment of the severity of symptoms, plus physical examination, chest radiograph, and ABG tests. Predicting which patients can be safely discharged from the ED versus those who need to be hospitalized requires evaluation of both clinical and psychosocial indicators (Smith et al., 2000).

Chest radiography can reveal underlying causes of an acute exacerbation, such as pneumonia or CHF. ABGs are useful in assessing initial hypoxia and hypercapnia, but also in monitoring the patient's response to judicious use of supplemental oxygen administered by nasal cannula or mask. Although relief of hypoxia reduces symptoms and improves cardiac function, it can also decrease the respiratory drive in a patient with chronic hypercapnia and partially compensated respiratory acidosis. For this reason, ABGs should be repeated within 30 minutes after starting oxygen, and ongoing hypoxia may be monitored with pulse oximetry (although oximetry becomes less accurate at SO_2 levels $<70\%$).

An immediate response is expected from inhaled β_2 -agonist therapy in asthma, but the response to bronchodilators in acute exacerbations of COPD can be modest. Some patients are more responsive to anticholinergic bronchodilators such as ipratropium, and others respond to β_2 -agonist agents, so these therapies are often combined in the acute setting. At home, patients can increase the dose or frequency of current medications or add a short-term agent to their chronic therapy (e.g., adding albuterol doses to LABA, or adding ipratropium to chronic tiotropium therapy). Spacer devices or mechanical nebulizer delivery systems may be used. Treatment of acute exacerbations of COPD with systemic corticosteroids (administered orally or parenterally) can reduce treatment failures by more than 50% and improve short-term dyspnea and PFTs, but there is some increase in adverse effects (Wood-Baker et al., 2005). Continuing these systemic steroids beyond 2 weeks has not been shown to have significant benefit.

Other acute treatments for COPD exacerbations include methylxanthines such as theophylline and aminophylline, which have a positive effect on the central drive to breathe, on diaphragmatic contractility, and on some mechanisms of bronchial inflammation. However, they probably do not significantly affect cyclic adenosine monophosphate (cAMP)-mediated bronchodilation. Antibiotics are indicated if there are signs of pneumonia, sepsis, or other bacterial infection. Recent changes in sputum production (copious, thick,

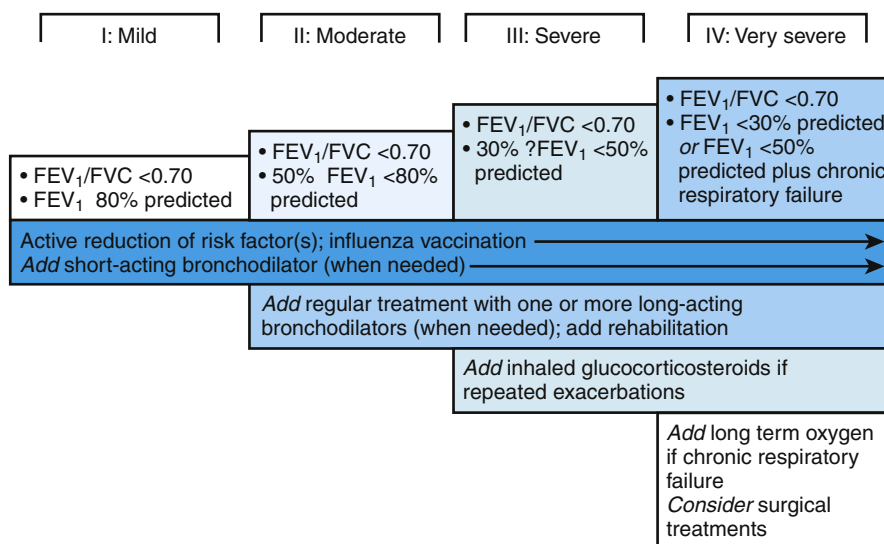

Figure 18-7 Classification and therapy at each stage of chronic obstructive pulmonary disease (COPD). Postbronchodilator FEV_1 is recommended for the diagnosis and assessment of severity of COPD. (From Global Initiative for Chronic Obstructive Lung Disease: Global Strategy for the Diagnosis, Management and Prevention of COPD. Updated 2008. <http://www.goldcopd.com/download.asp?intId=504>.)

multicolored, or blood tinged) just before the exacerbation can indicate bacterial overgrowth of chronically inflamed bronchial mucosa, another indication for antibiotics. Because of chronic bacterial colonization, second- and third-generation antibiotics may provide greater benefit.

Indications for hospitalization include severity of underlying illness, significant worsening during this exacerbation, failure of home or outpatient treatment efforts, significant comorbidities (CHF, arrhythmias, or electrolyte imbalance), and underlying pneumonia or other acute causes. Indications for admission to the ICU, or perhaps even intubation and mechanical ventilation, include severe dyspnea unresponsive to initial therapy, change in mental status (e.g., confusion, lethargy), or severe or worsening hypoxia ($\text{PaO}_2 < 40$ mm Hg), hypercapnia ($\text{PaCO}_2 > 60$ mm Hg), or respiratory acidosis ($\text{pH} < 7.25$). In a meta-analysis of treatment strategies for the patient hospitalized with an exacerbation of COPD, Quon and colleagues (2008) found that systemic corticosteroids decreased treatment failures by 46% and hospital stay by 1.4 days, although risk of hyperglycemia increased almost sixfold. Antibiotics also decreased treatment failures by 46% and in-hospital mortality by 78%. Noninvasive positive-pressure ventilation (NPPV) reduced the risk of intubation by 65%, in-hospital mortality by 55%, and hospital stay by 1.9 days. Noninvasive intermittent positive-pressure ventilation (NIPPV) is an option for treating moderate to severe respiratory failure in patients who have normal mental status, are stable hemodynamically, and do not have high risk for aspiration. About 80% of patients improve symptomatically within 4 hours of initiating NIPPV (Putinati et al., 2000; Wijkstra, 2003). On the other hand, chronic nocturnal use of NIPPV has yet to show significant benefit (Wijkstra et al., 2003).

Perhaps just as important as managing the pulmonary disease is to make sure other conditions do not complicate the exacerbation. Unless there are specific contraindications, a patient hospitalized for COPD exacerbation should be started on subcutaneous heparin to prevent DVT. Cardiac monitoring is often indicated in the ED and beyond to assess and treat related arrhythmias or cardiac ischemia. Electrolyte abnormalities are quite common, especially in the setting of rapidly changing PaCO_2 and acid-base balance. The incidence of pneumonia in ICU patients ranges from 7% to 40%, and the mortality rate from ventilator-associated pneumonia can be as high as 50%. Prophylactic antibiotics can reduce the incidence of respiratory infections in ICU patients by up to 50%, but antibiotics do not reduce mortality (Liberati et al., 2004).

Chronic Care and Disease Management

Each patient with COPD also needs an ongoing care plan, which includes the MAP elements described for asthma patients (daily management plan, action plan for acute exacerbations, and prevention plan). The treatment of acute exacerbations is described earlier, but each patient should have an individual action plan for increasing symptoms, to prevent hospitalization. Such action plans might include symptoms or signs that would trigger a call to the physician, as well as use of short-acting β_2 -agonists (albuterol, terbutaline), short-acting anticholinergic (ipratropium), or oral steroids. Use of short-course antibiotics triggered by changes in phlegm (increased sputum or change in sputum from clear to yellow-green) is common but untested by controlled trials.

A meta-analysis of controlled trials assessed the impact of various modalities of treatment for COPD (Sin et al., 2003). Outcome measures included hospitalizations, exacerbation rates, and health-related quality of life. Inhaled corticosteroids, long-acting β_2 -agonists (salmeterol, formoterol), and the long-acting anticholinergic tiotropium each decreased exacerbation rates by 20% to 25% in patients with moderate to severe COPD. The greatest effect was in patients with FEV_1 of 1 to 2 L. Combining inhaled corticosteroids with a long-acting β_2 -agonist provided modest additional benefit (30% reduction in exacerbations). Tiotropium may be added to inhaled corticosteroids and LABAs as triple therapy. Oral theophylline also appears to have some beneficial effects not only as a bronchodilator but also in increasing diaphragmatic muscle contractility and the central drive to breathe. As a result, there are improvements in FEV_1 , PaO_2 , and PaCO_2 , although these must be weighed against potentially significant side effects of theophylline, such as nausea, tremors, and palpitations.

Nonpharmacologic therapies have shown mixed results. Home oxygen therapy decreases dyspnea and increases survival significantly in those with hypoxia at rest ($\text{PaO}_2 < 60$ mm Hg), but not in those with only exertional or nocturnal hypoxia (Crockett et al., 2000). NPPV has not been shown to improve COPD outcomes except in severely hypercapnic patients ($\text{PaCO}_2 > 55$ mm Hg, or 50-54 mm Hg in presence of nocturnal oxygen desaturation or multiple hospitalizations in past year). Pulmonary rehabilitation focuses on improving strength, cardiopulmonary fitness, and exercise tolerance, and nutrition improves health status, as measured by the St. George's Respiratory Questionnaire (SGRQ) and Chronic Respiratory Questionnaire (CRQ), but does not appear to decrease hospitalization or mortality rates (Lacasse et al., 2001). Pulmonary rehabilitation appears to be beneficial in COPD and other chronic pulmonary diseases and is recommended by Joint ACCP/AACVPR Evidence-Based Clinical Practice Guidelines (Ries, 2007).

One disease management program using self-management and telephone follow-up showed a 36% reduction in hospitalizations and a 45% reduction in mortality in COPD patients (Bourbeau et al., 2003), but other trials of disease management programs have not shown such benefit. Despite evidence of significant nutritional deficits in patients with moderate to severe COPD, neither nutritional supplements to increase antioxidants (vitamin E or beta-carotene) nor nutritional supports to increase caloric intake have been demonstrated to improve outcomes or functional status in patients with COPD.

Surgical therapy using lung volume reduction surgery can improve quality of life and exercise tolerance in selected patients with FEV_1 less than 30% to 40% of predicted values (Fishman et al., 2003; Geddes et al., 2000; Goldstein et al., 2003). However, surgery does not improve 5-year mortality and can actually worsen short-term mortality (National Emphysema Treatment Trial Research Group, 2001).

Treatment guidelines for each stage of COPD are summarized in Figure 18-7.

Prevention

Smoking cessation is the most important factor in preventing COPD, as well as the cornerstone of COPD treatment to prevent exacerbations and progressive loss of pulmonary

function (Man et al., 2003). The decline in pulmonary function as measured by FEV₁ can be halved (from 60 to 30 mL/year) if COPD patients quit smoking (Anthonisen et al., 1994). Avoidance of secondary exposure to smoke, especially in the household, is also important. Physician advice to quit smoking alone has some impact, and combined interventions (counseling plus education or group strategies plus pharmacologic treatment with nicotine, bupropion) can achieve at least 25% long-term quit rates even in COPD patients. Use of spirometry for screening and early diagnosis of COPD to enhance smoking cessation interventions among smokers has not been shown to increase smoking cessation rates or other clinical outcomes.

Influenza vaccine should be administered every year; it can reduce hospitalizations and deaths from pneumonia, cardiovascular disease, and all causes by 30% to 40% (Govaert et al, 1994; Nichol et al, 2003). Pneumococcal vaccine is also indicated in all patients with COPD, and patients should be revaccinated after 10 years if the first pneumococcal vaccine was administered before age 65 years. Vaccination rates are increasing nationwide, but they are still significantly lower among the uninsured and among racial and ethnic minority populations (CDC, 2003b). Family physicians can improve vaccination rates in their own practice by establishing standing orders for influenza and pneumococcal vaccination (CDC, 2003c; 2009).

One critical role for the family physician in the chronic management of COPD is to facilitate open discussions with the patient and family members about end-of-life issues such as therapy during acute exacerbations. Although this has become routine in the management of cancer patients, the 5-year survival of patients with severe stages of COPD (as well as heart failure and other chronic organ failure) is often worse than that of many cancers. Many patients have a strong desire to avoid mechanical ventilation, only to end up intubated, unconscious, and having difficulty being weaned from the ventilator. Often, family members are asked to assist in end-of-life decision making when complications occur during a protracted downturn in the course of COPD, even though they have not previously discussed such issues with the patient. Facilitating such family discussions, providing templates for living wills and health care power of attorney forms, and referring for legal or psychological or pastoral counseling can dramatically ease a family's confusion and pain during these episodes and ultimately in dealing with the patient's death.

Acute Respiratory Failure

Acute respiratory failure can be the result of acute pulmonary infections, exacerbations of chronic pulmonary disease, or other conditions, such as pulmonary embolism, tension pneumothorax, or sepsis.

Clinical Presentation and Diagnosis

The clinical presentation of acute respiratory failure is usually obvious, although some patients slip into respiratory failure while being treated for initially less serious respiratory distress such as pneumonia or acute exacerbations of CHF, asthma, or COPD. Acute respiratory failure can have either or both of two components: inadequate oxygenation (hypoxia) and

KEY TREATMENT

Smoking cessation is the best intervention to slow the long-term rate of decline in FEV₁ (Anthonisen et al., 1994) (SOR: A).

Among patients with COPD, inhaled corticosteroid use for at least 24 weeks is associated with a significantly increased risk of serious pneumonia but not death, especially among those using the highest dose of ICS and those with the lowest baseline FEV₁ (Drummond, 2008; Singh, 2009) (SOR: A).

Patients with COPD receiving LABAs showed significant benefits in airflow limitation measures, health-related quality of life, and use of rescue medication, but the anticholinergic drug tiotropium decreased the incidence of severe COPD exacerbations even more than LABAs (Rodrigo, 2008) (SOR: A).

Tiotropium reduces the rate of decline of FEV₁ in patients with GOLD stage II COPD (Decramer, 2009). Unfortunately, inhaled anticholinergics may also be associated with a significantly increased risk of cardiovascular death, myocardial infarction, or stroke in COPD patients (Singh et al., 2008) (SOR: A).

All patients should be counseled on smoking cessation; combining effective behavioral therapies (behavioral group therapy, social support) with pharmacologic therapy (nicotine replacement therapy, antidepressants) (Hughes et al., 2004; Lancaster and Stead, 2004; Stead and Lancaster, 2005) (SOR: A).

Pulmonary rehabilitation, including patient education and cardiopulmonary exercise training, significantly improves clinical outcomes and health-related quality of life (Lacasse et al., 2001) (SOR: A).

Home oxygen therapy helps patients with resting Pao₂ less than 60 mm Hg but not patients with normal oxygen levels or with hypoxemia only on exertion (Crockett et al., 2000) (SOR: A).

inadequate ventilation (resulting in hypercarbia and respiratory acidosis). Although patients might initially present with severe shortness of breath, the hypoxia and increased PaCO₂ can ultimately lead to suppression of respiratory centers in the brain, as well as lethargy, stupor, or coma.

An especially serious form of respiratory failure that can occur is acute respiratory distress syndrome (ARDS), which can occur in patients with severe trauma, especially those who have received massive blood transfusions, overwhelming pneumonia, septic shock, and the acute chest syndrome associated with sickle cell disease.

Indications for intubation and mechanical ventilation include hypoxia and hypoventilation unresponsive to pharmacologic intervention and supplemental oxygen delivery by mask or cannula. Patients unable to protect their own airway because of central nervous system (CNS) depression or inadequate gag reflex might also need intubation. The detailed management of mechanical ventilation is beyond the scope of this chapter, but ventilation can be thought of in terms of ventilator settings that increase or decrease *ventilation* (ventilator mode, respiratory rate, and tidal volume) and ventilator settings that improve *oxygenation*: forced inspiratory oxygen concentration (FIO₂) and continuous positive airway pressure (CPAP) or positive end-expiratory pressure (PEEP).

Weaning patients from the ventilator, especially those with chronic lung disease, can be challenging. Reintubation carries risks of trauma and of ventilator-associated pneumonia. Protocols based on objective criteria (vs. individual clinical judgment) significantly reduce time, costs, and complications related to weaning patients from mechanical ventilation.

Other Chronic Bronchial Diseases

Bronchiectasis

Bronchiectasis is both a chronic airway infection and a disease of chronic lung inflammation. Bronchiectasis might be more common outside the United States (Tsang and Tipoe, 2004). Clinical course can be progressive or indolent. Cough is the predominant symptom, and some patients have significant hemoptysis or shortness of breath, or both. Malodorous (fetid) breath is a characteristic symptom. Bronchiectasis not associated with a genetic disorder is designated non-cystic fibrosis bronchiectasis.

Antibiotics are given over the long term, using antipseudomonal antibiotics either orally or as aminoglycosides nebulized for inhalation. Macrolide antibiotics such as azithromycin appear to have antibiotic and anti-inflammatory effects in treating bronchiectasis. A Cochrane review found a small but significant benefit for prolonged antibiotic therapy in the treatment of patients with purulent bronchiectasis (Evans et al., 2003). Sputum cultures should be monitored for the presence of fungal (aspergillus) and mycobacterial organisms as well, because they can complicate the polymicrobial mix of organisms in these patients (Morrissey and Evans, 2003). Bronchodilators, oxygen, and even noninvasive pulmonary ventilation may be tried when bronchial obstruction becomes a major component of pulmonary impairment. Surgical resection of affected lung segments can be helpful in patients with localized disease (Greenstone, 2002).

Cystic Fibrosis

Cystic fibrosis (CF) is a genetic disease attributed to autosomal recessive defects on a single gene of chromosome 7. It affects membrane functions in mucus-secreting glands (e.g., sweat glands), the pancreas, and gastrointestinal and respiratory tracts. Diagnosis of CF is suspected in the presence of pancreatitis and chronic or recurrent lung infections in infants or children. Definitive diagnosis may be made with a sweat chloride test. Treatment of CF has improved significantly over the past decades. Patients now routinely live into adulthood, and now more adults are living with CF than children. Family physicians and internists (in partnership with subspecialists) are increasingly involved in the care of patients with this complex condition.

Specific treatment modalities for CF include physical therapy, nutrition therapy, mucolytics, antibiotics, and increasingly, anti-inflammatory therapies. Self-administered airway clearance techniques appear to be as effective as chest physiotherapy (Main et al., 2005). Antibiotics must be broad-spectrum and antipseudomonal agents and often are given in combination during exacerbations or acute infections. In recent years, inhaled tobramycin has become effective antibiotic therapy in bronchiectasis and CF. Aminoglycosides also appear to suppress the expression of the CF transmembrane conductance regulator. Anti-inflammatory therapy includes oral corticosteroids and ibuprofen; azithromycin has both antibiotic and anti-inflammatory properties. Inhaled corticosteroids, methotrexate, and protease replacement do not appear to be effective (Prescott and Johnson, 2005). Viral vectors or other methods may soon allow delivery of gene therapy directly to the respiratory tract to achieve cure or long-term relapse in CF patients.

Acute Infectious Diseases

Bronchiolitis in Children

Bronchiolitis is a viral infection associated with bronchial obstruction. It occurs most often in the fall and winter. About half of all children experience bronchiolitis during the first 2 years of life, with a median age of 6 months. *Respiratory syncytial virus* (RSV) is the most common causative organism, but other viruses (adenovirus, influenza, parainfluenza, and rhinovirus) can also cause bronchiolitis.

Clinical Presentation

Typically, an infant or toddler presents with routine signs and symptoms of upper respiratory infection, such as cough, sneezing, rhinitis, and low-grade fever. Dyspnea and irritability and perhaps audible wheezing soon follow. Tachypnea and nasal flaring are typical, along with signs of airway obstruction, such as a hyperexpanded chest and wheezing on auscultation, with a prolonged expiratory phase. Chest radiograph can show air trapping, peribronchial thickening, atelectasis, and patchy infiltrates. Premature infants and children with chronic disease are at special risk for respiratory failure or complications such as bacterial pneumonia, and up to 5% of patients require hospitalization for severe respiratory distress.

Treatment

Infants with mild bronchiolitis may be managed at home using fluids, antipyretics, and β_2 -agonists if needed. Indications for hospitalization of children with bronchiolitis include age younger than 6 months, hypoxemia ($P_{aO_2} < 60$ mm Hg or $SO_2 < 92\%$), rapid deterioration, apnea, or poor oral intake.

Hospitalized infants should receive fluids (orally or intravenously) and supplemental humidified oxygen. Aerosolized bronchodilators, including aerosolized epinephrine, decrease airway obstruction. Aerosolized ribavirin may be used in infants or children with underlying risk factors, but a meta-analysis of eight randomized, controlled trials (RCTs) found no benefit for antiviral agents in general use. A systematic review of glucocorticoid treatment found no benefit in any subgroup of patients with bronchiolitis (Patel et al., 2004), and glucocorticoids do not appear to prevent post-bronchiolitic wheezing (Blom et al., 2007). Epinephrine treatment is better than placebo and might have a slight advantage over salbutamol in treating bronchiolitis in outpatient settings, but benefit has not been proved in hospitalized patients (Hartling et al., 2004). A Cochrane review concluded that nebulized hypertonic (3%) saline may significantly reduce the length of hospital stay and improve other clinical indicators in infants with acute viral bronchiolitis (Zhang et al., 2008).

Some patients ultimately have asthma, with the first episode diagnosed as bronchiolitis, but RSV has not been shown to be a causative agent of chronic asthma. A systematic review found treatment with RSV immune globulin to be effective in preventing hospitalizations and admission to the ICU but not in lowering mortality (Wang and Tang, 1999). Children with severe apnea or respiratory failure might require intubation and mechanical ventilation. Antibiotics are only indicated if secondary bacterial infection occurs.

Prevention

Smokers in the household predispose infants to bronchiolitis, and families should be counseled to make all homes with infants or children smoke free. In a small group of infants with underlying lung disease, heart disease, or low birth weight, monthly RSV hyperimmune gamma globulin has been proved to offer some protection from severe disease. Although influenza is a relatively infrequent cause of bronchiolitis, expanded recommendations for influenza vaccination include all children aged 6 to 23 months as well as all close contacts of children from birth through 23 months of age.

Acute Bronchitis

A frequently diagnosed infection in children and adults, acute bronchitis is typically a viral respiratory infection with lower tract symptoms, such as cough, phlegm, hoarseness, or wheezing. This syndrome should be distinguished from acute exacerbations in patients with chronic bronchitis, who are more vulnerable, who might be colonized with different bacterial flora in the respiratory tract, and who might require more aggressive treatment. In acute bronchitis in otherwise healthy patients, viral causes predominate. RSV and rhinovirus are common causative organisms even during influenza season.

Treatment of acute bronchitis in otherwise healthy patients should be primarily supportive because the condition is largely self-limited. Patients with underlying pulmonary disease, or even smokers, may have a higher rate of pulmonary complications (e.g., secondary pneumonia) or exacerbation of COPD. Options for symptomatic treatment include air humidifiers, cough suppressants, and antipyretic analgesics. Although β -agonists are sometimes prescribed, there is no evidence for a treatment benefit in the absence of measurable airway obstruction.

Antibiotic use is controversial. Because the most frequent cause is viral, bronchitis has often been overtreated with antibiotics, which would be a preventable source of antibiotic resistance. However, in patients with a productive cough persisting beyond 10 to 14 days, treatment with antibiotics may be indicated to treat bacterial co-infection, especially in smokers or in patients with underlying pulmonary disease. In a study of community-acquired acute bronchitis in France, polymerase chain reaction (PCR) testing revealed that 4.1% of patients were infected with *Chlamydia pneumoniae* and 2.3% with *Mycoplasma pneumoniae* (Gaillat et al., 2005).

A systematic review of RCTs comparing antibiotic therapy with placebo in the treatment of acute bronchitis or acute productive cough without underlying cause found a significant benefit for the antibiotic therapy, as measured by days of illness, persistent cough, and abnormal lung findings on examination (Smucny et al., 2004). An increase in adverse effects in the antibiotic-treated group compared with the placebo group outweighed many of these benefits, however, and caution in using antibiotics unnecessarily to prevent the spread of antibiotic-resistant bacteria is still valid at the population level. The specific choice of antibiotic seems to have little impact, despite known patterns of bacterial resistance in most communities. A systematic review of controlled trials that compared azithromycin to amoxicillin or

amoxicillin-clavulanic acid in patients with clinical evidence of acute bronchitis, pneumonia, and acute exacerbation of chronic bronchitis found no significant advantage for using the macrolide antibiotic (Panpanich et al., 2004).

Pneumonia

Key Points

- Pneumonia causes over a million hospitalizations per year in the United States.
- Influenza vaccine should be administered every year to patients older than 50 years and to those with chronic lung disease, diabetes, immune dysfunction, or other chronic organ failure.
- Patients should be revaccinated with pneumococcal vaccine after 10 years if the first vaccine was administered before age 65 years.
- Although atypical pathogens commonly cause community-acquired pneumonia, controlled trials show that beta-lactam antibiotics are as effective as macrolides and quinolones in most cases.

Pneumonia is an infection of the lungs that leads to consolidation of the usually air-filled alveoli. It occurs in all age groups and can be caused by various agents, including viruses, bacteria, mycobacteria, mycoplasma, and fungi. Systemic viral infections such as influenza A or B in adults and measles or varicella in children can also lead to bacterial pneumonia.

Epidemiology and Risk Factors

As shown in Table 18-3, pneumonia is the principal diagnosis for more than 1 million hospitalizations per year in the United States, with aggregate charges for these hospitalizations of almost \$23.5 billion per year (Health Care Utilization Project, 2002). In-hospital death occurs in 5.6% of these hospitalizations, and more than 10% of cases are in patients over age 85.

Clinical Presentation

Patients with pneumonia can present with cough, fever, dyspnea, or malaise. Cough can be productive or nonproductive, and blood tinged or with frank blood. The clinical presentation of pneumonia in otherwise healthy patients often follows one of two patterns that can indicate the cause. A rapid onset of cough and shortness of breath with a high fever can indicate classic bacterial lobar pneumonia such as that produced by a pneumococcus. Physical findings once consolidation occurs include decreased breath sounds, dullness to percussion, and egophony on the affected side. The white blood cell (WBC) count is often elevated (>15,000), with a predominance of neutrophils. A smoldering onset with low-grade fever and fewer constitutional symptoms can indicate an atypical pneumonia, which can be caused by organisms such as respiratory viruses or by *Mycoplasma*, *Chlamydia*, or *Legionella* species.

Patients with new-onset pneumonia can be categorized by whether they are living at home in a community setting or living in a nursing home or other institutional setting. Patients who have had prolonged hospitalizations or who

Table 18-3 Outcomes for Hospital Patients with Pneumonia*

| Age Group (yr) | Total Discharges | Length of Stay (mean days) | Aggregate Charges (\$) | In-Hospital Deaths |
|----------------|------------------|----------------------------|------------------------|--------------------|
| All discharges | 1,171,546 (100%) | 5.4 | 29,864,341,883 | 41,273 (3.52%) |

*Except pneumonia caused by tuberculosis or sexually transmitted diseases.

Data from Healthcare Cost and Utilization Project (HCUP). Weighted U.S. estimates from HCUP Nationwide Inpatient Sample, 2007. Agency for Healthcare Research and Quality, Rockville, Md. <http://hcupnet.ahrq.gov/>.

live in nursing homes may be colonized with gram-negative organisms (e.g., *Serratia*, *Pseudomonas*), anaerobes, or multi-drug-resistant bacteria.

Patients with pneumonia can be further categorized by whether they are immunocompetent or immunocompromised. Patients with immunodeficiencies (including HIV/AIDS) can present with opportunistic organisms including *Pneumocystis jiroveci* (*carinii*), cryptococci, *Coccidioides immitis*, atypical mycobacteria, and fungi. Alcoholism can predispose patients to lung infections with *Haemophilus influenzae* or to aspirated anaerobic organisms such as *Peptostreptococcus* or *Bacteroides*.

In children, signs of pneumonia can include malaise, cough, chest pain, tachypnea, and intercostal retractions. Children with viral pneumonias have a less toxic appearance, with low-grade fever, wheezing, and cough. Children with bacterial pneumonia appear more acutely ill, with a high-grade fever, chills, cough, and dyspnea. The earliest diagnostic clue in children may be tachypnea disproportionate to degree of fever.

In infants, potential causes of pneumonia are tied to specific periods in the first few months of life. Pneumonia in the newborn is often linked to bacteria that colonize the mother's vaginal flora. Group B streptococcal infections can occur within the first 48 hours of life or appear at 7 to 10 days after birth. Other neonatal infections include gram-negative organisms such as *Escherichia coli*. Although *Chlamydia* infections of the eye can appear in newborns at 1 to 2 weeks of age, chlamydial pneumonia is typically diagnosed in infants age 6 to 8 weeks. Other causes of pneumonia in infants age 1 to 3 months include *Ureaplasma urealyticum* and cytomegalovirus (CMV).

Viral pneumonias are most common in preschool and older children. Viral upper respiratory infections or bronchiolitis can also predispose to a bacterial pneumonia. Bacterial pathogens are responsible for only 10% to 30% of all cases of infectious pediatric pneumonia. *Streptococcus pneumoniae* has been the most common bacterial cause of childhood pneumonia, but it is declining in the face of universal pneumococcal vaccination. *H. influenzae* type B pneumonia is associated with bacteremia and other deep tissue

infections (e.g., meningitis, arthritis, cellulitis) but also has declined significantly with universal immunization. *Staphylococcus aureus* causes an aggressive pneumonia that can be complicated by acute respiratory failure, pneumatoceles, or empyema. Staphylococcal pneumonia typically occurs after a staphylococcal skin infection or a systemic viral illness such as varicella (chickenpox) or measles.

Diagnosis

Cases of pneumonia are often diagnosed presumptively based on the clinical presentation and perhaps a radiograph. Chest x-ray findings in viral pneumonias include patchy or streaky, often bilateral, interstitial patterns and hyperinflation of the lungs. Bacterial pneumonias show classic lobar consolidation and alveolar infiltrates, although x-ray findings typically lag behind the clinical course by 1 to 2 days and can be completely normal on day 1. Parapneumonic pleural effusions can also occur.

Sputum Gram stain and culture may be performed but have a low yield. Some bacterial agents such as *Legionella* may be identified by antigen detection from blood samples. *Mycoplasma pneumoniae* may be diagnosed with a positive cold agglutinin test of peripheral blood. Sputum smears and cultures for acid-fast bacilli (AFB) are appropriate when there has been possible contact with tuberculosis patients, in TB-endemic areas, or when clinical findings suggest TB. Invasive procedures (e.g., BAL, lung aspiration, bronchoscopy) are reserved for special circumstances, such as diagnosing pneumonia in the immunocompromised host or in ventilator-associated pneumonias.

Treatment

Although treatment of community-acquired pneumonia (CAP) is common in primary care, there are many controversies. Clearly, many patients may be managed on an outpatient basis (Segreti et al., 2005). Use of a formal instrument such as the pneumonia severity index (PSI) or CURB-65 (see Box 16-1) can more accurately identify patients eligible for outpatient treatment (IDSA/ATS, 2007). The choice of oral antibiotic

in the outpatient setting must cover common causes of bacterial pneumonia. Many treatment guidelines suggest using antibiotics that cover atypical organisms such as *Mycoplasma* and *Legionella*, but there is insufficient evidence to support any specific antibiotic strategy in the outpatient treatment of CAP (Bjerre et al., 2004). Treatment should be continued for a minimum of five days, and at least 48-72 hours beyond the patient's last signs of fever or clinical instability.

In cases of pneumococcal pneumonia with bacteremia, there is limited evidence to suggest that dual therapy with a beta-lactam antibiotic and an antibiotic with coverage of atypical organisms results in lower case-fatality rates than using a β -lactam alone. A meta-analysis of studies comparing the effectiveness of a β -lactam antibiotic with antibiotics active against atypical pathogens in nonsevere CAP found no advantage for the antibiotics that were active against atypical pathogens (Shefet et al., 2005). This was true even on subgroup analysis for patients infected with *M. pneumoniae* and *C. pneumoniae*, but there was a significantly lower treatment failure rate in the small number of patients with *Legionella* infections (relative risk [RR], 0.40) treated with a macrolide antibiotic (Mills et al., 2005). Patients with significant comorbidities or chronic organ failure and those at risk for drug-resistant *S. pneumoniae* should be treated with a respiratory fluoroquinolone or combination of β -lactam and macrolide antibiotic (IDSA/ATS, 2007).

Indications for hospitalization of any patient include failure to respond or tolerate oral antibiotics, moderate to severe respiratory distress, significant deficit in oxygenation (alveolar-arterial [A-a] O₂ gradient), more than one area of lobar consolidation, empyema, immunosuppression, abscess formation, pneumatocele, underlying cardiopulmonary disease, and high-risk PSI score. Two additional factors are the patient's age (e.g., infants <2 months, elderly patients) and comorbidities (underlying pulmonary or cardiovascular disease).

Even in the hospital, not all patients must be treated with intravenous antibiotics (Marras et al., 2004). The patient might require hospitalization for dehydration or oxygen therapy, but in select cases, oral antibiotics may be equally effective, cost less, and require fewer days in the hospital than IV antibiotic therapy. Other patients may start receiving IV antibiotics in the hospital, but an algorithm that provides for an early switch to oral antibiotics and early discharge can reduce hospital stay.

Treatment of neonatal pneumonia should target group B streptococci and gram-negative organisms such as *E. coli*. Older children with suspected bacterial pneumonia should be treated with antibiotics that provide appropriate coverage for *H. influenzae* and *S. pneumoniae*. Pneumonia in children older than 5 years should also include macrolide coverage for *M. pneumoniae*. When symptoms recur or persist for longer than 1 month, further evaluation for an underlying condition should be undertaken (TB skin test, serum immunoglobulin, bronchoscopy, barium swallow, sweat chloride test).

Prevention

Approximately half of all cases of adult pneumonia can be prevented by annual administration of influenza vaccine, plus a one-time pneumococcal vaccine when indicated (Vu et al., 2002). Vaccination with inactivated influenza vaccine

is appropriate for all age groups, but the live, attenuated influenza vaccine is approved for use only in healthy patients age 5 to 49 years. The CDC recommends that influenza vaccine be given to all children from 6 months to 18 years of age, all adults over age 50, and other persons at higher risk for complications of influenza (Box 18-4).

Health care workers are an important source of transmission of influenza from infected patients to other medically vulnerable patients. Therefore, they also should be immunized, preferably with inactivated vaccine if they have close contact with severely immunocompromised persons. Health care workers or family members vaccinated with live, attenuated influenza vaccine should avoid contact with severely immunosuppressed patients for at least 7 days after vaccination.

Two types of vaccine are available for immunizing against invasive pneumococcal disease. For children younger than 2 years, universal vaccination with heptavalent (7 serotypes) pneumococcal vaccine is recommended. For other indications and age groups, pneumococcal polysaccharide vaccines currently cover 23 serotypes of the disease. ACIP recommends the pneumococcal polysaccharide vaccine for all patients older than 2 years with pulmonary, cardiac, immune, or other medical risk factors, immunocompromised persons, and those older than 65 years. Specifically, the indications for pneumococcal polysaccharide vaccine are as follows:

- Adults 65 years or older
- Immunocompetent adults or children 2 years or older who are at increased risk for illness and death associated with pneumococcal disease because of chronic illness
- Adults or children 2 years or older with functional or anatomic asplenia
- Adults or children 2 years or older living in environments in which the risk for disease is high
- Immunocompromised adults or children 2 years or older who are at high risk for infection

A systematic review suggests that pneumococcal vaccination does not significantly reduce all-cause mortality or overall rates of pneumonia, but it is specifically effective in preventing invasive pneumococcal disease (Dear et al., 2003).

Box 18-4. Groups Who Should Receive Seasonal Influenza Vaccine*

All children age 6 months to 18 years
 All persons age 50 years or older
 Women who will be pregnant during the influenza season
 Persons who have chronic pulmonary (including asthma), cardiovascular (except hypertension), renal, hepatic, cognitive, neurologic/neuromuscular, hematologic, or metabolic disorders (including diabetes mellitus)
 Persons who have immunosuppression (including medication induced or HIV)
 Residents of nursing homes and other long-term care facilities
 Health care personnel
 Household contacts and caregivers of children younger than 5 years and adults 50 years or older, with particular emphasis on vaccinating contacts of children less than 6 months
 Household contacts and caregivers of persons with medical conditions that put them at higher risk for severe complications from influenza

*Centers for Disease Control and Prevention (CDC) recommendations, for all persons without contraindications in the groups listed.

Older patients should be revaccinated with pneumococcal polysaccharide vaccine after 10 years if the first pneumococcal vaccine was administered before age 65. Elderly persons with unknown vaccination status should be administered 1 dose of vaccine. Children older than 2 years at highest risk for serious pneumococcal infection and likely to have a rapid decline in pneumococcal antibody levels (asplenia, renal failure, HIV, cancer chemotherapy) should also be revaccinated after 3 to 5 years.

KEY TREATMENT

Treating uncomplicated community-acquired pneumonia with a macrolide or respiratory quinolone has no proven treatment advantage over cephalosporin or aminopenicillin therapy (Mills et al., 2005; Shefet et al., 2005), unless patients have significant comorbidities or other risk factors (IDSA/ATS, 2007) (SOR: A). Oral antibiotic therapy for uncomplicated CAP is safe and effective in outpatient or inpatient settings in patients younger than 65 years with no preexisting lung disease or other chronic disease with stable vital signs and no evidence of hypoxia or sepsis (Bjerre et al., 2004; Marras et al., 2004) (SOR: A). Influenza vaccination and pneumococcal vaccine are demonstrably effective among elderly patients and those with chronic disease (Vu et al., 2002) (SOR: A).

Chronic Infectious Diseases

Tuberculosis

Key Points

- Eighty percent of TB cases come from 22 high-burden nations, and one third of cases occur in India alone.
- Sputum cultures can confirm the diagnosis of TB, but they also are important for identifying patterns of drug resistance.
- Polymerase chain reaction techniques looking for genetic polymorphisms can provide more rapid diagnosis of drug-resistant TB.
- Latent infection (positive skin test in asymptomatic patient with normal chest radiograph) is treated with 6 to 9 months of isoniazid or 4 months of rifampin.
- Treatment of active pulmonary TB requires a multidrug regimen for 6 to 12 months; cultures should be negative in 80% of patients within 2 months.

Tuberculosis is caused by infection with *Mycobacterium tuberculosis*, transmitted by airborne exposure from close contact with infected patients. Pulmonary infection is the most common form, although extrapulmonary TB from hematogenous spread (meningitis, peritonitis, renal or adrenal TB, spinal TB [Pott's disease], others) can occur in young children, elderly people, persons in high-endemic areas, and patients with impaired immunity or malnutrition.

Epidemiology and Risk Factors

In many parts of the world, TB is one of the most common causes of fatal respiratory infection; 80% of cases come from 22 high-burden nations, and one-third occur in India alone.

WHO (2005) estimated 8.8 million new TB cases worldwide in 2003, including 674,000 HIV-infected patients, with 1.7 million deaths attributed to TB. TB cases are falling or stable in most regions but increasing in Africa. In North America, TB rates rose during the 1980s, but since 1992, TB rates have been in decline.

Children, elderly people, and immunocompromised patients are especially vulnerable. In the United States, 22% of TB cases occur in older adults, with the highest rates in elderly residents of long-term care facilities (Thrupp et al., 2004). The most important risk factor for developing TB is having household or other close contact with a patient who has active TB.

Clinical Presentation

Tuberculosis can be a life-threatening infection. For pulmonary TB, symptoms include cough, fever, dyspnea, night sweats, and weight loss or failure to gain weight. The few physical findings other than weight loss can include wheezes, rales, or signs of consolidation in the affected lung field. Hematogenous spread can lead to signs of extrapulmonary infection. Patients with an initial diagnosis of CAP might instead have TB. Patients with CAP who have symptoms suggesting TB or who do not respond to antibiotic treatment, who have upper lobe infiltrates or cavitory lesions, who come from endemic areas, or who have persistent cough or hemoptysis should be evaluated for TB (Kunimoto and Long, 2005).

For patients with symptoms or with a positive PPD, chest radiograph and sputum cultures for AFB are required. Typical chest x-ray findings include hilar or mediastinal lymphadenopathy, patchy infiltrates, apical scarring, and pleural effusions, but a cavitory lesion or miliary pattern (typical millet-seed granulomas scattered diffusely throughout lung fields) more specifically suggests TB.

Diagnosis

Skin testing is still the best method of testing for latent infection by prior exposure to *M. tuberculosis*. Intradermal testing with 5 tuberculin units (0.1 mL) of PPD is more accurate than multiprong tine testing. Interpretation depends on the patient's risk of disease. Patients with a history of direct exposure to active cases of TB, or with impaired immunity such as HIV, should be considered to have a positive test if the area of induration is greater than 5 mm at 48 to 72 hours. Most other patients should be considered positive with induration greater than 10 mm. Very-low-risk patients (age >5 years, no history of exposure, normal immune system, low rates of TB in population) may be considered positive only with induration greater than 15 mm. These criteria are summarized in Box 18-5 (CDC, 2000). Persons vaccinated with bacille Calmette-Guérin (BCG) vaccine may still be accurately tested with PPD skin testing. For high-risk populations, a percentage tuberculin response higher than 15 on the QuantiFERON-TB test (QFT) performed on venous whole blood is moderately correlated with a positive skin test. Neither PPD nor QFT is recommended as routine screening in low-risk populations (CDC, 2003a).

Clinical diagnosis in endemic areas is often based on history of exposure, clinical signs, AFB smears, and chest x-ray findings. Sputum cultures can confirm the diagnosis and also

- Nursing homes and other long-term care facilities for elderly persons
- Hospitals and other health care facilities
- Residential facilities for AIDS patients
- Homeless shelters

 Mycobacteriology laboratory personnel
 Persons with high-risk conditions

- Silicosis
- Diabetes mellitus
- Chronic renal failure
- Some hematologic disorders (e.g., leukemias, lymphomas)
- Other specific malignancies (e.g., head/neck or lung carcinoma)

 Weight loss $\geq 10\%$ of ideal body weight
 Gastrectomy
 Jejunioileal bypass
 Children < 4 yr of age, or infants, children, and adolescents exposed to high-risk adults

Reaction ≥ 15 mm of Induration

Persons with no risk factors for TB

*Risk of TB in patients treated with corticosteroids increases with higher dose and longer duration.

†For persons who are otherwise at low risk and are tested at the start of employment, a reaction of ≥ 15 mm induration is considered positive.

are important for identifying patterns of drug resistance. In infants and young children, sputum AFB smears and cultures plus gastric aspirates each morning for 3 days yields the diagnosis only 50% of the time. Other cases may need to be treated presumptively, based on exposure, symptoms, and chest radiograph. In culture-negative cases of TB, it is essential to find the index case and to obtain sputum cultures and drug sensitivities from that patient to guide therapy for patients with negative cultures but active disease.

Laboratory diagnosis of TB historically has relied on the use of sputum smears for AFB and culturing of the *M. tuberculosis* organism. Culture results can require 2 to 8 weeks, but more rapid methods can detect early growth within 5 to 14 days (Katoch, 2004; Schluger, 2003). Gene amplification using PCR techniques can be performed on sputum samples for rapid results, as well as on cerebrospinal fluid (CSF), gastric or pleural aspirates, and urine. PCR is highly sensitive (95%-98%) for diagnosing TB from sputum in smear-positive and

culture-positive cases, but it has lower sensitivity (57%-78%) for smear-negative and culture-positive cases (Rattan, 2000). PCR may also be used on organisms obtained from early growth on positive cultures to detect drug resistance more rapidly, taking advantage of the genetic polymorphisms in the *M. tuberculosis* organism, which are almost always associated with drug resistance. Although positive results are highly specific, failure to detect mutations does not entirely rule out drug resistance (Hazbon, 2004; Nachamkin et al., 1997).

Treatment

A positive PPD skin test in an asymptomatic patient with a normal chest x-ray film and negative HIV test represents latent infection with no active disease. A 6- to 9-month course of isoniazid is effective in treating this latent infection and in preventing the development of active TB. Isoniazid therapy is associated with clinical hepatitis in approximately 0.6% of treated patients (Smieja et al., 1999). An effective alternative is rifampin for 4 months. The short course of two drugs, rifampin and pyrazinamide for 2 months, is no longer recommended because of evidence of increased liver toxicity with this combination (CDC, 2001). Treatment of positive PPD latent infection is indicated even in patients with prior history of BCG vaccination and is also effective in patients co-infected with HIV (Wilkinson et al., 1998).

Treatment of active pulmonary TB requires a multidrug regimen for 6 to 12 months. For uncomplicated pulmonary TB, a short-course protocol of four drugs (isoniazid, rifampin, pyrazinamide, ethambutol) for the first 2 months and two drugs (isoniazid, rifampin) for the next 4 months is effective. Treatment with intermittent therapy 2 days per week has been less effective than daily therapy in RCTs (Mwandumba and Squire, 2001). Repeat cultures should be obtained after 2 months of treatment, when 80% of patients have negative cultures. Cavitory lesions, or persistent positive cultures after 2 months of therapy, are indications for an extended 9-month course of treatment. New drugs entering the pipeline of clinical trials include long-acting rifamycins and fluoroquinolones.

Directly observed therapy (DOT) is indicated for patients with specific risk factors for treatment failure caused by non-compliance, but RCTs in a variety of settings have not clearly demonstrated benefit over traditional public health strategies (Volmink and Garner, 2003). Enhanced DOT appears to be more effective. Box 18-6 lists strategies of social supports, barrier reduction, compliance monitoring, and incentives that can be blended in a broad-based strategy to ensure treatment compliance and cure (ATS, CDC, IDSA, 2003). WHO reports an 82% success rate for TB treatment worldwide, although the prevalence of multidrug-resistant TB is increasing.

Treatment of patients who have positive PPD and x-ray evidence of TB but negative sputum smears depends on the level of clinical suspicion for active TB. When suspicion is high, multidrug therapy should be initiated pending culture results. If cultures come back negative but the patient shows clinical or radiographic signs of improvement after 2 months of treatment, the patient is assumed to have culture-negative TB, and treatment should be completed using isoniazid and rifampin. If culture remains negative and there is no sign of clinical or radiographic improvement, treatment may be

From American Thoracic Society, Centers for Disease Control and Prevention, Infectious Diseases Society of America. Treatment of tuberculosis. *Am J Respir Crit Care Med* 2003;167:603-662, and *MMWR* 52(RR-11):1-77. <http://www.cdc.gov/mmwr/preview/mmwrhtml/rr5211a1.htm>.

discontinued after 2 months. For patients at low suspicion of TB, no treatment is indicated pending culture results. If cultures remain negative and the patient is asymptomatic with no progression on chest x-ray film, a standard course of treatment for latent TB (isoniazid for 9 months or rifampin for 4 months) is indicated (Fig. 18-8).

Prevention

The most important elements of prevention are screening for exposure, detection and follow-up of active cases, and prophylaxis of infected but clinically asymptomatic patients. PPD testing and treatment of latent infection is a more effective strategy than BCG vaccination in patient populations with relatively low incidence of pulmonary TB, but in highly endemic areas, infant BCG vaccination strategies can reduce childhood TB infection rates by as much as 50% (Colditz et al., 1995). Patients with a positive PPD but no symptoms and a negative chest film should be treated with isoniazid daily for 9 months or rifampin for 4 months. Maintaining an effective public health infrastructure, including TB surveillance, screening, and contact tracing, is essential. Sputum culture and sensitivity testing is an increasingly relevant component of an effective public health strategy to identify and contain the spread of multidrug-resistant TB.

KEY TREATMENT

A 9-month course of isoniazid or a 4-month course of rifampin is effective in preventing development of active TB in asymptomatic patients with a positive PPD test and negative chest x-ray film (i.e., latent infection), even in patients with HIV co-infection (Smieja et al., 1999; Wilkinson et al., 1998) (SOR: A).

Treatment with intermittent therapy 2 days per week has been less effective than daily therapy in RCTs (Mwandumba and Squire, 2001) (SOR: A).

BCG vaccine effectively reduces infection rates by about 50% in highly endemic populations (Colditz et al., 1995) (SOR: B).

AIDS-Related Infections**Key Points**

- Specific opportunistic infections are associated with HIV, and bacterial community-acquired pneumonias are also common.
- More than half of HIV-infected patients with CD4+ counts less than 200 cells/ μ L experience an AIDS-related opportunistic infection within the next 2 years.
- Tuberculosis is common in HIV patients. TB worsens the clinical course of HIV infection, and HIV infection complicates TB management.
- High-resolution CT scan is the best imaging study for diagnosing HIV-related pulmonary infections.
- Inactivated influenza and pneumococcal vaccines are recommended for HIV-infected patients who are still able to mount a significant immune response.

HIV/AIDS by definition compromises our host defense capacity for fighting otherwise-benign infections. Some of the most common opportunistic infections in patients with HIV/AIDS affect the lungs as their target organ.

Epidemiology and Risk Factors

Table 18-4 shows the relationship between opportunistic infections (OIs) and specific levels of immunocompromise as measured by CD4+ lymphocyte counts; 200 cells/ μ L is a critical threshold for prophylactic treatment (Clumeck and Wit, 2003). More than half of HIV patients with CD4+ counts below this level experience an AIDS-related OI in 2 years.

Human cases of *Pneumocystis carinii* pneumonia (PCP) are now understood to be caused by *Pneumocystis jiroveci*. Most healthy children have been infected asymptotically with *P. jiroveci* by age 4 years (Pifer et al., 1978), allowing cases in HIV patients to occur either by reactivation or by new exposure. Without antiretroviral therapy or PCP prophylaxis, more than 70% of HIV-infected patients could be expected to experience PCP, with 20% to 40% mortality (Phair et al., 1990).

Clinical Presentation

A wide range of clinical presentations can occur with OIs in HIV/AIDS. PCP can manifest with cough, tachypnea, and fever. Chest films may be relatively normal early in the course of disease but eventually may show diffuse, bilateral, symmetric interstitial infiltrates in a butterfly pattern. Hypoxia,

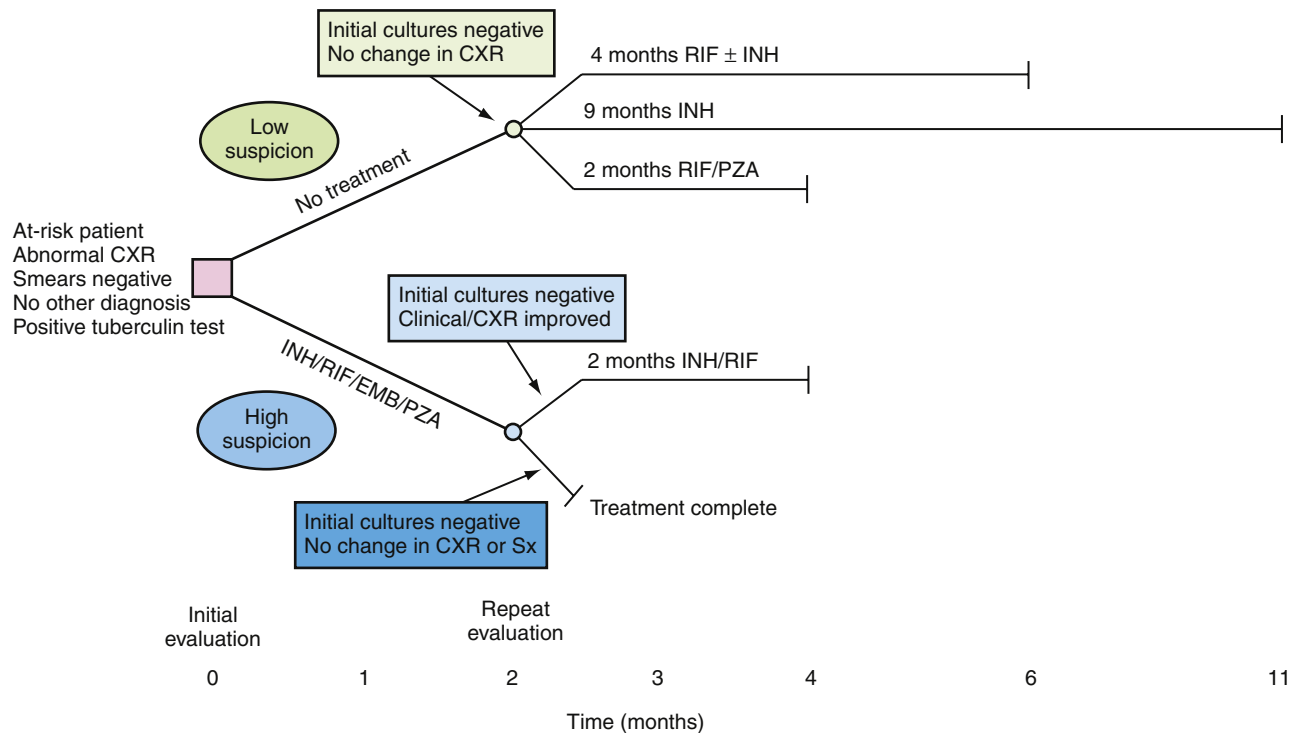

Figure 18-8 Treatment algorithm for inactive tuberculosis (TB) and for active, culture-negative pulmonary TB. (American Thoracic Society, Centers for Disease Control and Prevention, and Infectious Diseases Society of America: Treatment of tuberculosis. *Am J Respir Crit Care Med* 2003;167:603-662, and *MMWR* 52(RR-11):1-77. <http://www.cdc.gov/mmwr/preview/mmwrhtml/rr5211a1.htm>.)

P_{aO_2} less than 70 mm Hg, and an increased A-a O_2 gradient are typical. Pneumothorax occurring in a patient infected with HIV suggests PCP, which typically produces pneumatoceles as lung tissue is destroyed.

Clinicians should also have a high index of suspicion for pulmonary TB in HIV-infected patients. Presentation of pulmonary TB is fairly typical (upper lobe patchy infiltrates with or without cavitation) in patients with $CD4 \mu L$, whereas patients with more severe immune suppression often have atypical lung presentations (lobar infiltrates or miliary pattern) or extrapulmonary forms of TB. In severely immunocompromised patients, sputum AFB cultures can be positive even in the presence of normal chest radiograph.

The attention to OIs should not diminish clinical suspicion for bacterial pneumonia as a cause of significant morbidity and mortality in HIV-infected patients. *S. pneumoniae*, *H. influenzae*, *Pseudomonas aeruginosa*, and *S. aureus* are the most frequently isolated organisms (Rimland et al., 2002). Patients present with typical symptoms such as fever, tachypnea, cough, and constitutional symptoms and a pattern of lobar pneumonia or other infiltrates on chest x-ray film.

Diagnosis

Diagnosis of PCP may be obtained from laboratory testing, histopathology, and imaging studies. Histochemical stains and direct immunofluorescent studies can confirm the organism's presence in induced sputum, but sensitivities are much greater (90%-99%) when specimens are obtained from BAL or transbronchial biopsy (Cruciani et al., 2002). Open lung biopsy is the "gold standard" and may be safer than bronchoscopic techniques for patients with bleeding disorders.

Nuclear medicine and CT studies are also used extensively in evaluating pulmonary symptoms in patients with HIV/AIDS. For example, HRCT scan can show a patchy, ground-glass appearance or characteristic pneumatoceles in PCP. Gallium-67 scintigraphy is also useful. In a study of 57 immunocompromised patients with pulmonary infections, the first-choice diagnosis suggested by CT was accurate in most fungal infections (95.0%) and PCP (87.5%), but was less accurate for bacterial (73.7%) and viral (75.0%) infections, and missed both cases of mycobacterial infection (Demirkazik et al., 2008). A gallium scan showing diffuse increased uptake in the lungs of an HIV-infected patient can also suggest PCP. Sensitivity is high (>90%), but specificity can be as low as 51%. Features of an abnormal gallium scan that increase specificity and positive predictive value include increased uptake in the lungs in the presence of a normal chest film, intensity of uptake in the lung (greater than liver uptake), and a diffuse heterogeneous pattern. In a comparative study of gallium scanning versus HRCT in HIV/AIDS patients with pulmonary symptoms but normal or near-normal chest radiographs, HRCT resulted in both higher positive predictive values (86%) and negative predictive values (88%) than gallium scintigraphy (62% and 73%) (Kirshenbaum et al., 1998).

Sequential thallium and gallium scanning may be performed when Kaposi's sarcoma is suspected. The combination of a positive thallium and negative gallium scan is highly specific for Kaposi's sarcoma, but sensitivity is decreased by the presence of opportunistic infections, which can make the gallium scan positive as well. Other nuclear imaging studies include cell-surface peptide receptor-binding molecules radiolabeled with indium or technetium (van de Wiele et al., 2002).

Table 18-4 Risk Factors Associated with Development of Major Opportunistic Infections in HIV-Infected Patients

| Infection | CD4+ Count Risk Threshold (cells/mm ³) | Other Risk Factors |
|--|--|--|
| <i>Pneumocystis jiroveci</i> (carinii) pneumonia (PCP) | ≤200 | Prior PCP Present CD4+ cells <14% Fever of unexplained etiology Presence of oral candidiasis |
| <i>Mycobacterium tuberculosis</i> | Any | Tuberculin skin test (PPD) positive Exposure to infectious contact |
| <i>Mycobacterium avium</i> complex | ≤50 | Prior respiratory or gastrointestinal colonization Prior opportunistic disease High viral load (>105 copies/mL) |
| Cytomegalovirus (CMV) disease | ≤50 | Seropositive (IgG antibodies to CMV) CMV viremia Prior opportunistic disease High viral load (>105 copies/mL) |
| Cryptococcal meningitis | ≤50-100 | Environmental exposure |
| Toxoplasmosis | ≤100-200 | Seropositive (IgG antibody to <i>T. gondii</i>) |
| <i>Candida</i> esophagitis | ≤100 | Prior <i>Candida</i> colonization High viral load (>105 copies/mL) |
| Cryptosporidiosis | ≤100 | Environmental exposure (contaminated water, soil, animal exposure) |
| Histoplasmosis | ≤100 | Exposure (endemic areas: Midwest, Southwest U.S.) |
| Coccidioidomycosis | ≤100 | Exposure (endemic areas: Southwest U.S., Mexico) |

Prevention and Treatment

The treatment of HIV is covered in Chapter 17. However, there are specific opportunities for preventing pulmonary OIs in HIV-infected patients. Antiretroviral therapy (ART) has transformed HIV/AIDS into a chronic disease in which CD4+ counts can often be maintained above levels at which OIs are likely. For preventing pulmonary complications, prophylaxis regimens that were effective in decreasing OI rates in the pre-ART era still play a role in the care of patients with more advanced disease. ART has resulted in dramatic decreases in HIV-related mortality and OIs, but specific challenges are raised by the cost and complexity of the drug regimens as well as drug-drug interactions, particularly when mixing prophylactic antibiotics or antituberculous agents with protease inhibitors.

When an OI leads to the initial diagnosis of HIV/AIDS, treatment with ART and agents effective against the OI may be begun simultaneously. Fever and worsening of clinical

symptoms several weeks after ART initiation may be related to recovery of the patient's immune function, described as an "immune reconstitution or reactivation syndrome," and must be differentiated from treatment failure or progression of disease by measuring serial CD4+ counts and RNA viral loads.

Trimethoprim-sulfamethoxazole (TMP-SMX) prophylaxis has been demonstrated to prevent episodes of *P. jiroveci* pneumonia and to enhance survival in patients with low CD4 μ L (D'Egidio et al., 2007). Oral dapsone or inhaled pentamidine are alternatives for patients unable to tolerate TMP-SMX. It is also used to treat PCP infections, although side-effects of TMP-SMX are significantly higher in HIV/AIDS patients. Corticosteroids are added for patients with significant respiratory distress or hypoxemia.

Tuberculosis worsens the clinical course of HIV infection, and HIV infection complicates the management of TB (Sharma et al., 2005). All HIV-infected patients should undergo PPD testing for latent infection with *M. tuberculosis*. A PPD reaction greater than 5 mm is considered positive in an HIV-infected patient. If chest x-ray film is negative and there are no other signs of active pulmonary or extrapulmonary TB, an appropriate treatment regimen for latent TB should be initiated. Treatment of latent TB reduces significantly the risk of developing active TB in HIV patients with a positive skin test (Volmink and Woldehanna, 2004). Regimens are similar to those used in HIV-negative patients, but if isoniazid is chosen, the duration of treatment is 9 months rather than 6 months. Standard treatment regimens for active TB appear to be effective in HIV patients as well, but trials will determine the optimum duration, regimen, and dosing frequency in patients with TB and more severe HIV-related immunocompromise. Treatment with rifampin should be avoided or undertaken with great caution in patients receiving protease inhibitors or nonnucleoside reverse-transcriptase inhibitors (NNRTIs). Dosage of rifabutin should be decreased with these agents. Detailed guidelines for the combined treatment of TB and HIV are available and frequently updated (CDC, 2007).

Mycobacterium avium complex (MAC) infections can be prevented with clarithromycin or rifabutin prophylaxis, although there is increasing resistance to clarithromycin. Disseminated MAC infection often manifests with signs in multiple organ systems. Localized pneumonia can occur in patients with more intact immune function receiving ART.

Although other prophylactic regimens are available to prevent systemic viral or fungal infections, a survival benefit has not been demonstrated. Inactivated influenza and 23-valent pneumococcal vaccines are recommended for HIV patients who are still able to mount a significant immune response and should be initiated early in the disease, with annual influenza vaccine each year thereafter. Live vaccines should not be used.

KEY TREATMENT

Treatment of latent tuberculosis (positive skin test) reduces risk of progression to active TB in HIV/AIDS patients (Volmink and Woldehanna, 2004) (SOR: A).

Influenza vaccine is indicated for HIV/AIDS patients (SOR: A).

Treatment of asymptomatic HIV-infected patients with trimethoprim-sulfamethoxazole significantly reduces pulmonary infections with *Pneumocystis* pneumonia (Grimwade et al., 2003) (SOR: A).

Fungal Infections of the Lung

Endemic mycoses (histoplasmosis, coccidioidomycosis, and paracoccidioidomycosis) can cause primary pulmonary infections in exposed patients as well as reactivation syndromes in patients with HIV or other causes of immune suppression. The incidence of these infections has decreased with the widespread use of ART for HIV infection. Fungal infections related to *Aspergillus* spp. are more widespread geographically, but the incidence of aspergillosis has also decreased with increasing ART use.

Epidemiology and Risk Factors

Histoplasmosis (*Histoplasma capsulatum*) is most common in basins of the Ohio and Mississippi rivers. Blastomycosis (*Blastomyces dermatitidis*) is found in this same area of the United States as well as in portions of Canada. Coccidioidomycosis (*Coccidioides immitis*) is prevalent in desert areas of the southwestern United States, and paracoccidioidomycosis (*Paracoccidioides brasiliensis*) is the most common endemic mycosis in Central and South America. Airborne exposure to local soil is a risk factor. In South Asia and Southeast Asia (especially India, China, Thailand, and Vietnam), *Penicilliosis marneffeii* is another significant endemic mycosis affecting HIV/AIDS patients (Randhawa, 2000).

Aspergillosis occurs most often in the context of immune suppression, especially in HIV-infected patients with CD4+ lymphocyte counts less than 50 cells/ μ L. Leukopenia, systemic corticosteroids, bone marrow transplantation, and broad-spectrum antibiotic therapy also increase risk for aspergillosis.

Clinical Presentation

Presentation of any of the endemic mycoses depends on the patient's underlying immune status, as well as on the degree of exposure. For example, in patients with significant immune suppression (CD4+ lymphocyte counts $<150/\mu$ L), histoplasmosis can manifest with signs and symptoms of disseminated multiorgan infection, whereas patients with more intact immune symptoms can have more localized pulmonary symptoms and signs. Blastomycosis is often a self-limited infection, but it can lead to chronic pneumonia or skin, musculoskeletal, or CNS involvement (Pappas, 2004). Cough, dyspnea, and fever, with or without weight loss or night sweats, are the most common symptoms (Baumgardner et al., 2004). Coccidioidomycosis similarly can manifest as a self-limited pulmonary infection. In the case of intense exposure or in immunosuppressed patients, it can manifest as a severe fulminant pulmonary infection with ARDS or as a disseminated infection (peritonitis, lymphadenopathy, skin nodules, meningitis, musculoskeletal or liver involvement).

Respiratory disease caused by *Aspergillus* can take the form of pseudomembranous tracheitis or invasive pneumonia. Pseudomembranous tracheitis can lead to airway obstruction. Both respiratory syndromes are associated with cough, fever, dyspnea, and hemoptysis, and pneumonia also produces hypoxia. Chest x-ray films can show diffuse interstitial infiltrates or even signs of pulmonary infarction caused by fungal invasion of vascular tissue.

Diagnosis

In disseminated histoplasmosis, *Histoplasma* antigen is detectable in blood or urine with 85% to 95% sensitivity. For isolated pulmonary histoplasmosis, BAL or transbronchial biopsy may be required. *Coccidioides* organisms may be cultured or seen on histopathologic tissue stains or detected by serologic tests of blood or CSF. *Aspergillus* spp. may be cultured from sputum samples, which is sufficient for diagnosis in the presence of a typical clinical syndrome and no alternative diagnosis. More definitive diagnosis may be made by BAL (50% sensitivity) or open-lung biopsy.

Treatment

Acute, uncomplicated pulmonary histoplasmosis may be treated with watchful waiting in patients with normal immune systems (Wheat et al., 2004). Severe disseminated histoplasmosis or severe diffuse pulmonary histoplasmosis is treated with the liposomal form of amphotericin B for 3 to 10 days, followed by 12 weeks of oral itraconazole therapy, and then lifelong itraconazole prophylaxis. New antifungal agents such as voriconazole, caspofungin, and micafungin are potential alternatives (Herbrecht et al., 2005; Ruhnke, 2004). Detailed treatment guidelines for the management of histoplasmosis and blastomycosis infections are available from IDSA (Chapman et al., 2008; Wheat et al., 2007).

For coccidioidomycosis and blastomycosis, amphotericin B is usually chosen for initial therapy. Less serious infections might respond to fluconazole or itraconazole, and some treatment success has been demonstrated with voriconazole (Bakleh et al., 2005). Meningitis is treated with fluconazole or intrathecal amphotericin B. The CDC recommends treatment with voriconazole for invasive aspergillosis.

Prevention

The most important means of preventing fungal pulmonary infections is the ART of HIV/AIDS. HIV patients treated for histoplasmosis or coccidioidomycosis require chronic suppressive therapy with itraconazole or alternative antifungal therapy for life. TMP-SMX prophylaxis for PCP might also be protective against paracoccidioidomycosis. Education and protective gear (protective masks) during digging, excavation, and construction projects or cave exploration in endemic areas can help prevent acute pulmonary infections caused by high-level environmental exposures.

Vascular Disease

Pulmonary Embolism

Key Points

- Clinical decision rules using objective scoring algorithms help establish pretest probability and enhance the predictive value of other tests for pulmonary embolism (PE).
- A negative *quantitative* D-dimer test by ELISA less than 500 μ g/L can effectively rule out PE in patients with low or intermediate pretest probability of disease.

- High-resolution CT scan with contrast can be performed on the lungs and the deep veins of the legs at the same time in a PE protocol.
- Hemodynamically stable patients with submassive PE may be treated with dose-adjusted intravenous or fixed-dose subcutaneous heparin.
- Hemodynamically unstable patients with massive PE may be treated with thrombolytics or embolectomy.
- Prophylactic therapy is not effective if initiated after a clot has begun to form, so venous thromboembolism prophylaxis with subcutaneous heparin should be part of standard hospital admitting orders unless specifically contraindicated.

In the 19th century, Rudolf Virchow defined the pathologic process of pulmonary embolism, in which blood clots, usually from deep vein thromboses (DVTs) in one or both legs, break off and are trapped in the pulmonary arterial system, leading to pulmonary infarct, decreased oxygenation of venous blood returning from the periphery, and elevated right-sided pressures in the heart (Dalen, 2002). Two thirds of emboli reach both lungs and lodge in large or intermediate pulmonary arteries, most often in the lower lobes.

Epidemiology and Risk Factors

In 2003 there were 98,921 hospitalizations in the United States during which pulmonary embolism was diagnosed, generating charges of nearly \$2 billion. In-hospital mortality was 3% (Health Care Utilization Project, 2003). The importance of rapid diagnosis and treatment was underscored by Dalen and Alpert in 1975, who estimated that only 6% of PE deaths at that point in medical history occurred in patients diagnosed and treated for PE (Dalen, 2002).

The most important cause of pulmonary embolism is DVT, and both conditions are included under the broader term *venous thromboembolism* (VTE). Virchow's triad of risk included hypercoagulability, stasis, and vascular injury. Patients can develop DVT after surgery (especially hip or pelvic surgery), major trauma, prolonged hospitalization or bed confinement, or even prolonged sitting in a confined space (air travel, bus or car trips, medical school lectures). Patients at highest risk are those with a past history of DVT. Additional risk factors include smoking, cancer, obesity, pregnancy, heart disease, stroke, burns, and medications (e.g., estrogen therapy). Patients with inherited risk include those with antithrombin III deficiency, hyperhomocysteinemia, protein C or protein S deficiency, and factor V Leiden mutation, as well as those with acquired hypercoagulable states such as the antiphospholipid syndrome.

Clinical Presentation

Any suspicion of PE as a cause of acute shortness of breath requires specific diagnostic evaluation and quick intervention in this potentially life-threatening condition. Acute-onset shortness of breath coupled with pleuritic chest pain, hemoptysis, wedge-shaped pulmonary infarct lesions on chest radiograph, and S1Q3 pattern with tachycardia on ECG can all point specifically to a diagnosis of PE, but most patients have a nonspecific presentation. Collateral circulation from bronchial arteries makes pulmonary infarction relatively uncommon. Massive PE can lead to acute right

ventricular failure and cardiovascular collapse. Pao₂ greater than 80 mm Hg in room air and a normal A-a O₂ gradient make the diagnosis less likely but do not completely exclude PE. All patients with acute-onset shortness of breath with no apparent cause should be evaluated for PE.

Diagnosis

Diagnosing PE includes an evaluation for DVT. Physical examination for signs of DVT (asymmetry in calf or thigh diameter, calf tenderness, Homans sign) are relatively insensitive and nonspecific, and other tests (venous Doppler ultrasonography or spiral CT with contrast) can more accurately confirm the presence of significant underlying DVT.

Once suspected, PE must be confirmed or ruled out with a high degree of certainty. Failure to treat could be life threatening, but treatment carries significant risks as well. Clinical decision rules using objective scoring algorithms help establish pretest probability (high, intermediate, or low), which in turn enhances predictive value of other tests for PE (Ebell, 2004). One common decision tool uses only history and physical examination variables (Wells et al., 2001), and another scoring system adds variables from chest x-ray and arterial blood gas measurements (Wicki et al., 2001).

Several qualitative, semiquantitative, and quantitative laboratory methods are available for measuring D-dimer. Any negative D-dimer test can help exclude the diagnosis of PE in patients with low pretest probability of disease, but for patients with moderate pretest probability, only quantitative D-dimer test by enzyme-linked immunosorbent assay (ELISA) less than 500 µg/L can effectively rule out PE. Spiral CT with contrast and magnetic resonance angiography (MRA), two alternative imaging studies widely replacing V/Q scan, are more accessible and accurate in patients with underlying heart or lung disease, and perhaps more accurate for centrally located than peripheral emboli. Spiral CT also offers the advantage of potentially diagnosing other conditions, and when ordered in a PE protocol, may be combined with CT of the lower extremities to evaluate possible DVTs. Table 18-5 summarizes the results of strategies for excluding the diagnosis of PE (using criteria of post-test probability <5%) or for confirming the diagnosis (post-test probability >85%) (Roy et al., 2005).

Treatment

The options for treatment of PE include anticoagulation, thrombolysis, and (rarely) surgery. With controlled trials ongoing, no clear recommendation yet exists for thrombolysis in all cases of PE. One trial of alteplase plus heparin showed significantly decreased mortality in patients with submassive PE, compared with patients treated only with heparin (Konstantinides et al., 2002). However, a meta-analysis of all RCTs comparing thrombolytic therapy with heparin in patients with PE showed a survival benefit only in studies that included hemodynamically unstable patients (patients with massive PE). In trials that excluded these patients, there was no benefit found for thrombolysis (mortality slightly worse for thrombolytic therapy) (Wan et al., 2004). Treatment of DVT with thrombolytics has also been studied, and although venous blood flow may be improved and post-DVT syndrome decreased, there is a significant risk of hemorrhagic complications such as stroke.

Table 18-5 Diagnostic Tests to Exclude or Confirm Diagnosis of Pulmonary Embolism (PE)

| Pretest Probability Based on Objective Clinical Decision Rules | Exclude Diagnosis (PE <5%) | Confirm Diagnosis (PE >85%) |
|--|--|--|
| Low clinical probability (10%) | Negative D-dimer (quantitative or semiquantitative) Negative spiral CT scan Negative MRA Low-probability V/Q scan | Positive pulmonary angiogram (no other test is adequate to confirm positive diagnosis of PE in a patient with low prior probability) |
| Moderate clinical probability (35%) | Quantitative D-dimer <500µg/L (by ELISA method) Normal or near-normal lung scan Negative spiral CT scan <i>in combination with</i> negative venous Doppler ultrasound of leg veins | Positive spiral CT scan High-probability V/Q scan Positive MRA Positive venous Doppler ultrasound of leg veins |
| High clinical probability (70%) | Negative pulmonary angiogram (no other test is adequate to exclude or rule out diagnosis of PE in a patient with a high prior probability) | Positive spiral CT scan High-probability V/Q scan Positive MRA Positive echocardiogram ultrasound |

CT, Computed tomography; *ELISA*, enzyme-linked immunosorbent assay; *MRA*, magnetic resonance angiography; *V/Q*, ventilation/perfusion ratio.

In massive PE with cardiovascular collapse, thrombolysis is often used, but emergency pulmonary embolectomy is an option in settings where cardiothoracic surgery can be mobilized rapidly. Dauphine and Omari (2005) reported on 11 patients with massive PE treated with emergency embolectomy. Of the seven patients who did not have preoperative cardiac arrest, all survived to hospital discharge. One of the four patients who experienced cardiac arrest preoperatively also survived to discharge.

For patients who are hemodynamically stable and have less than massive pulmonary emboli, the initial treatment choice is dose-adjusted, intravenous unfractionated heparin or fixed-dose, subcutaneous low-molecular-weight (LMW) heparin. A meta-analysis comparing these two therapies in venous thromboembolism treatment found odds ratios favoring LMW heparin in both the rate of recurrence and the rate of bleeding complications, but these differences were not statistically significant (Erkens and Prins, 2010). LMW heparin by fixed-dose subcutaneous injection is at least as safe and effective as traditional dose-adjusted, unfractionated heparin therapy. Anticoagulation with warfarin is indicated for at least 3 to 6 months after an initial PE episode,

and lifetime therapy may be warranted for patients with hypercoagulability or recurrent episodes. Patients with recurrent episodes unresponsive to anticoagulation might benefit from surgical placement of an inferior vena cava filter.

Prevention

Primary prevention of PE begins with prevention of DVT. Trauma, hip or pelvic surgery, general surgery, and hospitalization or prolonged bed rest put patients at significant short-term risk. Many cases of VTE can be prevented in these patients if prophylaxis is initiated promptly. Prophylactic therapy is not effective if it is initiated after a clot has begun to form, so it is crucial to include VTE prophylaxis (subcutaneous heparin as well as mechanical interventions) on admitting orders for most patients admitted to a hospital for surgery or for serious medical conditions. Clinicians currently underutilize prophylactic therapies recommended in various clinical guidelines. They should order heparin prophylaxis on admission automatically unless there is a specific contraindication or the patient is clearly not at risk, rather than ordering prophylaxis only when risk factors are obvious (Tooher et al., 2005). Once DVT begins in the legs, prompt diagnosis and therapy can provide effective secondary prevention of the more life-threatening PE.

KEY TREATMENT

Deep vein thrombosis prophylaxis begun routinely on hospital admission, unless specifically contraindicated, can prevent many in-hospital PE episodes (Tooher et al., 2005) (SOR: A). An algorithm using clinical indicators, quantitative D-dimer test, and various imaging studies (spiral CT with contrast, MRA, venous Doppler ultrasound) can effectively rule in (>85% probability) or rule out (<5% probability) PE (Roy et al., 2005) (SOR: A).

Pulmonary Hypertension

Pulmonary hypertension is diagnosed when pulmonary artery pressures exceed normal levels, and symptoms ensue. The condition may be either primary or secondary to other causes, which can be pulmonary, cardiac, or systemic in origin.

Epidemiology and Risk Factors

Secondary causes of pulmonary hypertension include chronic lung disease (COPD and chronic bronchitis), cardiac disease (congenital defects, mitral stenosis, left atrial myxoma), autoimmune or inflammatory conditions such as scleroderma and SLE (Paolini et al., 2004), and granulomatous disease such as sarcoidosis. Certain drugs (fenfluramine) can also cause the condition, as can chronic liver disease with portal hypertension. Some patients experience pulmonary hypertension as a complication of arterial clotting or chronic damage from single or multiple episodes of PE.

Primary pulmonary hypertension is diagnosed when there is no obvious cause of the condition, and there is a familial form of the disease as well. Persistent pulmonary hypertension of the newborn occurs in 1.9 neonates per 1000 live births and results from shunting through a patent foramen

ovale and ductus arteriosus, with or without pulmonary hypoplasia (Greenough and Khatriwal, 2005).

Clinical Presentation

Symptoms include easy fatigability, exertional dyspnea, chest pain, dizziness or lightheadedness, and syncope. Underlying pulmonary or cardiac disease can mask the diagnosis in early stages. Pulmonary hypertension is often diagnosed late with signs of right-sided heart failure. Patients with COPD, pulmonary fibrosis, sarcoidosis, or recurrent PE who have evidence of right-sided heart failure (cor pulmonale) should be evaluated for pulmonary hypertension as well.

Diagnosis

In the primary care office, patients can have signs of right-sided chamber enlargement on ECG. Echocardiogram may also suggest increased right-sided pressures and decreased cardiac index and can be performed both at rest and during exercise. It may also reveal cardiac causes of secondary pulmonary hypertension (Bossone et al., 2005). Definitive diagnosis is made by recording of a pulmonary artery pressure greater than 25 mm Hg on catheterization.

Treatment

Nonspecific treatments of pulmonary hypertension include loop diuretics, digoxin, and anticoagulant therapy with warfarin when indicated. Traditional therapies include dihydropyridine calcium channel blockers such as nifedipine or amlodipine, which can modestly decrease pulmonary arterial pressures in vasoresponsive patients but can also cause sudden death in nonvasoresponsive patients (Humbert, 2004; Malik et al. 1997).

Other therapies include prostacyclins such as epoprostenol and treprostinil; both are pulmonary and systemic vasodilators, but must be given by continuous intravenous infusion through an indwelling catheter or by subcutaneous injection (treprostinil) (Paramothayan et al., 2005). Iloprost is an inhaled form of prostacyclin apparently with fewer side effects that can improve exercise capacity and symptom scores, but it requires frequent dosing (Baker and Hockman, 2005). Side effects and economic costs are significant obstacles to the use of all these agents. Bosentan is a nonselective endothelin receptor antagonist, and sitaxsentan is a selective endothelin receptor antagonist. Both improve functional status and physiologic measures in pulmonary hypertension (Liu and Cheng, 2005).

Sildenafil, which inhibits phosphodiesterase type 5 in the pulmonary vasculature, has also been approved for this indication based on results of a controlled trial that showed it improved 6-minute walk distance, New York Heart Association (NYHA) functional class, pulmonary artery pressure, cardiac index, and oxygenation. Sildenafil (2005) is also less expensive than the prostacyclins and endothelin receptor antagonists. Dipyridamole also has some phosphodiesterase type 5 activity.

Inhaled nitric oxide is a selective pulmonary vasodilator that is often used to treat persistent pulmonary hypertension of the newborn. In adults with pulmonary hypertension, a 2-year trial of inhaled nitric oxide therapy combined with

dipyridamole demonstrated improvements in exercise capacity, symptoms, and hemodynamic measures (Perez-Penate et al., 2005). A European consensus panel has released guidelines for the use of nitric oxide in this condition (Germann et al., 2005).

Surgical therapies may be general (lung transplant) or specific, as in the repair of congenital shunting lesions, mitral stenosis, or atrial defects. Pulmonary thromboendarterectomy is effective in some patients with pulmonary hypertension associated with saddle pulmonary embolus (Olsson et al., 2005).

Other Pulmonary Diseases of the Pulmonary Vasculature

Wegener's granulomatosis is a vasculitis (inflammatory condition) of the vascular bed that can manifest either with shortness of breath or hemoptysis or with progressive pulmonary fibrosis caused by repeated small hemorrhages at the alveolar level. It is now categorized as a systemic antineutrophil cytoplasmic antibody (ANCA)-associated small-vessel vasculitis, and it usually combines pulmonary features with glomerulonephritis. Tissue biopsy of either the lung or the kidney may be diagnostic. Clinical manifestations result from the combination of vasculitis, glomerulonephritis, and necrotizing granulomas of the respiratory tract. CT may be more sensitive than MRI for diagnosis of pulmonary lesions.

Diffuse alveolar hemorrhage may result from autoimmune collagen vascular disease or vasculitis, Goodpasture's syndrome, and other vasculitides. *Goodpasture's syndrome* results from the formation of anti-glomerular basement membrane antibodies, which can also attack the lung capillary membranes. Primary pulmonary vasculitides affect mostly small vessels, but systemic conditions can affect vessels of all sizes. *Churg-Strauss syndrome* is a small-vessel vasculitis that often manifests first as asthma. Most patients also have maxillary sinusitis, allergic rhinitis, or nasal polyposis. Gastrointestinal, neurologic, and cardiac involvement often follows. The condition responds well to systemic steroids, but patients can require long-term low-dose prednisone as maintenance therapy (Guillevin et al., 2004).

Pulmonary Complications of Sickle Cell Disease

Patients with sickle cell disease have complications that can manifest with pulmonary signs and symptoms. For example, patients with sickle cell disease are especially vulnerable to capsular bacteria such as *Streptococcus pneumoniae* (pneumococcus) and *Haemophilus influenzae*, and they can present with acute lobar pneumonia, sepsis, or even pneumonia-related ARDS. Pneumococcal and Hib vaccines, in combination with penicillin prophylaxis, have significantly reduced (but not eliminated) rates of serious infections with these organisms (Hord et al., 2002).

Acute chest syndrome is an acute complication of sickle cell disease. One third of patients with this syndrome have an identified infectious cause. Less than one in 10 has a documented fat embolism. Postulated mechanisms in most patients with no identified cause include hypoxia-induced pulmonary vasoconstriction, with microclot formation and decreased levels of nitric oxide and other chemical mediators

of vasodilation, inflammatory response, and cellular protection (Stuart and Setty, 2001). Hydroxyurea therapy promotes production of hemoglobin F (HbF) and appears to decrease the likelihood or severity of acute chest syndrome. Nitric oxide therapy might be of use acutely in acute chest syndrome or chronically in the treatment of pulmonary hypertension, but there is inadequate evidence from controlled trials.

Among adults with sickle cell disease, pulmonary hypertension is a significant cause of morbidity and appears to be a significant predictor of mortality, even with relatively modest elevations of pulmonary artery pressure. The pulmonary hypertension can be caused by widespread thrombosis of small arteries, although the cause is uncertain in many cases (Adedeji et al., 2001). Pulmonary hypertension complicates other chronic hemolytic anemias as well (Machado and Gladwin, 2005).

Malignant Disease

Lung Cancer

Key Points

- Lung cancer is the leading cause of cancer deaths in U.S. men and women.
- Smoking is the most serious and prevalent risk factor for lung cancer.
- Any pulmonary symptoms persisting beyond 3 weeks are indications for diagnostic evaluation. Smokers and patients older than 40 years should receive a more aggressive workup.
- High-resolution CT is more sensitive than chest radiography for diagnosing lung cancer. CT also provides anatomic detail for staging and operability.
- Patients with stage I, non–small cell carcinoma have 50% 5-year survival with appropriate surgical resection.
- The family physician plays a central role in facilitating family conversations about diagnostic and treatment options, advance directives, palliative care, and other end-of-life decisions.

Epidemiology and Risk Factors

Although not the most common cancer, lung cancer is the leading cause of cancer deaths in men and women in the United States. Lung cancer surpassed breast cancer as a cause of death among women in the 1990s because of increased smoking among women and better detection and treatment of breast cancer with decreased mortality. Smoking is clearly the most serious and prevalent risk factor for the development of lung cancer. According to the CDC, from 2000 to 2004, smoking resulted in an estimated annual average of 269,655 deaths among males and 173,940 deaths among females in the United States. The top three smoking-attributable causes were lung cancer, ischemic heart disease, and COPD (CDC, 2008).

Clinical Presentation

Smokers are at significant risk for lung cancer, but other patients can develop lung cancers as well, especially if they have significant secondary exposure to tobacco smoke or

other carcinogens. History of asbestos exposure is a specific risk factor for the development of mesothelioma. Patients can present with respiratory symptoms such as a cough, hemoptysis, or shortness of breath, or they can present with constitutional symptoms such as fatigue and unexplained weight loss. In some cases a chest radiograph done for other reasons reveals a pulmonary nodule or mass lesion. In patients with metastatic pulmonary lesions, the symptoms of the primary cancer may be predominant or occult.

Diagnosis

Any pulmonary symptoms persisting beyond 3 weeks are an indication for a more extensive evaluation, and smokers and patients older than 40 years should receive a more aggressive workup. Diagnostic evaluation can begin with chest x-ray film, but a negative film does not rule out lung cancer or provide tissue diagnosis or staging. HRCT scanning is a more sensitive test for identifying lung cancers even at asymptomatic stages. HRCT can also provide some anatomic detail for staging and determining operability of the cancer. Tissue diagnosis is essential not only for confirming the presence of malignancy but also for determining the histopathology. Fiberoptic bronchoscopy with biopsy brushings and washings is highly accurate for diagnosing centrally located bronchogenic carcinoma in the proximal bronchial tree. Transbronchial biopsy can reach deeper tissues for diagnosis of metastatic pulmonary nodules or even lymph node biopsy. Peripheral pulmonary lesions or pleural lesions can be reached by CT-guided needle biopsy or by surgical open-lung biopsy.

The combination of tissue biopsy and imaging studies yields both the histopathologic type and the stage of cancer. The non–small cell lung cancers may be further classified into various histopathologic cell types, such as adenocarcinoma and squamous cell carcinoma. Staging of non–small cell cancers is summarized in [Table 18-6](#) (American Cancer Society, 2005).

Treatment

General treatment principles and guidelines provide a framework for the primary care practitioner. Histopathology and stage at diagnosis drive treatment options. For example, surgical resection is not generally effective in treating small cell carcinomas of the lung, which may respond better to chemotherapy. On the other hand, a stage I, non–small cell carcinoma might have as much as a 50% 5-year survival rate with appropriate surgical resection. The European Respiratory Society and European Society of Thoracic Surgeons have published extensive clinical guidelines for evaluating any lung cancer patient's fitness for combined surgery and chemoradiotherapy (Brunelli, 2009).

Treatment options in addition to surgery include radiation therapy and chemotherapy. Response to any therapy differs by cell type (e.g., squamous cell vs. adenocarcinoma), stage of disease, and whether the tumor is primary or secondary. Metastatic pulmonary nodules from estrogen receptor–positive breast cancer may be treated quite differently from primary adenocarcinoma of the lung, although both generally receive some form of chemotherapy. The primary care practitioner must maintain a close working

Table 18-6 Staging and 5-Year Survival Related to Lung Cancers

| Clinical Stage | Defining Characteristics | Average 5-Year Survival |
|---|--|-------------------------|
| Non–Small Cell Cancers | | |
| I | Carcinoma confined to lung tissue; no spread to other organs or adjacent structures, and no lymph node involvement. Substages A and B refer to size of tumor. | 51% |
| II | Carcinoma confined to lung tissue; no spread to other organs or adjacent structures, but positive lymph node involvement. Substages A and B refer to size of tumor. | 26% } 8% } 17% |
| III | Carcinoma with spread to adjacent structures, such as chest wall, diaphragm, mediastinum, or contralateral lung. Stage IIIA may still be operable; IIIB is inoperable. | |
| Stage IV | Metastatic to distant organs or tissue beyond the thoracic cavity | 2% |
| Small Cell Cancers | | |
| Limited | Limited to one lung or one side of the chest with no distant spread | 10%-20% |
| Extensive | Spread beyond one lung to distant organs | 1%-2% |
| From Lung and bronchus cancer: survival rates by race, sex, diagnosis-year, stage and age. SEER Statistics in Review, 1975–2003. National Cancer Institute. http://seer.cancer.gov/csr/1975_2003/results_merged/sect_15_lung_bronchus.pdf . | | |

relationship with medical and surgical oncologists to help guide patients and families through various treatment options.

One specific role for the family physician is to help the patient and family address psychosocial needs in a proactive manner. The family physician may facilitate the first conversation between the patient and the patient's family in which the word "cancer" is mentioned or an ongoing conversation in which issues of death and dying can be addressed. The family physician must find the balance in encouraging the family to maintain hope but also in helping the family to develop contingency plans for potential crises, such as respiratory arrest or loss of function that leave the patient unable to live independently at home. Health care power of attorney and advance-directive documents are a much-needed complement to living wills, which cover only a narrow set of circumstances at the end of life. The family physician can help ensure that pain and other forms of discomfort are managed appropriately and can work closely with patient, family, oncologist, nurses, hospice, and the patient's faith community to manage proactively the balance between preserving life and preventing suffering, especially in a patient with a terminal illness.

Prevention

Smoking causes lung cancer (Khuder, 2001). Never smoking is the most important preventive measure available, but smoking cessation reduces the risk of all the major histologic types of lung cancer (Khuder and Mutgi, 2001). Beta-carotene and vitamin E do not prevent lung cancer, and in therapeutic doses beta-carotene might be associated with a slight increase in cancer (Albanes et al., 1995).

Regular chest x-ray screening with or without sputum cytology does not improve mortality rates (Manser et al., 2003). Studies suggest that routine screening of smokers with spiral CT every 6 months does increase detection of early stage cancer and might improve mortality by increasing the percentage of non–small cell cancers that are operable (Gohagan et al., 2005). Patients with stage I, non–small cell lung cancers may have a 5-year survival rate of 50%, but only 15% of lung cancers are found at this stage without routine screening.

Another aspect of preventing lung cancer deaths is the rates at which patients of different racial and ethnic groups receive potentially curative surgery in stage I disease. African American patients, for example, have significantly lower rates of surgery and significantly higher mortality rates. Causes of these racial disparities include patient factors (locus of control, acceptability of surgery, health beliefs about risks of opening such cancers to air during surgery), provider factors (biased treatment recommendations or assumptions about what patients might want), systemic or institutional factors (lack of insurance, poverty), and perhaps most importantly, the patient-physician dyad (issues of respect, trust, and effective communication influence the outcome of negotiating the treatment plan).

KEY TREATMENT

Smoking causes lung cancer. Never smoking is the most important preventive measure available, but smoking cessation also reduces the risk of all the major histologic types of lung cancer (Khuder, 2001) (SOR: A).

Routine screening of smokers with chest radiograph or sputum cytology does not improve survival. Use of frequent spiral CT suggests increased detection of early-stage cancer and improved mortality in non–small cell cancers (Manser et al., 2003; Gohagan et al., 2005) (SOR: A)

Beta-carotene and vitamin E do not prevent lung cancer and in therapeutic doses might be associated with a slight increase in cancer (Albanes et al., 1995) (SOR: B)

Occupational Lung Disease

Key Points

- At least 10% of asthma cases in adults can be attributed to occupational causes.
- The two key questions are, "Have you ever been exposed to fumes, gases, or dusts?" and "Do your symptoms get better when you are away from work, such as during weekends and vacations?"

- Asbestosis passed coal miner's lung as the leading cause of death from occupational pneumoconiosis in the United States.
- Because most occupational masks or respirators are imperfect and workers often remove them, preventive strategies should focus on worksite air-quality improvement.

Neoplasms of the lung are most frequently either primary lung carcinomas or metastatic lesions that arise in other organs. Lung carcinomas may be further divided into small cell and non-small cell cancers. Overall, survival for patients with lung carcinoma is only 15%, in part because lung cancers are often diagnosed at inoperable stages. Respiratory exposures cause a significant percentage of occupational illness and disability. Although a causative relationship cannot always be proved, a presumptive diagnosis may be made in the presence of typical signs and symptoms, confirmed by spirometry, chest radiography, or other diagnostic tests, in the presence of a work-related exposure known to cause pulmonary disease.

Taking a good occupational history is essential. In the occupational history, ask the specific type of work the patient performs and other jobs the patient has performed in the past. Two key questions are, "Have you ever been exposed to fumes, gases, or dusts?" and "Do your symptoms get better when you are away from work, such as during weekends and vacations?" Clinically, occupational lung diseases can be divided into five major groups (National Institute for Occupational Health and Safety [NIOSH], 1999): work-related asthma, pneumoconiosis, hypersensitivity pneumonitis, acute irritant or inhalant toxicity, and work-related cancers.

Work-Related Asthma

At least 10% of asthma cases in adults can be attributed to occupational exposures, so an occupational history should be obtained in every patient with asthma. Diagnostic criteria are the same as for other causes of asthma or airway obstruction, including spirometry (FEV_1/FVC ratio <0.7) and evidence of reversibility.

Chemical and natural agents can cause asthma or aggravate preexisting asthma. These include chemicals used in cleaning or manufacturing processes. Occupational exposures causing work-related asthma include dust exposures (e.g., cotton

dust, wood sawdust, cement powder, bakery flour), organic exposures (e.g., molds and fungi in agricultural grains), chemical exposures (e.g., solvents, plastics, epoxies, ammonia, chlorine, petroleum vapors), and fumes from welding or other industrial sources (van Kampen et al., 2000), as shown in Figure 18-9 (NIOSH, 2004a). Peak-flow meter readings measured at the same time each day on workdays, weekends, and vacation days can help establish the occupational cause of disability for insurance purposes.

Occupational Pneumoconioses

The occupational pneumoconioses are diffuse parenchymal lung diseases caused by airborne exposure to inorganic materials such as asbestos, silica, and coal dust. In 1998 and 1999, asbestosis passed coal workers' pneumoconiosis (coal miner's lung) as the leading cause of death from occupational pneumoconiosis in the United States. Men accounted for 98% of these deaths. The rise in deaths caused by asbestosis is illustrated in Figure 18-10 (NIOSH, 2004b). Other occupational lung diseases are linked to heavy metal dust or fumes in specific syndromes such as berylliosis (beryllium) and stannosis (tin). Byssinosis, or brown-lung disease, occurs most often among workers in yarn, thread, and fabric mills from exposure to cotton dust.

Patients with occupational pneumoconioses may first develop symptoms of cough and dyspnea, with signs of small-airway disease or overt airway obstruction on pulmonary function testing. As the disease progresses, patients may also develop spirometric evidence of restrictive lung disease as well as chest x-ray changes. Removing the patient from the exposure or workplace is the most important step for preventing progression of disease. These pneumoconioses respond poorly to corticosteroids. Smoking significantly worsens the progression of occupational pneumoconiosis (Wang and Christiani, 2000).

Hypersensitivity Pneumonitis

Exposure to organic materials such as fungi, plant proteins, animal danders, or other organic dust can cause a similar type of diffuse parenchymal lung disease known as hypersensitivity pneumonitis. Examples include farmers'

Figure 18-9 Causes of work-related asthma, 1993–1999. (From National Institute for Occupational Safety and Health. Distribution of agent categories most often associated with work-related asthma cases for all four SENSOR reporting States [California, Massachusetts, Michigan, New Jersey], 1993–1999. Worker Health Chartbook, 2004. <http://www2a.cdc.gov/niosh-Chartbook/imagdetail.asp?imgid=206>.)

Figure 18-10 Asbestos as a contributing or underlying cause of death in the United States, 1968–1999. (From National Institute for Occupational Safety and Health: Number of deaths of U.S. residents aged 15 or older with asbestosis recorded as an underlying or contributing cause on the death certificate, 1968–1999. Worker Health Chartbook, 2004. <http://www2a.cdc.gov/NIOSH-Chartbook/imagetail.asp?imgid=217>.)

lung, mushroom workers' lung, and bird fanciers' disease. Although fewer than 100 deaths per year in the United States are directly attributed to hypersensitivity pneumonitis, the number of cases and resulting short-term or long-term disability are potentially much higher.

Acute Irritant or Inhalant Toxicity

A number of acute pulmonary exposures each year are related to inhaled exposures to irritant chemicals. For example, when certain household chemicals such as bleach and ammonia are mixed, chlorine gas can be produced. Chlorine and chlorinated chemicals cause direct injury to tissues throughout the respiratory tract, including the bronchial mucosa. Injury can fill the alveolar sacs with fluid in a noncardiac form of pulmonary edema, or "chemical pneumonitis."

The large surface area of the alveolar sacs in close approximation to the pulmonary capillary system also provides a portal of entry to systemic toxicity from certain inhaled agents. For example, organophosphate and carbamate chemicals, whether used as nerve gas or as agricultural pesticides, can be absorbed readily throughout the respiratory tract. More than 5000 persons died within a week after inhaling methyl isocyanate gas released from a factory in Bhopal, India, in 1984. Pulmonary toxicity can also occur as a consequence of systemic exposures. For example, patients exposed to the toxic pesticide paraquat through skin absorption or by ingestion through the gastrointestinal tract often die from pulmonary hemorrhage or progressive pulmonary fibrosis.

Work-Related Cancers

The most obvious form of cancer associated with occupational inhalation exposures is mesothelioma, which is most often linked to asbestos exposure. Asbestos-related malignant

mesothelioma accounted for an estimated 21,500 deaths in the United States from 1985 to 2009 (Lilienfeld et al., 1988). Persons with an occupational history of welding, pipefitting, shipbuilding, or other exposure to asbestos are at risk.

Lung cancers have also been associated with various occupational exposures, including welding or smelting fumes, coal dust, silica dust, and organic solvents. A more common exposure that has more recently been recognized as occupational is secondary exposure to tobacco smoke. Bartenders, restaurant staff, and others who work in smoke-filled environments are at significant risk for tobacco-related disease, including lung cancers, even if they have never personally smoked.

Prevention

Smoking significantly worsens the progression of occupational pneumoconioses such as black lung disease (coal miner's lung) and silicosis. Because most occupational masks or respirators are imperfect even when worn (and workers often remove masks intermittently for comfort), preventive strategies that rely on daily consistent use of respirators or masks in occupational settings are less effective than worksite air-quality improvement (e.g., increased ventilation, air filters, decreased dust or toxin production) in preventing occupational lung disease.

Granulomatous Diseases

Sarcoidosis

Sarcoidosis is defined as a multisystem granulomatous inflammatory disease of unknown etiology. It is the most common granulomatous disease of the lungs not attributed to a known infectious cause such as tuberculosis.

Risk Factors

Sarcoidosis can be found worldwide, but regional and racial/ethnic variations in epidemiology and clinical manifestations are intriguing. For example, it affects persons of Scandinavian origin and African Americans at much higher rates than other populations, with an incidence of 35.5 per 100,000 in African Americans and a slight female predominance. Several occupational and environmental exposures have been studied as possible risk factors for sarcoidosis, but none has been conclusively identified. Genetic susceptibility has also been difficult to define. The HLA class II antigens have been most often associated with susceptibility and prognosis in sarcoidosis, although not in all subpopulations (ATS/ERS/WASOG, 1999). The Sarcoidosis Genetic Analysis study (SAGA) suggested specific genetic loci related to sarcoidosis susceptibility in African Americans (Gray-McGuire et al., 2006); other studies show promise of characterizing susceptibility loci in a broader range of racial/ethnic groups (Iannuzzi, 2007).

Clinical Presentation

Sarcoidosis typically presents in early adulthood, between ages 20 and 40. Although the disease is systemic, a spectrum of clinical manifestations may suggest the prognosis. The onset of fever, arthralgias, bilateral hilar adenopathy on chest radiograph, and a raised, reddish skin lesion along the anterior tibial surfaces (erythema nodosum) characterize *Löfgren's syndrome*, an acute, self-limiting form of sarcoidosis that often undergoes spontaneous remission and has a favorable prognosis. The insidious onset of dyspnea, dry cough, hilar adenopathy and infiltrates on chest film, new skin lesions of the trunk and extremities, and complaints of recent vision changes characterize a chronic progressive form of sarcoidosis marked by multiple flares of disease requiring repeated treatment throughout the patient's lifetime.

Symptoms that bring patients to medical attention most often emanate from the lungs, skin, or the eyes (uveitis and lacrimal gland enlargement). Diagnosis of sarcoidosis may be delayed if symptoms are attributed to more common lung diseases such as asthma or chronic bronchitis (Judson et al., 2003). Pulmonary symptoms may result from bronchial obstruction, either external compression caused by adenopathy or granulomas within the airways. Progressive disease may cause damage to the lung parenchyma, with a restrictive pattern of pulmonary function and decreased diffusion capacity, consistent with progressive interstitial lung damage. Clinical features associated with a worse outcome include the presence of lupus pernio, chronic uveitis, hypercalcemia or nephrocalcinosis, nasal mucosal involvement and bone cysts. Neurosarcoidosis and cardiac involvement can be especially challenging to diagnose.

Diagnosis

The diagnosis of sarcoidosis is one of exclusion. The disease is established when clinical and radiographic findings are supported by a tissue biopsy specimen showing *noncaseating granuloma* (NCG), although NCG inflammation may be seen in biopsies from fungal infection, foreign body inclusions, and other noninfectious granulomatous diseases such as Langerhans cell histiocytosis (also referred to as eosinophilic

granulomatosis or pulmonary histiocytosis X) and Wegener's granulomatosis. Tissue biopsy can usually be obtained from the lung, a palpable lymph node, a skin lesion, or the eye (conjunctiva or lacrimal gland). Percutaneous fine-needle aspiration specimen is less frequently obtained from the liver or from retroperitoneal or abdominal nodes by CT guidance. Biopsy from a CNS or cardiac location requires specialty consultation.

Along with clinical symptoms and biopsy, chest x-ray findings are added to support the diagnosis of sarcoidosis. The Scadding staging system classifies chest radiographs into stage 0 (normal), stage 1 (bilateral hilar adenopathy), stage 2 (adenopathy and infiltrates), stage 3 (infiltrates alone), and stage 4 (fibrosis and retractions). A chest film showing bilateral hilar adenopathy in HIV-negative patients with negative skin test and cultures for TB is suggestive, but lymphoma and other causes must be ruled out. HRCT can confirm the size and location of adenopathy as well as granulomas and early pulmonary fibrosis.

Transbronchial biopsy can document pathology and endobronchial involvement of the respiratory mucosa. Fine-needle aspiration of endobronchial lymph nodes is being used increasingly. Endobronchial ultrasound to localize more peripheral adenopathy enhances accuracy. Analysis of BAL fluid showing a C4/C8 lymphocyte ratio greater than 3.5 has high specificity for sarcoidosis. Open-lung biopsy is usually not needed but can be diagnostic. Several biomarkers and cytokine profiles that may be helpful in the diagnosis and disease activity in sarcoidosis are under investigation (Bargagli et al., 2008). The serum angiotensin-converting enzyme (ACE) level has historically been used and is often elevated in initial cases, but it is not fully reliable as the disease progresses. A sarcoidosis assessment instrument has been developed to help clinicians better characterize organ involvement in patients with sarcoidosis (Judson et al., 1999).

Treatment

Some sarcoidosis patients may require no treatment, or only intermittent nonsteroidal anti-inflammatory drugs (NSAIDs) for joint and constitutional symptoms. Topical corticosteroids may be effective for anterior uveitis and some skin lesions. Inhaled corticosteroids and bronchodilators are often used when cough is a prominent symptom in patients with pulmonary involvement, but response has been equivocal. Systemic therapy is needed for the majority of patients. Systemic corticosteroids are first-line therapy and, for patients with pulmonary involvement, improve symptoms, pulmonary function, and chest x-ray signs of disease.

Second-line therapies include cytotoxic agents and other immunomodulating agents (Baughman et al., 2008). Methotrexate and hydroxychloroquine can be used as steroid-sparing agents. In patients with cardiac or neural sarcoidosis, treatment regimens that include cytotoxic therapy (e.g., cyclophosphamide) are needed. Other treatment strategies include agents that inhibit tumor necrosis factor alpha (infliximab, adalimumab, etanercept) (Nunes et al., 2005). Comorbid illnesses and multiorgan involvement are common in sarcoidosis (Cox et al., 2004; Westney et al., 2007), so health-related quality-of-life instruments should be used to monitor global response to therapy (DeVries and Drent, 2007), and multidisciplinary team-based care is recommended.

Interstitial Lung Diseases

Interstitial lung diseases (ILDs) represent a broad range of acute and chronic lung disorders. The pathology may display varying degrees of pulmonary inflammation and fibrosis, leading ultimately to end-stage lung disease. ILDs are classified under the larger designation of *diffuse parenchymal lung disease*, which includes disorders from known causes (occupational and environmental exposures, as well as progressive infections), and unknown causes (sarcoidosis, lymphangiomyomatosis, pulmonary histiocytosis X, eosinophilic pneumonia, idiopathic interstitial lung diseases). The idiopathic ILDs have been subclassified by the American Thoracic Society and European Respiratory Society (2002) into the following clinicopathologic entities, in order of relative frequency: idiopathic pulmonary fibrosis (IPF), nonspecific interstitial pneumonia (NSIP), cryptogenic organizing pneumonia (COP), acute interstitial pneumonia (AIP), respiratory bronchiolitis-associated interstitial lung disease (RB-ILD), desquamative interstitial pneumonia (DIP), and lymphoid interstitial pneumonia (LIP).

Epidemiology and Risk Factors

Occupational risk factors and specific occupational lung diseases are reviewed in previous sections. Various medications, chemotherapeutic agents, and radiation therapy can all cause diffuse parenchymal lung disease and may result in end-stage lung disease with pulmonary fibrosis. Other causes include autoimmune connective tissue disorders (SLE, RA), granulomatous diseases (sarcoidosis, pulmonary Langerhans cell histiocytosis, eosinophilic granuloma), and metabolic diseases (Gaucher's, Niemann-Pick), congenital neoplasia (tuberous sclerosis, neurofibromatosis) malignancy (lymphangitic carcinomatosis, bronchoalveolar carcinoma, pulmonary lymphoma), and certain drugs (bleomycin, nitrofurantoin, amiodarone). Among the interstitial lung diseases, idiopathic pulmonary fibrosis occurs more often in patients over age 60 and in men more than women. Cigarette smoking, chronic aspiration, various environmental exposures (metal and wood dust), and numerous viruses (Epstein-Barr, influenza, CMV) have been implicated as potential risk factors. The remaining ILDs rarely occur and are designated as separate disease entities based on specific clinicopathologic differences (Lynch et al., 2005).

Clinical Presentation

The hallmark symptoms of ILDs are the insidious onset of progressive shortness of breath and exertional dyspnea with paroxysmal dry cough. A careful history may elicit symptoms of an earlier viral prodrome in patients that may also include cough with varying sputum production and systemic symptoms such as fever or weight loss. On physical examination, most patients can have the typical dry, end-inspiratory ("Velcro") crackles most appreciable in the lung bases. The finding of cyanosis and accentuated second heart sound, right ventricular heave, and lower-extremity edema suggest late phases of the disease caused by chronic hypoxemia and pulmonary fibrosis.

Diagnosis

The usual diagnostic approach for all ILDs is a thorough history and physical examination along with chest radiographic and pulmonary function studies. The chest film typically shows bilateral, often asymmetric reticular opacities in the peripheral and basal lung areas. A normal-appearing radiograph may rarely be encountered but does not exclude microscopic presence of an ILD. Often, x-ray abnormalities can be seen years before the development of symptoms, so past films should be reviewed. HRCT features of idiopathic pulmonary fibrosis may be distinct and include bibasilar subpleural honeycombing, traction bronchiectasis (as illustrated in Fig. 18-11), thick intralobular septa, and minimal ground-glass opacities. If the HRCT pattern shows a predominance of ground-glass opacification, especially located away from the subpleural areas, diagnoses such as nonspecific interstitial pneumonia, bronchiolitis obliterans organizing pneumonia (BOOP), or hypersensitivity pneumonitis should be considered. In some cases, fibrotic scarring and nodules create a mass lesion that must be distinguished from carcinoma or other neoplasm.

The typical PFT pattern is that of a restrictive ventilatory defect with decreased lung flow and volume, increased FEV₁/FVC ratio, and decreased DLCO. Biopsy may be necessary to exclude malignancy or to rule in specific conditions such as sarcoidosis. Documenting pulmonary function, exercise capacity (6-minute walk test), and relationship of the ILD to any occupational or environmental exposure are all essential for helping patients receive appropriate worker's compensation or disability support when needed.

Treatment

Smoking cessation is essential, and pulmonary rehabilitation may improve quality of life and functional capacity for patients with any ILD. Pharmacologic options include single-agent or combination corticosteroid therapy and immunomodulating or antifibrotic agents (azathioprine, cyclophosphamide, colchicine, D-penicillamine). Overall, these therapies have shown marginal to no benefit in cases

Figure 18-11 Computed tomographic scan of a patient with idiopathic pulmonary fibrosis.

of idiopathic pulmonary fibrosis, whereas patients with other ILDs may have a better response (Davies et al., 2003). A meta-analysis of 390 patients with pulmonary fibrosis did find that interferon gamma-1b therapy significantly reduced mortality (Bajwa et al., 2005). Causes of death identified for pulmonary fibrosis in one study included respiratory failure (39%), cardiovascular disease (27%), lung cancer (10%), pulmonary infection or emboli (6%) (Panos, 1990).

Unilateral lung transplantation may enhance survival and functioning in patients with advanced interstitial fibrosis with chronic respiratory failure, whereas pulmonary fibrosis with pulmonary hypertension may require bilateral lung transplantation (Alalawi et al., 2005). One-year survival after lung transplantation is 75%, with 44% of patients surviving 5 years or longer (Trulock, 2001).

Lung Manifestations of Autoimmune Connective Tissue Disorders and Other Systemic Diseases

Many connective tissue diseases can have an impact on the lungs and pleura or on pulmonary function. Rheumatoid arthritis, for example, can cause interstitial lung disease because of a fibronodular inflammatory response or even larger rheumatoid nodules. Inflammation can also lead to pleural effusion or scarring, and pleural biopsy can reveal rheumatic nodules. Patients with RA can also develop one of several varieties of inflammatory interstitial pneumonia.

Systemic lupus erythematosus can affect the lungs. The inflammatory response of SLE is more vasculitic in nature, which can manifest as pulmonary hemorrhage, thromboembolic disease, or an inflammatory pleuritis with effusion.

Other autoimmune diseases with pulmonary manifestations include mixed connective tissue disease (MCTD), Sjögren's syndrome, and progressive systemic sclerosis (scleroderma). Progressive systemic sclerosis can manifest with thickening and tightening of the skin of distal extremities, sclerodactyly, Raynaud's phenomenon, and multiorgan involvement of lungs, skin, kidney, heart, and gastrointestinal tract. Sixty percent of patients have shortness of breath; others have cough, pleuritic chest pain, or hemoptysis. Lung CT scan in progressive systemic sclerosis and other autoimmune conditions can show pleural scarring and ILD, especially a ground-glass fibronodular pattern and honeycombing.

Diseases of the Pleura and Extrapulmonary Space

Key Points

- In international settings, the most common cause of pleural disease is tuberculosis.
- More than 200 mL of pleural fluid may be detected by physical examination or by blunting of the costophrenic angles on upright chest x-ray film. Decubitus positioning of the patient can reveal as little as 10 mL of fluid on the dependent side.
- Thoracentesis may be done blindly if pleural fluid layers out to at least 1 cm on decubitus radiograph. Otherwise, ultrasound guided thoracentesis may be indicated.
- An exudate is diagnosed in pleural fluid by finding a pleural/serum protein ratio greater than 0.5 and a pleural/serum LDH level greater than 0.6 (or pleural LDH >200 IU/dL) or pleural protein greater than 3 g/dL.
- Purulent fluid in the pleural space is indicated by a high neutrophil count and pH less than 7.2, which can require a chest tube along with antibiotics.
- Rapid drainage of more than 1 L of fluid from large pleural effusions (or air from pneumothorax) can result in reexpansion pulmonary edema.

The lungs are lined by visceral pleura, and the inside of the thoracic cavity is lined by parietal pleura. Normally, these two are closely adjacent, with only enough fluid for lubrication in the space between them.

Epidemiology and Presentation

Outside the United States, the most common cause of pleural disease is tuberculosis. In the United States, TB is still significant, but other disorders, such as pneumonia, HIV-related infections, connective tissue disease (especially lupus), and malignancies (mesothelioma, peripheral lung cancer) must also be considered. Pleural effusions can be caused by systemic sources of transudate (CHF, hepatic failure with ascites, autoimmune disease) or by local inflammatory processes (parapneumonic effusion, pancreatitis, neoplasia).

Four major categories of pathology arise from the pleura or pleural space: pleural fluid (transudate, exudate, hemorrhage, or chylous effusion), pneumothorax, pleural scarring, and pleural mass.

Diagnosis

Pleuritic disease is suggested by thoracic pain on inspiration. More than 200 to 300 mL of fluid in the pleural space may also be detected by physical examination. Decreased breath sounds with dullness to percussion could suggest pleural fluid or lung consolidation, but pleural effusion may be distinguished by the presence of decreased tactile and vocal fremitus. Often, there is a small (1-2 cm) zone at the top edge of the pleural effusion where traditional signs of consolidation may be heard, including egophony. A pleural rub may be heard in areas of inflammation but disappears when significant fluid cushions the movement of visceral pleura against parietal pleura. For pneumothorax, significant air must be present in the pleural space to detect hyperresonance, although breath sounds are often decreased on the affected side. In the 1% to 2% of cases producing *tension pneumothorax*, in which air is able to enter the space but not equilibrate with either extrathoracic or bronchial air pressures, the clinician may detect tracheal shift, cardiac shift, or decreased heart sounds.

Chest radiography reveals blunting of the costophrenic angles and visible fluid when about 200 mL of fluid has accumulated in the pleural space. Decubitus positioning of the patient can reveal as little as 10 mL of fluid on the dependent side on chest films. Thoracentesis may be done blindly if the fluid layers out to at least 1-cm thickness on decubitus radiograph. Otherwise, ultrasound-guided thoracentesis may be indicated.

Pneumothorax is also visible on chest x-ray film, especially when it exceeds 10% or more than 100 mL of air is present in the pleural space. On radiographs, 2.5 cm of air space between the thoracic wall and the lung is equivalent to a 30% pneumothorax. This is best visualized on upright PA and lateral films or occasionally on the nondependent side when patients are in the decubitus position. Other imaging studies (CT, MRI) can give more anatomic detail in patients with mass lesions or scarring. These studies are also somewhat more sensitive than radiography in detecting small amounts of air in pneumothorax.

Diagnostic thoracentesis can help determine the type of fluid and potential causes. *Transudates* are serous fluids often associated with inflammatory conditions. Transudative fluid is thin and mildly yellow or straw colored, through which one can read newsprint. More specific laboratory criteria for differentiating exudate from transudate include a pleural/serum protein ratio greater than 0.5, pleural/serum lactate dehydrogenase (LDH) level greater than 0.6 (or measured pleural LDH >200 IU/dL), and pleural protein greater than 3 g/dL.

Exudates indicate the presence of white blood cells and often a response to infection such as pleural abscess or TB. Parapneumonic effusions may be inflammatory transudates initially or may progress to exudative fluid as WBCs and even the infectious organism itself spread to the pleural space. Infectious exudates are suggested by pH higher than 7.2, which can be an indication for chest tube drainage. More specifically, TB may be suggested by an exudative pleural effusion with elevated WBC count, more lymphocytes than granulocytes, and pleural glucose/serum glucose ratio less than 0.5. Hemorrhage into the pleural space is indicated by the gross or microscopic presence of red blood cells, although poor technique can result in a bloody tap that is not diagnostic. For mass lesions or scarring, pleural biopsy may be obtained (revealing granulomas or malignancy) either percutaneously with needle or surgically in an open biopsy.

Treatment

Treatment most importantly targets the underlying condition. For example, the inflammatory pleural effusions of SLE may be treated with systemic corticosteroids or other anti-inflammatory agents. Antibiotics treat pneumonia and parapneumonic effusions, although purulent fluid or abscess in the pleural space can require chest tube drainage in addition to antibiotics.

Other indications for chest tube placement include pneumothorax compromising ventilation, exceeding 25%, or recurring after initial needle thoracostomy. Trauma with hemorrhage into the pleural space can also require a chest tube, or even open-chest surgery to identify and treat the source of bleeding. Some pleural effusions may be treated with therapeutic pleural tap rather than chest tube. In these cases, up to 1 L of fluid may be drained through a pleural needle and catheter. For these therapeutic taps, attaching the thoracostomy needle to a tube and vacuum bottle may be more efficient and cause less risk of bleeding or pleural injury from movement of the needle during the procedure than the traditional technique of using a large syringe and stopcock to remove 30 to 50 mL at a time. Rapid drainage of

large pleural effusions or pneumothorax can result in reexpansion pulmonary edema.

Patients with recurrent pneumothorax may require surgery to repair a specific defect. Patients with malignant pleural effusion that has recurred after complete reexpansion may benefit from pleural sclerosis, instilling agents such as bleomycin or tetracycline. Pleural stripping is rarely used because of the high rate of complications.

Disorders of Breathing

Sleep apnea may be obstructive or central in origin, or a combination of both. The effects of recurrent apnea extend well beyond simple fatigue or sleep deprivation, causing significant cardiovascular and neurologic disease. Patients with *obstructive* sleep apnea are often but not always obese. They experience episodes of intermittent apnea, often associated with snoring, especially during deeper stages of sleep. In addition to obesity, adenoidal or tonsillar enlargement, macroglossia, and laxity of the soft palate and pharyngeal tissue can contribute to sleep apnea. Stroke, brain tumors, trauma, cerebral edema, and other CNS disorders can affect breathing at the *central* level as well. Brainstem infarctions can lead to respiratory arrest and death. *Cheyne-Stokes respirations* describe an undulating pattern of breathing of increased depth and frequency alternating with waves of shallow, slower breathing and even apnea.

Many patients with obstructive sleep apnea have elements of central apnea as well. For example, alcohol and sedatives can exacerbate the respiratory depression and contribute to pharyngeal muscle laxity. In addition, patients with chronic obstructive sleep apnea can develop chronic CO₂ retention that further depresses respiration. Patients with the classic "pickwickian syndrome" (obesity and hypoventilation syndrome) have a constellation of signs, including morbid obesity, obstructive apnea, polycythemia, pulmonary hypertension, and right-sided heart failure. Patients can present with symptoms of daytime drowsiness, sleepiness, or feeling inadequately rested. Family members often bring the problem to the attention of the patient or the family physician, having observed loud snoring and interruptions in breathing during sleep. Sometimes a motor vehicle crash resulting from somnolence while driving brings the condition to light. Depression can also develop.

In addition to symptoms related to loss of sleep or upper airway obstruction, sleep apnea can contribute to other major causes of morbidity and mortality. Bradyarrhythmias are common, and hypoxia can lead to ventricular arrhythmias or even myocardial ischemia or stroke. When episodic hypoventilation becomes frequent or chronic, with resultant hypoxia and hypercapnia, a metabolic response may counteract the respiratory acidosis associated with hypoventilation; the kidneys retain bicarbonate to foster a compensatory metabolic alkalosis. Systemic and pulmonary hypertension may be intermediate outcomes that lead to more serious cardiac complications.

Formal diagnosis of sleep apnea can be made in a sleep laboratory using multichannel recording (polysomnography) of EEG, ECG, airflow, upper airway muscle tone, and oximetry. Home oximetry alone might not be adequately sensitive. The most essential treatment is significant weight reduction to

decrease obesity. Other behavioral treatments include avoiding supine sleep and avoiding alcohol or sedatives. Nasal CPAP is effective for patients who tolerate it. Various oral or dental devices are also available, but data on effectiveness are limited. Surgical procedures attempt to reduce airway obstruction at the palate or tonsillopharyngeal or adenoidal

levels. The American Academy of Sleep Medicine (AASM) has published clinical guidelines with evidence-based recommendations and algorithms for the evaluation, diagnosis, treatment and follow-up of patients with sleep disorders (Epstein et al., 2009).

Emergencies

Key Points

- Drooling, posturing, and air hunger are classic signs of epiglottitis.
- A lateral neck radiograph showing a thumbprint sign can be diagnostic of epiglottitis.
- Although most peritonsillar abscesses should be drained, smaller and early abscesses may respond to medical therapy.
- Acute onset of wheezing in a child with no history of asthma should alert the clinician to a possible airway foreign body.
- A high index of suspicion is required for the timely diagnosis of retropharyngeal abscess.
- Adolescent boys with recurrent epistaxis may have a juvenile nasopharyngeal angiofibroma.

Epiglottitis

Epiglottitis (or “supraglottitis”) is a condition that requires prompt attention by the physician. Epiglottitis results from bacterial (and rarely viral) infection of the supraglottic

structures, that is, the epiglottis and arytenoid cartilages. A high level of suspicion is necessary to make a diagnosis and avoid significant morbidity. Rapid decompensation and complete loss of the airway are the sequelae of most concern. The physician should always be suspicious when a patient presents with fever, sore throat, and difficulty swallowing, and when the severity of oropharyngeal physical findings is not in proportion to the symptoms. Croup, tonsillitis, peritonsillar abscess, and other neck infection may be incorrectly diagnosed in these patients. Epiglottitis occurs mainly in children age 2 to 7 years, although infants, older children, and adults can be affected. Mortality rates of 6% to 7% have been reported in adults.

Signs and symptoms of epiglottitis include rapidly developing sore throat, high fever, restlessness, and lethargy. A “supraglottic,” muffled voice is common. Many patients have difficulty with their saliva and drool. Classically, these patients are in a sitting position leaning forward, because this position tends to alleviate obstructive symptoms from the supraglottic swelling. They may show signs of “air hunger” or may have stridor.

Differential diagnosis includes tonsillitis, peritonsillar abscess, retropharyngeal abscess, airway foreign body, and

Table 19-1 Distinguishing Features of Epiglottitis and Croup

| Feature | Epiglottitis | Croup |
|-------------------------|------------------|------------------------------|
| Cause | Bacterial | Viral |
| Age | 1 year to adult | 1 to 5 years |
| Location of obstruction | Supraglottic | Subglottic |
| Onset | Sudden (hours) | Gradual (days) |
| Fever | High | Low grade |
| Dysphagia | Marked | None |
| Drooling | Present | Minimal |
| Posture | Sitting | Recumbent |
| Toxemia | Mild to severe | Mild |
| Cough | Usually none | Barking, brassy, spontaneous |
| Voice | Clear to muffled | Hoarse |
| Respiratory rate | Normal to rapid | Rapid |
| Larynx palpation | Tender | Not tender |
| Clinical course | Shorter | Longer |

From Berry FA, Yemen TA. Pediatric airway in health and disease. *Pediatr Clin North Am* 1994;41:153.

croup. Physical examination with laryngoscopy is extremely useful in differentiating these diagnoses. Endoscopy should not be performed if there is concern of impending airway obstruction. Endoscopy will typically show erythema and edema of the epiglottis and arytenoid cartilages. Other findings include laryngeal tenderness on neck palpation, although palpation should be avoided when the diagnosis is being considered.

Any time the diagnosis of epiglottitis is in question, otorhinolaryngologic (ear-nose-throat, ENT) and infectious disease consultations are warranted. Placement of a tongue depressor has been known to precipitate acute airway obstruction and should be avoided entirely if epiglottitis is strongly suspected. Differentiation from croup can be difficult because there is considerable overlap of symptoms (Table 19-1) (Berry and Yemen, 1994). A lateral extended neck radiograph can help in the diagnosis. X-ray evidence includes the classic “thumbprint” sign. If epiglottitis is suspected or lateral neck radiography is confirmatory, the patient should be taken to the operating room (OR) for orotracheal intubation in the presence of an anesthesiologist and an otorhinolaryngologist. In any case of airway obstruction, cricothyrotomy or tracheotomy can be lifesaving, because orotracheal intubation can be difficult and sometimes impossible. Some patients, usually adults, may be treated expectantly with intravenous (IV) medications and intensive care unit (ICU) observation as long as personnel are available for control of the airway if necessary. If airway stability is questionable, observation is not recommended.

After control of the airway is achieved, cultures of the epiglottis should be obtained and directed antibiotics instituted. *Haemophilus influenzae* type b (Hib) is common and can be beta-

Figure 19-1 Large left peritonsillar abscess (arrow) that required surgical drainage.

lactamase producing. Other, less common organisms include beta-hemolytic streptococci, *Streptococcus pneumoniae*, and *Staphylococcus aureus*. Antibiotics should be administered parenterally; effective antibiotics include cefotaxime, ceftriaxone, ampicillin plus sulbactam, or ampicillin plus chloramphenicol. Steroids can be useful for edema and inflammation, but their effectiveness has not been proved in controlled studies.

The incidence of epiglottitis in children is decreasing since the introduction of the Hib vaccine in the late 1980s. However, the incidence has remained stable or slightly increased in adults.

Peritonsillar Abscess

A peritonsillar abscess is the accumulation of pus in the peritonsillar space that surrounds the tonsil. The same organisms responsible for common tonsillar infections—*Streptococcus* and *Staphylococcus* species and anaerobes—are also found in peritonsillar abscesses.

The typical signs and symptoms of peritonsillar abscess include fever, sore throat for 3 to 5 days, dysphagia, odynophagia, and a muffled, “hot potato” voice. Trismus is extremely common. Examination confirms asymmetric tonsils and peritonsillar edema and erythema. The soft palate and uvula are swollen and displaced away from the side of the abscess. It is often difficult to distinguish between abscess and peritonsillar cellulitis. If possible, it is helpful to palpate because fluctuance indicates a loculation of pus. Diagnosis is often made by clinical impression, but computed tomography (CT) can be confirmatory and useful when the diagnosis is uncertain (Fig. 19-1).

If untreated, a peritonsillar abscess may spontaneously drain, progress to involve the deep neck, or even lead to airway obstruction. The most important part of the treatment is drainage of

the abscess cavity by needle aspiration, incision and drainage, or tonsillectomy. Cultures of the aspirate can be obtained, and broad-spectrum antibiotics should be started. Appropriate antibiotics include ampicillin-sulbactam (Unasyn) or clindamycin (Cleocin). Many patients present with dehydration, and parenteral fluids should be given if necessary. Analgesics should be prescribed as needed. One or two doses of IV corticosteroids may be given to decrease inflammation and pain.

Children presenting with peritonsillar abscess should be admitted to the hospital. Treatment with IV hydration and parenteral antibiotics is appropriate initially. Patients with peritonsillar cellulitis/phlegmon or early abscess often demonstrate a rapid response to treatment, whereas those with a well-formed peritonsillar abscess do not improve. Drainage is necessary in nonresponders. Abscesses in cooperative adults can be drained under local anesthesia in the emergency department (ED) or office and treated in an outpatient setting. Children usually require general anesthesia for drainage, and a tonsillectomy may also be performed. An elective tonsillectomy is often recommended for any patient with a peritonsillar abscess to prevent recurrence, especially with a history of recurrent tonsillitis, although few, if any, controlled studies support this recommendation.

Sudden Sensorineural Hearing Loss

Although most types of hearing loss are nonurgent problems, sudden sensorineural hearing loss (SSNHL) deserves special note because it is considered "otologic emergency." Any patient complaining of sudden hearing loss requires prompt evaluation. An obvious cause such as cerumen impaction or middle ear fluid can be treated appropriately and routinely. If a cause is not identified, sudden sensorineural hearing loss should be suspected and prompt ENT referral arranged. SSNHL is thought to be secondary to vascular, thromboembolic, viral, or autoimmune causes. It may also be the result of ototoxicity. Without treatment, hearing returns in one third of patients, partial hearing returns in one third, and there is no improvement in the remaining third. Early intervention with oral corticosteroids (and possibly antivirals, directed at the herpesvirus [Awad et al., 2008]) appears to improve outcomes, although few controlled studies have been done. The Cochrane Collaboration believes that there is a lack of good-quality evidence to support the use of steroids and that more research is needed (Wei et al., 2006). Finally, for patients who do not respond to systemic steroids, controlled studies do support the use intratympanic infusion of corticosteroids, demonstrating improved outcomes (Xenellis et al., 2006). Intratympanic steroids are also appealing for patients with contraindications to oral steroids (e.g., "brittle diabetics")

Foreign Bodies

Swallowing or aspiration of objects is most common in children but also occurs in the adult population. These objects can become lodged anywhere in the upper aerodigestive tract.

Esophagus

The most common location for esophageal foreign bodies is at the level of the cricopharyngeal muscle. Other regions include the anatomic narrowings of the esophagus, such as

Figure 19-2 Lateral neck x-ray film of a child presenting with gagging and drooling, showing two coins (arrow) in the esophagus near the cricopharyngeal junction.

the gastroesophageal junction, and the area of indentation of the esophagus by the left main stem bronchus and the arch of the aorta. Coins are by far the most common objects found in the esophagus in children. Chicken or fish bones are more common in adults.

The diagnosis of an esophageal foreign body is primarily based on the medical history and physical examination, with the aid of radiologic studies. Parents might witness ingestion of the foreign body and subsequent coughing, gagging, refusal to eat, or drooling. Often, however, the incident goes unwitnessed, and reliance on other diagnostic techniques is necessary.

Plain radiographs (including lateral films) are often diagnostic in pediatric patients because most esophageal foreign objects are radiopaque (Fig. 19-2). Other radiologic findings that can suggest a foreign body include increased soft tissue density in the prevertebral space, mediastinal widening, air-fluid levels in the esophagus, and paraesophageal air. Disk batteries *require a high index of suspicion* because they can cause significant tissue injury and lead to esophageal perforation *if they are not removed emergently*. They have a classic appearance when viewed laterally, approximating a dime resting on a nickel (similar to the appearance of Fig. 19-2).

If there is sufficient evidence of an esophageal foreign body, ENT consultation is indicated for rigid esophagoscopy and removal. When radiolucent objects have been ingested, contrast esophagography might be indicated, although esophagograms can give a false-negative result and can also complicate visualization during rigid esophagoscopy.

Airway

As with esophageal foreign bodies, airway foreign bodies are much more common in infants and young children. Many deaths from foreign-body aspiration occur in the home before medical intervention can be administered. The most

Figure 19-3 Inspiratory (A) and expiratory (B) radiographs of 8-year-old boy with left airway foreign body (peanut). No foreign object is visible on plain films, but the expiratory film shows overinflation of the left lung with mediastinal shift to the contralateral side.

frequently aspirated foreign bodies are foods, with nuts leading the list. Foreign bodies aspirated into the airway are usually found lodged in the bronchial tree but can also be found in the larynx or trachea. If the event is witnessed and results in complete airway obstruction, a Heimlich maneuver should be administered; however, the event is often not witnessed. Symptoms can include hoarseness, persistent cough, wheezing, or stridor if the foreign body is lodged in the trachea or larynx. Because the potential for morbidity and mortality is substantial, this condition requires urgent diagnosis and timely intervention to prevent catastrophe.

Any time a small child presents with wheezing or noisy breathing without a previous history of reactive airway disease, an airway foreign body should be included in the differential diagnosis. Typically, patients and parents recount a transient episode of coughing during eating that then subsided; the patient might even be symptom free for a time, then later have symptoms such as coughing or wheezing.

The most important diagnostic step for identifying a foreign body is a high index of suspicion. Careful auscultation of the lung fields is essential because subtle asymmetric differences may be found. Because most airway foreign bodies are radiolucent, chest radiographs can be normal, but abnormalities such as hyperinflation, atelectasis, or pneumonia can be present (Fig. 19-3). If plain radiographs are equivocal or normal and the patient is in stable condition, airway fluoroscopy can be helpful.

Consultation with a physician experienced in foreign body removal is required. Definitive treatment of airway foreign bodies is direct laryngoscopy and rigid bronchoscopy to identify and remove the object.

Epistaxis

Although epistaxis is usually nothing more than a minor annoyance, some episodes are severe enough to require urgent medical attention and intervention. In rare cases, epistaxis can also be a life-threatening emergency.

Predisposing factors for epistaxis include trauma (facial trauma or self-inflicted digital trauma), dry weather,

hypertension, bleeding dyscrasias (factor deficiencies, hereditary hemorrhagic telangiectasia, lymphoproliferative disorders), anticoagulation therapy (acetylsalicylic acid, heparin, warfarin), and intranasal tumors. Special consideration should be given to adolescent boys with recurrent epistaxis and nasal obstruction, because these symptoms might be the result of a juvenile nasopharyngeal angiofibroma. These are benign but locally aggressive tumors. All these potential risk factors should be considered because they must be addressed to treat the patient appropriately.

Epistaxis is classified according to its location. Bleeding from the anterior nasal cavity is most common and usually originates from a rich plexus of vessels at the anterior septum called *Kiesselbach's plexus* (Fig. 19-4). Bleeding from this location, although troublesome, is less likely to be severe and is usually easier to control than posterior epistaxis. Posterior epistaxis originates from the posterior two thirds of the nasal cavity and can be quite severe and much more difficult to control.

Initial management of epistaxis includes assessment and stabilization of vital signs. Rarely, severe bleeding can lead to airway compromise or hemodynamic compromise, or both, especially in patients with underlying cardiopulmonary dysfunction. The airway should be assessed and stabilized, urgently if necessary. Hypertension, if severe, should be controlled, with care taken to avoid subsequent *hypotension*. Hematologic studies, including complete blood count (CBC), prothrombin time, and partial thromboplastin time, should be ordered. Intravenous access should be established, allowing administration of fluids as well as IV medications, if necessary during treatment.

Treatment

Effective treatment requires adequate visualization and patient cooperation. The level of intervention by the primary care physician depends on level of experience, comfort level, and availability of appropriate supplies and equipment. ENT consultation should be considered when any of these prerequisites cannot be met. The patient should be reassured and

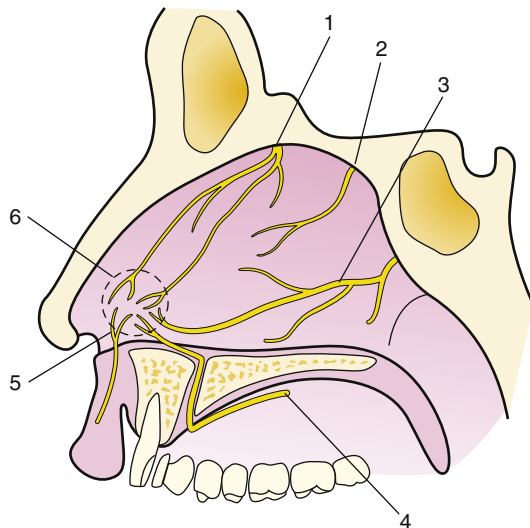

Figure 19-4 Kiesselbach's plexus. 1 and 2, Anterior and posterior ethmoid arteries; 3, septal branch of the sphenopalatine; 4, greater palatine; 5, branch from superior labial; 6, Kiesselbach's plexus. (From Colman BH, Hall IS (eds): *Hall and Colman's Diseases of the Ear, Nose and Throat*, 15th ed. Philadelphia, Churchill Livingstone, 2000, p 82.)

given an explanation of the planned treatment. This results in better cooperation and decreases patient anxiety, improving treatment success. A bright headlight, nasal speculum, large nasal (Frazier tip) suction, and bayonet forceps are required. If the patient is monitored and stable, a small dose of IV narcotics titrated for analgesia and anxiolytic effect may be given. Extreme caution should be taken not to oversedate the patient. Also, instrumentation of the nose can lead to a significant vasovagal response that may be accentuated in a hypovolemic patient given narcotics. It is advised to err on the side of caution with regard to narcotic medication both during and after treatment.

All clots should be suctioned. They can be quite tenacious and require forceps for removal. The nasal cavity should next be topically anesthetized and decongested (a mixture of 4% lidocaine and phenylephrine works well). If a bleeding site is easily identified, it may be cauterized with a silver nitrate stick.

Anterior Packing

If suction, decongestion, and cautery do not stop the bleeding and the site is still thought to be anterior, an anterior nasal pack should be placed. This can be done with 0.5-inch petroleum gauze coated in antibiotic ointment. Alternatively, a variety of preformed packs are available. Merocel nasal packs or prepackaged inflatable packs are usually readily available and quite effective. Remembering that the nasal cavity extends *posteriorly* from the nostril and not *superiorly* facilitates placement. The pack should be coated in antibiotic ointment before placement.

Placement of the pack can be quite uncomfortable for the patient. Discomfort can be minimized by ensuring optimal decongestion and topical anesthesia of the nasal cavity. If using a Merocel pack, it is sometimes helpful to hydrate and expand the pack *before* placing it. This can be done with sterile saline or phenylephrine. Although the pack appears quite large after it is expanded, it decompresses readily and slides in easily once it is covered in antibiotic ointment. The

entire length of the pack needs to be grasped with the bayonet forceps if this technique is employed. Preexpansion of the pack also minimizes further abrasions and bleeding that can occur with placement of the firm pack. This technique is especially advantageous if a septal deviation or spur exists on the bleeding side. Regardless of what type of pack is used, care must be taken not to distort or overstretch the nasal ala (nostril) once the pack is in place. This causes significant discomfort and can result in necrosis of the nostril.

After the pack is in place, the patient should be observed for further bleeding. If the patient remains stable, has no significant comorbid conditions, and has only a unilateral anterior pack, the patient may be discharged with mild narcotic pain medications and antibiotics for prophylaxis against toxic shock syndrome and sinusitis. The pack should be removed 2 to 5 days later, with instructions to use nasal saline and nasal ointment liberally for the next 2 weeks. Recurrent bleeding should prompt an ENT consultation.

Posterior Packing

If the bleeding is not controlled with an anterior pack, the origin of the bleeding may be posterior, requiring an *anterior-posterior pack*. An anterior-posterior pack is inserted similar to a nasogastric tube, then inflated with the *minimum amount* of saline to stop the bleeding. The recommended maximum amount of inflation should not be surpassed.

If a preformed anterior-posterior pack is not available or not effective, a traditional anterior-posterior pack may be placed. The posterior pack is necessary essentially to seal off the posterior nasal cavity and provide a buttress to prevent the anterior pack from slipping posteriorly. A Foley catheter and balloon is slid into the nasal cavity and serves as the posterior pack and buttress. Once the Foley catheter is in place, it is inflated with 5 to 10 mL of saline (or air) and pulled snugly to seal the posterior nasal choana. A large anterior pack is then placed, which should quickly control the bleeding.

Placement of a posterior pack requires experience, and even if it is successfully done, ENT consultation is indicated to assist with further bleeding, pack removal, and to monitor for pack complications. Anterior-posterior packs are associated with significant patient discomfort and potential complications during and after insertion. Local complications, including necrosis of the alae, septum, and palate, can occur, and close observation is required to prevent them. Hypoxemia can also result. Supplemental oxygen and monitoring of oxygen saturation is indicated. Patients with preexisting cardiopulmonary disease require closer observation, often in the ICU. The patient might require judicious doses of narcotics for pain and antibiotics for infection prophylaxis.

Other Techniques

Rarely, epistaxis cannot be controlled with packing, requiring further intervention. This can include intraoperative endoscopic cautery, endoscopic or open arterial ligation, or angiography with selective embolization of the offending vessel. There are advantages and disadvantages to each of these techniques. In general, the surgical techniques are usually favored over embolization if there are no significant contraindications to surgery. All the surgical techniques have very high success rates. Embolization is also effective when performed by an experienced invasive radiologist, but it does

carry the relatively low risk of inadvertent embolization of the internal carotid artery system and subsequent ischemic cerebral injury, which can be devastating.

Head and Neck Trauma and Respiratory Embarrassment

Key Points

- The ABCs of trauma include *airway, breathing, circulation*, and cervical spine clearance.
- Laryngeal and pharyngoesophageal injuries must be suspected in blunt or penetrating neck injuries.
- Intravenous access should be established and volume replacement initiated quickly.
- Isolated facial injuries can result in significant bleeding and can be associated with orbital or central nervous system injury.
- Overlooked facial fractures can result in long-term functional and cosmetic defects.

The ABCs of trauma should be remembered when treating a patient with cervicofacial trauma. This includes evaluation and treatment of *airway, breathing, circulation*, and cervical spine. The most pressing issue after significant face, head, or neck trauma is the potential for respiratory compromise, secondary to several causes. Altered mental status can lead to aspiration of blood or secretions with or without central hypoventilation. Comminuted facial fractures (midface or mandibular) can distort the oral and pharyngeal airway sufficiently to cause obstruction. An undetected expanding pharyngeal or neck hematoma can cause airway obstruction by extrinsic compression of the trachea or pharynx. Blunt or penetrating neck injuries can cause laryngeal fracture, bleeding, or hematoma, leading to critical airway obstruction.

Potential airway obstruction must be addressed quickly because complete obstruction can progress rapidly. The diagnosis is clinical because hypoxemia and carbon dioxide retention are late signs. Extensive facial edema or ecchymosis should arouse concern for facial fracture. A muffled voice can be the result of expanding hematoma. Laryngeal or tracheal injury should be suspected if the patient has a change in the voice, hemoptysis, subcutaneous emphysema, or stridor.

Stabilization of a compromised airway should be accomplished as soon as possible. Endotracheal intubation may be attempted, with plans for emergent cricothyrotomy as necessary. If time permits, the on-call anesthesiologist, trauma surgeon, or otorhinolaryngologist should be consulted to assist in airway management. Blind intubation (especially nasotracheal) or insertion of a laryngeal mask airway (LMA) is not recommended because this further compromises the already tenuous airway if intubation is unsuccessful. Although tracheotomy is the preferred procedure when endotracheal intubation is impossible or contraindicated, cricothyrotomy is also acceptable and can be lifesaving.

There is potential for significant blood loss after severe head and neck trauma. Intravenous access should be established and volume replacement initiated quickly. Bleeding from facial wounds can be controlled with direct pressure and suture ligation of arterial bleeding. Management of epistaxis is discussed earlier. Bleeding from the neck, or evidence

of expanding hematoma, implies a major vessel injury and requires immediate operative exploration by a trauma surgeon, vascular surgeon, or otorhinolaryngologist.

Unrecognized pharyngeal and esophageal injury can result in life-threatening infection. These injuries might not be obvious on initial evaluation and require a very high index of suspicion. Contrast studies and endoscopy are usually required to confirm the diagnosis. Treatment can include repair of the injury or external drainage to allow healing.

Isolated facial injuries are rarely life threatening but still can result in significant bleeding and, rarely, airway compromise and permanent disability. Significant facial trauma should be evaluated in the ED. The potential for intracranial and cervical spine injuries should be considered when major facial injuries are present. Trauma of the periorbital region requires ophthalmologic evaluation. All lacerations should be inspected, cleaned, and sutured. Antibiotics should be used if contamination is likely.

Deeper injuries can result in facial nerve transection. If facial nerve weakness is detected, plastic surgery or ENT consultation is necessary for expedient nerve exploration and repair. The parotid salivary duct can also be injured and requires repair over a stent. Facial fractures should be evaluated with CT (both axial and coronal images). Possible mandibular fractures should be evaluated with plain x-ray films, including panoramic (Panorex) films. Overlooked and untreated facial fractures can result in significant long-term functional and cosmetic deficits. Oral surgery consultation is sometimes required, especially with injury to the teeth or altered dental occlusion.

The Ear

Key Points

- In smokers with otalgia, the clinician should suspect laryngopharyngeal carcinoma.
- A white mass behind the tympanic membrane might be a cholesteatoma.
- Pneumatic otoscopy is most useful in confirming middle ear fluid.
- Tympanometry and acoustic reflex testing are complementary to audiometry in determining the location of hearing loss.
- A neoplastic process should be considered when a presumed infection does not respond to usual medical treatment.

Physical Examination

See the discussion online at www.expertconsult.com.

Otalgia

While the vast majority of patients with otalgia have an otologic cause, the clinician must recognize that otalgia may be *referred*. Sensory innervation of the ear includes cranial nerves V, VII, IX, and X, and therefore disorders of structures with similar innervation can cause otalgia. It is imperative that the physician not simply attribute otalgia to an ear infection unless the physical examination supports this diagnosis. Otalgia can result from dysfunction of the nose, sinuses, oral cavity, pharynx, larynx, dentition, temporomandibular joints, and salivary glands. These structures

must be thoroughly assessed, especially if the examination of the ear appears normal. This is especially true in smokers, whose initial symptom of laryngopharyngeal carcinoma may be otalgia. Otolaryngologic referral for laryngoscopy may be indicated with suspected referred otalgia. (See **eBox 19-1** and **eBox 19-2** online at www.expertconsult.com for differential diagnosis of otalgia.)

Tumors of the Ear

Tumors of the ear are rare. Classification is based on their location (external ear, middle ear, inner ear). A tumor of the external or middle ear is often easily diagnosed by visualizing a lesion on otoscopy. In some cases, symptoms may mimic infection (pain, otorrhea). Tumors of the inner ear can manifest with symptoms of hearing loss, tinnitus, disequilibrium, or facial weakness. (**eBox 19-3** online lists tumors of the ear by location.)

Vertigo

Key Points

- The most common cause of persistent vertigo is a peripheral vestibular disorder (38% to 56%).
- Central vestibular causes of vertigo represent less than 10% of all causes.
- Head movement always worsens the feeling of true vertigo.
- Benign paroxysmal positional vertigo is the most common cause of peripheral vestibular vertigo and is twice as common in women as men.
- Pneumatic otoscopy can cause nystagmus and vertigo in the presence of a perilymph fistula.
- Tinnitus is primarily caused by sensorineural hearing loss but occasionally can be the symptom of a vascular abnormality, hypermetabolic state, medication, or intracranial mass.

The sense of balance or equilibrium occurs when there is normal and harmonious function of several systems and organs in the body. These include the musculoskeletal system, the cardiovascular system, the central nervous system, the eyes, and the ears. Abnormal function of any of these can result in the sensation of dizziness or disequilibrium. The term *vertigo* is reserved to describe a perceived sensation of motion, usually spinning, of the person relative to the environment, or vice versa. Causes of disequilibrium can be categorized into one of three groups: *peripheral* (inner ear or labyrinthine), *central nervous system* (CNS), or *systemic* (e.g., cardiovascular, metabolic). Although not pathognomonic of a labyrinthine disorder, true vertigo most often indicates aberrant function of the inner ear.

Because patients use “dizzy” to describe many sensations, the actual sensation is best clarified by a detailed history (**Box 19-1**). The major studies on the causes of persistent dizziness, from Drachman and Hart (1972) to Davis (1994), all describe four diagnostic categories: lightheadedness, presyncope, disequilibrium, and vertigo. The investigators all conclude that the most common cause of persistent dizziness is a peripheral vestibular disorder (38%-56% of cases) followed closely by a psychogenic disorder (6%-33%). In about 25% of patients, the complaint is the result of the combined

Box 19-1 History for “Dizziness”

| |
|--|
| Description of the sensation (including associated symptoms) |
| Onset (acute, gradual) |
| Duration (date sensation was first noted, length of time it lasts) |
| Intensity (how troubling is it?) |
| Exacerbations (activities, positions, circumstances that worsen the situation) |
| Remissions (activities, positions, circumstances that make sensation better) |
| Medications (prescription, herbal, over the counter) |
| Other medical problems (e.g., diabetes, hypertension, heart disease) |
| Psychosocial (any stressors?) |

effects of multiple sensory deficits, medications, or orthostasis, leading to complaints of presyncope, lightheadedness, or disequilibrium. Finally, central vestibular etiologies are unusual and represent less than 10% of all causes.

A thorough medical history allows the physician to distinguish between true vertigo (a sensation of spinning) and other sensations, such as presyncope, lightheadedness, and unsteadiness. The physical examination and laboratory evaluation are guided by the accuracy of the history. A sensation of vertigo originates from within the vestibular system but can be either *peripheral* (vestibular nerve and inner ear) or *central* (cerebellum, brainstem, thalamus, and cortex).

Questions regarding hearing and neurologic deficits can help elicit which part of the vestibular system is involved (Wiet et al., 1999) (see **eTable 19-1** online). Peripheral vertigo tends to be episodic, whereas central vertigo is constant. Neurologic symptoms or loss of consciousness do not occur with peripheral vertigo but are possible with central vertigo. Nystagmus, which is labeled by the direction of the fast component, can be present in both types of vertigo and can be horizontal or rotary; vertical nystagmus occurs only in central vertigo.

The physical examination should include assessment of orthostatic blood pressure changes, a complete ocular examination, tuning fork tests (Weber’s and Rinne’s), pneumatic otoscopy (elicits vertigo in patients with perilymphatic fistula), balance tests (Romberg’s), gait (including tandem walking), and cranial nerve evaluation. The Dix-Hallpike maneuver (see **eFig. 19-3** online) is especially helpful in diagnosing benign paroxysmal positional vertigo (BPPV). Head movement always worsens the feeling of true vertigo. If it does not, the dizziness can be attributed to a cause other than vestibular dysfunction.

Laboratory testing can include an audiogram if no specific cause of vertigo can be found after the medical history and physical examination. Electronystagmography (ENG) is an objective study of the vestibular system and can help localize a vestibular lesion. Electrodes placed about the eye sense the movements of nystagmus as either spontaneous or initiated by maneuvers such as caloric testing, positioning, optokinetics, and pendulum tracing. A brain MRI scan is indicated in patients with unilateral otologic symptoms and in those unresponsive to treatment. Blood tests, when necessary, can include CBC, rapid plasma reagin (RPR), vitamin B₁₂ level, folate level, drug screens, and heavy metal testing when indicated.

Meniere's Disease

Meniere's disease is characterized by episodic severe vertigo lasting hours, with associated symptoms of unilateral roaring tinnitus, fluctuating low-frequency hearing loss, and aural fullness. Typical onset is in the fifth decade of life. The cause is uncertain but is speculated to result from allergic, infectious, or autoimmune injury. The histopathologic finding includes *endolymphatic hydrops*, which is thought to be caused by either overproduction or underresorption of endolymph in the inner ear.

Meniere's disease is a clinical diagnosis mostly based on history. Testing may be obtained to support the diagnosis and rule out other disorders. Audiometry often demonstrates a low-frequency sensorineural hearing loss. An FTA-ABS test may be obtained to rule out syphilis. ENG may demonstrate a unilateral peripheral vestibular weakness on caloric testing. When the diagnosis is uncertain, a brain MRI with contrast is obtained to evaluate for a retrocochlear lesion. The differential diagnosis of Meniere's disease includes acute labyrinthitis, neurosyphilis, labyrinthine fistula, autoimmune inner ear disease, vestibular neuronitis, and migraine-associated vertigo.

Although Meniere's disease has a highly variable clinical course, most patients have long symptom-free periods between clusters of episodes. The majority of patients have an excellent prognosis, with symptoms burning out over several years. However, some patients have a disabling course with frequent and severe attacks. On average, a moderate sensorineural hearing loss is the end result. The disease may become bilateral in about 45% of cases (wide variability exists).

Treatment of an acute episode involves vestibular suppressants and antiemetics. As with any vestibular disorder, vestibular suppressants should be limited for use during acute symptoms because of their addictive potential and impairment of central compensation. Maintenance therapy includes reduction of sodium intake to less than 1500 mg/day and a diuretic such as hydrochlorothiazide-triamterene (Dyazide). Patients are also instructed to minimize caffeine, alcohol, nicotine, and chocolate. Allergy treatment may be helpful in some patients. Most patients have adequate control of symptoms with this regimen.

Patients who fail conservative measures may be candidates for procedures and surgical treatment. Gentamicin, a vestibulotoxic aminoglycoside antibiotic, may be injected transtympanically into the middle ear to permeate into the inner ear. Control of vertigo may result in 90%, but with a risk of hearing loss. Endolymphatic sac decompression or shunting through a mastoidectomy appears to benefit most patients with minimal risk to hearing. Although a generally accepted procedure, adequate studies are lacking on its effectiveness. More invasive interventions, including vestibular nerve section and labyrinthectomy, are reserved for patients with severe disease who do not respond to other measures (Sajjadi and Paparella, 2008).

KEY TREATMENT

Treatment of acute episodes of Meniere's disease involves vestibular suppressants and antiemetics (SOR: A). Maintenance therapy includes reduction of sodium intake and use of a diuretic (SOR: A) (Thirlwall and Kundu, 2006).

Vestibular Neuronitis

Acute vertigo associated with nausea and vomiting (but without neurologic or audiologic symptoms) that originates in the vestibular nerve is known as *vestibular neuronitis*. Vestibular neuronitis can occur spontaneously or can follow viral illness. Nystagmus is horizontal, with the fast component beating away from the affected side. The symptoms peak within 24 hours and usually last 3 to 4 days. Autopsy studies have shown cell degeneration of one or more vestibular nerve trunks, a finding similar to that seen in Bell's palsy, which affects the facial nerve. A short course (3-5 days) of vestibular suppressants (e.g., meclizine [Antivert], diazepam [Valium]) and antiemetics such as promethazine (Phenergan) can provide symptomatic relief in the acute setting.

Distinguishing between vestibular neuronitis and bacterial labyrinthitis or labyrinthine ischemia is important. The diagnosis of *bacterial labyrinthitis* is based on hearing loss and otitis media or meningitis, and *labyrinthine ischemia* can be distinguished by hearing loss plus associated neurologic symptoms with a history of vascular disease.

Benign Paroxysmal Positional Vertigo

The most common cause of peripheral vestibular vertigo in adults is benign paroxysmal positional vertigo. BPPV occurs in all age groups but more often between ages 50 and 70. The incidence of BPPV is 11 to 64 per 100,000 persons per year and is twice as common in women as men (Froehling et al., 1991). It is caused when otoconia particles from the utricle or saccule lodge in the posterior semicircular canal and is also referred to as *canalithiasis*. This causes the canal to be a gravity-sensing organ, and head movement results in displacement of the otoconia and a sensation of vertigo.

The Dix-Hallpike maneuver reproduces this vertigo in the patient, resulting in nystagmus (see eFig. 19-3). Characteristics of the nystagmus of BPPV include fatigability, a latency period of 1 to 5 seconds before nystagmus begins after the head is moved, short duration of nystagmus from 5 to 30 seconds, and reversal of the nystagmus components when the patient is returned to the sitting position. If these characteristics are not present and treatment is not successful, BPPV cannot be diagnosed. In such a case, a CNS lesion is possible. BPPV can be the residual effect of Meniere's disease, ear surgery, vestibular neuronitis, or ischemia of the inner ear. Head trauma, even when it is minor, can lead to BPPV. However, one third of cases are idiopathic.

Treatment of BPPV consists of performing repositioning maneuvers with the goal of returning the otoconia to the utricle or saccule (Yacovino, 2009). In addition, the patient may attempt to reposition the otoconia at home by sitting upright on the bed and rapidly lying supine with the affected ear facing downward. After 1 minute, the head should be repositioned with the opposite ear facing downward, and the patient should wait another minute. The patient should then return slowly to the upright seated position and repeat this exercise four more times. The entire process is completed twice daily until the symptoms have abated.

An expert panel convened by the American Academy of Otolaryngology-Head and Neck Surgery Foundation recommended against "routinely treating BPPV with vestibular suppressant medication such as antihistamines or benzodiazepines" (Bhattacharyya et al., 2008). Because of

the variability of symptoms, the clinician must judge each case independently. Resolution occurs in a few weeks or months, and the condition is benign, although it can recur.

KEY TREATMENT

Unless the diagnosis of BPPV is uncertain, radiographic imaging and vestibular testing are not recommended (SOR: B). Patients with BPPV should be treated with an otoconia-repositioning maneuver (SOR: B) (Bhattacharyya et al., 2008). Residual dizziness after successful repositioning procedures abates within 3 months without further treatment (SOR: B) (Seok, 2008).

Perilymph Fistula

Rapid changes in air pressure (barotrauma), otologic surgery, violent nose blowing or sneezing, head trauma, or chronic ear disease may cause leakage of perilymph fluid from the inner ear into the middle ear and result in episodes of vertigo. Associated signs and symptoms are variable but can include a sudden pop in the ear followed by hearing loss, vertigo, and sometimes tinnitus. Diagnosis can be determined by a fistula test, in which negative and positive pressures are applied to the tympanic membrane using pneumatic otoscopy, causing nystagmus and vertigo.

Labyrinthitis

As with vestibular neuronitis, labyrinthitis causes sudden and severe vertigo. In contrast to vestibular neuronitis, the patient also has tinnitus and hearing loss. The hearing loss is sensorineural, is often severe, and can be permanent. Labyrinthitis is caused by inflammation within the inner ear. The cause is most often a viral infection but can be bacterial. Bacterial labyrinthitis usually results from extension of a bacterial otitis media into the inner ear. A noninfectious *serous* labyrinthitis can also occur after an episode of acute otitis media. Other, less common causes include treponemal infections (syphilis) and rickettsial infection (Lyme disease).

Symptomatic treatment of labyrinthitis is similar to that for vestibular neuronitis. Antibiotics are recommended if a bacterial cause is suspected. As with acute otitis media, bacterial labyrinthitis can, in rare cases, lead to meningitis. Few other conditions cause the constellation of hearing loss, tinnitus, and vertigo, but cerebrovascular ischemia, meningitis, brain abscess, and encephalitis should all be considered. Although the vertigo should resolve over days to weeks, hearing loss and tinnitus can persist.

Drugs known to be ototoxic can cause acute onset of hearing loss and disequilibrium, although this is not true labyrinthitis. These drugs include salicylates, aminoglycosides, loop diuretics, and various chemotherapeutic agents. This cause should be considered in patients who complain of hearing loss or dizziness while taking these medications.

Tinnitus

Tinnitus is a term used to describe an internal noise perceived by the patient. It is usually, but not always, indicative of an otologic problem. Tinnitus is most often subjective, that is, heard only by the patient. However, it can be objective and

Box 19-2 Causes of Tinnitus

Subjective

Otologic: Presbycusis, noise-induced hearing loss, Meniere's disease, otosclerosis

Metabolic: Hyperthyroidism, hypothyroidism, hyperlipidemia, vitamin deficiency

Neurologic: Basilar skull fracture, whiplash injury, multiple sclerosis, meningitic effects

Pharmacologic: Aspirin, nonsteroidal anti-inflammatory drugs, aminoglycosides, tricyclic antidepressants, loop diuretics, heavy metals, oral contraceptives, caffeine, cocaine, marijuana

Dental: Temporomandibular joint syndrome

Psychologic: Depression, anxiety

Objective

Vascular abnormalities: Arteriovenous malformation, glomus tumors, stenotic carotid artery, vascular loops, persistent stapedial artery, dehiscent jugular bulb, hypertension

Tympanic muscle disorders: Palatomyoclonus, idiopathic stapedial muscle spasm

Patulous eustachian tube

Central nervous system anomalies: Congenital stenosis of the sylvian aqueduct, type 1 Arnold-Chiari malformation

From Lucente FE, Har-El G: *Essentials of Otolaryngology*. Philadelphia, Lippincott-Williams & Wilkins, 1999, p 110.

heard by the patient and the examiner. In most cases, tinnitus is secondary to bilateral sensorineural hearing loss and requires no further evaluation. In rare cases, tinnitus can be a symptom of a vascular abnormality (aneurysm or arteriovenous malformation), hypermetabolic state, or intracranial mass that, if not evaluated, could result in delayed treatment. Middle ear and rarely external ear pathology can also cause tinnitus, as can numerous medications (Box 19-2). The patient's medications should be reviewed.

Evaluation of tinnitus begins with a complete medical history, including duration of symptoms, possible inciting event (e.g., acoustic trauma), and accompanying symptoms (e.g., vertigo, hearing loss, headache, vision changes). Specific questions regarding the tinnitus are critical: Is it unilateral or bilateral? What is the quality of the tinnitus (pitch, volume)? Does it sound like a heartbeat or rushing blood? Does it change? A complete ENT evaluation should be performed, and audiometry is mandatory.

In general, if the tinnitus is bilateral, not particularly intrusive, not pulsatile, and associated with symmetric hearing loss, it is likely secondary to the hearing loss itself. The hearing loss requires further evaluation with magnetic resonance imaging (MRI) with contrast if it is asymmetric.

In cases of *pulsatile* tinnitus with normal otoscopy, magnetic resonance angiography (MRA) is performed to evaluate for vascular abnormalities. If otoscopy identifies a retrotympanic mass, a temporal bone CT is obtained to evaluate for a vascular mass or abnormality. Blood tests can be performed to rule out anemia or hyperthyroidism, which can result in a hypermetabolic state and cause tinnitus secondary to increased blood flow near the cochlea. Auscultation of the neck, periauricular area, and chest may identify a bruit or murmur, indicating a need for a carotid duplex ultrasound

study or echocardiogram, respectively. Most cases of arterial pulsatile tinnitus are secondary to atherosclerotic carotid artery disease. Venous pulsatile tinnitus often improves with digital pressure over the internal jugular vein. Etiologies include idiopathic venous hum, a high-riding jugular bulb, or benign intracranial hypertension.

Effective treatment of tinnitus is difficult and usually requires various approaches. Finding and eliminating potential causes (especially pharmaceutical) is imperative. Patients should be counseled to avoid caffeine and nicotine. No single medicine has been proved effective in treating tinnitus. Antidepressants have shown promise, especially if depression coexists. Intravenous lidocaine eliminates tinnitus in some patients but is not practical and has obvious potential side effects. Various homeopathic treatments and nutritional supplements are effective in some cases, but most have not been evaluated in controlled studies. Hearing aids are beneficial in *masking* the tinnitus if hearing loss exists. Tinnitus maskers can be purchased that essentially drown out the tinnitus with various distracting noises. Bio-feedback and a technique called *tinnitus retraining therapy* are helpful for some patients. These techniques can be learned through various publications or at a tinnitus treatment center. All patients with obtrusive tinnitus are encouraged to join the American Tinnitus Association, the largest tinnitus support group and an excellent source of reliable information.

Disorders of the External Ear

Otitis Externa

The most common cause of pain in the external ear is acute otitis externa. It affects 3% to 10% of the patient population. The pain is caused by inflammation and edema of the ear canal skin, which is normally adherent to the bone and cartilage of the auditory canal. The inflammatory reaction can be caused by bacteria, fungi, or contact dermatitis (see eTable 19-2 online).

Cerumen protects the canal by forming an acidic coat that helps prevent infection. Factors that predispose to otitis externa include absence of cerumen, often from excessive cleaning by the patient; water, which macerates the skin of the auditory canal and raises the pH; and trauma to the skin of the auditory canal from foreign bodies or use of cotton swabs.

When a bacterial organism is suspected, treatment consists of cleaning the ear canal of any debris or drainage and then instilling antibiotic drops with or without steroids. Because the most common bacterial organisms in this infection are *Pseudomonas aeruginosa* and *Staphylococcus aureus*, drops containing ciprofloxacin or neomycin/polymyxin B are effective against these pathogens, combined with a steroid to decrease inflammation, pain, and pruritus (Ciprodex, Cortisporin, Coly-Mycin, Pediotic). A recent study found Ciprodex to be more effective against *P. aeruginosa* than neomycin/polymyxin B/hydrocortisone (Dohar et al., 2009).

The clinician must use judgment in assessing the severity of the infection and treat accordingly. If the infection spreads beyond the auditory canal, oral antimicrobials are indicated. If clinical improvement is not apparent after 48 hours, the patient needs to be reexamined for additional treatment or referral to an otorhinolaryngologist.

Fungal infections compose less than 10% of external otitis cases. The most common fungi are *Aspergillus niger* and *Candida* species and are more prevalent in tropical climates. Itching is a more common complaint than pain in fungal ear infections. Thorough cleaning of the ear canal is the primary duty of the physician in this infection. Drops that are effective include 2% acetic acid with or without a steroid. Clotrimazole drops or powder can also be used to treat fungal infections of the canal (van Bolen et al., 2003).

Approximately 90% of necrotizing (malignant) otitis externa is seen in immunocompromised patients such as diabetic patients, patients with acquired immunodeficiency syndrome (AIDS), and those receiving chemotherapy. Systemic antibiotics are mandatory in these cases. Antipseudomonal antimicrobials should be administered intravenously in the hospital setting, and surgical debridement is often necessary. Complications from necrotizing otitis externa include facial nerve palsy, mastoiditis, meningitis, and even death (Quick, 1999).

Other conditions that affect the external auditory canal include impacted cerumen, seborrheic dermatitis, psoriasis, contact dermatitis, and staphylococcal furunculosis. Symptoms and signs include pruritus, edema, scaling, crusting, oozing, and fissuring of the external auditory canal. Treatment of the underlying disease is the primary goal. Corticosteroid preparations are indicated for seborrheic dermatitis, psoriasis, and contact dermatitis. Oral antibiotics and sometimes incision and drainage are required for staphylococcal furunculosis.

KEY TREATMENT

Ciprofloxacin/dexamethasone 0.1% (Ciprodex Otic) applied ototopically in patients with acute otitis externa is more effective against *Pseudomonas aeruginosa* (most common isolate) than neomycin/polymyxin B/hydrocortisone (Cortisporin Otic) (SOR: A) (Dohar et al., 2009).

Using drops that have a steroid plus an antibiotic or acetic acid improves the cure rate compared to an antibiotic or acetic acid alone (SOR: A) (van Bolen et al., 2003).

Auricular Hematoma

Blunt auricular trauma, most commonly in wrestlers and boxers, may shear the perichondrium from the underlying cartilage, leading to a hematoma. The presence of a fluctuant swelling with loss of normal auricular landmarks helps to distinguish a hematoma from ecchymosis. If left untreated, an auricular hematoma may cause fibrosis and neocartilage formation, leading to a deformity of the auricle termed *cauliflower ear*. Therefore, treatment in a timely manner is recommended.

Although a Cochrane review could not define the best treatment for an acute auricular hematoma, a frequently successful treatment involves incision and drainage with dental rolls sutured to the anterior and posterior auricle (Fig. 19-5). Needle aspiration alone will often lead to recurrences. The bolster is usually left in place for 4 to 7 days, with the patient permitted to return to wrestling or boxing with headgear. Prophylactic antistaphylococcal antibiotics are given. For a long-standing hematoma or a cauliflower ear, debridement of fibrosis and cartilage is necessary (Jones and Mahendran, 2008).

Figure 19-5 Photograph of 16-year-old boy who sustained auricular hematoma in wrestling match. He underwent incision and drainage with placement of dental rolls.

KEY TREATMENT

Successful treatment of auricular hematoma is incision and drainage with dental rolls sutured to the anterior and posterior auricle (SOR: B) (Jones and Mahendran, 2008).

External Auditory Canal Foreign Bodies

A common problem seen in family physicians' offices is a patient with an external auditory canal foreign body. A wide variety of objects can be found. In one study of 191 patients with aural foreign bodies, 27 different objects were discovered (Ansley and Cunningham, 1998). The most common were beads, plastic toys, pebbles, insects (especially cockroaches), popcorn kernels, earrings, paper, peas, cotton, pencil erasers, and seeds. When a patient presents with a chronic dry cough that has not responded to the usual measures, the physician should look for an aural foreign body (causing irritation of the ninth cranial nerve).

Removal of an external auditory canal foreign body is simplified if the object is in the lateral one-third of the external auditory canal. Objects within the medial two-thirds pose a greater challenge. A variety of instruments can be used, depending on the object, including cerumen loops, alligator forceps, and otologic-tip suction. Irrigation with body-temperature sterile water often dislodges the object. Hygroscopic objects such as vegetables, beans, and other food matter can swell and make the object even more impacted and should not be irrigated. Disk batteries should be removed immediately because of the possibility of liquefaction necrosis of the external auditory canal. Aural irrigation is contraindicated because wetting of the battery leads to leakage of electrolyte solution.

Smooth, round objects pose a difficult problem because, in trying to remove them, they are often pushed farther into the canal. Aural irrigation or even cyanoacrylate glue on the tip of a straightened paper clip is effective in removing objects that are difficult to retrieve. Methods to remove

cockroaches or other insects include microscope immersion oil, mineral oil, or lidocaine. The effect of mineral oil or microscope immersion oil is to drown the insect, whereas lidocaine tends to make cockroaches crawl rapidly out of the canal (Bressler and Shelton, 1993). Otomicroscopy is often required for safe removal.

Depending on their age, fewer than 35% of patients should require anesthesia. The younger the patient, the more likely anesthesia will be required. Objects with sharp edges are best removed with an operating microscope with the patient under general anesthesia. Complications of foreign body removal include canal wall trauma and tympanic membrane perforation. Immobilization of the patient is the key to successful removal of aural foreign bodies, and at least two assistants are necessary.

Cerumen

Glandular secretions from the outer one-third of the external auditory canal and desquamated epithelium combine to form cerumen. Cerumen is necessary to provide a hydrophobic and acidic environment to protect the underlying external ear canal epithelium and prevent infection. The external auditory canal is self-cleaning, with cerumen slowly pushed laterally to the external meatus.

Cerumen impaction is the symptomatic accumulation of cerumen in the external canal or an accumulation that prevents a needed assessment of the ear. Complete occlusion is not necessary. Symptoms may include hearing loss, tinnitus, pruritus, fullness, otalgia, cough, odor, and dizziness. Impaction often results from instrumentation with cotton-tipped applicators, which should be discouraged. Elderly patients with changes to external canal epithelium, patients with external canal abnormalities (e.g., osteomas, exostoses, stenosis), and users of hearing aids and earplugs are also at risk for impaction. Excessive cerumen production as a primary problem is relatively rare.

In most people, cleaning the external meatus with a finger in a washcloth while bathing is sufficient to maintain the ear canals. Treatment of cerumen impaction by the clinician may involve ceruminolytic agents, irrigation, or manual removal. Ceruminolytic agents include water-based, oil-based, and non-water-, non-oil-based solutions. A Cochrane review found that any type of ear drop (including water and saline) is more effective than no treatment, but study quality was lacking. Office irrigations may be performed using a large syringe with a large angiocatheter tip. The type of irrigant solution used is probably not critical, although a tepid or warm temperature is important to prevent the patient from becoming vertiginous from a labyrinthine caloric response. Instilling a ceruminolytic 15 minutes before irrigation may improve the success rate. Irrigations should not be performed in those with tympanic membrane perforations or previous ear surgery. Of note, irrigation with tap water has been implicated as a causative factor in malignant otitis externa. Therefore, instilling an acidifying ear drop after irrigation in diabetic patients is recommended. Manual removal requires knowledge of ear anatomy and special care to avoid trauma. A handheld otoscope with a curette and other instruments may be used. Otolaryngologists will often use binocular microscopy to aid with visualization. Those patients inquiring about ear

candling should be informed that it has not been shown to be effective and presents a risk of thermal injury to the ear (Burton and Doree, 2008).

Frostbite

The ears, nose, and cheeks, in that order, are most at risk for frostbite. Exposure to subfreezing temperature is the main risk factor, but wind chill also greatly affects heat loss from the skin by convection. Protective clothing greatly diminishes the risk.

There are three grades: grade I frostbite, in which the skin is erythematous and edematous; grade II frostbite, in which the skin blisters and forms bullae; and grade III frostbite, which results in local necrosis of the dermis over 1 to 2 weeks. To assess the severity of frostbite, the physician must examine the tissue from several hours up to 2 days after the typical skin blanching occurs.

Treatment consists of quickly warming the ear with gauze soaked in saline at 38° to 40° C (100.4°-104.0° F). Any blisters that form should be allowed to reabsorb spontaneously. Topical antibiotic ointment can be applied, and viability of the tissue should be assessed periodically.

Lacerations

When there is trauma to the ear requiring suture closure, careful realignment is mandatory to maintain the auricular contour. The extent of the injury should be evaluated thoroughly with the tissue anesthetized with 1% lidocaine (without epinephrine). This allows a careful evaluation of the wound as well as a meticulous suture closure. Lacerations involving only the skin can be closed with everting nonabsorbable sutures. An earlobe that is torn from earring trauma can be closed in layers using absorbable chromic gut suture to close the dermis and nonabsorbable 5-0 or 6-0 suture to close the skin. Lacerations that involve cartilage, perichondrium, and skin must also be closed in layers but might best be referred to a specialist in otorhinolaryngology or to a plastic surgeon.

Disorders of the Middle Ear

Key Points

- Tympanic blistering (bullous myringitis) is simply a variant of acute otitis media (AOM) and should be treated as such.
- The most common infection in children seen in a physician's office is AOM.
- Three criteria are necessary for the diagnosis of AOM: acute onset, middle ear effusion, and signs or symptoms of middle ear inflammation.
- Severe AOM is defined as moderate to severe otalgia and fever greater than 39° C (102.2° F).
- When the diagnosis of AOM is uncertain (<2 criteria), observation is allowed in nonsevere illness.
- Amoxicillin is the drug of choice in treating AOM (80-90 mg/kg/day in 2 divided doses).
- Influenza vaccine decreases the number of cases of AOM in children 6 to 24 months of age.
- Surgical treatment is necessary for all middle ear and mastoid cholesteatomas.

- Antihistamines, decongestants, antibiotics, and corticosteroids are not recommended for routine use in otitis media with effusion.
- All traumatic perforations of the tympanic membrane require audiologic evaluation to rule out sensorineural hearing loss.
- Sudden sensorineural hearing loss is an otologic emergency.
- Facial weakness in the setting of AOM can require myringotomy with or without tube insertion in addition to broad-spectrum antibiotics.

Bullous Myringitis

Bullous myringitis refers to painful inflammatory bullae on the tympanic membrane. The blebs appear hemorrhagic. It was formerly thought that bullous myringitis was caused by *Mycoplasma pneumoniae* infection. Roberts (1980), however, summarized six studies involving 858 patients with bullous myringitis, and *M. pneumoniae* was isolated from only one. The cause is usually viral but can be bacterial in some cases. Studies have confirmed that bacterial cultures from bullous fluid are similar to cultures from middle ear fluid taken from patients with acute otitis media. The main isolates are *Streptococcus pneumoniae*, *Haemophilus influenzae*, and beta-hemolytic streptococci. The tympanic blistering is probably a nonspecific reaction and simply a variant of acute otitis media that should be treated as such.

It is important to distinguish bullous myringitis from acute otitis externa, which requires topical treatment, and from herpes zoster oticus, which can lead to cranial neuropathy and requires antiviral treatment. Neither of these conditions is usually limited to only tympanic membrane involvement.

KEY TREATMENT

No evidence supports the role of *Mycoplasma pneumoniae* as the causative agent in bullous or hemorrhagic myringitis (SOR: A) (Kotikoskie et al., 2004).
Bullous myringitis should be treated with antimicrobials used to treat acute otitis media (SOR: A).

Otitis Media

Acute Otitis Media

The most common infection for which children are seen in a physician's office is acute otitis media (AOM). The annual cost of AOM in the United States is an estimated \$5 billion (Bondy et al., 2000). By age 7 years, 93% of children have had at least one episode of AOM, and 75% have had recurrent infections. AOM can occur at any age, but the highest incidence is between 6 and 24 months in the United States.

The primary cause of bacterial colonization of the middle ear is eustachian tube dysfunction. Abnormal tubal compliance in addition to delayed innervation of the tensor veli palatini muscle leads to collapse of the eustachian tube. Aerobic and anaerobic organisms, as well as viruses, can contribute to middle ear infection (Heikkinen et al., 1999). The three most common bacteria involved in AOM are *S. pneumoniae* (25%-40% of cases), *H. influenzae* (10%-30%), and *Moraxella catarrhalis* (2%-15%) (Klein, 2004). Risk factors most often associated with AOM are child care outside

the home and parental smoking. Box 19-3 lists the common risk factors for AOM. A viral upper respiratory infection usually precedes an episode of AOM.

Three criteria are necessary to confirm the diagnosis of AOM: acute onset, presence of middle ear effusion, and signs or

Box 19-3 Common Risk Factors for Acute Otitis Media (AOM)

- Male gender
- Bottle-feeding, especially in the supine position
- Exposure to upper respiratory tract infections (e.g., daycare setting, winter season)
- Genetic factors
- Ethnic factors (e.g., Inuit or Native American)
- Parental smoking
- Allergy
- Craniofacial abnormalities (e.g., cleft palate)
- Previous episode of AOM, particularly during the preceding 3 months
- Use of a pacifier

From O'Handley JG. Controversies in the management of otitis media. *Prim Care Rep* 1999;5:43.

Box 19-4 Causes of Otolgia Other than Acute Otitis Media

- Abscessed teeth
- Cervical arthritis
- Dental malocclusion
- Nasopharyngeal carcinoma
- Sinus infection
- Sore throat
- Temporomandibular joint disorders

symptoms of middle ear inflammation (American Academy of Pediatrics [AAP], 2004; Level of evidence [Grade] B). Middle ear effusion can be diagnosed by direct visualization of air-fluid levels behind the tympanic membrane, a bulging drum, lack of movement on pneumatic otoscopy, or a flat tympanogram readout that indicates no tympanic membrane movement and therefore the presence of middle ear effusion. Redness of the tympanic membrane, pain, and fever are the most common signs and symptoms of middle ear inflammation (see eBox 19-4 online). Erythema of the tympanic membrane without middle ear effusion is myringitis or tympanitis and is a separate diagnosis from AOM. Ear pain in the presence of a normal-appearing, flaccid tympanic membrane indicates causes other than AOM (Box 19-4).

The standard of care for the treatment of AOM in children older than 2 years is not to treat with antibiotics at the first visit, but to treat the pain and either observe the patient or prescribe an antimicrobial agent depending on certain criteria. The decision either to begin antibiotics or to observe the patient without them is based on the certainty of diagnosis, severity of symptoms, and age of the patient (AAP, 2004). (Table 19-2).

When all three criteria for the diagnosis of AOM are met (acute onset, middle ear effusion, and inflammation), the diagnosis is certain, and antibiotic therapy is indicated for any child 2 years old or younger (AAP, 2004; Grade A). For children older than 2 years, observation is an option if the illness is not severe and the parents can be relied on to report the patient's status and can obtain medication if necessary. Severe illness is defined as moderate to severe otalgia and fever higher than 39° C. (102.2° F.) When two or fewer diagnostic criteria are present, diagnosis is considered uncertain, and observation is allowed for children 6 months and older with nonsevere illness.

Table 19-2 Treatment of Acute Otitis Media

| Features | Treatment |
|--|--|
| Low-Risk Patients | |
| Older than 6 years, no antimicrobial therapy within past 3 months, no otorrhea, not in daycare, and temperature <38° C (<100.5° F) | Amoxicillin: 40-50 mg/kg/day in divided doses for 5 days |
| High-Risk Patients | |
| Younger than 2 years, in daycare, treated with antimicrobials within past 3 months, otorrhea, or temperature >38° C (>100.5° F) | Amoxicillin: 80-90 mg/kg/day in divided doses for 10 days |
| Treatment Failure | |
| Signs and symptoms persisting after 3 days | Amoxicillin-clavulanic acid (Augmentin): 80-90 mg/kg/day for 10 days Cefuroxime axetil (Ceftin): 20-30 mg/kg/day bid for 10 days Ceftriaxone (Rocephin): 50 mg/kg intramuscularly for 1 dose |
| Penicillin-Allergic Patient | |
| Any | Cefuroxime axetil: <2 years, 125 mg bid; ≥2 years, 250 mg bid TMP-SMX (Bactrim, Septra): 8 mg/kg TMP, 40 mg/kg SMX, per 24 hours in 2 doses Cefprozil (Cefzil): 30 mg/kg/day in 2 doses Cefaclor (Ceclor): 40 mg/kg/day in 3 doses Cefixime (Suprax): 8 mg/kg/day as a single dose |

TMP-SMX, Trimethoprim-sulfamethoxazole; bid, twice daily.

Resistance of *Streptococcus pneumoniae* to penicillin is an increasing problem and ranges from 15% to 50% depending on the area. The mechanism of resistance is based on an alteration of penicillin-binding proteins rather than the production of beta-lactamase, as occurs with *H. influenzae* and *M. catarrhalis*. Resistance rates are higher in children than in adults, especially if the children are in daycare or have received antimicrobial therapy in the previous 3 months (Dowell and Schwartz, 1997).

The dose to treat AOM is 80 to 90 mg/kg/day in two divided doses (AAP, 2004). This allows the drug to overcome resistance in the causative organism (Dowell et al., 1999). For patients with a penicillin allergy, alternative medications include cefdinir, cefpodoxime, or cefuroxime. A meta-analysis found that first-generation cephalosporins have cross-allergy with penicillin, although the cross-allergy with second- and third-generation cephalosporins is negligible (Pichichero and Casey, 2007). Macrolides are not recommended for AOM in children because *H. influenzae* is the dominant organism causing AOM in this age group. Middle ear fluid becomes sterile 3 to 6 days after starting treatment (Carlin et al., 1991), so duration of therapy for uncomplicated AOM is 5 to 7 days, except for the child with an episode of AOM in the past 30 days, for whom a 10-day course of therapy is recommended (Pichichero and Brixner, 2006).

If the initial antibiotic fails to resolve symptoms in 72 hours (pain, fever, redness and bulging of the tympanic membrane, otorrhea), high-dose amoxicillin-clavulanic acid is recommended. Alternatives in penicillin-allergic patients include the antibiotics cited earlier. Patients who do not respond to amoxicillin-clavulanic acid therapy should be treated with intramuscular ceftriaxone for 3 days. This antibiotic in a single dose can also be used initially if the child is vomiting or unable to keep down oral medication. Doses of antimicrobials are given in Table 19-2.

Influenza vaccine has been shown to decrease the number of cases of AOM in immunized patients compared to controls and is recommended for all children age 6 to 24 months.

KEY TREATMENT

Antibiotics are most beneficial in children younger than 2 years with bilateral acute otitis media (AOM) and/or otorrhea (SOR: A). For most other children with mild disease, close observation and follow-up is an option (SOR: A) (Vouloumanou et al., 2009). Administration of the seven-valent pneumococcal vaccine (PCV7) in infancy reduces the risk for AOM by 6% to 7%. Administering PCV7 to older children with a history of AOM appears to have no benefit in preventing further episodes (SOR: A) (Jansen et al., 2009). Second- and third-generation cephalosporins may be used to treat AOM in penicillin-allergic patients (SOR: A) (Pichichero and Casey, 2007). Uncomplicated AOM may be treated for 5 to 7 days (Pichichero and Brixner, 2006).
SOR: A

Otitis Media with Effusion

Otitis media with effusion (OME) is defined as persistent middle ear fluid without pain, fever, or redness of the tympanic membrane. It is often the result of AOM but can occur de novo. About 90% of children have OME before they reach school age. About 80% to 90% of cases resolve within

3 months and 95% within 1 year. Table 19-3 provides the Agency for Health Care Policy and Research (AHCPR) guidelines for treatment of OME.

Tympanometry can be used to judge the presence of middle ear fluid. It is important to document the affected ear, the duration of the effusion, and the presence and severity of symptoms associated with OME. The latter include a feeling of fullness in the ear, popping, mild pain, hearing loss, balance problems, and delayed language development.

If OME persists for 3 months, a comprehensive hearing evaluation should be performed. A 40-decibel (dB) loss (or worse) in hearing bilaterally mandates referral for evaluation for polyethylene (PE) tube placement. Management of hearing loss between 6 and 39 dB depends on parent or caregiver preferences and can include strategies to improve the listening and learning environment or referral for tube placement. If the hearing loss is 5 dB or less, repeat testing in 3 months may be performed if the middle ear effusion continues at that time. Follow-up testing is recommended every 3 to 6 months until the effusion resolves, unless significant hearing loss occurs or there is evidence for structural abnormalities of the eardrum or middle ear. In these patients, PE tube placement is the preferred course.

When referring to a surgeon, the primary care physician must provide an adequate history of the duration of the middle ear effusion, developmental state of the child, and pertinent information such as a history of AOM. Physician and parental expectations for the referral should be clarified. Ultimately, the decision for PE tube placement should be based on a consensus among all parties involved. The possibility of repeat surgery after tube extrusion is 20% to 50%, and with reoperation, adenoidectomy is recommended in children with normal palates because it reduces the need for future surgery by 50%.

KEY TREATMENT

Otitis media with effusion is best diagnosed with pneumatic otoscopy.
In children with craniofacial abnormalities, visual impairment, autism, speech delay, or hearing impairment, appropriate management of OME is critical (AAFP et al., 2004).
Antihistamines and decongestants have not been shown to be effective and are not recommended for treatment of OME.
Antibiotics and corticosteroids are also not recommended for routine management of OME because they do not provide long-term efficacy.
SOR: A; B

Recurrent Otitis Media

Three episodes of AOM within 6 months with complete resolution between episodes or four episodes in 12 months defines recurrent otitis media. Although the evidence is conflicting, a double blind, placebo-controlled study comparing once or twice daily amoxicillin prophylaxis with placebo showed no benefit to using antibiotics. The authors recommended discouraging amoxicillin prophylaxis in children with recurrent otitis media not only because it is ineffective but also to prevent the acquisition of resistant pneumococci (Roark and Berman, 1997).

Tympanostomy tubes may be considered and may be beneficial in cases of recurrent AOM requiring multiple rounds of antibiotics within 6 to 12 months, especially if the episodes are severe.

Table 19-3 AHCPR Guidelines for Treatment of OME

| Duration of OME | Treatment |
|-----------------|---|
| 6 weeks | Observation or antimicrobial therapy Hearing evaluation optional |
| 3 months | Referral for hearing evaluation; with 20-dB hearing loss, patient should receive antimicrobial therapy or PE tube |
| 4 to 6 months | Referral for PE tube if there is hearing loss |

AHCPR, Agency for Health Care Policy and Research; *OME*, otitis media with effusion; *PE*, polyethylene.

Chronic Suppurative Otitis Media

Chronic suppurative otitis media (CSOM) is the presence of persistent purulent otorrhea through a perforated tympanic membrane or tympanostomy tube. A persistent tympanic membrane perforation may result from acute otitis media, chronic eustachian tube dysfunction, or trauma. A cholesteatoma or rarely a tumor may also result in CSOM. Otorrhea may also be from chronic otitis externa, which may be difficult to distinguish from CSOM until treatment is initiated. Causes of otorrhea from the middle ear may not always be from middle ear bacterial infection (see eTable 19-3).

Associated symptoms often include hearing loss and tinnitus. Increasing pain, vertigo, or facial palsy imply a possible impending complication of CSOM (discussed later) and requires urgent otolaryngologist consultation. Binocular otomicroscopy allows better visualization and suctioning of purulent material compared to routine otoscopy. Imaging is reserved for medical treatment failures or if a complication is suspected. CT is helpful to evaluate for bony erosion. MRI is indicated with suspicion of CNS involvement.

Initial management should include culture and sensitivity of the discharge to allow appropriate antibiotic selection. If chronic otitis externa is suspected, the specimen should also be sent for fungal culture. Empiric antimicrobials should be started with coverage against the usual pathogens, which include *S. pneumoniae*, *H. influenzae*, *S. aureus*, *Pseudomonas* spp., and anaerobes. A Cochrane review demonstrated that ototopicals are superior to oral antibiotics. Quinolone ototopicals are safe for use in the middle ear. Topical aminoglycosides carry a risk of ototoxicity, but in some cases their use outweighs the risk. Systemic antibiotics may be required in severe cases or when copious drainage impairs administration of ototopicals. Aural toilet with an acetic acid solution (1 part distilled water, 1 part white vinegar) may be helpful to clear debris and provide antiseptics (Macfadyen et al., 2006a, 2006b).

If otorrhea resolves but a tympanic membrane perforation persists, the patient may be offered a tympanoplasty (tympanic membrane repair) to reduce the risk of recurrence and improve hearing. If medical therapy fails to control inflammation, a tympanomastoidectomy may be indicated to eradicate infection, aerate the middle ear and mastoid, and repair the tympanic membrane. *Chronic tympanostomy tube otorrhea* is treated the same as typical CSOM. In recalcitrant cases, however, tube removal or replacement may be indicated.

Box 19-5 Complications of Otitis Media

- Acute mastoiditis
- Brain abscess
- Epidural abscess
- Facial nerve paralysis
- Labyrinthitis
- Meningitis
- Sigmoid sinus thrombophlebitis
- Subdural abscess
- Subperiosteal abscess
- Cholesteatoma

Also, adenoidectomy may be considered because chronic adenoiditis may act as a nidus for infection.

Complications

Although rare since the advent of antibiotics, complications of otitis media must be recognized early to avoid significant potential morbidity and mortality (Box 19-5). Chronic or recurrent otitis media can result in scarring of the tympanic membrane (*myringosclerosis* or *tympanosclerosis*), which alone is usually of no consequence. If scarring involves the ossicles, however, hearing loss can result. Tympanic membrane retraction or perforation can also occur.

Intratemporal Complications

Extension of the infection into the mastoid air cells can lead to *acute mastoiditis*. The signs and symptoms of acute mastoiditis are fever and postauricular tenderness, erythema, and edema. It is important to recognize that acute mastoiditis is a clinical and not a radiologic diagnosis. Therefore, inflammatory changes on a temporal bone CT must be correlated with examination findings to be called acute mastoiditis. Furthermore, acute mastoiditis must be distinguished from an auricular cellulitis secondary to acute otitis externa. *Facial paralysis* may result from AOM or CSOM because of inflammation along the facial nerve as it courses through the middle ear space. Treatment of acute mastoiditis and facial nerve paralysis includes IV antibiotics, insertion of a tympanostomy tube for drainage, and sometimes emergent mastoidectomy. Infection within the middle ear space can extend into the inner ear, leading to labyrinthitis. Symptoms may include vertigo, tinnitus, and sensorineural hearing loss. Expedient initiation of broad-spectrum antibiotics and in some cases insertion of a tympanostomy tube may be necessary. *Petrositis* is a rare complication involving inflammation of the petrous apex mastoid air cells. *Gradenigo's syndrome*, which includes retro-orbital pain, otorrhea, and cranial nerve VI palsy, may result. Treatment includes IV antibiotics and surgical drainage.

Intracranial Complications

The most serious complications of otitis media involve CNS extension of the infection and include sigmoid sinus thrombosis, meningitis, and brain abscess. Warning signs of an impending CNS complication include increasing pain, headache, spiking fever, or altered mental status. Evaluation may include MRI and lumbar puncture. Suspicion of CNS complication often requires urgent neurosurgical, ENT,

and infectious diseases consultations. High-dose IV antibiotics and sometimes urgent surgery (mastoidectomy or craniotomy) are required to prevent significant morbidity or mortality. Otitic meningitis is a major cause of morbidity in the pediatric population. Fortunately, vaccines against *H. influenzae* type B and *Pneumococcus* spp. (Prenar) have decreased these occurrences.

A “cholesteatoma” is a destructive epithelial cyst in the middle ear that may extend to the mastoid air cells. The term is a misnomer because of the lack of cholesterol and presence of only squamous epithelium and keratin debris. The external ear canal and outer layer of the tympanic membrane are lined with squamous epithelium. Keratin debris is continuously sloughed as new epithelial cells mature. In a normal ear the debris slowly migrates to the external meatus, where it is washed away. In contrast to the external ear, the middle ear space is lined with respiratory epithelium, which produces no keratin debris. Cholesteatomas form when squamous epithelium is abnormally located within the middle ear space, allowing the keratin debris to accumulate.

Cholesteatomas often result in CSOM with findings of purulent otorrhea, polyps, and granulation. However, some cholesteatomas are dry, with the finding of a white mass visible behind the tympanic membrane or a white mass or crusting on the tympanic membrane itself. A cholesteatoma must be differentiated from *myringosclerosis*, which is usually flat, white scarring on the tympanic membrane. Enzymatic properties, inflammation, and pressure may lead to bone erosion and hearing loss. If left untreated, serious problems may result, including facial nerve paralysis, labyrinthine fistula, and intracranial complications (see Complications of otitis media).

Congenital cholesteatomas occur without a history of tympanic membrane perforation or retraction and are postulated to result from congenital rests of epithelium in the middle ear space. These may occur in children with no significant history of otitis media and are usually diagnosed as an incidental white mass behind the tympanic membrane.

Primary acquired cholesteatomas result from prolonged eustachian tube dysfunction. Negative middle ear pressure results in a *retraction pocket* of the tympanic membrane, usually at the region of the pars flaccida. Squamous epithelium may become trapped and accumulate in the retraction pocket, resulting in a cholesteatoma. Any retraction pocket of the tympanic membrane requires further evaluation to prevent progression to cholesteatoma.

Secondary acquired cholesteatomas occur as a result of a tympanic membrane perforation. In some cases, a perforation of the tympanic membrane may allow the outer squamous epithelium to migrate into the middle ear space, leading to cholesteatoma formation.

Although aggressive medical treatment may reduce inflammation, surgical treatment is necessary for almost all cholesteatomas. In less advanced cholesteatomas, the external auditory canal is spared in surgery, a “canal wall up” tympanomastoidectomy. Close follow-up is required because of the risk of recurrence from microscopic disease or persistent eustachian tube dysfunction. In more advanced disease, the posterior canal is removed, termed a “canal wall down” tympanomastoidectomy (modified radical and radical mastoidectomy). The canal wall-down procedures are more likely to result in a conductive hearing loss, but the mastoid

cavity becomes accessible through a larger external canal, thereby exteriorizing the cholesteatoma. Typically, semi-annual mastoid bowl debridement is necessary to remove squamous and ceruminous debris to prevent inflammation.

Traumatic Tympanic Membrane Perforations

Traumatic perforation of the tympanic membrane may result from barotrauma (water skiing/diving injuries, blast injuries, blows to side of head), ear canal instrumentation (cotton-tipped applicators, bobby pins, paper clips, cerumen cures), or otitis media (see earlier discussion). The patient usually complains of acute pain that subsides quickly, associated with bloody otorrhea. Severe vertigo can occur but is transient in most cases. Persistent vertigo suggests inner ear involvement (perilymphatic fistula). Hearing loss and tinnitus are also common.

Findings may include fresh blood in the canal and around the perforation. Any medial canal clots or debris should not be removed or irrigated except under microscopy. Secondary bacterial infection may require treatment with ototopical antibiotics. Topical fluoroquinolones are safe for use in the middle ear. Audiologic evaluation is necessary to rule out sensorineural hearing loss. If a tuning fork examination indicates sensorineural hearing loss or is unreliable, the patient should be referred for complete audiologic and ENT evaluation.

In uncomplicated cases the perforation is expected to heal spontaneously over days to weeks. The patient should be instructed to keep the ear dry during this time. If the perforation has not healed after several weeks, a tympanoplasty to close the perforation and, if necessary, repair ossicles is indicated. Repair of the perforation may improve hearing, reduce infection, and prevent cholesteatoma formation.

Barotrauma and Barotitis

Changes in altitude while flying (or scuba diving) can lead to rapid changes in middle ear pressure, leading to accumulation of serous middle ear fluid or blood. Symptoms may include aural fullness, otalgia, and conductive hearing loss. In most cases the fluid is resorbed, although this may take several weeks. *Autoinflation* maneuvers (popping the ears) may hasten recovery. Oral and topical decongestants, nasal steroid sprays, or a short course of corticosteroids may be helpful. Antibiotics are indicated only if there are signs of infection. If fluid persists or is troublesome to the patient, a myringotomy allows the fluid to be drained. Tympanostomy tube insertion may be indicated for persistent middle ear fluid.

Rarely, a rapid change in middle ear pressure can lead to the creation of a *perilymphatic fistula* between the inner and middle ear. The patient complains of severe vertigo and hearing loss (sensorineural) (see Vertigo). Urgent ENT consultation is indicated.

Hearing Loss

Hearing loss results from an interruption in the transmission of sound or subsequent nerve impulses in one or more areas of the ear. Recognition and treatment of hearing loss are imperative; unrecognized or untreated hearing loss may

result in severe psychosocial ramifications in both adults and children. In the elderly population, hearing loss may lead to social withdrawal and depression. In the pediatric population, hearing loss may cause speech or cognitive delays. Hearing loss also has significant safety implications when it interferes with awareness of warning sounds (e.g., car horns, sirens, fire alarms). The four types of hearing loss follow:

1. *Conductive hearing loss* (CHL) occurs when there is a failure of normal propagation of acoustic energy through the conducting portions of the ear, which include the external auditory canal and the middle ear.
2. *Sensorineural hearing loss* (SNHL) occurs from dysfunction of the inner ear, which may be caused by a failure of the generation of nerve signals in the cochlea by the cochlear hair cells or propagation of electrical signals along the cochlear division of the eighth cranial nerve.
3. *Mixed hearing loss* (MHL) occurs when hearing loss results from both CHL and SNHL.
4. *Central hearing loss* can result from ischemic or traumatic brain injuries.

Hearing loss may be subclassified according to whether it is *acquired* or *congenital*. Hearing loss is further classified based on its *severity* (mild, moderate, severe, profound), *side* (right, left, bilateral), *stability* (stable, progressive, fluctuating), and *cause*.

Evaluation includes noting the onset and duration of the hearing loss, any inciting events, the subjective severity of the hearing loss, and any psychosocial impact. Associated ear symptoms, medical history, and a history of ototoxic medication exposure are also important. Although history and examination provide clues to the etiology of the hearing loss, comprehensive audiometric evaluation is essential to making a diagnosis. Box 19-6 lists the most common types of CHL and SNHL.

Otosclerosis

Otosclerosis is caused by sclerotic fixation of the stapes and is the most common cause of CHL in the adult population with no previous history of trauma or infection. It is autosomal dominant in inheritance and more common in women than in men. Otosclerosis is usually bilateral and progressive. Treatment options include no treatment, amplification (hearing aid), fluoride treatment (stabilizes but does not improve hearing), and surgery (stapedectomy). Stapedectomy involves removing and replacing the stapes with a tiny prosthesis. This procedure has a success rate of greater than 95%. Risks of surgery, although rare, include worsened hearing, tympanic membrane perforation, changes in taste, and disequilibrium.

Sudden Sensorineural Hearing Loss

See Emergencies.

Presbycusis

Presbycusis is an all-inclusive term to describe the process of hearing loss related to aging. An estimated 30% to 35% of adults age 65 to 75 and 40% to 50% of adults older than 75 have hearing loss. Symptoms of presbycusis include gradu-

Box 19-6 Common Types of Conductive and Sensorineural Hearing Loss

Conductive Hearing Loss

- Cholesteatoma
- Cerumen impaction
- Foreign body in ear canal
- Ossicular problems
- Otitis media with effusion
- Otosclerosis
- Retracted tympanic membrane (eustachian tube dysfunction)
- Tumor of the ear canal or middle ear
- Tympanic membrane perforation
- Tympanosclerosis

Sensorineural Hearing Loss

- Acoustic neuroma
- Diabetes
- Hereditary (congenital) loss
- Idiopathic loss
- Meniere's disease
- Multiple sclerosis
- Noise-induced loss
- Ototoxicity
- Perilymphatic fistula
- Presbycusis
- Syphilis

ally decreasing hearing acuity, especially for higher-pitch tones (women's and children's voices) and in certain situations (with background noise). Tinnitus is common.

The cause of presbycusis is likely multifactorial, but ultimately the loss of cochlear *hair cell* function is thought to be the cause in most cases. Hair cell damage or loss can result from chronic noise exposure, genetic predisposition, and ototoxic medications. The hearing loss may also be caused by neurovascular injury from chronic conditions such as hypertension or diabetes, which can affect the cochlea or cochlear nerve. Hormonal conditions such as hypothyroidism should be considered, as should unusual conditions such as tertiary syphilis. Central auditory problems might be the cause, from dementia, cerebrovascular disease, or cerebrovascular accident (CVA, stroke).

Although the term "presbycusis" implies sensorineural loss, conductive hearing loss should also be considered, including cerumen impaction, chronic OME, and otosclerosis (see Box 19-6).

Acoustic Neuroma

An acoustic neuroma (or more precisely, *vestibular schwannoma*) is a benign tumor that arises from the Schwann cells of cranial nerve VIII. Acoustic neuromas account for about 10% of all intracranial tumors. They are most commonly diagnosed in middle age. They are slightly more common in women than men. They are usually sporadic but may be associated with neurofibromatosis 1 or 2 (NF-1, NF-2). Most patients with NF-2 will develop bilateral acoustic neuromas. Acoustic neuromas in NF-1 are much less common.

The primary symptoms of vestibular schwannoma are asymmetric hearing loss (sensorineural) and tinnitus. The hearing loss is usually gradual in onset and progressive but can occur suddenly. Disequilibrium is not usually the chief complaint on presentation, but patients often admit to mild unsteadiness. Larger tumors can cause dysesthesia around the ear or facial weakness, or both. If the neuroma is diagnosed late, patients can manifest cerebellar symptoms and symptoms of mass effect and obstructing hydrocephalus.

After a complete neuro-otologic examination and audiologic evaluation, an MRI scan of the brain with fine cuts through the internal auditory canal with gadolinium contrast is necessary for diagnosis.

Treatment options include observation, surgery, or stereotactic radiotherapy. Most vestibular schwannomas require treatment to prevent cerebral complications from future growth. If the patient is aged or infirm, watchful waiting may be considered. Very small tumors may be observed because the rate of growth is often slow. Surgical treatment involves either a translabyrinthine resection if hearing is poor or a craniotomy for hearing preservation. Stereotactic radiotherapy has the obvious advantage of avoiding major surgery. Success is similar to surgery for smaller tumors. Shortcomings of this treatment include delayed facial paresis, tumor recurrence (which requires routine monitoring), and the potential for radiation-induced malignancies in the future.

Hearing Loss from Acoustic Energy

Excessive noise exposure is an important and usually preventable cause of hearing loss. Hearing loss can result from chronic or acute noise exposure, usually causing injury at the level of the cochlear hair cells. However, acute acoustic trauma can also cause injury to the tympanic membrane and middle ear structures.

Chronic noise exposure may be recreational or vocational. The Occupational Safety and Health Administration (OSHA) has established guidelines for safe limits for acute and chronic noise exposure to prevent occupational noise-induced hearing loss. Exposure to noise of 90 dB or less is permissible for up to 8 hours per day. As the noise intensity increases, the permissible duration of exposure decreases. OSHA outlines procedures for hearing protection and monitoring. These standards also can help provide guidelines to minimize excessive recreational noise exposure. Recreational activities known to cause excessive noise include hunting or target shooting with firearms, use of power tools or power lawn equipment, attendance at sporting venues, motor racing events, action movies, or concerts and listening to loud music on headphones. Hearing protection or avoidance is recommended for such activities.

Acute exposure to excessively loud noise can cause conductive or sensorineural hearing loss. CHL can result from a blast-type injury that leads to tympanic membrane perforation or ossicle injury. The conductive component of the hearing loss is usually reparable, but severe acoustic trauma can also cause sensorineural loss. SNHL from acute acoustic trauma is usually the result of temporary hair cell dysfunction or permanent injury, leading to transient or permanent *threshold shifts*, respectively. A concussive or blast injury (e.g., slap, airbag deployment to ear) can result in the formation of a labyrinthine fistula from the inner ear into the middle ear,

which causes severe vertigo and SNHL. Most fistulas close spontaneously with bed rest, but some require middle ear exploration and repair. However, the sensorineural hearing loss is usually permanent.

Hearing Loss in the Pediatric Population

Congenital hearing loss is often hereditary but may be secondary to an intrauterine insult or infection. Of the hereditary variety, the majority are autosomal recessive and nonsyndromic. Risk factors for congenital hearing loss include family history of hearing loss, facial abnormalities, ICU admission, history of meningitis, syndromes known to be associated with hearing loss, low Apgar scores at birth, medications known to cause hearing loss (e.g., aminoglycosides), elevated bilirubin, some prenatal maternal infections, or suspicion of hearing loss.

Universal newborn hearing screening using otoacoustic emissions and auditory brainstem response allows early identification of impaired children. Intervention by age 6 months appears to improve language development. A temporal bone CT is often obtained to evaluate for inner ear malformations that would predispose the patient to further hearing loss with even mild head trauma. A genetics evaluation and counseling may be indicated. Mutations of the Connexin-26 gene, an autosomal recessive disorder, accounts for a significant percentage of nonsyndromic hereditary hearing loss. Hearing loss may coexist with other conditions (e.g., renal, ophthalmologic, thyroid, infectious, cardiac), so other testing may be indicated based on clinical suspicion.

In children with a significant hearing loss, hearing aids are recommended. A cochlear implant may be indicated for those with hearing so poor to be considered unaidable. A cochlear implant is a surgically implanted device that receives sound, converts it to electrical signals, and directly stimulates the cochlea. Results are excellent in properly selected patients.

An important and often unrecognized cause of hearing loss in children is chronic OME. Children with either unilateral or bilateral middle ear effusions refractory to medical treatment for more than 3 months should have audiometric testing. Myringotomy with tube insertion is indicated if bilateral CHL is found and should be considered in some cases of unilateral loss as well.

Treatment of Hearing Loss

Individual treatments for specific causes of hearing loss vary greatly. This section gives a brief overview of options available to improve hearing in patients with the most common causes of hearing loss.

Surgery is often performed for CHL. Myringotomy with or without tube insertion corrects hearing loss in cases of OME. The procedure is performed under brief general anesthesia in children or under local anesthesia for most adults. A tympanoplasty is performed for tympanic membrane perforations and to reconstruct ossicles with a prosthesis. A stapedectomy with placement of a prosthesis is often a successful option in patients with otosclerosis.

Cochlear implantation is indicated for profound SNHL in patients who do not benefit from conventional hearing aids. The procedure is indicated for adults and children as young as 12 months old.

Table 19-4 Causes of Facial Paralysis in Order of Occurrence

| Cause | Percentage | Characteristics |
|---------------------------------------|------------|--|
| Idiopathic (Bell's palsy) | 60-85 | Acute onset; viral prodrome (60% of cases) |
| Trauma | 20-50 | Acute-onset paralysis or paresis of previously functioning nerve |
| Herpes zoster | 10-15 | Ramsay Hunt syndrome with cranial nerve VII involvement, vestibular (vertigo), cochlear (hearing loss) |
| Tumor | 10-15 | Slow progression to complete paralysis |
| Birth | 10-15 | Part of congenital syndrome or birth trauma at delivery |
| Infection | 4 | Mastoiditis, otitis media, direct cranial nerve VII infection, Lyme disease |
| Brain lesion (central nervous system) | <10 | Supranuclear or in brainstem |

From Brody R, Har-El G. From Lucent FE, Har-El G. *Essentials of Otolaryngology*. Philadelphia, Lippincott Williams & Wilkins, 1999, p 131.

A variety of styles of hearing aids are used to rehabilitate hearing loss in patients with SNHL and CHL. The simplest (and least expensive) are larger, behind-the-ear aids with analog amplification of sound. The most complex (and most expensive) are completely-in-the-canal aids with programmable digital amplification. Several other types of aids fall between these two extremes. A certified audiologist, under the supervision of an otorhinolaryngologist, assists the patient with proper selection of an appropriate hearing aid.

Facial Nerve Paralysis

Facial paralysis occurs for various reasons. Possible causes are listed in Table 19-4. The eponym "Bell's palsy" is reserved for cases of idiopathic facial paralysis. It has been shown, however, that many if not most cases of idiopathic facial paralysis are actually caused by reactivation of latent herpesvirus living in the facial nerve or geniculate ganglion.

Although the most common cause of facial paralysis is indeed Bell's palsy, it is incumbent to rule out *other* potentially serious causes of facial paralysis before making this *diagnosis of exclusion*. Initially, a complete history and physical examination are required, including otologic and neurologic evaluation. The patient should be questioned regarding history of recurrent cold sores, which suggest herpetic involvement. Recent travel (especially camping) should be noted because Lyme disease is an often-overlooked cause of facial paralysis. Involvement of facial nerves is a concern in patients with a history of chronic otitis media or cholesteatoma. Other symptoms should be noted. Otagia is common with Bell's palsy and does not always imply that the ear

is involved. Of course, questions regarding risk factors for cerebrovascular disease or previous CVA should be obtained.

Evaluation of facial nerve function requires careful attention and comparison between the two sides of the face. The patient should be evaluated at rest and with voluntary movement. The patient should be asked to wrinkle the nose, raise the eyebrows, squeeze the eyes shut, and purse the lips to assess all branches of the facial nerve. The facial skin should be assessed, because a rash can indicate *herpes zoster oticus* (Ramsay Hunt syndrome). The eyes should be inspected to rule out exposure keratitis from lack of eye closure and dryness. If keratitis is suspected, ophthalmologic consultation should be obtained to prevent loss of vision. A complete neurologic examination must be done. If other neurologic deficits are found, neurology consultation is indicated. Lesions in the auditory canal should raise suspicion of herpes zoster oticus or malignancy of the external auditory canal with facial nerve involvement. Otitis externa and facial weakness can represent malignant otitis externa, especially if the patient is diabetic or immunocompromised. Signs of otitis media imply involvement of the facial nerve as it courses through the middle ear. The parotid gland and rest of the neck should be checked to rule out a parotid salivary gland mass that involves the facial nerve. Any of these associated ear findings should prompt ENT consultation because early intervention can improve outcome. Audiometry is recommended in the evaluation of facial paralysis because of the proximity of cranial nerves VII and VIII in the temporal bone.

In cases in which no identifiable cause is found, the diagnosis of Bell's palsy is made (though this diagnosis is not certain until a facial or acoustic neuroma has been ruled out either with return of facial function or with MRI scan). In the past, Bell's palsy was treated expectantly because the cause was not clear, making treatment difficult. Evidence now indicates that most Bell's palsy cases are secondary to a reactivation of the herpes simplex virus in the geniculate ganglion, causing neural edema and neurapraxia. On the basis of this research, treatment with antivirals and steroids are thought to improve outcomes. If no contraindications to steroids exist, prednisone (1 mg/kg, up to 60 mg, for approximately 7 days with a 7-day taper) is reasonable. In addition to steroids, an oral antiviral with activity against the herpesvirus is given (200 mg acyclovir [Zovirax] five times daily or valacyclovir [Valtrex] 500 mg twice daily for 7-10 days). Of the utmost importance is protection of the eye. Moisturizing eyedrops and nightly lubrication should be prescribed. Any signs of irritation should prompt an ophthalmology evaluation.

If the facial weakness is secondary to Ramsay Hunt syndrome, treatment is similar to that of Bell's palsy, but the clinical course and expected outcomes differ. This syndrome is caused by herpes zoster (rather than herpes simplex) involvement of the facial (geniculate), vestibulocochlear, and/or trigeminal ganglia. The infection causes pain and eventually vesicular eruptions around the auricle and external ear canal. Vesicles may appear only in the pharynx or hard palate in some cases. Facial weakness and at times dense paralysis are common. Hearing loss, tinnitus, and persistent vertigo also occur in 20% to 30% of patients (Adour, 1994). As with Bell's palsy, prompt initiation of oral steroids and acyclovir should begin when the diagnosis is suspected. This therapy can lessen vertigo and improve recovery of facial

nerve function, although outcomes are not as favorable as for Bell's palsy. Some patients struggle with persistent facial weakness, pain, and hearing loss (Robillard et al., 1988).

In cases of facial paralysis associated with otitis externa or otitis media, treatment differs. If malignant otitis externa is suspected, the patient requires hospital admission, control of diabetes, and infectious diseases and ENT consultation. IV antibiotics and sometimes surgical debridement are required. CNS complications are possible.

Facial weakness in the setting of AOM requires treatment with a broad-spectrum antibiotic covering the usual pathogens of otitis media. In addition, a myringotomy with or without tube insertion is thought to hasten resolution and improve outcomes by allowing decompression of the infection. This also allows a culture to be done and antibiotic sensitivities determined. If facial weakness occurs in the setting of chronic otitis media or known cholesteatoma, topical and systemic antistaphylococcal and antipseudomonal antibiotics should be started and an urgent ENT consultation obtained in hopes of preventing permanent facial paralysis and further complications.

Expected outcome for true Bell's palsy is full return of function in 80% of patients. The remaining 20% have variable recovery. If recovery is incomplete, MRI is indicated to rule out neoplastic process (most likely a facial neuroma) that could mimic Bell's palsy. Patients with diabetes mellitus have a higher incidence of Bell's palsy and often have a poorer outcome. Permanent facial weakness is also more common after herpes zoster oticus. Outcomes of facial paralysis secondary to the other causes discussed are variable and depend on the severity of the pathology, the patient's general state of health, and the response to treatment.

In patients who have poor return of facial function, rehabilitation is necessary. The most important goal is protection of the eye, followed by improved cosmesis. Ophthalmologic and ENT involvement is continued (Almeida et al., 2009).

The Nose and Paranasal Sinuses

Key Points

- A CT scan of the sinuses is not necessary to diagnose uncomplicated acute sinusitis. CT should be considered when the diagnosis is uncertain, treatment has failed, or a complication or neoplasia is suspected. MRI is useful in evaluation of sinus tumors.
- Adenoid hypertrophy is a common cause of nasal symptoms in children, but in an adult can indicate a lymphoproliferative disorder or HIV infection.
- A nasal foreign body should be suspected in a child who presents with recent unilateral nasal obstruction, rhinorrhea, and odor.
- Nasal polyps can be seen with asthma, cystic fibrosis, and rarely neoplasia.
- After allergen avoidance and antihistamines, topical corticosteroids are the mainstay of treatment for seasonal allergic rhinitis.
- Leukotriene receptor antagonists can reduce the symptoms of allergic rhinitis.
- Treatment to restore mucociliary function in sinusitis is as important as antimicrobial therapy.

- Unlike adults, children with sinusitis rarely complain of facial pain.
- Prompt diagnosis and treatment of a nasoseptal hematoma can prevent subsequent cartilage destruction.

History

Signs and symptoms of most nasal and sinus disorders include nasal congestion, rhinorrhea, bleeding, facial pressure, halitosis or pain, headache, cough, otalgia, facial or periorbital swelling, altered (diminished, absent, or distorted) sense of smell, or postnasal drainage. Initial evaluation of the patient with nasal complaints begins with a complete history, with specific questions directed at the timing and chronicity of the symptoms and modifying factors. The patient should be questioned specifically about previous nasal trauma.

Patients should be asked about prescription and over-the-counter nasal, sinus, and allergy medications. Many patients try OTC remedies before seeking medical advice. Excessive use of decongestant nasal sprays can exacerbate and even cause nasal obstruction secondary to *rhinitis medicamentosa* and rebound nasal congestion. The patient should also be questioned about previous nasal surgery. Rarely, the patient admits to unorthodox self-treatment that may be significant (e.g., peroxide irrigation, overzealous nasal cleaning). This can explain continued symptoms and may indicate an underlying problem. The underlying problem may be true nasal pathology or rarely may be obsessive-compulsive disorder manifesting as repeated nasal cleaning.

Information about past medical history and social history is also necessary. Knowledge of the patient's work environment may be relevant. Exposure to chemicals or fumes can cause nasal symptoms. Woodworkers are known to have a higher incidence of sinonasal carcinoma. A history of environmental allergies or immune dysfunction is relevant. Many medical conditions (e.g., asthma, autoimmune disorders) are associated with sinonasal dysfunction. Other conditions (e.g., hypertension) will limit the use of decongestants. History of migraine is noteworthy because migraine headaches can be confused with sinus pain. Some prescriptions can exacerbate or even cause nasal dysfunction, especially medications (antihistamines, diuretics, antidepressants) that can lead to excessive nasal dryness (*sicca*). Drug allergies should be noted. Previous nasal surgery, if done, may not have been successful or even led to increased problems. Cigarette smoking and excessive use of alcohol and caffeine have negative effects on mucociliary function that can lead to congestion. A history of nasal or facial trauma is important. Previous or current use of intranasal cocaine can lead to significant pathology and symptomatology.

Physical Examination

See the discussion online at www.expertconsult.com.

Radiography

Plain radiographs do not approach the sensitivity and specificity of CT but are useful in some cases. Plain films are often ordered in cases of facial trauma, especially isolated nasal trauma. The films can be complementary to the physical examination.

Figure 19-6 Coronal computed tomography scan showing complete opacification of the right maxillary and ethmoid sinuses with partial opacification of the left maxillary and ethmoid sinuses. Arrow indicates ostiomeatal complex.

Plain radiographs of the sinuses are still useful in certain circumstances. Plain sinus radiographs are reasonably accurate in assessing the maxillary and frontal sinuses in cases of *acute* sinusitis. Complete opacification or an air-fluid level in one of these sinuses usually indicates acute sinusitis. However, the relatively low sensitivity and specificity of plain films, especially in evaluating the ethmoid sinuses, have limited their usefulness.

Computed tomography has become an invaluable diagnostic tool for evaluating chronic nasal and sinus problems and has essentially supplanted the use of plain sinus films. CT of the sinuses allows unparalleled imaging of the complicated anatomy of the nose and paranasal sinuses. It has also increased understanding of the pathophysiology of sinusitis. CT scanning can show areas of mild mucosal thickening in the sinuses (indicating chronic sinusitis), complete opacification (seen in acute sinusitis, polyps, or sinus tumors), bone erosion, or abscess formation in adjacent critical structures such as the orbit or brain (Fig. 19-6). CT can show whether the *ostiomeatal complex* (the “bottleneck” of normal sinus drainage) is patent or obstructed and shows the myriad nasal and sinus normal variants, some of which predispose to sinonasal pathology.

Computed tomography of the sinuses should be ordered when the diagnosis of chronic sinusitis is suspected, medical treatment of sinusitis has failed and surgery is being contemplated, a complication of sinusitis is suspected, or a nasal or sinus mass is suspected. CT is not required as a confirmatory test in the treatment of uncomplicated acute sinusitis except in certain circumstances. The scan is helpful, however, in cases of *recurrent acute sinusitis* or when the diagnosis is not certain. Obtaining a scan during a patient’s presumed

infection allows the diagnosis to be confirmed or ruled out. Although some abnormalities require further treatment occasionally, the scan identifies abnormalities or variations of normal anatomy that require no intervention. Mucus retention cysts, for example, are seen in up to 20% of the population. Unless they are large or infection is suspected (the patient complains of pain in the vicinity of the cyst), no treatment is required.

Magnetic resonance imaging is not particularly helpful in evaluating sinusitis and has two main limitations in evaluating inflammatory sinus conditions. First, MRI often tends to be too sensitive, showing mucosal thickening that is clinically insignificant. Second, MRI fails to show bony anatomy, which is critical in diagnosis and surgical planning in chronic sinusitis. MRI is useful in evaluating suspected sinonasal tumors and fungal infections of the sinuses. The limitations of MRI and its relatively high cost compared with CT do not justify its routine use in evaluating chronic sinusitis. When incidental sinusitis is noted on an MR image and the degree of sinusitis is severe, is asymmetric, or the patient is symptomatic, treatment (and sometimes ENT referral) is indicated.

Clinical Problems

Complaints related to the nose and sinuses are among the most common seen in a family medicine practice. Acute rhinitis (the common cold), allergic rhinitis, and sinusitis compose the vast majority of these complaints and, taken together, result in an enormous socioeconomic impact in terms of missed workdays and schooldays and pharmaceutical costs. Nasal complaints are usually related to nasal congestion, rhinorrhea, bleeding, facial pressure or pain, headache, cough, otalgia, facial or periorbital swelling, altered (diminished, absent, or distorted) sense of smell, or postnasal drainage.

Epistaxis

See also earlier Emergencies section. (p. 300). Epistaxis can be caused by trauma, dry weather, hypertension, bleeding dyscrasias, anticoagulation therapy, and intranasal tumors. Adolescent boys with recurrent epistaxis and nasal obstruction might have juvenile nasopharyngeal angiofibroma. Epistaxis typically responds to conservative treatment, including nasal hydration with saline mist, nasal ointment, environmental humidification, avoidance of digital trauma, and control of hypertension if present. If bleeding continues to be a problem, the patient should be referred to an ENT consultant for a complete evaluation of the nasal cavities and possible cautery. Screening blood studies for coagulopathy may be necessary.

Nasal Obstruction

The sensation of unilateral or bilateral nasal obstruction is relatively common and can range from mildly annoying to extremely frustrating to the patient. Nasal obstruction may be associated with other symptoms such as rhinorrhea, lost or altered sense of smell, or facial discomfort. Nasal obstruction may result from pathology of the nasal cavity or nasopharynx. (eTable 19-4 online summarizes the most

common causes, associated signs and symptoms, and treatment for nasal obstruction).

Physical Examination

See the discussion online at www.expertconsult.com.

Treatment

Successful treatment of nasal obstruction depends on making a correct diagnosis. Once the diagnosis has been established, a treatment plan should be developed. If the nasal obstruction is secondary to one of the various types of rhinitis, it is treated medically. This includes nasal steroids, antihistamines, leukotriene inhibitors, mucolytics, oral decongestants, topical decongestants, and nasal saline. These medications may be used alone or in various combinations. The choice of medications is determined by the severity of symptoms and the patient's medical history, response to treatment, and wishes. Oral steroids can be used in select severe cases but are associated with potential significant side effects. Nasal decongestant sprays are very effective for treating severe nasal congestion but should be used sparingly and never for longer than 3 days, to prevent rebound nasal obstruction (rhinitis medicamentosa). Allergy testing is done when allergies are suspected and the standard regimen is largely ineffective. Antibiotics are administered if a bacterial infection is suspected (acute rhinosinusitis).

Adenoid Hypertrophy

Adenoid hypertrophy is common in children. If identified in an adult, adenoid hypertrophy could indicate a lymphoproliferative disorder or HIV infection. The patient may present with nasal symptoms or symptoms of eustachian tube dysfunction. In the pediatric population, adenoid hypertrophy causes chronic or recurrent nasal obstruction, rhinorrhea, snoring, cough, or otitis media. The diagnosis is usually clinical but can be confirmed with lateral neck radiograph. If symptoms are severe or persistent, adenoidectomy is indicated; improvement is usually dramatic.

Foreign Body

A nasal foreign body should be suspected in a child with or without a history of previous nasal problems who presents with recent unilateral nasal obstruction, rhinorrhea, and odor. The nasal foreign body might not be visible secondary to the presence of mucosal edema, mucus, or pus.

If the foreign body is identified, removal may be attempted in a cooperative child. If removal is not possible or the diagnosis is uncertain, ENT consultation should be obtained. The ENT evaluation may be done in the office setting or in the operating room, depending again on patient cooperation and degree of suspicion. The nasal cavity is suctioned, decongested, and anesthetized with topical lidocaine. Endoscopy may be done. If the foreign body is seen, removal is undertaken.

If old enough, asking the child to blow the nose after decongestion might remove the foreign body or at least move it anteriorly. Removal can be difficult, and experience helps. Problems that can hinder removal include bleeding that obscures visibility. The foreign body can also be inadvertently pushed posteriorly. Softer foreign bodies, such as food matter and tissue paper, can disintegrate, requiring piecemeal removal.

A headlight and bivalve nasal speculum are recommended. Suction should be available. A small alligator or bayonet forceps is sometimes used, but may simply push the foreign body posteriorly. In many cases a useful instrument is a small, ball-tipped, right-angle probe, actually an otologic surgical instrument called an "attic hook." This can be gently passed posterior to the foreign body, turned 90 degrees, and then used to pull the foreign body anteriorly and out of the nose.

Once the foreign body is removed, the nasal cavity should be reinspected for retained, more distal foreign bodies. The other nasal cavity and ears should also be inspected because the child might be a "repeat offender." Antibiotics are recommended if there is evidence of obvious infection or complete removal is not certain and reexamination is planned.

Nasal Vestibulitis

A low-grade infection of the anterior nasal vestibule will cause chronic irritation, crusting, and sometimes bleeding. The examination typically shows mild erythema, cracking, and yellow crusting just inside the nostril, but it may be fairly normal. The etiology is usually *Staphylococcus aureus* but may be fungal. Herpetic infections are typically more severe and not as protracted. Treatment is with OTC topical antibiotic ointment (without neomycin because of patient sensitivity) and avoidance of irritating the area. If symptoms continue, methicillin-resistant *S. aureus* (MRSA) infection is possible and should respond to mupirocin ointment. Continued symptoms require ENT consultation.

Choanal Atresia

Choanal atresia is a common cause of nasal obstruction in children but can also be seen in adults. If bilateral, it manifests shortly after birth as an airway emergency, because neonates are "obligate nasal breathers" and cannot tolerate nasal obstruction. Typically they will oxygenate well while crying but will become cyanotic when crying stops and they cannot feed. This condition requires urgent ENT consultation. The airway is stabilized and the atresia repaired shortly thereafter. If unilateral, the atresia can go undiagnosed until later in childhood or even adulthood. The patient will report a lifelong history of nasal obstruction and rhinorrhea. Diagnosis is made with endoscopy and CT. Treatment is surgical.

Nasal Polyps

Nasal polyps are the result of nasal mucosal inflammation and edema. On examination, nasal polyps are usually silver-gray in color and may be translucent. If there is associated infection, polyps can appear erythematous or may be obscured by mucus. Polyps cause significant and sometimes complete nasal obstruction but are painless and insensate. Nasal polyps predispose the patient to sinusitis and often cause anosmia.

The exact cause of nasal polyps is unclear. Polyps are often associated with reactive airway disease and less often with environmental allergies. In children the presence of polyps should prompt testing for cystic fibrosis. Sinonasal tumor or fungal involvement should be considered, especially if the polyps are unilateral. If polyps are identified, further evaluation includes allergy and asthma testing and CT scan.

Medical treatment is initially offered but is often inadequate. Initial treatment includes topical steroids, allergy treatment, and treatment of sinusitis. In many patients, endoscopic sinus surgery is an important adjunct to medical treatment and results in significant improvement in symptoms. Unfortunately, polyps often recur after surgery, requiring repeated removal.

Deviated Septum

Most patients have some degree of asymptomatic septal deviation, but in some patients it is severe enough to cause symptoms of obstruction. Septal deviation is usually the result of previous nasal trauma. The trauma might have seemed relatively minor at the time or might have resulted in a nasal fracture. Some deviated septums are congenital. Physical examination may clearly demonstrate the septum obstructing the nasal airway if anterior. If more posterior, nasal endoscopy or CT may be necessary to make the diagnosis. Any patient complaining of persistent nasal obstruction deserves further evaluation, especially if the cause is not immediately evident. Symptomatic septal deviation is readily treatable with outpatient surgery.

Septoplasty is done through an intranasal incision, allowing deviated portions of cartilage and bone to be replaced to the midline or removed, resulting in a symmetrically patent nasal airway. Septoplasty is often combined with a turbinate reduction procedure. The procedures are usually well tolerated. Postoperative pain, formerly a greater problem, usually resulted from the need for nasal packing and removal. Newer devices such as soft-silicone (Silastic) splints now cause much less postoperative discomfort than traditional packing.

In pediatric patients, septoplasty is not usually recommended because of concern about disrupting nasal and facial growth, although this risk appears to be low. For this reason, "limited" septoplasty may be considered in select patients.

Hypertrophied Turbinates

Inferior turbinate hypertrophy is relatively common in adults and children. This usually occurs with chronic inflammation, usually resulting from allergy or rhinosinusitis. Turbinate hypertrophy usually responds to medical treatment addressing the primary problem. If the turbinates remain significantly hypertrophied despite medical treatment, turbinate reduction is offered, using cautery, radiofrequency treatment, fracture, excision, laser treatment, or cryotherapy. Submucosal resection of a portion of the conchal bone and stromal tissue seems to provide the greatest success.

Rhinitis

Allergic Rhinitis

Seasonal allergic rhinitis affects 10% to 30% of adults and up to 40% of children in the United States. Although half the patients with allergic rhinitis have symptoms for only 4 months per year, 20% experience symptoms more than 9 months per year. Direct medical costs of treating this condition plus indirect costs of lost productivity and absences from work or school are estimated at up to \$2.4 billion per year in the United States. Unfortunately, seasonal allergic

rhinitis is not self-limiting and often coexists with more serious conditions such as asthma, sleep apnea, nasal polyps, sinusitis, and OME.

Understanding the immunologic mechanisms of seasonal allergic rhinitis directs the physician to the appropriate therapy. Allergens such as pollens are deposited on the nasal mucosa and processed by macrophages. The allergens are then brought to T lymphocytes and B cells, the latter producing immunoglobulin E (IgE), which in turn attaches to receptors on mast cells and basophils, causing the release of histamine and other inflammatory substances. The action of these substances on the nasal mucosal cells and nerve endings produces the localized symptoms of nasal discharge, nasal congestion, sneezing, and itching. This is considered the early or immediate phase of the allergic reaction. The delayed-phase response can occur 6 to 8 hours after the initial exposure, even when there are no allergens present. A continued influx of immune cells into the nasal mucosa causes a recurrence of symptoms.

The annual cycle of allergens causing allergic rhinitis begins in the early spring with the flowering of deciduous trees, followed by the release of pollen from grasses during the summer months and from weeds during the late summer months and early fall. Mold spores can be present throughout the year but increase during the warm months.

The diagnosis of seasonal allergic rhinitis is made primarily by history. Differentiation from the common cold is through examination of the nasal mucosa. A pale-pink to blue, boggy nasal mucosa usually indicates allergic rhinitis, whereas a red mucosa is more likely the result of a viral infection or nonallergic vasomotor rhinitis. A horizontal nasal crease on the nose of children and allergic "shiners" are other physical signs to look for in making the diagnosis. Seeing eosinophils under the microscope from a nasal smear using a Wright's stain also points to a diagnosis of allergic rhinitis. Skin testing for specific allergens may be done when the symptoms warrant. The term *perennial rhinitis* simply indicates that the symptoms are present throughout the year and are often caused by allergens (dog or cat dander, mold, dust mites).

The treatment is the same for perennial rhinitis and for seasonal allergic rhinitis. The link among seasonal allergic rhinitis, asthma, and sinusitis is based on the one-airway theory. Because the mucosa in each of those areas consists of basement membrane, a capillary system, mucous glands, goblet cells, and nervous innervation, each area reacts similarly to allergens and responds to like treatments.

After allergen avoidance, antihistamines are most often used to treat seasonal allergic rhinitis. They can also be beneficial for asthma, although they have not been traditionally used as part of asthma treatment. The second generation of nonsedating antihistamines has shown clear benefits in treating seasonal allergic rhinitis and asthma (Grant et al., 1995). (eTable 19-5 online shows the onset of action, sedating properties, cardiac side effects, and dosage regimens of first- and second-generation antihistamines.) Cetirizine (Zyrtec) and loratadine (Claritin) can be taken with food, whereas fexofenadine (Allegra) is less well absorbed when taken with food. A topical antihistamine, azelastine (Astelin) has shown efficacy in treating allergic rhinitis.

Adding a decongestant such as pseudoephedrine or phenylephrine can help relieve nasal congestion through its vasoconstrictor properties. The patient should be cautioned about

Table 19-5 Doses for Nasal Corticosteroids

| Nasal Spray | Age: Dosage |
|--|--|
| Mometasone furoate (Nasonex) | 2-12 yr: 2 sprays each nostril qd (200 µg/day) |
| Fluticasone propionate (Flonase) | 4-16 yr: 1-2 sprays each nostril qd (100-200 µg/day) ≥15 yr: 2 sprays each nostril qd (200 µg/day) |
| Budesonide (Rhinocort, Pulmicort) | ≥6 yr: 2 sprays each nostril bid or 4 sprays each nostril qd (256 µg/day) |
| Beclomethasone dipropionate (Beconase, Vancenase, Beconase AQ) | 6-12 yr: 1 spray each nostril bid (168 µg/day) ≥12 yr: 1 or 2 sprays each nostril bid (168 or 336 µg/day) |
| Flunisolide | 6-14 yr: 1 spray each nostril tid or 2 sprays each nostril bid (1500-2000 µg/day) ≥14 yr: 2 sprays each nostril bid or tid (200-300 µg/day) |
| Triamcinolone acetonide (Nasacort AQ) | 2-5 yr: 1 spray each nostril daily 6-12 yr: 2 sprays each nostril qd (200 µg/day) ≥12 yr: 2 sprays each nostril qd or bid (220-440 µg/day) |

qd, Daily; *bid*, twice daily; *tid*, three times daily.

side effects such as nervousness, irritability, and insomnia when taking decongestants. Decongestants should be used carefully in patients with hypertension and with symptoms of prostatic hypertrophy.

Topical corticosteroids are effective in reducing the inflammation of the late-phase reaction (Weiner et al., 1998). The onset of action is within 24 to 72 hours, with full effects within 1 to 2 weeks. The initial dose may be two to three times daily for the nasal corticosteroids, followed by a reduction in the dose for maintenance (Jacobsen, 2001). The main side effects of corticosteroid nasal sprays are epistaxis (5% of patients) and nasal dryness (10%). These can be managed by using saline nose drops or a small amount of petroleum jelly before insufflation of the corticosteroid. No sign of nasal mucosal atrophy has been seen after as long as 1 year of therapy.

There is no evidence that nasal corticosteroids suppress adrenal function, but because of the concern about the effect of topical corticosteroids on the hypothalamic-pituitary-adrenal axis, several newer nasal corticosteroids have been developed to be less well absorbed. Mometasone (Nasonex) and fluticasone (Flonase) are less than 2% bioavailable, whereas budesonide (Rhinocort) and beclomethasone (Beconase, Vancenase) are 11% and 17% bioavailable, respectively. Age-appropriate dosages for the nasal corticosteroids are shown in Table 19-5.

Leukotriene receptor antagonists have been shown to inhibit the early phase of antigen response and to attenuate the late-phase inflammatory response. Several randomized, placebo-controlled trials have proved that antileukotrienes can reduce the symptoms of allergic rhinitis and improve the quality of

life (Meltzer, 2002). In addition, they reduce nasal congestion and improve the sense of smell. Zafirlukast (Accolate) and montelukast (Singulair) are effective when patients either refuse or fail antihistamines and nasal sprays and can be used in combination with antihistamines. Zafirlukast can cause liver enzyme abnormalities and should not be prescribed for children younger than 12 years. Montelukast has no serious side effects and can be prescribed for children as young as 6 years.

Patients who respond poorly to pharmacotherapy, who develop adverse side effects, or who simply wish to use an alternative to pharmacotherapy may consider immunotherapy. They must realize the commitment to this therapy is 3 to 5 years, and that local reactions are seen in 15% of patients and systemic reactions in 0.5%. A cost comparison between immunotherapy and medication done under the auspices of the American Academy of Allergy, Asthma, and Immunology demonstrated a significant reduction in cost of single-injection immunotherapy over medication in allergic rhinitis (Huggins and Looney, 2004).

The family physician is crucial to the diagnosis and treatment and can educate patients about the importance of allergen avoidance, adherence to the treatment regimen, and potential side effects of the medications.

KEY TREATMENT

As immunotherapy for allergic rhinitis, montelukast shows efficacy similar to loratadine but less than intranasal fluticasone. Montelukast used concomitantly with loratadine or cetirizine shows increased benefit compared with either drug alone (Nayak and Langdon, 2007).
Intranasal steroids continue to be the mainstay of treatment for allergic rhinitis. For steroid-intolerant patients, however, montelukast with loratadine or cetirizine can produce comparable results. Intranasal antihistamine therapy is effective for both allergic rhinitis and vasomotor rhinitis (Kaliner, 2007).
SOR: A

Vasomotor Rhinitis and Idiopathic Rhinitis

The term “vasomotor rhinitis” is a misnomer because there is no inflammation. The primary symptoms are a feeling of nasal congestion and rhinorrhea. Box 19-7 lists some of the conditions that are included in the category of vasomotor rhinitis. Allergy skin tests in patients with vasomotor rhinorrhea are negative, with less than 25% eosinophils present on a nasal swab. These patients do not fully respond to topical or systemic corticosteroids. The condition suggests hyperactivity of parasympathetic tone, blockage of sympathetic tone with vasodilation of submucosal venous sinusoids, and excessive seromucous secretions from the mucous glands. A good analogy to vasomotor rhinorrhea is functional bowel disease. Treatment is with systemic decongestants and antihistamines or topical anticholinergic agents such as ipratropium bromide (Atrovent 0.06% nasal spray). Because of the persistence of symptoms, patients should be warned about excessive use of OTC nasal sprays, which can lead to rhinitis medicamentosa.

Rhinitis Medicamentosa

The prolonged use of topical decongestants for the nose can itself induce nasal stuffiness. The condition is caused by *rebound swelling* after dissipation of the decongestive effect

Box 19-7 Conditions Included under Vasomotor Rhinitis

Drug-induced rhinitis (reserpine, nonselective β -blockers, antidepressants, oral contraceptives)
 Irritant rhinitis (smoke, gases)
 Temperature- and humidity-induced rhinitis
 Emotion- and stress-induced rhinitis
 Hormonal rhinitis (pregnancy, premenstrual, hypothyroidism)
 Idiopathic rhinitis

Modified from Mikaelian AJ. Vasomotor rhinitis. *Ear Nose Throat J* 1999;68:207.

of the nasal spray. Increasing the dose of the spray is the patient's response to the rebound swelling, and the vicious cycle is difficult to break without education and medical help.

To treat rhinitis medicamentosa, the patient must stop using the topical decongestant to allow recovery of the damaged nasal mucosa. To relieve the subsequent rebound mucosal swelling, topical and oral corticosteroids are recommended. The length of time needed to successfully treat rhinitis medicamentosa varies depending on the duration the patient has used nasal decongestants. It takes at least 2 weeks to reverse the edema and histamine sensitivity. Other forms of treatment include systemic antihistamines or decongestants, corticosteroid injection into the inferior turbinate, and nocturnal sedation. Surgery is helpful if nasal septal deviation is present. Graf and colleagues (1995) achieved a 100% success rate at the end of 6 weeks of nasal corticosteroid therapy and avoidance of nasal decongestants. It takes time and patience to educate the patient about rhinitis medicamentosa, and both are essential for the treatment to be successful.

Atrophic Rhinitis

Elderly patients are more prone to develop atrophic rhinitis, which leads to nasal congestion, crusting, and foul odor. Treatment consists of saline nose sprays and topical antibiotics. Atrophic rhinitis can also result from previous nasal surgery, use of cocaine, and autoimmune or systemic inflammatory disorders (e.g., lupus, Wegener's granulomatosis). If the cause is unclear, further workup is indicated.

Sinusitis

Symptoms of rhinitis and sinusitis are often very similar and even difficult to differentiate in many cases. Sinusitis implies inflammation of the mucosa of one or more of the paranasal sinuses. This usually coexists with rhinitis and is actually more accurately referred to as *rhinosinusitis*. Studies have shown that CT scans of patients with uncomplicated viral upper respiratory infections (URIs) have mucosal thickening and opacification of the sinuses. For this reason, most URIs are technically considered *viral rhinosinusitis*. In most cases, these changes resolve with time and symptomatic treatment. The terms *rhinosinusitis* or *sinusitis* are typically used when a bacterial infection of the sinuses is suspected. About 5% of viral URIs will progress to bacterial rhinosinusitis. An estimated 20 million cases of bacterial sinusitis occur in the United States annually, accounting for 9% and 21% of all pediatric and adult antibiotic annual prescriptions, respectively (Sinus Partnership, 2004).

Inflammatory conditions of the paranasal sinuses cause significant socioeconomic impact annually, secondary to considerable medical expense and missed workdays. Chronic sinusitis can be quite debilitating. Studies have shown that quality-of-life scores of patients with chronic sinusitis are often similar to those of other, more severe conditions (CHF, COPD). Chronic sinusitis can also exacerbate coexisting medical conditions, most notably reactive airway disease.

Sinusitis represents one of the most common disorders requiring antibiotic treatment in adults. The challenge to the clinician in evaluating the patient with possible sinusitis is to differentiate viral URI, allergic rhinitis, and even a migraine headache, which do not require antibiotics, from bacterial sinusitis, which does respond to antibiotic treatment. There still seems to be a public perception that antibiotics hasten recovery from the common cold. Some physicians prescribe antibiotics in these situations, not wanting to disappoint the patient and seeing no significant risk. In fact, evidence suggests that there is a greater likelihood of *harming rather than benefiting* the patient with inappropriate use of antibiotics (Scott and Orzano, 2001). The emergence of bacteria highly resistant to broad-spectrum antibiotics has forced the medical community to modify its behavior regarding the treatment of URIs. Antibiotics should not be prescribed unless a bacterial infection is certain or at least probable. The patient should be educated about the rationale for this and usually responds favorably.

The underlying cause of most cases of sinusitis is mucociliary dysfunction and sinus obstruction. The maxillary sinuses, anterior ethmoid sinuses, and frontal sinuses all drain through small ostia that converge into a small channel called the *ostiomeatal unit*, which then empties into the middle meatus, beneath the middle turbinate. Obstruction at the ostiomeatal unit leads to obstruction of these sinuses and secondary infection. The posterior ethmoid sinuses and sphenoid sinuses are usually affected later. Sinusitis most often follows a viral URI or an episode of allergic rhinitis. Mucosal edema, impaired local immunity, and ciliary dysfunction lead to impaired sinus drainage and mucus stasis, followed by bacterial infection. Less frequently, sinusitis can result from direct bacterial contamination from an infected tooth or trauma.

Sinusitis is classified into *acute* (symptoms up to 3 weeks), *subacute* (symptoms from 3 to 6 weeks), and *chronic* (symptoms longer than 6 weeks) cases. Cases of acute sinusitis that clear completely only to develop again quickly are referred to as *recurrent acute sinusitis*. Although the types of sinusitis share many characteristics, there are several critical differences in pathogenesis and treatment.

The most important risk factor for the development of sinusitis is rhinitis (e.g., viral, allergic). Other risk factors include anatomic abnormalities (abnormality within the sinuses, septal deviation, choanal atresia, foreign body, adenoid hypertrophy), nasal polyps (which can also occur secondary to chronic sinusitis), conditions of local or systemic immunodeficiency, cystic fibrosis, primary ciliary dysfunction (Kartagener's syndrome), secondary ciliary dysfunction (cigarette smoking, nasal decongestant abuse, cocaine abuse), gastroesophageal reflux disease (GERD), systemic inflammatory conditions (sarcoidosis, Wegener's granulomatosis), dental disease, and nasal or sinus tumors. Any of these conditions can mimic or cause rhinosinusitis. Further

workup or referral is indicated if a patient continues to struggle with nasal or sinus symptoms despite medical therapy.

The diagnosis of sinusitis is initially clinical. Imaging and cultures are not initially indicated (Reider, 2003). In 1996 the Task Force on Rhinosinusitis sponsored by the American Academy of Otolaryngology–Head and Neck Surgery developed diagnostic criteria for sinusitis. The signs and symptoms of sinusitis are divided into major and minor. *Major* signs and symptoms include facial pain and pressure, nasal congestion and obstruction, nasal discharge, discolored posterior discharge, anosmia or hyposmia, fever (acute only), and purulence on intranasal examination. *Minor* signs and symptoms include headache, otalgia or ear pressure, halitosis, dental pain, cough, fever (nonacute), and in children, fatigue and irritability. The diagnosis of sinusitis is *probable* if the patient has two or more major factors or one major and two or more minor factors. A *suggestive* history is indicated by the presence of one major factor or two minor factors.

Microbiology of sinusitis varies according to its chronicity. Acute sinusitis is most often *initially* viral. If symptoms persist, the likelihood of bacterial infection increases. Bacteria most often involved in acute sinusitis are *Pneumococcus* spp., *Haemophilus influenzae*, and *Moraxella catarrhalis*, with beta-lactamase production common in all these. Chronic sinusitis is caused by the same bacteria as in acute sinusitis, but anaerobic bacteria, *Pseudomonas* spp., and staphylococci become involved more often. The incidence of antibiotic-resistant bacteria, including MRSA and multidrug-resistant *Pneumococcus*, seems to be increasing. Polymicrobial infections are not uncommon.

Sinusitis can also be caused by fungi. *Invasive* fungal sinusitis (caused most often by *Aspergillus* or *Mucor* spp.) can be seen in patients with impaired immune function and poorly controlled diabetes. It is life threatening even with aggressive medical and surgical treatment. Much more common is a more indolent fungally mediated sinusitis. *Allergic fungal sinusitis* is seen in patients with normal immune function. This is often seen in association with nasal polyps and is thought to be the result of an aberrant immune response to the fungus rather than a true infection. Patients do not always have type I hypersensitivity to fungi. Secondary bacterial infection is often associated with this problem.

Rarer causes of sinusitis are secondary to mycobacterial or parasitic infection.

Complications of Sinusitis

Most cases of sinusitis would resolve with or without medical treatment. Sinusitis is usually treated, however, to avoid potential complications and hasten recovery. The proximity of the paranasal sinuses to the orbits and brain potentially allows infection to spread to these locations. Orbital and CNS involvement of sinusitis can lead to loss of vision and can be life threatening and therefore requires early recognition and treatment. Table 19-6 lists the potential complications of sinusitis and treatment recommendations. A high degree of clinical suspicion is required in cases of possible complicated sinusitis, especially in young children. Patients with a recent URI who present with periorbital erythema, vision change, increasing or severe headache, high fever, or altered mental status require *urgent evaluation* and treatment. Ophthalmologic, infectious diseases, and ENT consultations are obtained in cases of orbital complication. Periorbital and

Table 19-6 Complications of Sinusitis

| Complication | Physical Findings | Treatment |
|----------------------------|---|-----------------------------------|
| Periorbital cellulitis | Periorbital erythema, edema | Antibiotics: PO or IV |
| Orbital cellulitis | Erythema, edema, proptosis ± vision loss | IV antibiotics, close observation |
| Orbital abscess | Erythema, edema, proptosis ± vision loss | IV antibiotics + drainage, FESS |
| Cavernous sinus thrombosis | Erythema, edema, proptosis + vision loss | IV antibiotics + FESS |
| Meningitis | Headache, altered mental status, nuchal rigidity, fever | IV antibiotics ± FESS |
| Intracranial abscess | Headache, altered mental status, high fever | IV antibiotics + drainage, FESS |
| Mucocele or pyocele | Facial swelling ± fever ± pain | Drainage |

FESS, Functional endoscopic sinus surgery.

orbital cellulitis usually can be managed with intravenous antibiotics. The more severe orbital complications, however, usually require drainage procedures in combination with IV antibiotics. Surgical drainage also allows cultures to be obtained. Recovery from orbital complications is usually complete with prompt and aggressive treatment. Permanent vision impairment can occur even after appropriate treatment.

The CNS complications require neurosurgical, ENT, and infectious diseases consultation. High-dose IV antibiotics are administered. Surgical drainage of the sinuses is sometimes recommended to treat the nidus of the infection and identify the exact pathogen. Recovery from CNS complications is more variable and depends on the patient's age and medical history, severity of the infection, and response to treatment.

Although not always complicated infections, sphenoid and frontal sinusitis deserve special mention. In some cases, drainage of the frontal sinuses is compromised. Chronic and recurrent frontal sinusitis can lead to both intracranial and ophthalmologic complications if untreated. Large *mucoceles* or *mucopyelocetes* can also form within the frontal sinus, causing disfigurement and diplopia. These conditions usually require surgical drainage. Similarly, sphenoid sinusitis can rarely be aggressive. The carotid artery and optic nerves traverse the lateral walls of the sphenoid sinuses. The sphenoid sinus occupies a space inferior and anterior to the cranial vault. Acute or long-standing sphenoid sinusitis can progress to CNS or eye complications, or both. If frontal or sphenoid sinus involvement is noted on CT scan, ENT evaluation is usually indicated.

Medical Treatment of Acute Sinusitis

Treatment of acute sinusitis is almost always medical. Medical treatment of sinusitis, in general, is intended to restore normal mucociliary function, eradicate infection, and improve patient symptoms. Treatment to restore mucociliary function is critical and is as important as antibiotic treatment.

Improved mucociliary function allows the patient's local immunity to function better and often leads to resolution of the infection.

The patient's medical history, including allergies, must be considered. Patients with poorly controlled hypertension or coronary artery disease may not tolerate decongestants. In acute cases of sinusitis, mucociliary function can be improved by a combination of medications, including oral or topical decongestants (topically for less than 3 days), mucolytics (guaifenesin), and nasal toilet (saline mist or irrigations). Nasal saline irrigations are available over the counter or can be homemade. Both 0.9% isotonic saline and hypertonic saline irrigations are extremely beneficial. Nasal steroids are *not indicated* for acute sinusitis but may decrease symptoms and hasten recovery in some patients. Antihistamines are usually not helpful, unless there is a strong allergic component, and can actually be counterproductive by increasing mucus viscosity and mucosal dryness. Oral steroids are usually not indicated in acute sinusitis, but they may be helpful in select patients.

This leaves the practitioner with the responsibility of using good clinical judgment to appropriately prescribe antibiotics to treat acute sinusitis. Antibiotics are empirically chosen based on the expected pathogens and local antibiotic-resistance patterns. The high incidence of beta-lactamase-producing strains of *H. influenzae* and *M. catarrhalis* and the penicillin-resistant pneumococci must be considered. More prudent use of antibiotics seems to have resulted in a plateau of the emergence of antibiotic resistance of these pathogens. MRSA seems to be more common, however, especially in chronic sinusitis.

According to Cochrane Collaboration recommendations for treatment of acute sinusitis, antibiotics provide a minor improvement in simple, acute (uncomplicated) sinus infections. However, 8 of 10 patients improve without antibiotics within 2 weeks. The small benefit gained may be overridden by the negative effects of antibiotics, both on the patient and on the population in general. For acute sinusitis confirmed by radiology or nasal endoscopy, current evidence is limited but supports the use of *intranasal steroids for acute sinusitis* as a monotherapy or as an adjuvant therapy to antibiotics. Clinicians should weigh the modest but clinically important benefits against possible minor adverse events when prescribing therapy.

Many antibiotics are indicated for the treatment of acute bacterial rhinosinusitis. In addition, there are antibiotics that do not have Food and Drug Administration (FDA) approval for treatment of sinusitis but are still appropriately used.

The Sinus and Allergy Health Partnership (2004) made the following comprehensive recommendations regarding the treatment of acute rhinosinusitis:

1. A bacterial infection should be suspected if symptoms of a viral URI do not improve after 10 days, or if symptoms worsen after 5 to 7 days.
2. Antibiotic resistance is common. Specifically, intermediate resistance of *Streptococcus pneumoniae* to penicillin (PCN) is 15%, and complete resistance is estimated at 25%. Resistance of *S. pneumoniae* and *Haemophilus influenzae* to trimethoprim-sulfamethoxazole (TMP-SMX) is common, as is resistance of *S. pneumoniae* macrolides. Beta-lactamase production of *H. influenzae* and *Moraxella catarrhalis* is 30% and 100%, respectively.
3. Selection of an antibiotic should be based on severity of symptoms, whether the patient has received an antibiotic in the last 4 to 6 weeks, and the response to current antibiotic therapy after 72 hours. Mild symptoms include rhinorrhea and fatigue. Moderate symptoms include congestion, low-grade fever, and facial pain.
4. The widespread use of fluoroquinolones for mild sinusitis may promote resistance to this class of antibiotics.
5. Antibiotic choices for adults with mild disease and no recent antibiotics include amoxicillin (1.75-4 g/day, with or without clavulanate), cefpodoxime proxetil, cefuroxime axetil, or cefdinir. TMP-SMX, doxycycline, azithromycin, erythromycin, and clarithromycin may be considered in PCN-allergic patients, but the failure rate may be as high as 20% to 25%. Failure of therapy should prompt reevaluation of the patient or a switch in therapy.
6. Antibiotic choices for adults with moderate disease or with mild disease who have received recent antibiotics include amoxicillin-clavulanate (4 g/day) or a respiratory fluoroquinolone (levofloxacin or moxifloxacin). Ceftriaxone (1-2 g parenterally for 5 days) or combination therapy for gram-positive and gram-negative bacteria may also be considered. Failure of therapy should prompt reevaluation of the patient, CT scan, endoscopy with culture, or a switch in therapy.
7. Antibiotic choices for children with mild disease and no recent antibiotics include amoxicillin (90 mg/kg/day, with or without clavulanate), cefpodoxime proxetil, cefuroxime axetil, or cefdinir. TMP-SMX, doxycycline, azithromycin, erythromycin, and clarithromycin may be considered in PCN-allergic patients (especially immediate type I hypersensitivity), but the failure rate may be as high as 20 to 25%. If the patient has a true type I hypersensitivity to beta-lactams, desensitization, sinus culture, CT scan, or other intervention may be necessary. Less severe reaction may allow use of another beta-lactam antibiotic. Failure of therapy should prompt reevaluation of the patient or a switch in therapy.
8. Antibiotic choices for children with moderate disease or with mild disease who recently received antibiotics include amoxicillin-clavulanate (90 mg/kg/day). Cefpodoxime proxetil, cefuroxime axetil, or cefdinir may be used if there is a nonsevere PCN allergy (rash). Cefdinir is preferred because of high patient acceptance. Ceftriaxone (50 mg/kg/day parenterally for 5 days) or combination therapy for gram-positive and gram-negative bacteria may also be considered. Failure of therapy should prompt reevaluation of the patient, CT scan, endoscopy with culture, or a switch in therapy.

As recurrence or severity of the infection increases, broader-spectrum antibiotics are indicated. Macrolides, fluoroquinolones, augmented penicillins, and cephalosporins are useful in these cases. Culture-directed antibiotic treatment may be indicated in more refractory cases. Obtaining a culture usually requires an ENT referral, because simply swabbing the nasal cavity is not reliable. Cultures can be obtained from an endoscopically guided middle meatus swab. Maxillary sinus aspiration can also be done but is more invasive and not much more accurate than a middle meatal culture. Adjunctive treatment to help improve mucociliary function becomes more important as recurrence increases.

KEY TREATMENT

The American Academy of Otolaryngology–Head and Neck Surgery produced a consensus statement of Clinical Practice Guidelines for Treatment of Presumed Sinusitis (Rosenfeld et al., 2007). The following summary guidelines are for acute viral sinusitis (VRS), presumed acute bacterial rhinosinusitis (ABRS), and chronic rhinosinusitis (CRS). The key symptoms of sinusitis were rhinorrhea, nasal obstruction, and facial pressure or pain.

STRONGLY RECOMMENDED TREATMENT

The quality of data supporting the benefits of treatment outweighing the potential harm is strong (Grade A, B):

1. Clinicians should attempt to differentiate between viral and bacterial sinusitis.
2. The level of pain should be assessed when treating ABRS.

RECOMMENDED TREATMENT

The benefits of treatment outweigh the risks, but the data are not as strong (Grade B, C):

1. Imaging studies are not recommended for cases of uncomplicated VRS.
2. If a decision is made to treat ARS, amoxicillin should be used as first-line therapy if no PCN allergy.
3. If the patient worsens or fails to improve in 7 days, antibiotics should be started or changed.
4. The clinician should attempt to differentiate CRS from recurrent ARS.
5. The clinician should assess the patient with CRS or recurrent ARS for conditions or anatomic abnormalities that would predispose the patient to these conditions.
6. The clinician should obtain a CT scan when evaluating a patient with recurrent ARS or CRS.
7. The patient should be educated on control measures for ARS and CRS.

OPTION

There is only weak evidence that the benefit of treatment outweighs the risk (Grade D):

1. Symptom relief should be offered when treating VRS.
2. Symptom relief should be offered when treating ARS.
3. Observation without use of antibiotics may be done in cases of uncomplicated ARS with temperature less than 101° F (T <38.3° C).
4. Diagnostic nasal endoscopy should be employed in the evaluation of recurrent ARS or CRS.
5. Testing should be done for allergy and immune system dysfunction in patients with recurrent ARS or CRS.

SOR: B

Medical Treatment of Chronic Sinusitis

Medical treatment of chronic sinusitis is based on the same principles as for acute sinusitis: improvement of mucociliary function and eradication of bacteria. If chronic sinusitis is suspected, CT scan of the paranasal sinus should be ordered to confirm the diagnosis before further treatment is initiated; treatment of chronic sinusitis requires more aggressive therapy, with potential side effects. This contrasts with acute sinusitis, for which CT is not necessary before treatment. In addition to confirming the diagnosis and severity of the infections, CT can identify abnormalities that can predict a poorer response to medical treatment. This includes a posterior septal deviation, polyps, allergic fungal sinusitis, and various sinus abnormalities. The scan may also arouse suspicion of sinonasal mass or tumor, which would require earlier ENT evaluation. For all

these reasons, referral to an ENT should also be considered as risk of recurrence or chronicity increases.

Medical treatment of chronic sinusitis requires more diligence than for acute sinusitis. Mucociliary improvement is accomplished with the same medications as for acute sinusitis. It is noteworthy that there are *no* medications with indications for treatment of chronic sinusitis (and relatively few for acute sinusitis). Topical and systemic steroids can be used to improve drainage in cases of chronic sinusitis by decreasing mucosal inflammation, edema, and mucus production. Most topical nasal steroids must be used daily for several weeks to have significant benefit. Although oral steroids significantly improve symptoms, the effects may be short-lived, and the potential side effects must be considered. Patients with known allergies should be aggressively treated. It should be remembered, however, that antihistamines cause mucosal drying and mucus stasis. These may need to be stopped in patients with acute exacerbation of chronic sinusitis. Saline irrigations are extremely helpful. Allergy and asthma medications such as leukotriene inhibitors and IgE antagonists can also benefit coexisting sinusitis.

The efficacy of antibiotics in treating chronic sinusitis has not been validated in controlled studies in adults. Two consensus statements do report that antibiotic treatment is likely beneficial in adults but *not in children* (Duiker, 2004; Grade B). Because of the apparent benefit, antibiotics are typically used to treat chronic sinusitis in adults. An antibiotic with activity against staphylococci, as well as the more typical pathogens (with predicted antibiotic resistance), must be chosen. In cases of nasal polyps, an antibiotic with antipseudomonal activity may be necessary. Although no antibiotics have FDA indications for “chronic sinusitis,” appropriate choices include macrolides, broader-spectrum cephalosporins, fluoroquinolones, and augmented penicillin. “Older” antibiotics, such as TMP-SMX, clindamycin, doxycycline, and linezolid, may be quite useful in documented staphylococcal infections. Also, the addition of rifampin may be useful in treating documented staphylococcal infections.

Once chronic rhinosinusitis is suspected, ENT consultation is indicated to assist in medical management and to offer surgical options if indicated. Also, simply obtaining a middle meatal culture is extremely helpful in choosing an appropriate antibiotic. Treating chronic sinusitis requires a longer course of antibiotic treatment, often 3 to 8 weeks.

According to Cochrane Collaboration recommendations for medical treatment of chronic sinusitis, *nasal saline irrigations* for the symptoms of chronic rhinosinusitis are well tolerated. Although minor side effects are common, the beneficial effect of saline appears to outweigh these drawbacks for the majority of patients. The use of topical saline could be included as a treatment adjunct for the symptoms of chronic rhinosinusitis.

Failure of Medical Treatment of Sinusitis

When medical treatment of recurrent acute sinusitis or chronic sinusitis is not successful, further evaluation and treatment are indicated. An ENT consultation should be obtained for patients unresponsive to medical treatment of chronic sinusitis. The risk factors listed previously should be considered and modified if possible. Allergy testing should be arranged. Immunologic testing may be indicated. Pulmo-

nary evaluation may be helpful if the patient has poorly controlled reactive airway disease.

If CT has not been done, a scan of the sinuses should be ordered to evaluate the anatomy of the sinuses. If CT has already been done, and symptoms have changed or significant time has elapsed since the first scan, a repeat scan may be helpful. Before repeating the scan, ENT consultation should be considered because the consultant might have a preference for type of scan ordered. A standard sinus CT scan often contains only coronal views; more detailed scans may be necessary for surgical planning.

The CT scan will show any evidence of chronic mucosal edema of the sinuses or even complete opacification. Partial or complete bilateral sinus opacification is typically seen in cases of long-standing chronic sinusitis or polyposis. Unilateral opacification or bony erosion is more worrisome for neoplastic disease or fungal sinusitis. The size of the turbinates and position of the nasal septum can also be assessed. In cases of medical failure or intolerance to continued aggressive medical treatment, surgery should be considered. *Endoscopic sinus surgery* (ESS), or *functional ESS* (FESS), has become the mainstay of surgical intervention for chronic sinusitis. Although earlier external surgical techniques are still occasionally indicated, FESS has the advantage of leaving no external scars and specifically addresses the critical area within the sinuses: the ostiomeatal unit. The procedure is typically done under general anesthesia but can be done under local anesthesia. Success rates of greater than 90% are expected and have been reported in many studies. Some patients experience relapse of their condition, especially if they had nasal polyps. Revision surgery is offered in these cases and is usually quite successful.

Successful sinus surgery often results in fewer and less severe infections and improved response to future medical treatment. The procedure is often done with septoplasty and turbinate surgery and is well tolerated. Advancements in minimally invasive surgical techniques have allowed preservation of more normal tissue and less surgical morbidity. Nasal packing is often not necessary. When used, resorbable packs are typically applied, obviating the need and discomfort of pack removal. Potential complications of ESS include bleeding, scarring leading to further sinus blockage, loss of smell, and rare orbital and CNS injury. For this reason, surgery is undertaken only after appropriate medical treatment and careful patient consideration.

According to Cochrane Collaboration recommendations for chronic rhinosinusitis, FESS as currently practiced is a safe procedure. The limited evidence suggests that FESS has not been demonstrated to confer additional benefit to that obtained by medical treatment (with or without sinus irrigation) in chronic rhinosinusitis. More randomized, controlled trials (RCTs) comparing FESS with medical and other treatments are required, with long-term follow up.

Advances in medical and surgical treatment deserve mention. Newer allergy and asthma medications (leukotriene inhibitors and IgE antagonists) show promise in the future treatment of chronic sinusitis. New antibiotics continue to be released to treat antibiotic-resistant bacteria. Compounding pharmacies have made available topical antibiotic and antifungal formulations that are quite effective in some patients. Topical treatment is appealing because it delivers extremely high concentrations of antibiotic to the target area,

minimizing systemic side effects and, theoretically, development of resistance. Topical treatment seems more effective in patients with sinus surgery that created open sinuses, allowing antibiotic delivery. Research into the genetics of sinusitis continues and should lead to further advances in treatment.

Surgical advances include improved power surgical debridementers that spare normal mucosa, have more efficient surgery, and reduce blood loss. Packing materials have improved and often are resorbable. Image-guided surgery has become more commonplace. Balloon techniques allow dilation of the sinus ostia without tissue removal. Although not a substitute for an experienced surgeon, these advances often allow more focused and safer surgery.

Pediatric Sinusitis

Although the sinuses are not completely developed until adolescence, children can still develop sinusitis, usually involving the ethmoid and maxillary sinuses. Young children can have 5 to 10 episodes of acute rhinitis (viral URI) in a year. The usual symptoms of a URI lasting longer than 2 weeks can indicate development of bacterial sinusitis. Other symptoms indicating sinusitis in children include nighttime cough and foul breath. Children rarely complain of facial pain, which is common in adults.

Diagnoses other than sinusitis should also be considered in children with prolonged URI-type symptoms. Previously undiagnosed choanal atresia or stenosis can be present. Unilateral or bilateral nasal foreign bodies can also cause these symptoms. Environmental allergies should be considered, as should immunodeficiency, GERD, and cystic fibrosis. Many children with asthma also have coexisting sinusitis, which can complicate asthma management. Recurrent sinusitis can cause or worsen asthma exacerbations.

Chronic adenoid hypertrophy or chronic adenoiditis can mimic sinusitis in children. Adenoid hypertrophy can also *cause* sinusitis secondary to nasal obstruction, mucus stasis, and subsequent infection. This can occur with or without the presence of tonsil hypertrophy. Adenoid hypertrophy can lead to facial changes caused by chronic mouth breathing. Children with long-standing nasal obstruction tend to have an elongated, narrow face with open-mouth breathing, the "adenoid facies." Differentiating chronic adenoiditis from sinusitis can be difficult because the symptoms may be identical and the disorders often coexist.

According to Cochrane Collaboration recommendations, limited evidence suggests that *intranasal corticosteroids* may significantly improve nasal obstruction symptoms in children with moderate to severe adenoidal hypertrophy. This improvement may be associated with a reduction of adenoid size. The long-term effect of intranasal corticosteroids in these patients remains to be defined.

Medical treatment of pediatric acute sinusitis is similar to that for adults: decongestants, nasal saline irrigations or mist, and antibiotics (Duiker, 2004). The pathogens are similar to those of adults: pneumococci, *H. influenzae*, and *M. catarrhalis*. Coexisting problems (e.g., allergies) should be controlled. Diligence on the part of the parents is required because children might not tolerate nasal saline sprays willingly. If compliance is ensured, medical treatment should result in improvement in the vast majority of patients.

Children who fail medical therapy should be referred to an otorhinolaryngologist. Often, adenoidectomy is recom-

mended. In properly selected patients, this procedure has a high success rate in greatly improving symptoms. For children unresponsive to medical treatment and adenoidectomy, a CT scan should be obtained. If significant sinusitis exists, the child likely has chronic sinusitis. Medical treatment should be reattempted because it might be more effective once the obstructing adenoids have been removed. If not previously done, the child should be screened for allergies, immune deficiency, and cystic fibrosis.

The efficacy of antibiotics in the treatment of pediatric chronic sinusitis has not been validated. Unlike adults with chronic sinusitis who likely benefit from longer courses of antibiotics, evidence-based research indicates that this is not the case for children (Duiker, 2004).

If symptoms persist, ESS is considered. The surgery targets the ostiomeatal unit in hope of improving sinus drainage and aeration. A ciliary biopsy may also be done to evaluate for ciliary dyskinesia. Cultures should also be obtained to tailor postoperative antibiotics. In properly selected patients, sinus surgery has an extremely high success rate. Although rare, significant risks, including bleeding and orbital and intracranial injury, must be considered. Surgery may be especially beneficial in children with coexisting pulmonary disease (asthma or cystic fibrosis).

Sinonasal Tumors

Intranasal and sinus tumors often manifest with symptoms identical to those of more benign sinonasal conditions. Nasal obstruction, facial pressure or pain, and bloody rhinorrhea are common symptoms of a neoplastic process within the nasal cavity or sinuses. Because these symptoms are also common with sinusitis, a high index of suspicion is required, and diagnosis is often delayed.

Tumors of the external nose are usually related to prolonged exposure to the sun. Basal cell and squamous cell carcinoma are most common (see Chapter 33). Intranasal tumors can be benign or malignant. The most common growth within the nasal cavity is the *benign squamous papilloma*, caused by the human papillomavirus (HPV). This typically appears as an exophytic lesion within the nose, often at a junction between squamous and respiratory epithelium, and causes irritation and bleeding. Treatment consists of simple excision, and recurrence is uncommon. Malignant degeneration is extremely unlikely.

A much more aggressive papillary lesion is an *inverted papilloma*. These tumors often manifest as unilateral polyps and can cause symptoms of nasal obstruction, bleeding, and sinusitis. These lesions require excision because they can be locally destructive, and malignant degeneration can occur. Endoscopic excision is usually possible, although external approaches are sometimes required.

The *juvenile nasopharyngeal angiofibroma* is a tumor that occurs exclusively in adolescent boys. The tumor is located within the nasopharynx but typically causes nasal symptoms. Patients present with nasal obstruction and recurrent epistaxis. Because nosebleeds and nasal obstruction are both common problems, a high index of suspicion is required to make a timely diagnosis. These tumors can be extremely aggressive, and surgical excision is required. Recurrences are possible, and radiation therapy is recommended for some patients.

Malignant tumors of the nose and sinuses include squamous cell carcinoma, adenocarcinoma, adenoid cystic carcinoma, hemangiopericytoma, osteosarcoma, and malignant melanoma. Again, early symptoms are similar to those of sinusitis, which often results in delayed diagnosis. The prognosis ranges from extremely good to extremely poor, depending on tumor type and stage. Orbital and intracranial extension often occurs. Both regional and distant metastases result in poorer prognosis. Aggressive treatment is required and involves combined treatment with surgery and radiation, sometimes with chemotherapy.

Nasal Polyps

Nasal polyps result from inflammation, with resultant exuberant swelling of the respiratory epithelium of the nasal and sinus mucosa. Typically, polyps cause symptoms of nasal obstruction and anosmia and can lead to sinusitis. Once formed, polyps have a grayish, translucent appearance. Nasal polyps are typically bilateral and are painless and insensate if touched. Typical nasal polyps are benign. Suspicion of neoplasia or fungal infection should be higher in cases of unilateral polyps. Their exact cause is not completely understood. Nasal polyps are often seen in atopic patients. Some patients are found to have nasal polyps, aspirin sensitivity, and asthma—the “asthma triad.” Nasal polyps often coexist with chronic sinusitis. If seen in pediatric patients, nasal polyps should raise suspicion of cystic fibrosis.

Treatment of polyps consists of the usual medical treatment of sinusitis and allergies if present. *Oral steroids for nasal polyps* may reduce the need for surgery, but there are concerns about possible side effects with long-term oral steroid use. The side effects of short courses of oral steroids are less clearly defined. Duiker (2004) found only one trial that met inclusion criteria, involving 80 participants, about 75% of whom were randomized to receive oral prednisone. Quality-of-life and nasal symptom scores improved with a significant reduction in polyp size after 2 weeks of treatment versus no steroid treatment. However, the trial was small and of low methodologic quality. Oral steroids often result in temporary shrinkage of the polyps. Regrowth typically occurs shortly after the steroids are stopped. Topical nasal steroids are also sometimes effective in shrinking polyps or stabilizing their growth. Newer, more potent leukotriene inhibitors have shown promise in slowing or even reversing polyp growth in some patients, although these medications are not indicated for this use. If the polyps cause significant symptoms of nasal obstruction or sinusitis, ESS should be considered to remove the polyps and eradicate any chronic infection within the sinuses. Surgery also allows a biopsy to be done.

Although polyps often recur after ESS, the patient's subjective improvement is marked, and recurrence is often slow. In addition, the response to medical treatment is often greatly improved once the polyps have been removed. Revision surgery (and sometimes multiple surgeries over years) may be necessary.

Nasal Trauma

Traumatic injuries to the nose are extremely common and usually of little long-term significance. In some patients, however, trauma can result in significant cosmetic and

functional problems. In severe cases, nasal trauma can result in severe bleeding and cerebrospinal fluid (CSF) leakage and can even be life threatening.

Evaluation of a patient who has sustained nasal trauma requires a thorough history. The mechanism of injury must be understood. If the injury was recent, the patient must be examined for signs of cervical, mandibular, maxillary, orbital, or intracranial injury. Bleeding can be quite severe after isolated nasal trauma but usually stops spontaneously or with only digital pressure.

Initial evaluation includes assessment of the gross appearance of the face, with special attention to the possibility of other facial fractures (orbital, zygomatic, mandibular). Obvious deformity of the nose should be noted, although marked edema obscures this in some cases. Radiographs may be ordered, but their utility is variable because nondisplaced fractures usually require no treatment, and displaced nasal fractures are usually obvious on examination.

Intranasal examination is done to rule out the presence of a septal hematoma or CSF leakage. A septal hematoma results when bleeding occurs between the septal perichondrium and the underlying cartilage. The hematoma can be unilateral or bilateral. It results in a widened septum with nasal obstruction. Successful treatment requires prompt diagnosis followed by incision and drainage and packing to prevent reaccumulation. If untreated, and especially if bilateral, the hematoma leads to ischemic necrosis of the cartilage or can result in abscess formation. This can ultimately result in loss of enough septal cartilage to cause external nasal collapse, called saddle nose deformity. Because it is extremely difficult to repair, avoiding saddle nose deformity is paramount.

Severe bleeding after nasal trauma can result from a vascular injury of the ethmoidal, the sphenopalatine, or rarely the carotid arteries. ENT consultation should be obtained if severe bleeding persists. *CSF leakage* is diagnosed when clear drainage is seen dripping from one or both sides of the nose. Leakage can increase in a more dependent position. Nasal CSF leakage requires urgent ENT and neurosurgical consultation. It often resolves spontaneously but can lead to life-threatening problems such as pneumocephalus (air within the cranial vault), meningitis, and brain abscess.

Isolated nasal deformity after nasal trauma results from displacement of the nasal bones, the external nasal cartilages, or the septum. The nasal bones can often be repositioned with excellent results by performing a *closed reduction*. This is done under local or general anesthesia, usually after the initial edema has subsided and before the bones have set (7-10 days after injury). Sometimes an *open reduction*, which involves refracturing the nasal bones, is required. If the septum is greatly deviated, it can be repaired at the same time. If significant nasal deformity persists, a formal *rhinoplasty*, which more precisely addresses all aspects of the external nose, can be done later. In children with nasal fractures, closed reduction is usually recommended sooner than for adults because their fractures heal more quickly. Repair should be done within 7 days of the injury, if possible. Open reduction is generally not recommended in children because of concern for affecting future nasal growth. If necessary, rhinoplasty is delayed until nasal growth is complete, which is shortly after puberty.

KEY TREATMENT

Radiographic imaging is not recommended in patients who meet the clinical criteria for acute bacterial rhinosinusitis. Diagnosis of ABRs can be made if signs or symptoms are present 10 days beyond the initial onset of upper respiratory symptoms, or if there is a worsening within 10 days after an initial improvement ("double sickening") (Rosenfeld et al., 2007). Amoxicillin is the first line of treatment for most adults with ABRs (SOR: B).

Oral Cavity and Pharynx

Key Points

- The Infectious Diseases Society of America now recommends the rapid antigen test alone to confirm the presence of group A beta-hemolytic streptococcal (GABHS) pharyngitis in adults.
- Cephalosporins appear to be superior to penicillin in bacterial eradication and clinical cure in GABHS pharyngitis.
- Motor disorders of the esophagus are more likely to cause difficulty swallowing liquids, whereas mechanical obstruction produces dysphagia with both solids and liquids.
- From 23% to 60% of patients presenting with a globus sensation have gastroesophageal reflux disease.
- Snoring is the most common symptom of obstructive sleep apnea and is more common in men than women.

Physical Examination and Radiography

See the discussion online at www.expertconsult.com.

Acute Pharyngitis and Tonsillitis

Viral agents cause the majority of sore throats. Even when exudates are present, less than 15% of children and 10% of adults have documented group A beta-hemolytic streptococci (GABHS) as the cause. In children younger than 3 years, the predominance of a viral cause is even higher than in school-age children.

Pharyngitis caused by GABHS (*Streptococcus pyogenes*) has its peak incidence in late winter and early spring. The incubation phase is 2 to 5 days and leads to sudden onset of sore throat, painful swallowing, fever, and chills. Less frequent symptoms include headache, abdominal pain, and nausea. On physical examination, a purulent white exudate is often seen on the tonsils, and the anterior cervical nodes are tender and enlarged. There is sometimes a scarlet fever rash (a diffuse, erythematous, macular, rough rash that tends to coalesce) and soft palate petechiae. Scarlet fever is the result of exotoxin-producing strains of GABHS. Pastia's lines are caused by prominence of the rash in the flexor creases of the antecubital space or axilla. A strawberry tongue is another sign of GABHS.

A throat culture is the "gold standard" for diagnosing GABHS infection. A 5% sheep blood agar plate is used to plate the throat swab and can be read in 24 hours (sensitivity 96%). Serologic tests (antistreptolysin O [ASO] titer) are accurate but not practical to use in diagnosing an acute infection because of the time involved in obtaining results.

Rapid antigen detection tests or optical immunoassays (OIAs) are the most popular tests for detection of GABHS. Although most manufacturers claim 95% to 97% true negatives (specificity), clinical trials suggest a lower figure of 90%. True positives (sensitivity) are claimed to be 90% to 95%, but again, clinical trials show closer to 60% to 80% sensitivity.

Scoring systems based on features of sore throat have been developed. The Centor criteria for screening consist of tonsillar exudates, tender anterior cervical lymphadenopathy, absence of cough, and history of fever (Centor et al., 1981). These findings in patients with sore throat can help determine the likelihood of GABHS. When three or four Centor criteria are met, the physician may use a rapid antigen detection test. However, Centor found that only 56% of adults with all four criteria had a positive throat culture, and only 30% to 34% of adults with three criteria had a positive culture. Therefore, 60% of adults with three or four Centor criteria are probably culture negative (Bisno, 2003). The negative predictive value of two or fewer Centor criteria is very high, and testing or treatment would not be indicated. The Infectious Disease Society of America (IDSA) now recommends the use of the rapid antigen test alone to confirm the presence of GABHS in adults (Bisno et al., 2002).

A study comparing five management strategies (no treatment or testing, empiric treatment with penicillin, throat culture, OIA with culture if results negative, OIA alone) found empiric therapy the least cost-effective and culture the most cost-effective strategy when GABHS prevalence was 10%. OIA alone was as effective as OIA followed by throat culture when OIA was negative (Neuner et al., 2003). Once a test result is positive, treatment with penicillin or a cephalosporin is recommended because there has been no incidence of in vitro resistance to these drugs.

Treatment for GABHS is penicillin VK, 250 mg two or three times daily in children and 500 mg three or four times daily in adolescents and adults for 10 days. Intramuscular penicillin G benzathine, 600,000 U for a child weighing less than 60 lb (27 kg) or 1.2 million U for patients weighing more than 60 lb, can be used if compliance is a problem or if the child cannot swallow or is vomiting. Mixing the benzathine penicillin with 300,000 U procaine penicillin alleviates some of the discomfort. Penicillin-allergic patients can use erythromycin, 40 mg/kg in two or four divided doses daily for 10 days. In recurrent disease, cephalexin, 12.5 mg/kg or 250 mg three or four times daily for 10 days, can be prescribed. Alternative antibiotics include cefpodoxime (Vantin), cefprozil (Cefzil), cefuroxime axetil (Ceftin), cefixime (Suprax), cefaclor (Ceclor), ceftibuten (Cedax), loracarbef (Lorabid), azithromycin (Zithromax), clarithromycin (Biaxin), and amoxicillin-clavulanic acid (Augmentin). Cephalosporins appear to be superior to penicillin in terms of bacterial eradication and clinical cure (Pichichero and Brixner, 2006).

After treatment, 15% of throat cultures remain positive for GABHS. This is considered a carrier state. One effective way to eliminate the carrier state is to use clindamycin (Cleocin), 20 mg/kg/day in three divided doses (maximum, 450 mg/day) for 10 days (Tanz et al., 1998). Contagiousness to others is inversely proportional to the length of time that GABHS is carried. Culturing contacts is indicated only when the contact is symptomatic. Pets have been considered a reservoir for GABHS, but some evidence casts doubt on this supposition (Wilson et al., 1995).

Although antimicrobial treatment is believed to decrease the suppurative (peritonsillar abscess) and immunologic (acute rheumatic fever, acute glomerulonephritis) sequelae of GABHS infection, much is not known. *Acute rheumatic fever* had become rare until 1986, when its incidence increased; any explanation is mere speculation. There is good evidence that antimicrobial treatment shortens the symptomatic period of GABHS and plays a part in preventing acute rheumatic fever. However, acute rheumatic fever can still occur in the presence of appropriately diagnosed and treated cases of GABHS pharyngitis and even in the absence of a symptomatic infection.

Only specific serotypes of GABHS (12, 49, 55, 57, Red Lake strain) cause *acute glomerulonephritis* (AGN) because of an antigen-antibody deposition on the kidney glomerular membrane. When a patient does have GABHS infection caused by one of these strains, only 15% develop AGN. Edema, hypertension, and rusty urine are the hallmarks of AGN and occur 10 days after the infection. Prompt treatment of GABHS pharyngitis with penicillin does not appear to prevent AGN. Treatment is symptomatic to control the blood pressure and edema.

The indications for tonsillectomy after GABHS infections are six episodes within 1 year or three to four episodes within each of 2 years (Pichichero, 2004). The severity of the infections and the total number of missed workdays or school-days should also be taken into account when considering tonsillectomy.

Viral causes of pharyngitis include rhinovirus (20% of all pharyngitis) and coronavirus, adenovirus, and parainfluenza virus (5% of all pharyngitis) (Middleton, 1996). Coxsackievirus A can cause 1-mm to 2-mm red-ringed vesicles on the tonsils, uvula, and soft palate and is known as *herpangina*. Coxsackievirus A16 is the major cause of hand, foot, and mouth disease, a 1-week illness with 4-mm to 8-mm ulcers on the tongue and buccal mucosa and vesicles on the palms and soles. Incubation time for this illness is 4 to 6 days.

A type of pharyngitis similar to coxsackievirus A16 pharyngitis is caused by herpes simplex virus (HSV). Painful, shallow, red-bordered ulcers develop on the soft palate, gums, lips, or buccal mucosa and cause fever, pain, and lymphadenopathy. Acyclovir (Zovirax), 200 mg five times daily for 5 days; famciclovir (Famvir), 125 mg twice daily for 5 days; or valacyclovir (Valtrex), 500 mg twice daily for 5 days, can be used in severe cases of herpes stomatitis and lessen the duration of symptoms and viral shedding.

Epstein-Barr virus (EBV) as a cause of pharyngitis can mimic GABHS infection. It can also occur concurrently with GABHS infection. Studies have shown the two infections occurring together in 2% to 33% of cases. Prodromal symptoms to severe sore throat include malaise, anorexia, chills, and headache. Fatigue, lymphadenopathy, and hepatosplenomegaly can follow in 5 to 14 days. Pharyngitis with tonsillar hypertrophy and a membranous white tonsillar exudate lasts 5 to 10 days. Lymphadenopathy and hepatosplenomegaly can persist 3 to 6 weeks. Contact sports should be avoided for 6 weeks because of the possibility of splenic rupture. Complications that occur in less than 2% of patients with EBV infection include thrombocytopenia, hemolytic anemia, Guillain-Barré syndrome, Bell's palsy, transverse myelitis, and aseptic meningitis. Hepatitis can be seen in 20% to 50% of patients with EBV infection.

Diagnosis is made on clinical grounds supported by positive antibody tests. A CBC shows atypical lymphocytes, and

Box 19-8 Bacterial Causes of Pharyngitis Other than GABHS*

Haemophilus influenzae (epiglottitis)

*Group A β -hemolytic streptococci.

a monospot test is positive in 95% of cases of infectious mononucleosis (Middleton, 1996). Steroids (and rarely urgent tonsillectomy) are indicated when the tonsillar hypertrophy causes pharyngeal obstruction or when other life-threatening complications occur. Amoxicillin should be avoided because it often causes a rash in patients with infectious mononucleosis.

When the symptoms point to infectious mononucleosis but the monospot test or EBV titer result is negative, the patient may be infected with cytomegalovirus (CMV). The illness lasts 2 to 6 weeks and is characterized in older patients by higher fever and greater malaise but milder pharyngitis than with infectious mononucleosis. A CMV-specific immunoglobulin M (IgM) antibody test is the best means of diagnosing this infection. In immunocompromised patients, ganciclovir (Cytovene) or foscarnet (Foscavir) can control the infection. Bacterial causes of pharyngitis other than GABHS are shown in Box 19-8.

KEY TREATMENT

Although current treatment guidelines recommend oral penicillin V or intramuscular penicillin G benzathine as drugs of choice for GABHS, strong evidence supports cephalosporins as a first choice for this infection (SOR: A) (Casey and Pichichero, 2007). In countries with low rates of rheumatic fever, 3 to 6 days of oral cephalosporins to treat GABHS has comparable efficacy to the usual 10-day oral penicillin regimen (SOR: A) (Altamimi et al., 2009). Once-daily amoxicillin (750 mg to 1 g) for 10 days is as good as twice-daily or three-times-daily dosing (SOR: A) (Lennon et al., 2008).

Abnormalities of the Oral Region (eTable 19-6)**Swallowing Disorders**

Patients who experience difficulty swallowing solids or liquids have *dysphagia*. About 7% of Americans experience dysphagia in their lifetime, and 30% to 40% of nursing home residents have swallowing disorders. Motor disorders of the esophagus are more likely to cause difficulty in swallowing liquid, whereas mechanical obstruction causes dysphagia with both solids and liquids.

Pharyngeal muscle weakness or CNS disease can lead to difficulty beginning the act of swallowing. The proximal one

third of the esophagus is composed of striated or voluntary muscles, the middle one third is a combination of striated and smooth muscles, and the distal one third is entirely smooth muscle tissue. The two sphincters involved in swallowing are the upper and lower esophageal sphincters (UES and LES).

Food sticking in the throat is known as *oropharyngeal dysphagia*, and 80% of the cases are the result of neuromuscular disease (see eBox 19-5 online for causes) (Trate et al., 1996). Inability to move solids from the esophagus to the stomach is referred to as *esophageal dysphagia*, which is more common than oropharyngeal dysphagia (see eBox 19-6 online for causes). The history is extremely important in determining the cause of the dysphagia. If dysphagia is associated with chest pain, especially difficulty swallowing cold liquids, diffuse esophageal spasm is the most likely diagnosis.

A constant sensation of a lump in the throat is known as *globus hystericus* and is not necessarily associated with the act of swallowing. This diagnosis can be made only by ruling out anatomic or motor abnormalities of the pharynx, larynx, or esophagus. From 23% to 60% of patients presenting with a globus sensation have GERD as the origin (Ahuja et al., 1999). eBox 19-7 online lists head and neck symptoms related to GERD versus gastroesophageal symptoms.

If the food bolus sticks in the distal esophagus, a stricture, malignancy, or ring is most likely the cause. Achalasia or degeneration of the nerve cell bodies of the myenteric plexus leads to esophageal dilation and food retention associated with increased tone of the LES.

Motor disorders of the esophagus cause progression of dysphagia over months to years. A carcinoma should be suspected when there is a rapid progression of dysphagia for solids in an older person with anorexia and weight loss; a history of smoking and alcohol use makes this diagnosis more likely. Medication-induced esophagitis is characterized by acute retrosternal pain exacerbated by swallowing. The most common medications associated with this syndrome are the tetracyclines (doxycycline, minocycline), potassium chloride pills, iron preparations, quinidine and its derivatives, aspirin, and nonsteroidal anti-inflammatory drugs (NSAIDs).

Another mechanical reason for dysphagia is an *esophageal web*, a thin diaphragm most often in the proximal esophagus. When associated with iron deficiency anemia, the condition is known as *Plummer-Vinson syndrome*. *Pulsion diverticula* are usually seen at the level of the cricopharyngeal muscle and occur predominantly in men older than 50 years. Regurgitation of food and liquid immediately after swallowing is the hallmark of this condition, with large diverticula that can cause almost complete obstruction. A *Zenker's diverticulum* originates from the posterior aspect of the esophagus and is bounded superiorly by the cricopharyngeal muscle and inferiorly by the inferior pharyngeal muscle. Treatment is usually surgical.

Dysphagia in the pediatric population is often secondary to tonsillar hypertrophy or esophageal foreign body. Diagnostic studies include a barium esophagram with views of the pharynx, esophagus, and stomach. To detect rings and early strictures, a barium-coated tablet or marshmallow can reveal the site of narrowing. When there is radiographic evidence of a lesion, esophagogastroscopy is indicated.

If no abnormality is found, esophageal manometry should be performed. The goal of esophageal manometry is to assess the characteristics of esophageal contractions and to define the LES and the UES and their response to swallowing. Only

about 50% of patients show a definitive abnormality with this test. Provocative testing with manometry involves infusion of edrophonium, esophageal balloon dilation, or acid perfusion into the esophagus. Recording esophageal pH in an ambulatory setting can indicate if acid reflux episodes are present at the same time as the patient's symptoms.

The management of swallowing difficulties is directed toward the specific cause involved. eTable 19-7 lists the treatments for the various causes of dysphagia.

Snoring and Obstructive Sleep Apnea

Snoring is extremely prevalent but is also the most common symptom of obstructive sleep apnea. OSA occurs when the upper airway collapses during sleep, leading to obstruction, hypoventilation, and hypoxemia. OSA has been associated with development or exacerbation of hypertension, coronary artery disease, pulmonary hypertension, poor concentration, impotence, obesity, depression, and increased risk of motor vehicle crashes. It is a potentially serious medical condition that can be overlooked if not specifically sought.

Men have OSA more than women, and children can also be affected. Adults with OSA are often overweight or stocky. They are told that they snore loudly, and episodes of respiratory obstruction or gasping might be witnessed by a family member. Symptoms of OSA include loud snoring, daytime fatigue, morning headache (secondary to hypoxemia), restless sleeping habits, and frequent catnaps (often unintentionally, sometimes while driving).

Physical examination should be performed with attention to the patient's body habitus. The oral cavity should be inspected for tonsillar hypertrophy and evidence of excess soft palate tissue. The size and position of the tongue should be noted. The nose should be inspected for nasal obstruction. The size and position of the mandible and its relationship to the neck should be evaluated.

Strong suspicion of sleep apnea should be confirmed with an overnight sleep study or polysomnogram. The sleep study measures intensity of snoring, presence of apnea or hypopnea (partial apnea), oxygen saturation, sleep efficiency, and cardiac rhythm. The data are compiled and analyzed by a sleep specialist. A numeric value of the total number of apneas and hypopneas is derived, called the apnea-hypopnea index or *respiratory distress index* (RDI). An RDI of less than 5 is considered normal. An RDI greater than 5 with or without oxygen desaturation indicates sleep apnea. Some patients are found to have normal RDI values but have snoring with disrupted sleep. This condition has been described as "upper airway resistance syndrome." Treatment is similar to that for OSA.

Treatment for OSA is either nonsurgical or surgical. Nonsurgical methods are always attempted first and include weight loss and assisted nighttime ventilation by continuous positive airway pressure. CPAP essentially splints the collapsed airway open with positive pressure, given as the patient initiates inhalation. It is generally well tolerated, safe, and extremely effective in compliant patients. Unfortunately, some patients either do not tolerate CPAP or choose not to use it. Surgery is a potential option in these patients.

Numerous surgical procedures exist for the treatment of OSA. The gold standard is tracheotomy, which bypasses the upper airway obstruction and is almost always successful in eliminating sleep apnea. Obviously, most patients do not

see this as an appealing solution. For patients with severe OSA and morbid obesity, however, a tracheotomy can give extremely satisfying results. More popular procedures have been devised to try to eliminate (rather than bypass) the upper airway anatomic obstruction. Uvulopalatopharyngoplasty is used most often and entails removal of redundant oropharyngeal tissue, including the tonsils, the uvula, and a strip of soft palate. Its success depends on the severity of the OSA and the patient's anatomy. Other procedures use laser or radiofrequency tissue ablation to eliminate excess pharyngeal tissue. If nasal obstruction exists, it is corrected. In severe cases, procedures directed at the tongue base and facial skeleton have been effective in properly selected patients.

The Larynx

Key Points

- Most cases of acute stridor are secondary to inflammatory disorders such as croup, epiglottitis, and tracheitis.
- Neoplasia must be considered in adults with voice or swallowing complaints.
- Visualization of the laryngopharynx is required to evaluate any patient with persistent or severe stridor or with voice or throat symptoms.
- Parainfluenza virus is the most common cause of croup.
- Laryngomalacia is the most common cause of chronic stridor in neonates.
- Vocal cord nodules are always bilateral; polyps and cysts are usually unilateral.
- It is essential to elicit smoking and alcohol histories in patients with voice complaints because of the association with cancer.
- Although often idiopathic or iatrogenic, vocal cord paralysis requires thorough investigation.
- Vocal cord dysfunction is often misdiagnosed as asthma.

Initial Evaluation

Hoarseness, stridor, foreign body (globus) sensation, and dysphagia are all symptoms of laryngeal or hypopharyngeal pathology. When a patient presents with any of these persistent symptoms, a complete past medical and social history is essential. In addition, if hoarseness has persisted, laryngoscopy is indicated. Laryngoscopy can be performed indirectly using a mirror. If the hypopharynx and larynx are not adequately visualized with the mirror because of an excessive gag reflex, direct flexible fiberoptic laryngoscopy can be performed. A topical vasoconstrictor (e.g., 0.5% ephedrine) with a topical anesthetic (e.g., topical lidocaine) can be applied in the nose to improve patient comfort; however, this is not always necessary. The flexible fiberoptic nasopharyngoscope is then passed through the pharynx to visualize the larynx.

Radiography

Indications for imaging the larynx include evaluation of laryngeal tumors and traumatic laryngeal injuries. CT or MRI is performed to evaluate depth of invasion with tumors. CT is the preferred method for imaging malignant and nonma-

lignant disease, although MRI has certain indications. Traumatic injuries are best evaluated by CT scan. The modalities to assess stridor are directed by the history and physical examination. Available imaging techniques include chest radiography (PA and lateral films), neck radiography (PA and lateral films), and fluoroscopy. Contrast esophagography may be necessary to evaluate for vascular anomalies that can cause airway and esophageal compression or to rule out tracheoesophageal fistulas.

Special Studies

Airway fluoroscopy is useful for evaluating pediatric stridor. Fluoroscopy provides a dynamic picture of the entire airway from the nasopharynx to the carina. This facilitates the identification of obstructive lesions or foreign bodies during both phases of respiration.

A more specialized examination called video laryngeal stroboscopy (VLS) is performed by a speech/language pathologist. This technique allows highly detailed views of the larynx and also allows evaluation of the gross movement of the vocal cords and their vibratory motion. VLS is an excellent modality to photo-document lesions of the laryngopharynx. VLS is also helpful to voice therapists in identifying and following patients with voice disorders, including hoarseness and paradoxical vocal cord dysfunction (see later discussion).

Finally, direct laryngoscopy using a rigid laryngoscope can be performed, usually in the OR. Indications include the need for further evaluation and biopsy of pathology of the larynx.

Laryngitis

Laryngitis is the most common cause of acute hoarseness. It is secondary to diffuse swelling of the larynx. Viral infections are the most common cause and are often associated with other upper respiratory tract symptoms. Treatment is conservative, and recommendations include relative voice rest and avoidance of inhalational substances such as cigarette smoke or other irritating substances. Humidification may be helpful. Symptoms from viral laryngitis usually improve within days; if hoarseness persists longer than the typical several days, the physician should consider other causes, such as bacterial infection with respiratory organisms (e.g., *M. catarrhalis*, *H. influenzae*). For this reason, a course of antibiotics directed at these pathogens may be helpful, especially if symptoms persist even after conservative treatment.

Other uncommon infectious causes of laryngitis include tuberculosis and syphilis. Fungal infections can also localize to the larynx. Of these, *Candida albicans* is the most common and is found in immunocompromised patients, patients using inhaled steroids, and those using long-term, broad-spectrum antibiotics. Characteristic findings on examination include a diffuse reddened mucosa covered by white patches. Topical treatment includes nystatin, miconazole, or clotrimazole; systemic therapy includes fluconazole or ketoconazole.

Stridor

Stridor is noisy breathing. Stridor is a symptom, not a definitive diagnosis. It results from turbulent airflow and results from some degree of airway obstruction, usually at the level

of the laryngopharynx or trachea. Stridor can affect both adults and children, but children present special diagnostic and therapeutic challenges because the antecedent history may be limited, physical examination is more challenging, and their small airways are more susceptible to critical obstruction. Because of the small airway diameter in infants and children, even small and subtle abnormalities can cause stridor and obstruct the airway.

It is helpful to localize stridor in the respiratory cycle. In general, *inspiratory* stridor typically is caused by an obstruction at or above the level of the true vocal cords, whereas *expiratory* stridor is usually localized to the more distal tracheobronchial tree. Biphasic stridor is usually caused by an obstruction at the true vocal cords, typically at the immediate subglottic level.

The medical history provides valuable information in the evaluation of stridor. In the pediatric population, a history should include questions about cyanosis, feeding difficulty, failure to gain weight, and retractions. Time of onset of stridor, birth history, prematurity, and need for immediate intubation at birth may help to identify the cause of stridor. A past medical history of smoking or ethanol abuse in an adult patient should raise the suspicion of a neoplastic process. Factors that tend to exacerbate the stridor are noted. These include change of intensity of stridor when in different positions, when crying, and when feeding. Previous intubation or laryngotracheal trauma can lead to acquired subglottic or tracheal stenosis. The presence of fever and a history of acute onset may be significant for an infectious process, including epiglottitis, croup, or tracheitis. New-onset stridor or increased stridor may portend impending airway distress, which would require more immediate workup, close monitoring, and possibly the need to stabilize the airway.

The severity of the obstruction and the need for intervention are sometimes difficult to determine. A child with a partially obstructed airway can have stridor but may not appear to be in respiratory distress. Intervention might or might not be needed. Examination should include documentation of stridor in the phase of respiration and whether suprasternal or intercostal retractions are present. The patency of the nose, oral cavity, and oropharynx should be noted. Large tonsils and adenoids can contribute to obstruction of the airway. The neck should be palpated for any masses that can cause extrinsic compression. Significant obstruction can cause signs of tachycardia, tachypnea, confusion, restlessness, or obtundation. Visualization of the larynx is paramount. Flexible fiberoptic laryngoscopy is the most useful modality in the workup of stridor. This usually requires an ENT consultation. It is easily performed in infants and adults.

There are many causes of stridor in the adult and pediatric population. The differential diagnosis includes lesions affecting various parts of the airway (see **eBox 19-8** online). Pediatric patients are more likely to have congenital causes of stridor, whereas any age group may have stridor secondary to trauma; inflammation; neoplasia, polyps, or papillomas; and foreign bodies. Common congenital anomalies include laryngomalacia, true vocal cord paralysis, subglottic stenosis, laryngeal webs and clefts, subglottic hemangiomas, anomalous great vessels, and complete tracheal rings. Most cases of acute stridor are caused by inflammatory disorders, including croup, epiglottitis, and tracheitis. Chronic causes

of stridor are more likely to be congenital, neoplastic, or from airway stenosis.

The most common cause of acute stridor in the pediatric population is *croup* (laryngotracheobronchitis). The parainfluenza virus is the most common cause and affects primarily the subglottic area but can also affect other portions of the laryngotracheal complex. Stridor can be inspiratory or biphasic and is often associated with a barking cough. Radiographs usually show the typical subglottic narrowing caused by edema. The typical age group is 6 months to 2 years, but the condition can be seen in children up to 5 years. The infection and inflammation are usually self-limiting, and conservative management is recommended. Evidence supports the routine use of corticosteroids in most children with croup (Husby et al., 1993). Intervention at an earlier phase of the illness reduces the severity of symptoms and the rates of return to a health care practitioner for additional medical attention, ED visits, and hospital admissions. Many children respond to a single, oral dose of dexamethasone. For those who do not tolerate the oral preparation, nebulized budesonide or intramuscular dexamethasone are reasonable alternatives.

According to Cochrane Collaboration recommendations regarding glucocorticoids for croup, dexamethasone and budesonide are effective in relieving the symptoms of croup as early as 6 hours after treatment. Fewer return visits and (re)admissions are required, and hospital stay is shortened. Dexamethasone is also effective in patients with mild croup (SOR: A).

Severe cases of croup can manifest with significant respiratory distress or even obstruction. Therapy in these patients requires hospitalization (ICU in some cases); treatment includes corticosteroids, supplemental oxygen, fluids, humidification, nebulized racemic epinephrine aerosols, heliox, and occasionally intubation. Complications from croup include airway obstruction, pneumonia, pulmonary edema, and cardiac failure.

Laryngomalacia is the most common cause of chronic stridor in neonates and is characterized by high-pitched inspiratory stridor that can be intensified with agitation, feeding, and placement in the supine position. The disorder is caused by immaturity of the laryngeal cartilages and is typically seen on examination as an omega-shaped epiglottis and floppy aryepiglottic folds that partially obstruct the laryngeal inlet on inspiration. The key to the diagnosis lies in the history and typical findings on flexible fiberoptic laryngoscopy. Airway fluoroscopy provides a dynamic evaluation of the laryngotracheal complex and often shows a component of tracheomalacia as well (laryngotracheomalacia). Treatment is rarely needed, because the problem is self-limiting and resolves by 18 months of age. Gastroesophageal reflux is extremely common, because the increased pressure gradient needed for adequate ventilation causes an increase in acid reflux into the esophagus. This exacerbates the condition by causing a component of reflux laryngitis. Rarely, failure to thrive because of feeding problems, cor pulmonale, or persistent desaturations while asleep can indicate the need for surgical intervention to improve the airway. Even if uncomplicated laryngomalacia is suspected, ENT evaluation is still recommended to confirm the diagnosis.

True *vocal cord paralysis* is another common cause of congenital stridor and usually occurs at birth to 2 months of age. In newborns, the cause is usually injury to the vagus nerve sustained at birth, or it can be secondary to CNS abnormali-

ties. Unilateral paralysis is fortunately more common than bilateral paralysis, which causes airway obstruction. The diagnosis is confirmed by flexible fiberoptic laryngoscopy. Workup also includes barium swallow, neck and chest radiography, and cardiology consultation to rule out a cardiothoracic cause of vagal paralysis. Treatment is rarely necessary because most patients improve or compensate adequately with the opposite vocal cord. Bilateral vocal cord paralysis manifests with a high-pitched stridor. MRI of the brain should be included in the workup to rule out hydrocephalus and Arnold-Chiari malformation. Emergent airway intervention by intubation or tracheotomy might be necessary.

Adults may also be affected by vocal cord paralysis, either unilateral or bilateral. Possible etiologies include neoplastic processes, traumatic injuries to the recurrent laryngeal nerve, or idiopathic causes. If the cause is known (e.g., occurring after cervical surgery resulting in recurrent laryngeal nerve injury), further workup may not be recommended. If the cause is not clear, imaging of the brain, neck, and chest is ordered to rule out a compressive lesion affecting the recurrent laryngeal nerve.

Recurrent respiratory papillomatosis occurs in all ages but is more common in children. It is the most common benign tumor of the airway and is usually found on the true vocal cords and supraglottic and subglottic areas. The causative agent is human papillomavirus. Symptoms usually begin with hoarseness or aphonia and progress to stridor and dyspnea at a later stage of disease. Treatment is by endoscopic removal using the carbon dioxide laser or pulsed dye laser (PDL), and recurrence is common. It can progress to complete airway obstruction and eventually death. Repeated procedures are required. Interferon has been used for severe cases. The antiviral drug cidofovir has demonstrated efficacy against recurrent respiratory papillomatosis and is considered a promising new adjuvant treatment for this disease. The HPV vaccination program in the female adolescent population may lead to a decreased incidence of pediatric laryngeal papillomas by reducing the vertical transmission of the virus from mother to baby.

Subglottic tracheal stenosis is caused by cicatricial scarring of the subglottic trachea and can be congenital or acquired. This area is often affected because the cricoid cartilage is the only complete ring in the trachea and is the narrowest segment in the airway. Acquired subglottic stenosis is most frequently a result of long-term intubation, with traumatic injury to the subglottic segment causing pressure necrosis and subsequent scarring. It may be idiopathic. Subglottic stenosis can occur in adults or children. Patients with severely stenotic segments causing significant respiratory symptoms usually require surgical intervention that includes splitting the subglottis with short-term stents, use of cartilage grafts, or placement of long-term stents.

Although many of the etiologies previously listed may also cause stridor in the adult population, most often an adult who presents with stridor will have this symptom secondary to subglottic tracheal stenosis, inflammation or edema of the larynx, neoplasia, or vocal cord paralysis. The workup is tailored to the history and endoscopic findings. In general, treatment of stridor depends on the etiology. The critical issue is stabilizing the airway in hopes of preventing catastrophe. Some conditions may respond to medical treatment, but any patient with stridor should be treated as having an impending

airway obstruction until proved otherwise. ICU observation may be required, with personnel available to stabilize the airway by intubation or tracheotomy. ENT consultation is recommended for further evaluation and more definitive treatment.

Laryngeal Trauma

Injury to the airway is an important cause of death in patients with head and neck trauma. Laryngeal trauma must be recognized early to avoid catastrophic sequelae. Securing the airway is the most important initial step in the management of these injuries to preserve life. The most preventable factor in morbidity and mortality is likely a delay in diagnosis. Less severe laryngeal injuries may initially go undiagnosed, whereas major injuries can lead to early mortality.

Blunt trauma is a common cause of death in motor vehicle crashes. The mechanism of blunt laryngeal trauma is typically caused by a hyperextension of the neck (i.e., against the dashboard) with compression and fixation of the larynx against the cervical spine, which leads to fracture or comminution of cartilage with associated soft tissue injury. Laryngotracheal disruption can occur from “clothesline” injury, which can occur with motorcycle and snowmobile accidents.

Penetrating trauma is becoming more common with an increase in civilian violence. Knife and gunshot wounds are the most common cause of death in homicide cases. Other traumatized structures in the neck can include the great vessels, the esophagus, and the cervical spine.

Signs of laryngotracheal trauma include tenderness over the larynx, anterior neck contusion, subcutaneous emphysema, palpable fractures or crepitus, loss of thyroid prominence, tracheal deviation, and hemoptysis. Symptoms include hoarseness, shortness of breath, inability to tolerate the supine position, and dysphagia.

Examination should include flexible fiberoptic laryngoscopy in every patient, if possible, to evaluate the anatomy and function of the larynx. Diagnostic imaging includes cervical spine films, chest films, and CT scan. Unless physical examination and flexible fiberoptic laryngoscopy are normal, CT should be done in most cases. The decision to take a patient to the OR is based on history, physical examination, flexible fiberoptic laryngoscopy, and CT scanning.

As with any trauma patient, management of the airway is of primary importance. Some controversy still exists on the optimal management of the airway. Most authors recommend awake/local tracheotomy as the safest and least traumatic method of securing the airway in an adult patient with laryngeal trauma. Some reports recount the disastrous outcome of a lost airway after attempted oral or nasal intubation in patients with laryngeal trauma. However, many still advocate intubation as the initial method of securing the airway. Emergency cricothyroidotomy can be performed if time does not permit a formal tracheotomy.

Hoarseness

All patients who present with hoarseness should be questioned about the history, the duration, and the progression of symptoms. Hoarseness may be categorized as chronic or acute. Acute hoarseness is rarely secondary to a malignant process. Acute hoarseness usually results from vocal abuse, laryngitis, or smoking. Malignancy should be considered in

patients with chronic hoarseness, but the differential also includes GERD, polyps, nodules, neurologic disorders, papillomas, and functional voice disorders (see eTable 19-8 online).

Other symptoms can coexist with hoarseness. Cough can be secondary to irritation of the vocal cords from acute or chronic inflammation but can also indicate cancer of the larynx or lung. Dysphagia or odynophagia can be present from disorders of the pharynx and esophagus. Hemoptysis with hoarseness should be considered secondary to a malignancy until proved otherwise. A history of smoking and vocal abuse is an important consideration. Clear visualization of the larynx by indirect or direct laryngoscopy is absolutely necessary for all patients who present with hoarseness that does not resolve on its own or with medical therapy. This can require referral to an otorhinolaryngologist unless the family physician has training and experience in the procedures.

An unusual cause of voice problems is *spasmodic dysphonia* (or laryngeal dystonia). The exact etiology is unknown but is thought to be a CNS condition classified under “focal dystonias.” It typically causes a harsh staccato voice but may cause breathiness. Spasmodic dystonia responds poorly to voice therapy but has been shown to respond very well to botulinum toxin injections into the larynx, done endoscopically or externally. The treatment weakens the muscles and lessens the symptoms for several months. Repeat injections are usually done, and response to treatment can decrease over time.

Vocal Cord Paralysis

Vocal cord paralysis can manifest itself as hoarseness. However, many patients are able to maintain a relatively normal voice because of compensation from the opposite vocal cord. Patients can present with shortness of breath while conversing, cough when swallowing, aspiration, or recurrent pneumonia. They may complain of the inability to hold a breath while exerting against a closed glottis (Valsalva maneuver). Visualization of the larynx by indirect or flexible fiberoptic nasolaryngoscopy usually reveals an immobile, sluggish vocal cord in a paramedian position.

Paralysis can result from peripheral (recurrent laryngeal or vagus) nerve involvement or a CNS disorder (e.g., CVA). Approximately 90% of vocal cord paralysees result from dysfunction of the peripheral nerve. Most causes of paralysis are found after a careful history and physical examination (see eBox 19-9 online). Because of the course of the recurrent laryngeal nerve around the arch of the aorta on the left and around the subclavian artery on the right, a chest x-ray film is initially necessary to rule out compression from an intrathoracic process invading or compressing the nerve. CT or MRI may be useful for imaging the brain or the course of the recurrent laryngeal nerves. VLS is very useful and often yields further diagnostic and prognostic information.

Surgical trauma remains the most common cause of unilateral vocal cord paralysis. This is common after thyroidectomy, carotid artery surgery, or transcervical spine procedures. Neoplastic processes, including thyroid, lung, and esophageal cancers, must always be ruled out as a cause of either compression or invasion. Skull base tumors and mediastinal lesions are less common causes of paralysis. Careful palpation of the neck to rule out masses and evaluation of other cranial nerves help identify these problems.

KEY TREATMENT

The American Academy of Otolaryngology–Head and Neck Surgery produced a consensus statement of Clinical Practice Guidelines for Hoarseness (Dysphonia).

STRONGLY RECOMMENDED TREATMENT

The quality of data supporting the benefits of treatment outweighing the potential harm is strong (Grade A, B):

1. Clinicians should not routinely prescribe oral antibiotics to treat hoarseness.
2. Voice therapy should be employed for patients with hoarseness that affects voice-related quality of life.

RECOMMENDED TREATMENT

The benefits of treatment outweigh the risks, but the data are not as strong (Grade B, C):

1. Hoarseness should be diagnosed in a patient with an altered quality of voice.
2. Patients with hoarseness should be assessed with history or physical exam with attention to previous factors or treatments that may have affected the recurrent laryngeal nerve or larynx. This may include neck or chest surgery or radiation therapy, endotracheal intubation, tobacco use, or occupational vocal overuse.
3. The clinician may perform laryngoscopy (or refer) if hoarseness persists after 3 months, or sooner if suspicion of serious illness is high.
4. CT or MRI should not be performed until the larynx has been visualized (these tests may not be necessary).
5. Antireflux medications should not be prescribed in the absence of other signs or symptoms of reflux.
6. Clinicians should not routinely prescribe oral corticosteroids to treat hoarseness.
7. Laryngoscopy should be performed before recommending voice therapy.
8. Clinicians should advocate for surgery as an option in cases of suspected malignancy, soft tissue lesion, or glottic insufficiency.
9. Patients should be referred for possible treatment with botulinum toxin in cases of spasmodic dysphonia.

OPTION

There is only weak evidence that the benefit of treatment outweighs the risk (Grade D):

1. The clinician may perform laryngoscopy (or refer) at any time after diagnosis of hoarseness.
2. Antireflux medications may be prescribed in patients with hoarseness if there are signs of chronic laryngitis with laryngoscopy.
3. Patients with hoarseness should be educated on control and prevention methods.

SOR: A; B.

Bilateral vocal cord paralysis typically manifests with significant respiratory distress caused by obstruction of the glottis from bilateral medialization of vocal cords. Many of these patients need emergent establishment of the airway by intubation or tracheotomy. Causes of bilateral vocal cord paralysis include thyroid or cervical spine surgery or CNS disorders. Hydrocephalus or an Arnold-Chiari malformation can cause bilateral paralysis via brainstem herniation with stretching of the vagus nerves. Treatment in these circumstances is aimed at stabilizing the airway and treating the underlying problem, with the paralyzed cord usually returning to normal function after a few months.

There are numerous surgical techniques to improve vocalization. Endoscopic injection of autologous, allogenic, or alloplastic substances can provide temporary and even permanent improvement by medializing the weak vocal cord so that the

Figure 19-7 Intraoperative photograph of true vocal cords with nodules in 25-year-old teacher.

mobile vocal cord can make contact. Open surgical approaches can also be performed for permanent unilateral paralysis, with excellent results. Medialization of the vocal cord with the use of alloplastic materials is now common. Surgical options to correct permanent bilateral vocal cord paralysis include removal of a portion of the arytenoids or vocal cords to open the airway; permanent tracheotomy is a last resort.

Vocal Cord Nodules

Vocal cord nodules result from long-term vocal overuse or abuse. Nodules are typically seen as symmetric raised areas at the anterior aspect of each vocal cord. These occur more often in women, boys, lecturers, coaches, and professional singers. The most common symptom is hoarseness and a persistent raspy voice. Smoking, allergies, and GERD tend to aggravate the condition and can prevent healing.

Nodules are always bilateral and classically occur at the junction of the anterior one third and posterior two thirds of the vocal cords (Fig. 19-7). Nodules must be distinguished from polyps, which are smooth and often unilateral, and granulomas, which tend to be located more posteriorly on the vocal cord. Treatment is initially conservative. The patient is referred for voice therapy, which consists of counseling, vocal reeducation, relative voice rest, and psychotherapeutic rehabilitation. Most patients respond after several sessions of voice therapy, but satisfactory improvement can take up to 12 to 18 months. Measures to control acid reflux and avoidance of irritating substances such as cigarette smoke are also routinely recommended. Surgery is reserved for rare patients who do not respond to voice therapy and consists of endoscopic removal. Postoperative voice therapy and acid reflux control are always indicated after surgical removal of nodules.

Reflux Laryngitis

Reflux laryngitis, also known as *laryngopharyngeal reflux* (LPR), is a relatively common condition. Many patients do not have the classic symptoms of GERD, including heartburn, and

the correct diagnosis is often initially overlooked. Constant throat clearing may be the only presenting symptom. Other manifestations include a feeling of a lump in the throat with a choking sensation (*globus pharyngeus*), odynophagia, dysphagia, chronic cough, and hoarseness. The patient may also complain of postnasal drainage. Spicy foods, fats, caffeine, chocolate, beer, milk, and orange juice are known to exacerbate the condition by lowering LES pressure. Several medications increase reflux of acid into the esophagus, such as beta blockers, calcium channel blockers, diazepam, and progesterone. Obesity and sleep apnea also predispose the patient to GERD and reflux laryngitis.

A careful history and examination allow the diagnosis to be made. Findings on indirect or flexible fiberoptic laryngoscopy are nonspecific and include edema, erythema, and redundancy of the mucosa around the arytenoids and postcricoid area. Occasionally, small granulomas are present posteriorly near the vocal processes of the arytenoids. Studies that help confirm the diagnosis of GERD include barium swallow, pH probe, esophageal manometry, and esophagoscopy. Gastroenterology consultation may be necessary.

Often the diagnosis of reflux laryngitis cannot be confirmed or excluded with a trial of empiric therapy. The treatment for reflux laryngitis consists of diet and lifestyle modifications and acid-reducing medications. Diet modification includes avoidance of foods and substances known to increase acid reflux. Lifestyle modifications include avoidance of eating near bedtime, elevation of the head of the bed 6 to 10 inches (15-25 cm), weight loss, and avoidance of tight-fitting clothing. Medical therapy usually begins with a trial of H₂ blockers or preferably daily dosing of proton pump inhibitors (PPIs). Refractory or severe cases usually respond well to twice-daily PPI therapy. Although most patients respond to treatment, resolution of symptoms can take several months after initiating proper treatment. It is critical that visualization of the larynx be obtained early if the patient's symptoms persist, to rule out more serious pathology such as neoplasia.

Cancer of the Larynx

Squamous cell carcinoma is by far the most common malignancy of the larynx. Laryngeal cancer accounts for 1% to 4% of all malignancies detected every year. Peak age group is between 60 and 65 years old, and it is more prevalent in men than in women (8:1), although the incidence in women is rising. Malignancies of the larynx are most common in smokers and alcohol abusers. When both these factors are present, the risk of developing cancer becomes 50% greater than the additive risk of each. Only 2% to 5% of laryngeal cancer patients have no history of smoking. Thus, it is extremely important to elicit smoking and alcohol histories in patients with head and neck complaints.

Hoarseness can be a very early symptom, making most cancers of the larynx curable because they are detected early. For this reason, hoarseness should never be simply attributed to "laryngitis" without proper evaluation. Other symptoms, including sore throat and referred otalgia, can exist without hoarseness. These patients are often treated incorrectly with antibiotics for an extended period and referral is delayed, thereby increasing morbidity and mortality.

Detection of cancer requires visualization of the larynx. Indirect or direct laryngoscopy usually shows a discrete, well-circumscribed exophytic lesion in the endolarynx, most frequently on one of the true vocal cords. A critical concern is potential airway obstruction in bulky tumors; emergent airway intervention is fairly common. The neck should be palpated to evaluate for cervical lymphadenopathy. Metastasis to the lungs or brain is also possible.

Several modalities of treatment exist for laryngeal cancer. Carcinoma in situ and leukoplakia can be treated with laser vaporization. Invasive carcinoma is usually treated with radiation or surgery or both, depending on the stage of disease. Numerous partial-laryngectomy surgical techniques are available that have high cure rates and preserve the voice. Total laryngectomy with a permanent tracheostomy is reserved for late-stage and recurrent tumors. Speech restoration is still possible after total laryngectomy. In some institutions, cancers of the larynx are treated initially with radiation, with significant rates of cure and voice preservation. Radiation therapy and chemoradiation can also be used to preserve the larynx, avoiding total laryngectomy. Studies to determine the ideal chemo/radiation treatment are ongoing. Patients unresponsive to radiation or chemotherapy are treated surgically, usually with total laryngectomy. Neck dissection is required in patients with cervical metastases.

The Neck

Physical Examination

See the discussion online at www.expertconsult.com.

Neck Masses

Proper evaluation of a neck mass includes obtaining a complete history and performing a thorough examination of the neck and all mucosal surfaces. Imaging options include CT with contrast, MRI with contrast, and ultrasound, which may assist in the diagnosis and help define the extent of a lesion. Classification includes congenital, inflammatory, and neoplastic disorders. In general, pediatric neck masses are usually inflammatory, followed by congenital lesions. Neoplasia occurs less often in pediatric patients. In adults, neoplasia is by far the most common entity, with inflammatory causes less common and congenital masses rare.

Congenital Neck Masses

Congenital neck masses are common in children but can occur in any age group. These are the most common cause of noninflammatory neck masses in the pediatric population. Classifying these into midline or lateral location helps in the workup because congenital neck masses occur in consistent anatomic sites (see eBox 19-10 online).

Midline Neck Masses

Thyroglossal duct cysts are the most common anterior midline neck masses in children. They are remnants of the descending tract of the thyroid gland from the foramen cecum at the base of the tongue to its normal position in the lower neck.

Figure 19-8 Photograph of 9-year-old child with midline neck mass (arrow) near the hyoid bone. Swallowing produced movement in the mass. Surgical excision with pathologic evaluation demonstrated a thyroglossal duct cyst.

Cysts or fistulas can occur anywhere along this tract and can intermittently become infected. Physical examination usually reveals a 2-cm to 4-cm mass in the anterior neck that moves with swallowing and elevates with tongue protrusion (Fig. 19-8). Treatment is surgical excision of the cyst and the tract, including the midhyoid bone, to the base of the tongue (Sistrunk procedure). There have been reports of neoplastic transformation of these cysts. Recurrence is possible.

Dermoid cysts typically develop along midline embryonic fusion planes and are composed of ectodermal and mesodermal embryonic remnants. Their usual location in the neck is in the submental area. They are also found frequently along the dorsum of the nose. Dermoid cysts tend not to move with swallowing or elevate with tongue protrusion, unlike thyroglossal duct cysts. Treatment is surgical excision.

Ranulas are cystic lesions that are usually present in the floor of the mouth. They can become “plunging” and extend through muscle planes into the upper midneck area. Plunging ranulas are thought to occur from mucus extravasation from a blocked salivary duct. Physical examination of a plunging ranula reveals a cystic mass in the submental area with or without a cystic mass in the floor of the mouth.

Lateral Neck Masses

Branchial cleft cysts are common congenital abnormalities found in the lateral neck area and are caused by failure of obliteration of the embryonic branchial clefts during development. Abnormalities can also manifest as sinus tracts or fistulas in the skin. These can become intermittently infected, especially after URIs.

Second branchial cleft abnormalities are by far the most common. These usually manifest as masses anterior to the sternocleidomastoid muscle with or without a fistulous opening. The sinus tract passes between the external and internal carotid arteries and ends in the tonsillar fossa. Treatment is

complete surgical excision of the cyst and sinus tract after control of infection with appropriate antibiotics. First branchial cleft cysts are less common and manifest as a duplication abnormality of the external auditory canal (type I) or as an infected mass near the angle of the mandible with a sinus tract passing superiorly through the parotid salivary gland (type II).

Lymphangiomas (cystic hygromas) are congenital lymphatic masses often found in the neck. They usually manifest during the first year of life and often enlarge after a URI. They can also increase in size after hemorrhage into the cystic cavities. Lymphangiomas form from a failure of complete development and subsequent obstruction of the lymphatic system. They are most frequently found as an asymptomatic mass in the posterior triangle of the neck but can also be found anteriorly, causing airway or swallowing problems. Physical examination reveals a nontender, fluctuant, soft, spongy mass without discrete margins. Surgery is the mainstay treatment for lymphangiomas, although other modalities of interest include intralesional injection sclerotherapy and systemic interferon.

Hemangiomas are the most common congenital malformations. Most are cutaneous, but they can also be found in deep tissues. The most common deep location in the head and neck is the masseter muscle. Hemangiomas are characterized by appearance at or after birth, followed by a rapid proliferative phase at 6 to 18 months of age. The lesion then reaches a plateau phase, followed by a slow, involutional phase over 6 to 8 years. Even large, uncomplicated lesions left untreated usually undergo almost complete resolution. Conservative management is almost always recommended.

Certain locations, including the nasal tip, lips, and eyelids, can cause severe functional or cosmetic deformities, and referral for removal may be appropriate. Massive lesions can cause high-output heart failure or a consumptive coagulopathy (Kasabach-Merritt syndrome), whereas others can become ulcerated, infected, or hemorrhagic. Other forms of treatment for complicated lesions include interferon alfa-2b and corticosteroids. Cutaneous lesions may be treated with laser therapy.

Neoplastic Neck Masses

Benign lesions in the head and neck include *lipomas* and *fibromas* and require no treatment unless they cause significant functional or cosmetic deformity. Sebaceous cysts and epidermal inclusion cysts are also common and usually need to be excised because of the high incidence of recurrent infection.

All neck masses in adults should be presumed to be malignant until proved otherwise. The most common malignant neck mass in adults is metastatic *squamous cell carcinoma*. Primary tumors are usually found in the upper aerodigestive tract or skin. Smoking and alcohol abuse are etiologic factors. Careful examination of all mucosal surfaces of the head and neck is crucial to identify the primary tumor site. Endoscopy with biopsies is the first step in the diagnosis; surgical treatment of the primary site involves neck dissection, radiation, or both.

Lymphomas are one of the most common malignancies of the neck in children but can occur at any age. Patients can present with lymphadenopathy associated with constitutional symptoms (night sweats, fever, weight loss), hilar adenopathy, or hepatosplenomegaly. Diagnosis is confirmed

by excisional biopsy. Most head and neck lymphomas are treated with a combination of radiation and chemotherapy.

Rhabdomyosarcoma is a common childhood neoplasm with peak incidence at age 5 years. Early symptoms include a painless, enlarging mass or symptoms related to obstruction by tumor. Approximately 35% of rhabdomyosarcomas manifest in the head, neck, and orbit. Embryonal rhabdomyosarcoma and botryoid sarcoma (a variety of embryonal rhabdomyosarcoma) are most common in the head and neck, accounting for 75% of cases. Other forms include alveolar and pleomorphic. Diagnosis is made by excisional biopsy, and treatment is multimodal, including surgery, radiation, and chemotherapy.

Carotid body tumors are paragangliomas that arise from the adventitia of the common carotid bifurcation. They are thought to arise from derivatives of neural crest cells and are members of the diffuse neuroendocrine system. They can be associated with other tumors of similar origin, including medullary thyroid carcinoma, parathyroid adenoma, and pheochromocytoma, in up to 7% of cases. Familial incidence is 8% to 10%, and inheritance is autosomal dominant. A high incidence of bilateral carotid body tumors occurs in familial paraganglioma syndromes, and 1% to 3% of these tumors actively secrete substances such as catecholamines or serotonin. Symptoms of catecholamine secretion include headache, perspiration, palpitations, pallor, and nausea. Screening for blood and urinary catecholamines should be performed to rule out a secreting tumor or pheochromocytoma. Symptoms of serotonin secretion are carcinoid syndrome, including diarrhea, flushing, severe headaches, and hypertension.

Other tumors of the head and neck arise from neurogenic tissue. These include schwannomas, neurofibromas, neurofibrosarcomas, and neuroblastomas. These tumors can manifest with associated cranial nerve deficits. Treatment is surgical excision.

Inflammatory Neck Masses

Reactive lymph nodes from a viral infection should be treated expectantly, whereas bacterial infections such as streptococcal tonsillitis or pharyngitis should be treated with appropriate antibiotics. In some cases, inflamed lymph nodes can suppurate and become abscessed, requiring incision and drainage. Masses thought to be reactive lymph nodes not responding to conservative management (antibiotics) often need referral for further evaluation to obtain a definitive diagnosis.

Cervical lymphadenitis can be caused by atypical mycobacteria, which may appear as a subcutaneous abscess with erythematous overlying skin (Fig. 19-9). Treatment includes excisional biopsy and appropriate antibiotics according to culture sensitivities. Incisional drainage is contraindicated and can cause chronic fistulization.

Cat-scratch disease is another pediatric infection that can manifest with lymphadenopathy. Most patients recount exposure to a cat, and many have a cutaneous lesion representing an inoculation site. The diagnosis is made by serologic testing for *Bartonella henselae*. The disease is self-limited.

Tuberculous cervical lymphadenitis (scrofula), caused by *Mycobacterium tuberculosis*, can manifest with bilateral lower lymph node enlargement. It is usually associated with pul-

Figure 19-9 Photograph showing cervical adenitis with overlying skin erythema in a young child. Cultures revealed atypical mycobacteria.

monary involvement, and treatment is with a multidrug regimen. Nodes not responding to treatment should be excised.

Patients infected with *human immunodeficiency virus* (HIV) can present with asymptomatic lymph node enlargement. Persistent lymphadenopathy in AIDS patients is common, and most are followed if the nodes remain stable. Because of the higher incidence of non-Hodgkin's lymphoma and Kaposi's sarcoma in these patients, any suspicious neck masses with other constitutional symptoms should be referred for biopsy and tissue diagnosis. Fine-needle aspiration biopsy is appropriate, with indeterminate cytology requiring open excisional biopsy. Other possible causes of neck lymphadenopathy in immunocompromised patients include histoplasmosis, tuberculosis, atypical mycobacterial infections, and toxoplasmosis.

Sarcoidosis is a granulomatous disease that causes cervical lymphadenopathy and may be the presenting sign in 10% to 15% of cases. This disorder typically affects the African American population. Other findings include fever, sinusitis, parotid swelling, and hilar adenopathy on chest x-ray films. Diagnosis is classically made by tissue biopsy showing non-caseating granulomas. High angiotensin-converting enzyme level is common but not diagnostic. Other studies include cytoplasmic antineutrophil cytoplasmic antibody (c-ANCA) to rule out other granulomatous diseases, purified protein derivative and acid-fast bacillus stains to rule out tuberculosis, and Venereal Disease Research Laboratory (VRDL) and RPR tests to exclude syphilis.

Disorders of the Salivary Glands

The salivary glands consist of the paired parotid, submandibular, and sublingual glands and the minor salivary glands. Disorders of the salivary glands can be categorized into inflammatory, metabolic, and neoplastic problems (see eBox 19-11 online). The history and physical examination facilitate differentiation among these categories.

Inflammatory Disorders

Acute sialoadenitis is a common cause of painful enlargement of the parotid and submandibular glands. The organism is usually *S. aureus*, but it can also be caused by *S. pneumoniae* and other bacteria. The infection is secondary to salivary stasis caused by decreased production (dehydration, poor oral hygiene) or intrinsic or extrinsic obstruction (stones, strictures, masses). Patients present with exquisite tenderness over the gland, fever, and sometimes skin erythema. Purulence can be expressed from the duct with manual massage of the gland. Treatment includes antistaphylococcal antibiotics, adequate hydration, massage of the gland, sialagogues, and warm compresses. Abscess can occur and requires incision and drainage.

Mumps is a relatively common cause of painful unilateral or bilateral parotid gland enlargement in children. It is caused by a paramyxovirus, and diagnosis is confirmed by elevation of antibodies to the S and V virus antigens or by isolation of the virus in the urine. The incubation period is 2 to 3 weeks, and infection lasts 7 to 10 days. Treatment is conservative, with close follow-up to observe for possible complications such as pancreatitis, meningitis, orchitis, and hearing loss.

Sialolithiasis is a cause of intermittent salivary gland enlargement and is usually associated with eating. Most calculi occur in the submandibular duct, and most are radiopaque. Calculi arising in the parotid duct are less common and tend to be radiolucent. Symptoms include recurrent, unilateral, tender salivary enlargement that subsides within 24 to 48 hours. Physical examination usually reveals a palpable stone in the duct of the gland. Sialography is successfully diagnostic if a calculus is not palpable. CT scan and ultrasound are also effective in identifying calculi. Treatment depends on the location of the obstruction. Calculi near the terminal orifice are easily removed transorally. Symptomatic calculi located near the hilum of the gland usually require excision of the gland.

Patients with HIV infection can present with enlargement of salivary glands. Glands can become infiltrated with benign lymphoid tissue or *lymphoepithelial cysts*. The cystic lesions often occur in the tail of the parotid gland, and aspiration can provide temporary relief of symptoms. These patients are treated conservatively because cysts tend to recur after excision or aspiration procedures. Differential diagnosis of salivary gland enlargement in HIV-infected patients includes non-Hodgkin's lymphoma and Kaposi's sarcoma. Fine-needle aspiration or excisional biopsy of suspicious masses is performed for diagnosis of malignancy.

Included in the differential diagnosis of inflammatory lesions of the major salivary glands are tuberculosis, cat-scratch disease, CMV infection, and first branchial arch cysts and sinuses.

Autoimmune Disorders

Sjögren's syndrome is characterized by xerostomia (dry mouth) with or without parotid gland enlargement. Chronic inflammatory cells and lymphocytes infiltrate the glands, leading to fibrosis and atrophy of the parenchyma. Xerophthalmia suggests involvement of the lacrimal gland and causes a gritty or painful sensation of the eye. Primary Sjögren's syndrome involves the exocrine glands, only without association with other connective tissue disorders. Secondary Sjögren's

syndrome is often associated with rheumatoid arthritis and other autoimmune disorders.

The SS-A and SS-B autoantibodies are positive in most cases of primary Sjögren's syndrome. Other useful laboratory tests include rheumatoid factor, antinuclear antibody, thyroid globulin antibody, and thyroid antimicrosomal antibody titers. Lip biopsy can confirm the diagnosis of Sjögren's syndrome, and referral to an immunologist is appropriate. Treatment includes proper oral hygiene, mouth rinses, and medications that stimulate salivary flow. Steroids are useful for severe cases.

Other causes of xerostomia include surgery and irradiation of the head and neck. Several common classes of medications can cause mouth dryness as a side effect. These include antihistamines, analgesics, anticonvulsants, antidepressants, and antihypertensives. Systemic disorders that can be associated with xerostomia include dehydration, diabetes, anemia, and overall debilitation.

Neoplastic Disorders

Most salivary gland neoplasms arise in the parotid gland, and most are benign. Approximately 80% of parotid gland tumors are benign, with *pleomorphic adenoma* (mixed tumor) being the most common in adults. *Hemangiomas* are the most common benign tumor in children, but malignancy in children is more likely than in adults when a solid mass is found in the salivary gland. Other benign tumors include Warthin's tumors (papillary cystadenoma lymphomatosum) and oncocytomas. The most common malignancy in adults and children is *mucoepidermoid carcinoma*. Other malignancies include adenoid cystic carcinoma, malignant mixed tumor, and squamous cell carcinoma. Treatment of salivary gland neoplasms is surgical excision.

Thyroid Masses

Careful examination for thyroid abnormalities should be performed on each patient in routine office visits. *Thyroid nodules* occur in about 5% to 10% of the population; of these, approximately 10% are malignant. Differential diagnosis of thyroid masses is presented in **Box 19-9**. Risk factors for malignancy include exposure to radiation and family history of medullary carcinoma. Factors that increase the possibility of carcinoma include hoarseness; age younger than 20 years or older than 45 years; male gender; presence of a firm hard nodule; and vocal cord paralysis.

The most common disorder in patients who present with a thyroid nodule is *nontoxic multinodular goiter*. The presence of multiple nodules is helpful in diagnosis, but only one dominant nodule may be apparent on physical examination. Nontoxic multinodular goiter may be endemic in iodine-deficient areas or sporadic. Nodularity is thought to be secondary to repeated episodes of deficiency of thyroid hormone, causing increased levels of thyroid-stimulating hormone (TSH), which results in hyperplasia of the gland. Symptomatic compression on the trachea or esophagus can occur. Surgery is reserved for functional problems caused by compression or to rule out malignancy. Chest radiography and CT are helpful in evaluating substernal extension of goiter.

Graves' disease is an autoimmune disease that causes diffuse thyroid enlargement, hyperthyroidism, infiltrative ophthalmopathy, and myxedema. It is the most common cause

of hyperthyroidism and is more common in women age 20 to 50. Treatment modalities include antithyroid medications, radioactive iodine ablation, or surgical excision when medical treatment fails.

Thyroiditis can cause nodular enlargement of the thyroid gland. Subacute thyroiditis may be a cause of intermittent hyperthyroidism from the release of stored thyroid hormone. Chronic lymphocytic (Hashimoto's) thyroiditis can cause diffuse nodular enlargement of the thyroid. Measurement of antithyroid microsomal antibodies is helpful but not specific for this disorder. Fibrous (Riedel's) thyroiditis is a rare cause of thyroid enlargement, and distinction from neoplasia can be difficult.

Neoplasms of the thyroid are classified as malignant or benign tumors. Follicular adenoma is the most common benign tumor. Malignancies include papillary (65%), follicular (20%), medullary (5%), and anaplastic (10%) carcinomas.

Medullary carcinoma is associated with an elevated calcitonin level, with pheochromocytoma and parathyroid hyperplasia in multiple endocrine neoplasia (MEN) IIA, and with pheochromocytoma, mucosal neuromas, ganglioneuromatosis, and marfanoid body habitus in MEN IIB. Measurement of urinary catecholamines, vanillylmandelic acid, and metanephrine levels is necessary to aid in the diagnosis of pheochromocytoma, which must be treated before surgery for medullary thyroid carcinoma. Hypercalcemia is diagnosed by measuring serum calcium levels.

Initial evaluation of a suspected or palpable nodule includes a thyroid ultrasound and TSH level. If the TSH level is low, a radioiodine scan is obtained. If the nodule corresponds to an area of increased uptake, a biopsy is not necessary because almost all "hot" nodules are benign. Ultrasound will define the number and size of nodules and identify characteristics suggesting malignancy.

Fine-needle aspiration biopsy (FNAB) is indicated for nodules larger than 1 cm or with suspicious ultrasound or examination features. Ultrasound guidance may be used to improve the diagnostic yield for difficult-to-palpate nodules (see eFig. 19-9). FNAB is highly accurate. Results are reported as benign, indeterminate, malignant, or nondiagnostic. Benign nodules should be followed with serial examination and ultrasound. Repeat FNAB is indicated with a significant size change. An indeterminate diagnosis may represent a follicular lesion. Follicular neoplasms are not distinguishable as benign or malignant because fine-needle aspiration fails to identify the critical factor of vascular or capsular invasion. Therefore, a thyroid lobectomy may be necessary for diagnosis. Alternatively, a radioiodine scan may be obtained and surgery performed if the nodule is "cold." Nondiagnostic aspirates should undergo repeat FNAB. A malignant diagnosis often requires a total thyroidectomy with central compartment lymphadenectomy. Postoperative radioactive iodine is often given. Risks of thyroid surgery include recurrent laryngeal injury and hypoparathyroidism.

Prognosis for papillary thyroid carcinoma is excellent, especially in younger patients. Prognosis is good for medullary and follicular carcinoma and universally poor for anaplastic carcinoma (Cooper et al., 2006).

Key Points

- Symptoms of allergic rhinitis include allergic shiners, allergic salute, pale nasal mucosa, loss of taste or smell, nasal speech, eustachian tube dysfunction, and disrupted sleep.
- Ophthalmologist referral should be provided to prevent cornea complications.
- Treatment of acute rhinitis includes environmental control, medications, and immunotherapy.
- Use environmental controls such as air conditioning with change of filters, HEPA filters, and masks with microfoam filters for dust allergy.
- Wash linens in hot water, using impermeable encasings for pillows and mattresses.
- Avoid fans and cool-mist vaporizers, and remove carpets.
- Oral second-generation antihistamines provide less sedation than previous drugs.
- Medications include intranasal steroids, topical antihistamines, leukotriene modifiers, and decongestants.
- Immunotherapy is directed at specific allergens with possible resolution of allergy.

The allergic patient differs from nonallergic patients in several ways (Box 20-1). The cause is unknown, but these abnormalities clearly are associated with abnormal cytokine production (Table 20-1). The result of these abnormalities is that allergic persons suffer from diseases such as allergic rhinitis and allergic asthma.

It must always be remembered, however, that these diseases are defined by their *phenotype*, and for each allergic disease, there is an almost identical phenotypic expression

unrelated to allergy, including allergic and nonallergic (intrinsic) asthma, allergic and nonallergic rhinitis, and IgE-mediated and non-IgE-mediated anaphylactic events. Thus, when approaching the patient, the physician must always consider the mechanism of production of the symptoms because subtle differences may exist in treatment between allergic and nonallergic forms of disease, often with significant differences in prognosis.

The most important aspect of establishing the diagnosis of each of these illnesses is the history. The distinction between the allergic and nonallergic forms can only be conclusively determined by allergy testing. The most sensitive and least expensive (per test) means of assessing the presence of allergy is the allergy skin test. In vitro testing is often helpful, however, as a screening procedure.

The other important phenomenon to recognize is that the major allergic diseases (allergic rhinitis, allergic asthma, and anaphylaxis) are all increasing in incidence. The cause is unknown, but several hypotheses have been proposed. The *hygiene hypothesis* postulates that the rise in allergic disease is related to infection control in infants and children (e.g., through vaccination) and improved public health (e.g., through hygienic measures). Another hypothesis is that the allergic response is the same response used to defend against parasites. With a reduction in parasitic disease in more technically developed countries, a population has arisen that is free from exposure to parasites but still maintains a vigorous antiparasitic immune response that is aberrantly directed against the normally harmless organic substances such as pollen, animal dander, and food. Regardless of the mechanism, the burden of allergic disease in developed countries has increased rapidly since the 1970s.

Box 20-1 Abnormalities Described in Allergic Patients

Predisposition to manufacture large amounts of IgE directed against formerly harmless substances (e.g., pollen and food)

Abnormalities in the autonomic nervous system

- Hyporesponsive beta-adrenergic system
- Hyperresponsive alpha-adrenergic system
- Hyperactive cholinergic responses in the airways
- Hyperreleasability of mast cells and basophils

Allergic Rhinitis

Allergic rhinitis is a symptom complex caused by airborne antigens. It occurs as *seasonal rhinitis* (hay fever) when pollens are in high concentration in the air. When it is intermittent or continuous without seasonal variation, it is termed *perennial allergic rhinitis*. Often occurring in families with an allergic history, perennial allergic rhinitis and mixed perennial and seasonal rhinitis were found to be twice as common as seasonal allergic rhinitis (Skoner, 2001).

Manifestations

In seasonal allergic rhinitis, exposure is followed by complaints of paroxysmal sneezing, a watery nasal discharge with congestion, and nasal pruritus. Conjunctival and pharyngeal itching often occurs. Less specific symptoms are postnasal drainage or fullness or aching in the frontal areas.

The patient might exhibit an *allergic salute*, an upward thrust of the palm against the nares to relieve itching and open the nasal airways and a gaping expression from mouth breathing. *Allergic shiners* or Dennie's lines are wrinkles beneath the lower eyelid. Speech can have a nasal quality. In children, nasal irritation can result in nose picking and recurrent epistaxis. Sleep disruption is often associated with nasal obstruction and mouth breathing. Patients might have sleep apnea-like symptoms, including restless sleep, snoring, or nighttime coughing, associated with postnasal mucus drainage and mild hoarseness. The nasal mucosa is typically moist, with enlarged, pale turbinates and serous discharge. Because the sense of smell is impaired, appetite may be decreased. Maxillomandibular alignment problems (overbite or underbite) result from chronic symptoms.

In perennial allergic rhinitis, nasal congestion, itching, obstruction, and frequent sniffing may be associated with a loss of sense of taste or smell, with decreased hearing and a popping sensation in the ears. A lower sneezing threshold often occurs with altered autonomic reflexes in perennial allergic rhinitis. Paroxysms of sneezing and rhinorrhea can result from changes in ambient temperature, head movement, odors from perfume, tobacco smoke, irritants, alcohol, and exposure to small quantities of antigen. Exercise reverses nasal congestion temporarily, from minutes to hours.

The turbinates are usually swollen and edematous and may be mistaken for nasal polyps, which are pearl-gray gelatinous masses and unusual in uncomplicated allergic rhinitis. Below the turbinates, the floor of the nostril is often prominent as a result of mucosal edema. One third to one half of children with allergic rhinitis have eustachian tube obstruction and resultant serous otitis. Otoscopy reveals a retracted or bulging

Table 20-1 Cytokine Production Abnormalities and Effects in Allergic Patients

| Cytokine | Effects |
|-------------------------------|--|
| Increased production of IL-4 | Enhanced IgE production |
| Increased production of IL-13 | Enhanced IgE production |
| Increased production of IL-5 | Enhanced eosinophil activity and prolongation of the life of eosinophils |
| Increased production of IL-9 | Bronchial hyperreactivity |

Ig, Immunoglobulin; *IL*, interleukin.

tympanic membrane, impaired mobility, or a fluid level. In patients with intact tympanic membranes, tympanometry to measure middle ear pressures provides an indirect measure of eustachian tube function (Lazo-Saenz et al., 2005). The edematous nasal mucosa can obstruct the ostia, resulting in congestion or sinusitis with pressure symptoms or headache that is particularly notable with bending forward. Up to one third of patients have a lower respiratory tract component, including exercise-induced and mild persistent asthma.

Diagnosis

A seasonal history or an association with an inhaled allergen is helpful. It is often difficult to associate specific allergens with perennial rhinitis, although late-evening or early-morning symptoms may be seen with dust allergy. Occasionally, improvement of symptoms with a change in environment, such as a vacation, indicates the presence of environmental allergens. A nasal smear, stained with Hansel's stain to identify eosinophils, can support a diagnosis of nasal allergy, but it is not itself diagnostic. An elevated peripheral eosinophil count may be helpful; however, marked allergic symptoms can occur in the absence of blood eosinophilia.

Treatment**Nonspecific Measures**

Removing known allergens is of prime importance because it can eliminate symptoms. When exposure is unavoidable, environmental control should reduce symptoms and prevent exacerbations. The patient or the family must assume responsibility for environmental control, so an understanding of allergens is helpful. Commonly inhaled allergens include pollens, which can produce symptoms of seasonal allergic rhinitis, conjunctivitis, and asthma. Allergenic pollens come from trees, grasses, and weeds. Pollens from flowering plants are insect-borne and are not important allergens. Pollen prevalence is usually determined by gravity slides, which sample pollen fallout without regard to wind direction, speed, and turbulence, so that daily reports of pollen prevalence often do not reflect the true concentration in the air or individual exposure.

Inhaled fungal allergens in fungus-sensitive subjects can produce seasonal symptoms during situations that promote fungal growth, such as humid and rainy weather and exposure to hay, mulch, commercial peat moss, and compost. Indoors, areas of spore formation can be identified at sites of

water condensation such as shower curtains, window moldings, and damp basements. In addition, cool-mist vaporizers can serve as sources of fungal contamination.

A prime role for the patient and family is controlling house dust. House dust is a heterogeneous mixture of bacteria, fibrous matter of plant and animal origin, human epidermis, food remnants, fungi, insect debris, and animal dander and contains one major source of antigen: the dust mite. Mites are ubiquitous in households and are most prevalent in bedding, mattresses, carpeting, and upholstered furniture, particularly where warmth and humidity are high. Air conditioners and dehumidifiers are useful for these patients. High-efficiency particulate air (HEPA) filters are effective in removing dust and animal dander. Fans should not be used so that these lightweight particles can settle. Minimizing clutter and removing carpets are also effective measures. Linens should be washed in hot water (130° F, 55° C). Impermeable cases can be used for pillows and mattresses. The use of a mask over the nose and mouth with replaceable microfoam filters significantly reduces the effects of temporary exposure to inhaled allergens such as dust or pollens.

Animal allergens are derived from dried saliva on shed cat fur, rodent urine, and epidermal material from farm animals. The allergic respiratory reactions produced by animal allergens are species specific. Finished furs and wools are not allergenic. Feathers are often nonallergenic when fresh, and they produce allergic symptoms only after degradation. A careful history to identify environmental allergens is important for advising avoidance and treatment.

Control of Symptoms

Antihistamines are effective for symptomatic control of allergic rhinitis, whether it is seasonal or perennial (Bousquet et al., 2008; Wallace et al., 2008; SOR: A). For optimal results, antihistamines should be used before exposure to the known allergen. Complete control might not be achieved when patients use antihistamines only sporadically. During the implicated season, around-the-clock administration provides maximal symptomatic relief. Because compliance is always an issue, the new second-generation antihistamines offer a convenient dosing regimen (Table 20-2). These groups of drugs, with specific binding properties, allow little to no penetration into the central nervous system (CNS), thus greatly reducing their side effects, primarily sedation. The second-generation antihistamines also have anti-inflammatory effects.

Fexofenadine (Allegra), an analog of terfenadine, is safe and effective. Through its effects on T cells, fexofenadine can decrease airway inflammation. Loratadine (Claritin) is available as a once-daily (qd) product. It provides safe and effective control of most symptoms of allergic rhinitis if taken regularly. Desloratadine (Clarinex), also a once-daily medication, is a metabolite of loratadine. In murine models, desloratadine inhibits bronchial hyperresponsiveness and airway inflammation. Cetirizine (Zyrtec), a metabolite of hydroxyzine, is available in once-daily dosing. Cetirizine has anti-inflammatory properties and may be effective in patients with allergic rhinitis and reactive airway disease. Cetirizine's chemical properties, however, allow greater CNS penetration, and sedation is its chief side effect (16% vs. 4% for fexofenadine and loratadine). Levocetirizine (Xyzal), also

Table 20-2 Second-Generation Oral Antihistamines for Treatment of Allergic Rhinitis

| Drug (Brand)t | Formulation | Dosing Frequency | Age of Patient |
|--------------------------|---|---------------------------------|----------------|
| Cetirizine* (Zyrtec) | 5 mg/5 mL syrup 5-mg, 10-mg chewable tablet 10-mg tablet | Once daily (qd) qd qd | 6 months |

*Available as over-the-counter (OTC) generic drug.

a once-daily medication, is a metabolite of cetirizine. Less sedation is associated with it than cetirizine.

Herbal medications have been used with effectiveness in treating perennial and seasonal allergic rhinitis. Butterbur (32 mg daily) was effective in treating seasonal allergic rhinitis when compared to cetirizine (10 mg daily) in 125 patients. After 2 weeks, patients treated with butterbur had improved vitality, general health, and physical activity as well as less sedation (Schapowal, 2002; SOR: A).

Second-generation antihistamines are available in combination with alpha-adrenergic decongestants and might be more effective in this form than antihistamines alone. Alpha-adrenergic drugs are also effective applied topically. Topical vasoconstrictors (sprays and drops) are best restricted to temporary use, such as when taking an airplane trip or during a severe flare-up of symptoms. Unfortunately, the side effect profile increases in these combinations. Intranasal antihistamines have the most rapid onset of action and are as effective as oral second-generation antihistamines in the treatment of seasonal allergic rhinitis (SOR: A). Azelastine (Astelin), available in a nasal spray formulation, decreases nasal airway resistance and is an effective treatment for rhinitis. Olopatadine (Patanase) is another topical antihistamine with effectiveness against symptoms of rhinitis. Leukotriene receptor antagonists, such as montelukast (Singulair), are also effective for the treatment of perennial and seasonal allergic rhinitis (Wallace et al., 2008).

Topical intranasal glucocorticoids—beclomethasone, fluticasone, mometasone, triamcinolone, flunisolide, ciclesonide, and budesonide—are the most effective medication in the treatment of allergic rhinitis (Wallace et al., 2008; SOR: A). Their effectiveness is directly related to proper and daily use, posing problems with patient compliance. Side effects are related primarily to nasal dryness and epistaxis. Using saline as a moisturizer can relieve these side effects. The therapeutic effects are generally not immediate, and some patients must take these medications for 1 to 3 weeks before they achieve maximum benefit.

When symptoms are severe and not responsive to trials of topical therapy, oral glucocorticoid therapy can be used as a last resort and only for limited duration. The rationale for glucocorticoid therapy for allergic rhinitis is that the condition, although mediated by immunoglobulin E (IgE), has a dual component: the immediate phase of edema and hypersecretion and a late inflammatory phase (Ciprandi et al., 2005). This dual reaction occurs in asthma as well.

Specific Immunotherapy

When skin tests identify sensitivity to an unavoidable inhalant allergen, immunotherapy may be indicated for treating allergic rhinitis. Its efficacy has been shown to be 80% for controlling pollen symptoms and 60% for controlling mold and house dust symptoms. Immunotherapy is therefore more effective in seasonal allergic rhinitis than perennial allergic rhinitis. When considering immunotherapy, the ease of control of other therapies should be weighed against the frequency and severity of symptoms as well as the possibility of complete resolution of allergy with immunotherapy.

KEY TREATMENT

Oral antihistamines, including fexofenadine, cetirizine, loratadine, levocetirizine, and desloratadine, improve symptoms (e.g., runny nose, nasal pruritus, sneezing and quality of life in patients with seasonal allergic rhinitis compared with placebo (SOR: A). Herbal medications have been used with effectiveness in treating perennial and seasonal allergic rhinitis (SOR: A). Inhaled corticosteroids were more effective than oral antihistamines in treating most nasal symptoms of seasonal allergic rhinitis, including nasal congestion, runny nose, pruritus, and sneezing (SOR: A). Immunotherapy is effective against allergic rhinitis and can prevent the development of asthma in children (SOR: A).

Nasal Polyps

Key Points

- Nasal polyps may be associated with aspirin sensitivity.
- Nasal polyps can aggravate sinus disease.
- Topical glucocorticoids are important in long-term treatment.
- Polyps can recur after polypectomy.

Perennial allergic rhinitis may be associated with nasal polyps, but usually only when it is complicated by sinus infection. In adults, polyps may be associated with sensitivity to aspirin manifested by aggravation of rhinitis, asthma, and even shock.

Nasal polyps often develop in the absence of or only coincidentally with allergy. Polyps arise from diseased ethmoid and maxillary sinuses and are easily visible in the nasal cavity. Nasal polyps can cause obstruction and aggravate the preexisting sinus disease. The size of nasal polyps may be reduced by brief treatment with systemic glucocorticoids and by daily use of topical glucocorticoids for longer periods.

If sinus infection or the underlying allergic factors are not appropriately controlled, polypectomy may be necessary. Unfortunately, polyps tend to recur without sinus surgery.

Nonallergic Rhinitis

Key Points

- Symptoms of nonallergic rhinitis include chronic nasal obstruction and eosinophils on nasal smear, in the absence of allergy.
- Topical glucocorticoid steroid therapy is useful in treatment of NARES.
- Aggravating factors include physical changes or irritants for vasomotor rhinitis.
- Ipratropium bromide is best for controlling symptoms of vasomotor rhinitis.

Some patients with perennial rhinitis are not atopic by history or skin testing. Chronic nasal obstruction is the predominant symptom, and the condition may be associated with sinus disease and nasal polyps. Although there is no evidence of allergy by skin testing, numerous eosinophils are present, and the diagnosis is readily made by examining the nasal secretions for eosinophils and eosinophilic cationic protein (Kramer et al., 2004). The condition is also called *nonallergic rhinitis with eosinophilia* (NARES). A substantial number of patients have chronic rhinitis with rhinorrhea, postnasal drainage, and chronic or intermittent nasal obstruction. Symptoms are aggravated by many physical or irritant factors, such as cold air, odors, and smoke. Skin tests are negative, and no eosinophils are present in the tissue or secretions.

Topical glucocorticoid therapy is much more effective than antihistamines or decongestants for NARES. As with asthmatic patients, patients with associated sinus disease and nasal polyps are at risk for adverse reactions to aspirin and nonsteroidal anti-inflammatory drugs (NSAIDs). Patients with NARES are also at risk for obstructive sleep apnea (Wallace et al., 2008). Ipratropium bromide (0.03%) spray solution, fluticasone, and azelastine nasal sprays have all been shown to be effective treatment. Some patients benefit from antihistamine-decongestant combinations. The regular use of buffered saline lavage can also provide satisfactory symptomatic relief.

Allergy in the Eye

Key Points

- Symptoms of eye allergy include pruritus, erythema, and lacrimation.
- Treatment includes oral antihistamines plus topical medications such as mast cell stabilizers or H₁ blockers.

Conjunctivitis is the usual ocular reaction to airborne allergens. As in other forms of allergic inflammation, the mast cell plays a key role. Itching is the first symptom and may be associated with lacrimation. Dilation of the conjunctival blood vessels produces a "red" eye. Transudation of fluid through vessel walls results in edema of the conjunctiva, and exuded cells with increased glandular mucus secretions result in ocular discharge. In most atopic patients, conjunctivitis and allergic rhinitis occur together, but some patients

are bothered only by eye symptoms. In contrast to other forms of conjunctivitis, the secretions contain eosinophils.

Vernal conjunctivitis is so called because of its occurrence in spring and summer. It is characterized by a bilateral recurrent inflammation of the conjunctiva. Vernal conjunctivitis typically occurs between ages 5 and 20 years. It often spontaneously resolves in 10 years. More than 50% of children with vernal conjunctivitis also have an atopic disorder such as allergic rhinitis, eczema, or asthma. Signs and symptoms include acute itching, tearing, photophobia, and excess mucus production. The patient often has a sense of a foreign body in the eye.

The topical conjunctival appearance establishes the diagnosis, which is confirmed by cytologic smears showing numerous eosinophils. In the tarsal (palpebral) form, there are flat-top cobblestone papillae; in the limbal form, there may be gelatinous hypertrophy and limbal papillary hypertrophy often associated with white dots (Trantas' dots). Although vernal conjunctivitis is usually self-limiting, corneal complications can occur, and ophthalmology consultation should be obtained. Although conjunctivitis is typically seasonal and common in atopic patients, no allergens have been identified as causal or aggravating factors.

The usual therapy for allergic conjunctivitis is an oral antihistamine with a topical medication (Table 20-3). Cromolyn (Opticrom) and lodoxamide 0.1% (Alomide) are mast cell stabilizers. Topical H₁ histamine blockers are also effective for treating allergic conjunctivitis. Ophthalmic histamine blocker solutions include emedastine (Emadine) and levocabastine (Livostin). Azelastine (Optivar), epinastine (Elestat), ketotifen (Zaditor, Claritin Eye, Zyrtec Itchy Eye) and olopatadine (Patanol, Pataday) are dual-acting drugs, preventing mast cell release and exerting antihistamine activity as well. Ketorolac (Acular) is a NSAID. Regular daily use is necessary to obtain maximum positive results with all topical agents. In severe cases and in vernal conjunctivitis, a soluble steroid such as fluorometholone ophthalmic solution (0.1%) is effective. The dose should be titrated to the minimum required to control symptoms. Use should be intermittent because glucocorticoids can lead to the development of cataracts, potentiate a secondary bacterial infection or a herpes simplex keratitis, and increase intraocular pressure. Steroid eyedrops should always be used under supervision by an ophthalmologist.

Asthma

The definition of asthma has undergone many changes over the years, but three elements are key to the diagnosis: reversible airway obstruction, airway inflammation, and increased airway responsiveness to a variety of stimuli. Physicians must remember that not all wheezing is asthma, and not all asthma has wheezing. Asthma is a chronic inflammatory disorder of the airways in which many different cells play a role. In patients with asthma, this inflammation causes breathlessness, chest tightness, recurrent episodes of wheezing, and cough, particularly at night. These symptoms are usually associated with variable airflow limitation that is partly reversible with treatment or sometimes spontaneously. This inflammation causes an associated increase in airway

responsiveness to a variety of stimuli (Busse et al., 2007). Data from the Centers for Disease Control and Prevention (CDC) have shown an increase in the prevalence of asthma in the United States from 1980 to 2001. However, there has been no increase in mortality and hospitalization rates since 1997 (cdc.gov/asthma; see also Chapter 20).

Diagnosis

Because of the lack of any specific symptom or sign to define asthma by history or physical examination, some patients are mistakenly thought to have asthma. Numerous other diseases must be considered in the differential diagnosis of asthma (Box 20-2). Although parental history of asthma is present in half of children with asthma, the positive predictive value of this history ranges from 11% to 37% (Burke et al., 2003). The diagnosis of asthma should occur in three stages. First, suggestive symptoms referable to the chest with precipitating factors should raise the possibility of asthma. Second, further testing should be performed to confirm the diagnosis. Third, the patient should have symptomatic improvement with the appropriate asthma therapy (see Classification). When all the stages have been performed and meet the criteria, the diagnosis of asthma can be made.

Table 20-3 Ophthalmic Solutions Useful in the Treatment of Allergic Conjunctivitis

| Drug (Brand) | Formulation | Dosage |
|---|-------------|-------------------------------|
| Mast Cell Stabilizers | | |
| Cromolyn (Opticrom) | 4% | 1-2 gtt OU every 4-6 hr daily |
| Lodoxamide (Alomide) | 0.1% | 1 gtt OU qid |
| H₁ Histamine Blockers | | |
| Emedastine (Emadine) | 0.05% | 1 gtt OU qid |
| Levocabastine (Livostin) | 0.5 mg/mL | 1 gtt OU bid |
| Combination Stabilizers/Blockers | | |
| Ketotifen (Zaditor) | 0.025% | 1 gtt OU bid 8-12 hr apart |
| (Zyrtec Itchy Eye) | 0.025% | 1 gtt OU bid 8-12 hr apart |
| (Claritin Eye) | 0.025% | 1 gtt OU bid 8-12 hr apart |
| Epinastine (Elestat) | 0.05% | 1 gtt OU bid |
| Olopatadine (Patanol) | 0.1% | 1 gtt OU bid 6-8 hr apart |
| (Pataday) | 0.2% | 1 gtt OU qd |
| Azelastine (Optivar) | 0.05% | 1 gtt OU bid |
| Nonsteroidal Anti-Inflammatory Drugs | | |
| Ketorolac (Acular) | 0.5% | 1 gtt OU qid |

 Chronic obstructive pulmonary disease
 Congestive heart failure
 Eosinophilic pulmonary infiltration
 Gastroesophageal reflux disease
 Mechanical obstruction of the airway
 Paradoxical vocal cord motion
 Pulmonary embolism

ACE, Angiotensin-converting enzyme.

Precipitating Factors

All patients suspected of having asthma should be questioned about early warning signs and precipitating factors. Early warning signs of an attack include symptoms such as cough, scratchy throat, and nasal stuffiness, especially if an attack follows an upper respiratory tract infection. Many other precipitating factors can provoke asthma symptoms or an acute attack (Box 20-3). Identification of these precipitating factors can help patients manage their asthma by learning their early warning signs and avoiding any exposure that triggers an exacerbation. These symptoms and identification of triggers are the first stages of diagnosis of asthma.

Confirmatory Testing

Pulmonary function testing is the “gold standard” for the diagnosis and management of asthma and is the second stage in the diagnosis of asthma. The only exclusion for obtaining pulmonary function tests should be the lack of an ability to perform the testing, most often determined by the patient’s age (usually <4 years).

Spirometry is the most useful test in diagnosis of asthma. Spirometry includes measurements forced expiratory volume of air in 1 second (FEV₁) and forced vital capacity (FVC), the amount of air one can expel during forced expiration. FEV₁ is the most important value for the assessment of airflow obstruction. It declines in direct and linear proportion of worsening airway obstruction and increases with successful treatment of airway obstruction. Degrees of airway obstruction are defined according to the percentage of predicted FEV₁ achieved by the patient (Table 20-4) (American Thoracic Society [ATS], 2005).

Administration of a bronchodilator such as albuterol is indicated when performing spirometry. Improvement of FEV₁ by 12% or 200 mL after administering a bronchodilator suggests significant reversibility of the airway obstruction. Another useful value is the FEV₁/FVC ratio. A reduced ratio below the

Box 20-3 Factors that Can Precipitate Asthma

Environmental allergens such as pollen, molds, house dust mites, cockroach excreta, and animal danders
 Environmental changes or climate change
 Exercise
 Exposure to irritants (e.g., tobacco smoke), strong odors, and air pollutants
 Exposure to medication: salicylates, NSAIDs, β-blockers
 Exposure to occupational chemicals or allergens
 Exposure to some food additives
 Gastroesophageal reflux disease
 Menses
 Pregnancy
 Sinusitis
 Strong emotional feelings
 Viral respiratory infections

NSAIDs, Nonsteroidal anti-inflammatory drugs.

Table 20-4 Severity of Any Spirometric Abnormality Based on FEV₁*

| Degree of Severity | FEV ₁ (% Predicted) |
|--------------------|--------------------------------|
| Mild | >70% |
| Moderate | 60–69% |
| Moderately severe | 50–59% |
| Severe | 35–49% |
| Very severe | <35% |

From Brusaco V, Crapo R, Viegi G: Interpretative Strategies for lung function tests. Eur Respir J 2005;26:948-968. American Thoracic Society. Available at www.thoracic.org/sections/publications/statements/pages/pfet/pft5.html.
 *Forced expiratory volume in 1 second.

5th percentile of the predicted value suggests obstructive airway disease. A reduced FVC with a normal or increased FEV₁/FVC ratio (>5% of predicted value) suggests a restrictive pattern of lung disease (ATS, 2005). Additional testing by bronchoprovocation may be considered if one suspects a patient has asthma but spirometry testing is normal. The only absolute contraindications to methacholine bronchoprovocation testing are severely reduced airflow (FEV₁ <50%), acute coronary syndrome or stroke in the past 3 months, uncontrolled hypertension, or known aortic aneurysm.

Peak-Flow Monitoring

The home use of peak-flow meters is helpful in the self-management of asthma but not in the diagnosis. The National Asthma Education and Prevention Program (2007) recommends daily monitoring for patients with moderate to severe persistent asthma. There is no evidence that peak-flow monitoring improves patient outcomes over self-monitoring of symptoms. However, if a practitioner provides a peak-flow meter, the patient should be properly instructed in its use (Busse et al., 2007). The patient should establish a baseline peak flow in the absence of asthma symptoms. Three zones on the meter are then set—green, yellow, and red. The green

| Components of severity | | Classifying Asthma Severity and Initiating Therapy in Children | | | | | | | |

| | | In 2–6 weeks, depending on severity, evaluate level of asthma control that is achieved. • Children 0–4 years old: If no clear benefit is observed in 4–6 weeks, stop treatment and consider alternative diagnoses or adjusting therapy. • Children 5–11 years old: Adjust therapy accordingly. | | | | | | | |

Figure 20-1 Classifying asthma severity and initiating therapy in children. (From Busse WW, Boushey HA, Camargo CA, et al. Guidelines for the Diagnosis and Management of Asthma. National Asthma Education and Prevention Program, Expert Panel Report 3. NIH Pub No 08-5846, October 2007.)

zone is 80% to 100% of the patient's "personal best" and reassures the patient to continue the current regimen. The yellow zone is 50% to 80% of personal best and should signal the patient to change the measurement plan according to the clinician. The red zone is less than 50% of the personal best and should signal the patient to seek medical attention. The use of the peak-flow meter can help give some patients objective findings of the severity of their asthma.

Treatment

Classification

Asthma is classified into four categories based on subjective symptoms of frequency and severity and objective measurements of pulmonary function (Figs. 20-1 and 20-2).

Classification is initially based on the highest step at which any feature occurs, realizing that clinical features for individual patients can overlap. An individual patient's classification can and should change over time so the patient can move to a lower classification with adequate therapy.

The goal of asthma therapy is to maintain control of asthma with the least amount of medication and the least risk for adverse side effects. Obtaining control of asthma can be difficult to define for the patient and the clinician. Several keys to the definition of controlled asthma are prevention of troublesome symptoms (cough or wheezing), maintenance of normal pulmonary function, maintenance of normal activity levels, prevention of recurrent exacerbations, and meeting patients' and families' expectations of asthma care.

| Components of severity | | Classification of Asthma Severity ≥12 years of age | | | |
|---|---|--|---|--|---|
| | | Intermittent | Persistent | | |
| | | | Mild | Moderate | Severe |
| Impairment Normal FEV ₁ /FVC: 8–19 yr 85% 20–39 yr 80% 40–59 yr 75% 60–80 yr 70% | Symptoms | ≤2 days/week | >2 days/week but not daily | Daily | Throughout the day |
| | Nighttime awakenings | ≤2x/month | 3–4x/month | >1x/week but not nightly | Often 7x/week |
| | Short-acting beta ₂ -agonist use for symptom control (not prevention of EIB) | ≤2 days/week | >2 days/week but not daily, and not more than 1x on any day | Daily | Several times per day |
| | Interference with normal activity | None | Minor limitation | Some limitation | Extremely limited |
| | Lung function | • Normal FEV ₁ between exacerbations • FEV ₁ >80% predicted • FEV ₁ /FVC normal | • FEV ₁ >80% predicted • FEV ₁ /FVC normal | • FEV ₁ >60% but <80% predicted • FEV ₁ /FVC reduced 5% | • FEV ₁ <60% predicted • FEV ₁ /FVC reduced 5% |
| Risk | Exacerbations requiring oral systemic corticosteroids | 0–1/year (see note) | ≥2/year (see note) → | | |
| | | ← Consider severity and interval since last exacerbation. → Frequency and severity may fluctuate over time for patients in any severity category. Relative annual risk of exacerbations may be related to FEV ₁ . | | | |

| | | | | |
|---|---|--------|--------|-------------|
| Recommended step for initiating therapy (See “Stepwise Approach for Managing Asthma” for treatment steps.) | Step 1 | Step 2 | Step 3 | Step 4 or 5 |
| | In 2–6 weeks, evaluate level of asthma control that is achieved and adjust therapy accordingly. | | | |

Figure 20-2 Classification of asthma severity. (From Busse WW, Boushey HA, Camargo CA, et al. Guidelines for the Diagnosis and Management of Asthma. National Asthma Education and Prevention Program, Expert Panel Report 3. NIH Pub No 08-5846, October 2007.)

Classification of asthma is the last stage in the diagnosis of asthma. Patients with asthma should respond to traditional treatment based on the stage of asthma. The National Heart, Lung and Blood Institute (NHLBI) provides the current clinical guidelines (Figs. 20-3 and 20-4) (Busse et al., 2007). The physician should keep the following points in mind when using the NHLBI guidelines:

1. The stepwise approach is intended to assist, not replace, the clinical decision making required to meet individual patient needs.
2. Classify severity; assign the patient to the most severe step in which any feature occurs.
3. Gain control as quickly as possible (a course of short systemic corticosteroids may be required); then step down to the least medication necessary to maintain control.
4. Minimize the use of short-acting inhaled β₂-agonists. Overreliance (e.g., use of short-acting inhaled β₂-agonist every day, increasing use or lack of expected effect, or use of approximately one canister a month even if not using it every day) indicates inadequate control of

asthma and the need to initiate or intensify long-term-control therapy.

5. Provide parent education on asthma management and controlling environmental factors that make asthma worse at all points of care (e.g., allergens, irritants).
6. Consultation with an asthma specialist is recommended for patients with moderate or severe persistent asthma. Consider consultation for patients with mild persistent asthma.

Intermittent Asthma: Step 1

For intermittent asthma, short-acting inhaled β₂-agonists taken as needed are usually sufficient therapy so long as they are used less than twice a week (SOR: A). If therapy is repeated more often than every 6 weeks, a step-up in long-term care is recommended. Patients with intermittent asthma have symptoms of asthma less than twice per week, two or fewer nocturnal awakenings per month, and peak-flow measurements that are normal (peak expiratory flow rate [PEFR] >80% of predicted normal) (Busse et al., 2007).

| | | Step up if needed (first check inhaler technique, adherence, environmental control, and comorbid conditions) Assess control | | | | | |
|----------------------------|--------------------------------|---|---|--|--|--------------------------------------|--|
| | | Step down if possible (and asthma is well controlled at least 3 months) | | | | | |
| | | Step 1 | Step 2 | Step 3 | Step 4 | Step 5 | Step 6 |
| Children 0–4 years of age | | Intermittent asthma | Persistent asthma: daily medication Consult with asthma specialist if step 3 care or higher is required. Consider consultation at step 2. | | | | |
| | Preferred | SABA PRN | Low-dose ICS | Medium-dose ICS | Medium-dose ICS + LABA or montelukast | High-dose ICS + LABA or montelukast | High-dose ICS + Oral corticosteroids ICS + LABA or montelukast |
| | Alternative | | Cromolyn or montelukast | | | | |
| | Quick-relief medication | <ul style="list-style-type: none"> • SABA as needed for symptoms. Intensity of treatment depends on severity of symptoms. • With viral respiratory symptoms: SABA q 4–6 hours up to 24 hours (longer with physician consult). Consider short course of oral systemic corticosteroids if exacerbation is severe or patient has history of previous severe exacerbations. Caution: Frequent use of SABA may indicate the need to step up treatment. See text for recommendations on initiating daily long-term-control therapy. | | | | | |
| Children 5–11 years of age | | Intermittent asthma | Persistent asthma: daily medication Consult with asthma specialist if step 4 care or higher is required. Consider consultation at step 3. | | | | |
| | Preferred | SABA PRN | Low-dose ICS | Low-dose ICS + LABA, LTRA, or theophylline <i>OR</i> Medium-dose ICS | Medium-dose ICS + LABA | High-dose ICS + LABA | High-dose ICS + LABA + Oral corticosteroids |
| | Alternative | | Cromolyn, LTRA, nedocromil, or theophylline | | Medium-dose ICS + LTRA or theophylline | High-dose ICS + LTRA or theophylline | High-dose ICS + LTRA or theophylline + Oral corticosteroids |
| | Quick-relief medication | <ul style="list-style-type: none"> • SABA as needed for symptoms. Intensity of treatment depends on severity of symptoms: up to 3 treatments at 20-minute intervals as needed. Short course of oral systemic corticosteroids may be needed. Caution: Increasing use of SABA or use >2 days a week for symptom relief (not prevention of EIB) generally indicates inadequate control and the need to step up treatment. | | | | | |
| | | Each step: Patient education and environmental control | | | | | |
| | | Each step: Patient education, environmental control, and management of comorbidities Steps 2–4: Consider subcutaneous allergen immunotherapy for patients who have persistent, allergic asthma. | | | | | |

Figure 20-3 Step therapy for children with asthma. (From Busse WW, Boushey HA, Camargo CA, et al. Guidelines for the Diagnosis and Management of Asthma. National Asthma Education and Prevention Program, Expert Panel Report 3. NIH Pub No 08-5846, October 2007.)

Mild Persistent Asthma: Step 2

Patients with mild persistent asthma should receive daily treatment with inhaled corticosteroids (SOR: A). Leukotriene modifiers (cromolyn and nedocromil) may be considered as alternative, not preferred, controller medications for those with persistent asthma. Inhaled corticosteroids are now the preferred controller medication based on

their greater efficacy. Long-term use of inhaled corticosteroids within labeled doses is safe for children in terms of growth, bone mineral density, and adrenal function. The most important factor in monitoring symptom control is the use of short-acting β_2 -agonists, which should be less than twice per week. Mild persistent asthma is defined when a patient has asthmatic symptoms requiring relief

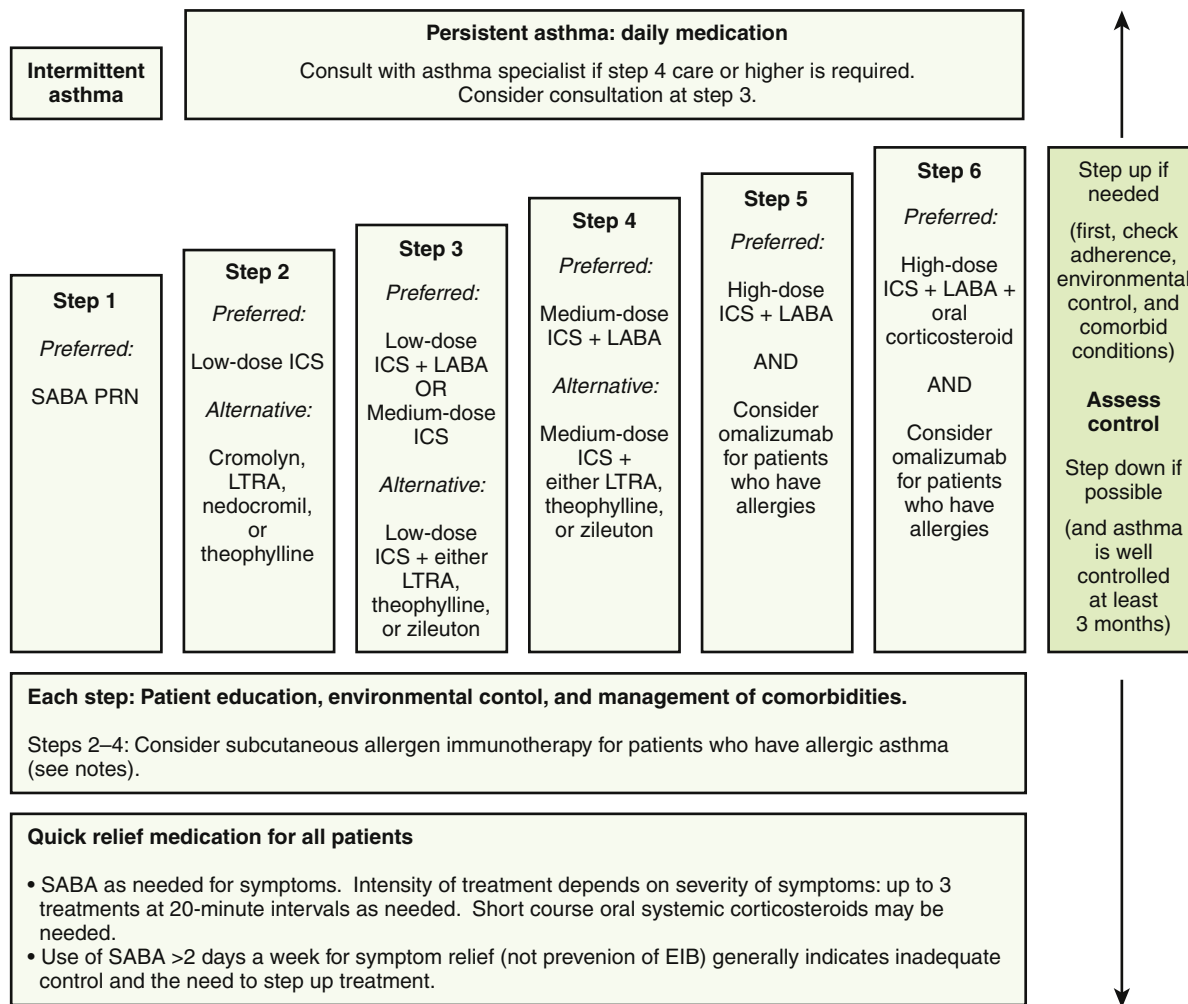

Figure 20-4 Step therapy for adults with asthma. (From Busse WW, Boushey HA, Camargo CA, et al. Guidelines for the Diagnosis and Management of Asthma. National Asthma Education and Prevention Program, Expert Panel Report 3. NIH Pub No 08-5846, October 2007.)

with an inhaled bronchodilator more than twice per week, nocturnal awakenings more than twice a month, or observed fluctuation in PEFr of more than 20% (Busse et al., 2007).

Moderate Persistent Asthma: Step 3

Moderate persistent asthma is defined as daily symptoms of asthma, daily need for bronchodilator medications, asthmatic attacks that interfere with activity, nocturnal awakenings more than once per week, or PEFr 60% to 80% of normal. Any one of these criteria should prompt the consideration of escalating asthma therapy. However, physicians should first review the patient's inhaler technique and adherence to therapy and determine if environmental factors are worsening the condition. Consultation with an asthma specialist may be considered to help with therapeutic options. Currently the preferred treatment option is addition of a long-acting inhaled β_2 -agonist at a low to medium dose of inhaled corticosteroid (SOR: A). Other options include increasing the dose of inhaled corticosteroids with or without adding a long-acting β_2 -agonist or adding a leukotriene modifier (SOR: B) (Busse et al., 2007).

Severe Persistent Asthma: Step 4 or 5

Severe persistent asthma is defined as waking from sleep 4 to 7 nights per week; frequent asthma exacerbation even from minor exposures to viruses, allergens, exercise, or air pollutants; an FEV₁ less than 60% of predicted; and inability to achieve normal lung function despite appropriate treatment. Patients with severe persistent asthma usually have continuous symptoms that should be treated with high doses of inhaled corticosteroids and long-acting inhaled β_2 -agonists (SOR: B). If the asthma is not controlled, oral corticosteroids to gain and maintain control is the next therapeutic option. Current evidence suggests using omalizumab to avoid using systemic corticosteroid therapy in those patients with allergies (SOR: A). For patients who require long-term systemic corticosteroids, clinicians should use the lowest possible dose to control symptoms and monitor patients closely for adverse side effects (Busse et al., 2007).

Management of Asthma in Children

More than half of children with asthma develop symptoms before their fifth birthday. However, diagnosis can be difficult because there are no reliable tests for children at this

age, and diagnosis must rely solely on clinical presentation. Among children younger than 5 years, the most common cause of asthma symptoms is a viral upper respiratory tract infection. Based on expert opinion, daily long-term control therapy should be initiated in young children who consistently require symptomatic treatment more than twice per week and those who experience severe exacerbations that occur less than 6 weeks apart. Therapy is recommended for children who had more than four episodes of wheezing in the past year that lasted more than 1 day and affected sleep and who have a positive asthma predictive index. A positive asthma predictive index is either one of two major risk factors (parental history of asthma or physician diagnosis of atopic dermatitis) or two of three minor risk factors (wheezing apart from colds, peripheral blood eosinophilia higher than 4%, or evidence of sensitization of foods) (Busse et al., 2007). Therapy may be given by metered-dose inhalers with a spacer; evidence suggests they are as good as or better than nebulizers for children with asthma (SOR: A) (Hsu et al., 2004).

Management of Asthma Exacerbation

Asthma exacerbations consist of episodes of progressively worsening shortness of breath, cough, wheezing, or chest tightness. These exacerbations are characterized by decreases in FVC and PEV_1 that can be measured by peak-flow meters. Peak-flow monitoring can help grade the severity of an exacerbation. Early treatment is the best strategy for effective treatment of asthma exacerbations. Patients should receive a written action plan to guide self-management of exacerbation, especially patients with persistent asthma or any history of a severe exacerbation. Patients should be able to recognize the early indicators of an exacerbation, such as a decline in PEF_r. There should be prompt communication between the clinician and patient during any abrupt worsening of asthma, as well as availability of a short course of systemic corticosteroids even before this communication takes place. The goals of treating an exacerbation are correction of any significant hypoxemia, rapid reversal of airflow obstruction, and reduction of the likelihood of recurrence of severe airflow obstruction by intensifying therapy.

The NHLBI expert panel recommends increasing the frequency of inhaled β_2 -agonists and initiating or increasing oral corticosteroid treatment. The panel does not recommend drinking large volumes of liquids or breathing warm, moist air. They also discourage the use of over-the-counter (OTC) products such as antihistamines, cold remedies, or bronchodilators. For patients who present to emergency departments (EDs), the clinician should obtain a brief targeted history as well as objective data such as peak-flow measurement and pulse oximetry. Clinicians should be aware of risk factors for asthma-related deaths: previous intubation or intensive care unit (ICU) admission for asthma, two or more hospitalizations, or more than three ED visits in the past year, use of more than two canisters of short-acting β_2 -agonist per month, low socioeconomic status, illicit drug use, major psychosocial problems, and comorbidities such as cardiovascular or chronic lung disease. Chest radiographs should be obtained only in patients suspected of having a more complicated process such as pneumothorax, pneumonia, or congestive heart failure. Treatment of exacerbations in the ED should

include nebulizer therapy with short-acting β_2 -agonists and nebulized anticholinergics such as ipratropium bromide (SOR: A) (Busse et al., 2007). However the NHLBI does not recommend continued use of nebulized anticholinergics during hospitalization. In general, patients should be discharged if their FEV₁ or PEF_r has returned to greater than 70% of their predicted personal best and they are in no respiratory distress.

Exercise-Induced Bronchospasm

Exercise-induced bronchospasm is a bronchospastic event that usually occurs during or minutes after vigorous activity. The peak of the bronchospasm occurs 5 to 10 minutes after stopping the activity and usually resolves by 30 minutes. The goal of management is to allow patients to participate in any activity they choose without being hindered by asthma symptoms.

Beta-2 agonists used shortly before exercise help prevent exercise-induced bronchospasm in more than 80% of patients. Cromolyn or nedocromil taken shortly before exercise are acceptable options but should be considered alternatives. If symptoms are not controlled with these options, long-term controller medications such as an inhaled corticosteroid or leukotriene modifier may be considered. A warm-up period before exercise can benefit patients who can tolerate continuous exercise with minimal symptoms (Busse et al., 2007).

KEY TREATMENT

Pulmonary function testing is the "gold standard" for the diagnosis and management of asthma and should be performed in all patients over 4 years of age (SOR: C).
 Minimize the use of short-acting inhaled β_2 -agonists for asthma patients (SOR: C).
 Short-acting inhaled β_2 -agonists should be used less than twice a week for asthma, or step therapy should be increased (SOR: C).
 Inhaled corticosteroids are the preferred therapy for all patients with persistent asthma (SOR: A).
 Asthma exacerbations should be treated with oral corticosteroids (SOR: A).
 Nebulized ipratropium can be used for asthma exacerbation in the ED setting but should not be used in the inpatient setting (SOR: A).

Paradoxical Vocal Cord Motion

Paradoxical vocal cord motion is defined by an inappropriate adduction of the true vocal cords on inspiration and adduction on expiration. The functional airway obstruction results in marked inspiratory stridor and wheezing, and the symptoms are similar to asthma. Often misdiagnosed as refractory asthma, paradoxical vocal cord motion appears to be psychogenic and occurs most often in young women with a history of prior psychiatric illnesses (e.g., depression, personality disorder, posttraumatic stress disorder, sexual abuse, generalized anxiety). Diagnosis is made by direct laryngoscopy with visualization of the cords throughout the respiratory cycle. Treatment is difficult because there are no published studies on the efficacy of psychodynamic therapy or pharmacologic treatment.

Anaphylaxis

Anaphylaxis has been traditionally defined as an acute, systemic, immediate hypersensitivity reaction produced by IgE-mediated degranulation of mast cells and basophils (Lieberman, 1998). The term *anaphylactoid* has referred to a clinically similar event not mediated by IgE-induced mast cell and basophil degranulation. An alternative classification by the World Allergy Organization (Johansson et al., 2004) eliminates anaphylactoid and refers to all events as *anaphylactic*, subdividing them into immunologic and nonimmunologic episodes. Immunologic episodes are then further subdivided into those caused by IgE-mediated mast cell and basophil degranulation and those resulting from other immunologic processes. An example of a non-IgE immunologically mediated event is a transfusion reaction. An example of a nonimmunologic event is a reaction to the administration of radiocontrast that can directly degranulate mast cells and basophils without intervening IgE.

Manifestations

Almost all patients with anaphylaxis express cutaneous symptoms, the most common of which are urticaria and angioedema. However, anaphylactic events can occur without any cutaneous manifestation. The most common cause is probably the rapid onset of hypotension and shock, which diverts blood flow from the skin. Anaphylaxis can clearly be the cause of syncope without any other manifestation and therefore must be considered as a cause of any syncopal episode. Table 20-5 lists signs and symptoms of anaphylaxis and their frequency (Lieberman et al., 2005).

Criteria have been established for the diagnosis of anaphylaxis (Box 20-4) (Sampson et al., 2006). Anaphylaxis usually requires at least two-system involvement; in most cases the skin is involved, and respiratory, vascular, or gastrointestinal symptoms accompany skin involvement. Single-system involvement (usually the skin) may be sufficient when this symptom appears after exposure to a known allergen (e.g., person known to be allergic to shellfish who develops urticaria within 30 minutes of shellfish ingestion); the diagnosis of anaphylaxis can be made without two-system involvement. This concept is important because rapid administration of epinephrine in such a patient might prevent further manifestations.

The differential diagnosis and most common causes of anaphylaxis are shown in Boxes 20-5 and 20-6. The most frequent cause of anaphylaxis is foods, and the next most common is drugs. The most common food to cause anaphylaxis in adults is shellfish. In children, peanuts are the most common offenders. As many as 50% of cases of anaphylaxis occur without a known cause despite intense investigative efforts (Webb et al., 2004). Laboratory testing can be useful to establish a diagnosis of anaphylaxis and to rule out other causes of symptoms caused by conditions that mimic anaphylaxis (Table 20-6). The most common test to confirm a diagnosis of anaphylaxis is serum tryptase, with high specificity but low sensitivity. Plasma histamine and 24-hour urinary histamine metabolites can also be measured.

Table 20-5 Signs and Symptoms of Anaphylaxis and Frequency of Occurrence

| Signs and Symptoms | Percent |
|---|--------------|
| Cutaneous | 90 |
| Urticaria and angioedema | 85-90 |
| Flushing | 45-55 |
| Pruritus without rash | 2-5 |
| Respiratory | 40-60 |
| Dyspnea, wheeze | 45-50 |
| Upper airway angioedema | 50-60 |
| Rhinitis | 15-20 |
| Abdominal | |
| Nausea, vomiting, diarrhea, cramping abdominal pain | 25-30 |
| Miscellaneous | |
| Dizziness, syncope, hypotension | 30-35 |
| Headache | 5-8 |
| Substernal pain | 4-6 |
| Seizure | 1-2 |

Box 20-4 Diagnosis of Anaphylaxis

Acute onset of an illness (minutes to hours) with involvement of skin and mucosal tissue (e.g., hives, generalized itch and flush, swollen lips, tongue, and uvula)

and

Airway compromise (e.g., dyspnea, wheeze or bronchospasm, stridor, reduced lung functions)

or

Reduced blood pressure or associated symptoms (e.g., hypotonia, syncope)

Two or more of the following after exposure to known allergen for that patient (minutes to hours):

History of severe allergic reaction

Skin or mucosal tissue involvement (e.g., hives, generalized itch or flush, swollen lips, tongue, uvula)

Airway compromise (e.g., dyspnea, wheeze/bronchospasm, stridor, reduced lung function)

Reduced blood pressure or associated symptoms (e.g., hypotonia, syncope)

In suspected food allergy: gastrointestinal symptoms (e.g., cramping abdominal pain, vomiting)

Hypotension after exposure to known allergen for that patient (minutes to hours)

Infants and children: low systolic blood pressure (age specific)

Adults: systolic blood pressure less than 100 mm Hg

Caution: These criteria describe classic cases of anaphylaxis. Other presentations can also indicate anaphylaxis. Physicians must remember the potential for false-positive symptoms or signs resulting from panic, vasovagal episodes, and other causes.

Treatment

Special equipment is necessary to deal with anaphylactic events that occur in the office (Box 20-7). An algorithm for the management of the acute episode is shown in Figure 20-5.

On suspicion that an anaphylactic event has occurred, therapy should be initiated immediately (Box 20-8). The airway, circulation, and level of consciousness should immediately be assessed. Oxygen should be started and the patient placed in the recumbent position with feet elevated. The recumbent position is important because death has been associated with the upright position. The upright position allows decreased venous return to the heart, resulting in pulseless ventricular contractions and arrhythmias.

Simultaneous with assessment, epinephrine should be administered. Intramuscular (IM) injection in the lateral thigh gives a more rapid peak level than subcutaneous or deltoid IM injection; therefore the lateral thigh is the preferred site of injection. For adults, the dose is 0.2 to 0.5 mL of a 1:1000 aqueous epinephrine preparation. For children, the

Table 20-6 Tests Used to Confirm a Diagnosis of Anaphylaxis

| Test | Comment |
|---|--|
| Tests Used to Rule in Anaphylaxis | |
| Serum tryptase | Peaks at 60 to 90 minutes after onset of symptoms. May be elevated up to 6 hours. Ideal time to obtain blood is 1 to 2 hours after symptoms begin. |
| Plasma histamine | Begins to rise 5 to 10 minutes after onset of symptoms. Remains elevated only up to 60 minutes. |
| 24-hour urinary | May be assayed in urine for up to 24 hours after initiation of histamine metabolite symptoms. |
| Tests Used to Rule out Other Conditions | |
| Serum serotonin | Rules out carcinoid. |
| Urinary 5-hydroxyindoleacetic acid | Rules out carcinoid. |
| Serum vasointestinal hormonal polypeptide panel* | Rules out vasoactive polypeptide–secreting gastrointestinal tumor or medullary carcinoma of thyroid. |
| Plasma-free metanephrine and urinary vanillylmandelic acid | Rules out paradoxical response to pheochromocytoma. |
| *For example, pancreastatin, pancreatic hormone, vasointestinal polypeptide, and substance P. | |

dose is 0.01 mg/kg to a maximum of 0.3 mg. A more precise dosage regimen has been recommended by the Resuscitation Council of the United Kingdom (Box 20-9). If symptoms do not improve, this dose can be readministered at 5-minute intervals (or more frequently if the physician deems necessary). After several injections, if there is no response, an intravenous (IV) infusion of epinephrine may be considered. An infusion can be prepared by adding 1 mg (1 mL of 1:1000 dilution of epinephrine) to 250 mL of D5W, yielding a concentration of 4.0 µg/mL. This solution is infused at a rate of 1 to 4 µg/min (15–60 drops/min with microdrop apparatus), increasing to a maximum of 10.0 µg/min for adults and adolescents. For children, the dose is 0.01 mg/kg (0.1 mL/kg of 1:10,000 solution up to 10 µg/min); maximum recommended dose is 0.3 mg.

Epinephrine is mandated and the drug of choice for anaphylaxis. Other drugs include H₁ and H₂ antagonists; a combination of both is more effective than an H₁ antagonist alone for vascular manifestations. Diphenhydramine, 25 to 50 mg for adults and 1 mg/kg for children, can be given by slow IV infusion. Ranitidine can be administered in a dose of 1 mg/kg in adults and 12.5 to 50 mg in children, infused over 10 to 15 minutes. No controlled studies have demonstrated efficacy of corticosteroids, but they should help in prolonged reactions. Although there is no established dose, the suggested dose equivalent is 1 to 2 mg/kg of methylprednisolone every 6 hours.

For persistent hypotension, fluids or other vasopressors (or both) should be administered. For adults with persistent hypotension, 1 to 2 L of normal saline can be administered

Box 20-7 Equipment and Medication for Therapy of Anaphylaxis in the Office**Primary**

Epinephrine solution (aqueous) 1:1000 (1-mL ampules and multidose vials)
 Epinephrine solution (aqueous) 1:10,000 (commercially available preloaded in a syringe)
 Tourniquet
 1-mL and 5-mL disposable syringes
 Oxygen tank and mask or nasal prongs
 Diphenhydramine injectable
 Ranitidine or cimetidine injectable
 Injectable corticosteroids
 Ambubag, oral airway, laryngoscope, endotracheal tube, no. 12 needle
 Intravenous setup with large-bore catheter
 IV fluids: 2000 mL of crystalloid solution, 1000 mL of hydroxyethyl starch
 Aerosol beta-II bronchodilator and compressor nebulizer
 Glucagon
 Electrocardiogram
 Normal saline: 10-mL vial for epinephrine dilution

at rates of 5 to 10 mg/kg in the first 5 minutes. After resolution of symptoms, patients should be observed because biphasic reactions can occur in up to 23% of cases (Scranton et al., 2009). The observation period should range from 6 to 24 hours, depending on the severity of the reaction (Tole and Lieberman, 2007).

Patients who have experienced episodes of anaphylaxis and who are at further risk of future events (e.g., insect sting hypersensitivity, food allergy) should have a prescription for an epinephrine autoinjector and should be instructed in its use. In addition, such patients should not take, if at all possible, drugs that might increase the severity of any future event or interfere with the use of epinephrine to treat such an event (Table 20-7).

KEY TREATMENT

Epinephrine should be the first medication used in the treatment of anaphylaxis (SOR: A).
 Patients should be placed in supine position and oxygen administered, if needed (SOR: A).
 Treatment with IV fluids, antihistamines (both H₁ and H₂), and corticosteroids should be considered after epinephrine administration (SOR: A).
 Glucagon or atropine should be considered in anaphylaxis recalcitrant to treatment (SOR: A).

Table 20-7 Drugs that Can Worsen or Complicate Therapy in Anaphylaxis

| Drug Class | Effect |
|------------------------------|---|
| Beta blockers | Can worsen hypotension or wheeze and simultaneously decrease the β -adrenergic response to epinephrine as well as accentuate its α -adrenergic response. |
| ACE inhibitors | ACE metabolizes kinins that are activated during anaphylactic events; therefore an ACE inhibitor can worsen episodes. |
| ACE blockers | Although there is no clear-cut admonition regarding ACE blockers, theoretically they can have an effect similar to an ACE inhibitor. |
| Monoamine oxidase inhibitors | Interfere with catabolism of epinephrine and thus complicate calculation of correct dose of these drug inhibitors. |
| Tricyclic antidepressants | Prevent catecholamine reuptake and therefore can accentuate effect of a dose of epinephrine, thus complicating calculation of a proper dose. |

ACE, Angiotensin-converting enzyme.

Key Points

- The United States ranks 30th in infant mortality.
- The causes of infant mortality are preterm birth, birth defects, sudden infant death syndrome, respiratory distress syndrome, and maternal pregnancy complications.

The American Academy of Family Physicians (AAFP) describes the specialty of family practice as the enhanced expression of general medical practice that is uniquely defined within the context of the family. Providing care across the continuum of the family life cycle, the family physician provides care to the pregnant woman as part of the full expression of the

field. The family physician incorporates a comprehensive approach to maternity care that includes the assessment and management of psychosocial and biomedical risk factors. The family physician provides care to patients with low-risk pregnancies and equips them to birth their children without unnecessary interventions.

The family physician brings a unique approach to the management of the pregnant woman, who is often a healthy individual undergoing a natural process. This approach is patient centered, prevention oriented, educational, and noninterventional. Nationwide, approximately 29.6% of all family physicians provide routine obstetric services as part of their hospital care (AAFP, 1998). This number has been steadily declining, with regional variations reflecting the needs of the population and local attitudes. The majority of family physicians do not desire to practice obstetrics because of lifestyle issues, increasing costs of malpractice insurance, and difficulty obtaining hospital privileges. However, the family physician may be asked to counsel or care for the pregnant woman, even if not part of daily practice. It becomes incumbent on the individual practitioner to have a fundamental knowledge and appreciation of the field of obstetrics, including the obstetric emergency. Given that the family physician may be the sole provider of obstetric services, particularly in rural or underserved areas, the need to maintain the knowledge and skills to treat the problems and emergencies unique to obstetrics becomes increasingly important. The Advanced Life Support in Obstetrics (ALSO) course developed in 1990 effectively incorporates the techniques of other established life support courses as it applies to obstetric care.

For the successful practice of obstetrics, it is imperative for the family physician to practice in concert with an obstetric specialist. A collaborative relationship among obstetricians, family physicians, and in some cases, nurse midwives is essential for provision of consistent, high-quality care to pregnant women. Access to reliable consultation and suitable referral facilities for the complicated patient will optimize patient care and outcomes.

The integration of prenatal care into the clinical practice of the family physician not only reflects the full scope of the field but also provides a continuous infusion of pediatric patients into the practice. It serves as a model for the training of medical students and residents interested in the practice of obstetric care in the context of family practice.

This chapter provides an overview of the field of obstetrics that includes prenatal, intrapartum, and postpartum care of the pregnant woman. An evidence-based approach to areas of controversy and empiric practice is used while addressing the unique needs of family physicians, emphasizing their contribution and role in the research and development of the obstetrics literature.

Woman and Child Health

The health of a nation is often reflected in the health of its mothers and newborns. The World Health Organization (WHO) often uses a nation's maternity and neonatal morbidity and mortality statistics as a proxy for the health status of its population. It is an important summary reflecting social, political, health care delivery, and medical outcomes in a geographic area. The United States, despite its economic

wealth and medical resources, consistently ranks poorly in such measures as maternal and infant mortality rates. In 2005 in the United States, 28,384 infants died before reaching their first birthdays, an infant mortality rate (IMR) of 6.9 per 1000 live births. Despite a more than 9% reduction in IMR between 1995 and 2005, the United States ranks 30th, after such select countries as Japan, the Scandinavian countries, and Canada (Box 21-1). In 2005, the U.S. IMR was more than three times as high as that in Singapore (2.1 per 1000 live births), the country with the lowest reported IMR. This number reflects in part the continuing disparities in health access and delivery for U.S. citizens (National Center for Health Statistics [NCHS], 2009).

*Under 1 year of age; rankings are from lowest to highest IMR (per 1000 live births). Countries with the same IMR receive the same rank. Some of the variation in IMRs is caused by differences among countries in distinguishing between fetal and infant deaths.

Note: U.S. data used in this table is final mortality data. After 1994, PeriStats uses period-linked birth/infant death data to calculate IMRs. Rates in table may vary slightly from other rates on PeriStats: www.marchofdimes.com/peristats.

The causes of infant mortality are multiple, with birth defects being the leading cause, with a 2005 rate of 134.6 per 100,000 live births. Preterm birth (birth at <37 completed weeks of gestation) or low birth weight (LBW) is the second leading cause of infant mortality in the United States. Preterm birth rates differ by race; during 2003–2005 (average), IMR (per 1000 live births) in the United States was highest for black infants (13.3), followed by Native Americans (8.4), whites (5.7), and Asians (4.8) (NCHS, 2010). This persistent disparity contributes to the relative high IMR in the United States compared with similarly developed countries. Other causes of infant mortality include sudden infant death syndrome, respiratory distress syndrome, and maternal pregnancy complications. These five causes accounted for more than half of all infant deaths in 2005 (Fig. 21-1). Despite gains, the rate of preterm birth, birth defects, and LBW remain relatively constant. This indicates a need for further health initiatives to address the health needs of the pregnant woman and the unborn.

Preconception Counseling

Key Points

- Preconception care is an integral part of prenatal care and permits health promotion and early identification of risk factors that can then be treated before pregnancy
- Folic acid supplementation should be started before conception, if possible, or immediately on diagnosis of pregnancy.

Ideally, women should plan pregnancy and discuss this plan with their physicians. Often, however, this option is not considered. It becomes the task of the physician to anticipate the potential and discuss preparation for pregnancy just as for methods of birth control. Primary care physicians are in

the best position to anticipate the need for this counseling, being most aware of ongoing medical problems and social concerns of the women in their care. Indeed, the practice of preconception care has been formally recommended since at least 1989 (Caring for Our Future, 1989). However, we believe that preconception care, in particular education, should begin at the time a woman reaches reproductive age, not only when she announces the desire to become pregnant.

The preconception period is an ideal time for education and counseling regarding cessation of cigarette, alcohol, or drug use. Often, the incentive of a healthier pregnancy is sufficient impetus for change in behavior. Although many women are able to cease cigarette, alcohol, or drug use during the pregnancy, the majority will resume use after delivery or breastfeeding. This is an opportune time for the family physician to reinforce further health-conscious behavior.

The preconception use of folic acid supplementation was formally recommended by the U.S. Centers for Disease Control and Prevention (CDC) in 1991 and others (American Academy of Pediatrics, Committee on Genetics, 1999). Evidence supports a reduction in neural tube defects by 50% when folic acid stores are replenished before pregnancy (Milunsky et al., 1989). It is now recommended that all reproductive-age women take 0.4 mg of folic acid daily (CDC, 1992). This is easily accomplished by prescribing prenatal vitamins before pregnancy as well as throughout gestation. Alternately, over-the-counter (OTC) vitamins can also be used because many now contain this higher amount of folic acid. For couples with one or more children with a neural tube defect or a family history, there should be a referral for specific counseling. From 2 to 4 mg of folic acid daily is recommended for these women at least 1 month before pregnancy and during the first 3 months of pregnancy.

Many genetic disorders are now amenable to prenatal diagnosis through direct analysis of the underlying mutations, analysis of their protein products, or abnormal metabolites. Genetic counseling should include a systematic assessment of family history of both parents. This can be through a targeted questionnaire or formal genetic counseling by a genetic counselor or geneticist (Box 21-2). The family physician should be aware of the ethnic makeup of the practice and especially familiar with disorders in these groups (Table 21-1). When targeted screening reveals an area of potential concern, formal genetic counseling should be obtained. With advances in discovery of the genetic basis for many diseases, the list of disorders amenable to prenatal diagnosis grows daily.

Figure 21-1 Infant deaths by cause of death, United States, 2005. Rates per 100,000 live births. *SIDS*, Sudden infant death syndrome; *RDS*, respiratory distress syndrome; *Maternal Preg. Comp.*, maternal complications of pregnancy. (Modified from National Center for Health Statistics. Period-linked birth/infant death data. www.marchofdimes.com/peristats. Accessed March 2010.)

KEY TREATMENT

Folic acid supplementation is 0.4 mg for women without risk factors and up to 4 mg for those with risk factors (SOR: A).

Nutrition

There is sufficient data to confirm that poor nutrition during the prenatal period is associated with adverse pregnancy outcome, specifically *intrauterine growth restriction* (IUGR) and preterm delivery. Specific nutritional guidelines have been developed based on a woman's prepregnancy weight or, more specifically, her body mass index (BMI) (Table 21-2).

Box 21-2 Genetic Screening/Teratology Counseling

1. Will you be 35 at the time of your baby's birth?
2. What medications, prescribed, herbal, or over the counter, have you taken since your last menstrual period?
3. How much alcohol, cigarettes, or street drugs have you used since your last menstrual period?
4. Have you had miscarriages or stillborns? How many?
5. Do you have any metabolic disorders (such as diabetes or phenylketonuria)?
6. Have you been ill or had any infections since your last menstrual period?
7. What are the ethnic backgrounds of you and the baby's father? Are you related in any way?
8. Do you, the baby's father, or anyone in either of your families have:
 - a. Neural tube defects (meningomyelocele, spina bifida, or anencephaly)?
 - b. Congenital heart defects?
 - c. Down syndrome?
 - d. Tay-Sachs disease (Jewish, Cajun, French Canadian)?
 - e. Sickle cell disease or trait (African American)?
 - f. Thalassemia (Italian, Mediterranean, Asian or African American)? (MCV <80?)
 - g. Muscular dystrophy?
 - h. Cystic fibrosis?
 - i. Huntington's chorea?
 - j. Fragile X, mental retardation, or autism?
 - k. Other chromosomal or inherited disorders or birth defects?

Caloric intake of an extra 300 kcal daily is sufficient for adequate maternal weight gain and fetal growth.

The practice of prenatal supplementation of vitamins and minerals is widespread, although many nutritionists believe it is unnecessary. Only the following two supplements are recommended in an adequately nourished female with a singleton pregnancy:

1. Iron, 30 mg/day, in the second and third trimester to meet the fetal demands for erythropoiesis.
2. Folic acid, 400 µg/day, in the preconception period and during the first trimester for prevention of birth defects.

However, because many U.S. women do not consume adequate vitamins and minerals (Block and Adams, 1993), and specific assessment of nutritional intake is often difficult, supplements are now widely used. Recommended daily allowances for pregnant women have been established and continue to be reevaluated (Table 21-3). Care must be taken to avoid toxicity of the fat-soluble vitamins, in particular vitamin A (retinol), where "more" is not necessarily better. Daily doses of retinol greater than 10,000 IU, approximately 3000 retinol equivalents (RE), have been associated with birth defects (Rothman et al., 1995). Women who do not consume sufficient milk products may benefit from calcium supplementation. This can easily be accomplished by prescribing an antacid that is made of calcium carbonate, most easily taken in chewable form. This will not only replenish calcium stores but also treat reflux esophagitis, which often occurs in the latter half of pregnancy.

Recent data suggest that supplementation with omega-3 fatty acids, specifically docosahexaenoic acid (DHA) plus eicosapentaenoic acid (EPA), may be beneficial (Dunstan et al., 2008). Both DHA and EPA may be beneficial for fetal

BMI, Body mass index.

brain development and are found in large amounts in wild fish. However, increased fish intake in pregnancy is not recommended because of the risk of increased mercury ingestion. Therefore, supplementation would be required. Large, well-controlled studies are needed before recommendation in pregnancy, but supplementation may be considered on an individual basis. The U.S. Food and Drug Administration (FDA, 2004) has formally warned women of childbearing age, pregnant and lactating women, and young children to avoid eating swordfish, shark, king mackerel, and tilefish and to consume no more than one 6-ounce can of albacore tuna per week. In all pregnant women, nutritional risk factors should be addressed, including low starting BMI, prior LBW infants, adolescence, religious and cultural dietary restrictions, medical illnesses requiring dietary manipulation, substance abuse, and eating disorders (Kolasa and Weismiller, 1995). Certain woman may benefit from formal dietary counseling from a dietician/nutritionist.

KEY TREATMENT

Iron (30 mg/day) is recommended in the second and third trimesters (SOR: A).
Folic acid (400 µg/day) is recommended in the preconception period and first trimester (SOR: A).

Medical Risk Assessment

The preconception period is the ideal time to assess and counsel the prospective pregnant woman regarding medical disorders or risks she may encounter during the pregnancy. Of medical problems that have substantial impact on the fetus, hypertensive disorders and diabetes are among the most common.

Hypertension may have many effects on the pregnancy depending on the degree of abnormality. Fetal effects range from none to increased miscarriage, IUGR, abruptio placentae, and fetal death. Underlying blood pressure disorders should be treated appropriately before pregnancy. Some hypertensive, reproductive-age women are treated with angiotensin-converting enzyme (ACE) inhibitors. This class of therapeutics can cause significant risk to the developing fetus. These medications should be stopped and alternate medications started if needed. Women with preexisting hypertension should be referred for concurrent care with a physician experienced in managing hypertension in pregnancy.

Diabetes can also have many effects on the developing fetus. The preconception control of the maternal metabolism, reflected as normal blood glucose values before and after meals and normal hemoglobin A_{1c}, has been shown to decrease the incidence of diabetes-associated embryopathy to almost that of a nondiabetic pregnant woman (Mills et al., 1988). Women with preexisting diabetes should be referred for specialized care if pregnancy is contemplated.

Less attention is directed to emotional and psychiatric disorders. Pregnancy may be a stressor that precipitates an acute event or worsens ongoing anxiety or depression. This is more likely in the postpartum period.

KEY TREATMENT

Preconception care is an integral part of prenatal care and permits health promotion and early identification of risk factors that can then be treated before pregnancy, such as diabetes or hypertension (SOR: A).

Women with preexisting diabetes should be referred for specialized care if pregnancy is contemplated (SOR: C).

Routine Prenatal Care

In most Western countries, women attend between 7 and 11 prenatal visits, although recent data suggest that a reduced number of antenatal visits could be introduced into clinical practice without adverse effect to the mother and child (Carrolli et al., 2001). Obstetric care provided by obstetricians, family physicians, and midwives has been found to be equally effective; however, patients were slightly more satisfied by the care provided by midwives and family physicians (Villar et al., 2004). Prenatal care services typically include screening and treatment for medical conditions and identification and interventions for behavioral risk factors associated with poor birth outcomes (e.g., smoking, poor nutrition).

One of the most important goals of prenatal care is recognizing which women have high-risk pregnancies and triaging these women to appropriate care (Kontopoulos and Vintzileos, 2004). It is important to identify the women at risk for adverse outcomes and refer them to appropriate specialty care. Adequate prenatal care has been shown to increase the chances that a woman has a healthy pregnancy and baby.

First Prenatal Visit

The first prenatal visit is one of the most important, particularly if the woman has not had preconception care (Box 21-3). The first prenatal visit should occur shortly after

the woman discovers she might be pregnant and should be viewed as a continuation of preconception counseling. Home pregnancy test kits have a sensitivity and specificity of at least 95%; many can detect pregnancy by the fifth menstrual week. The most important aspects of the first prenatal visit include education, risk assessment, appropriate laboratory testing, and establishment of gestational age.

Education is an important component of prenatal care, particularly for women who are pregnant for the first time. Frequency of prenatal visits should be explained, with information about the physiologic changes that occur during

Box 21-4 Recommendations for Exercise in Pregnancy

1. Established exercise routines can be continued with mild to moderate intensity.
2. High-intensity or high-impact routines should be avoided or reduced.
3. The supine position should be avoided in the second and third trimesters.
4. Hyperthermia should be avoided.
5. Weight-bearing exercise should minimize strain because joints are more lax.
6. Routines should be designed to minimize risk of maternal trauma (falling).
7. Adequate nutritional intake to compensate for pregnancy should be assured.
8. Resumption of prepregnancy routines in the postpartum period should be gradual.

pregnancy. Preparation for the birthing process is a key theme around which to discuss care issues and choices such as breastfeeding. Structured educational programs to promote breastfeeding have unclear effectiveness. Pregnant women should be counseled about the risks of possible teratogens, including smoking, alcohol, and drug use, including exposure to medications, prescriptions, OTC drugs, and herbal remedies. Good handwashing is always encouraged because this is one of the best ways to avoid community-acquired infectious diseases. Appropriate immunizations such as influenza and novel influenza A (H1N1) virus should be offered. Common exposures such as workplace conditions and use of hot tubs and saunas should be explored. Exercise should also be encouraged if there is no obstetric contraindication (Box 21-4). Intercourse during pregnancy should be actively addressed because some women are reluctant to discuss this topic even with their physician. Sexual activity can generally continue during pregnancy except for few situations, such as placenta previa and preterm labor. Counseling regarding sexually transmitted diseases (STDs) and their avoidance should occur. Nutrition should be individualized, with an estimate of desirable weight gain given to the pregnant woman.

The estimated date of delivery (EDD) should be calculated by accurate determination of the last menstrual period (LMP). The first day of the LMP is a good clinical sign from which to calculate EDD, remembering that it must be adjusted for cycles shorter or longer than 28 days. The EDD can be calculated by Nagle's rule, that is, subtracting 3 months and adding 7 days to the first day of the LMP. EDD should then be extended by the number of days longer than a 28-day cycle or shortened by the number of days shorter. This approach should be considered if there is uncertainty about the LMP.

The physical examination during the first prenatal visit should include careful assessment of uterine size. If there is a discrepancy between menstrual age and uterine size, ultrasound should be considered early in the pregnancy to resolve the issue of dating. Recent evidence suggests that early sonography provides more accurate dating, which is important for timing screening tests and interventions and for optimal management of complications such as

post-term pregnancies (Neilson, 2004). Late ultrasound, after 24 weeks, is not as sensitive for confirming gestational age. Additionally, any irregular bleeding or abdominal pain should prompt the practitioner to obtain sonographic confirmation of viability of the pregnancy as well as its normal intrauterine location.

A history and directed physical examination should be performed to detect conditions associated with increased maternal and perinatal morbidity and mortality. The first prenatal examination provides an opportunity for cervical cancer screening with a Papanicolaou (Pap) test in women who have not been screened recently. However, Pap tests performed in pregnant women may be less reliable. Risk factors should then identify other testing that might be done at this time, including blood glucose, sickle cell screening, Tay-Sachs screening, and surveillance for other infectious diseases.

Routine fetal heart auscultation, urinalysis, and assessment of maternal weight, blood pressure, and fundal height generally are recommended, although the supportive evidence varies (Kirkham et al., 2005). Women should be offered ABO and Rh blood typing and screening for anemia during the first prenatal visit. Genetic counseling and testing should be offered to couples with a family history of genetic disorders, a previously affected fetus or child, or a history of recurrent miscarriage. All women should be offered prenatal serum marker screening for neural tube defects and aneuploidy. Women at increased risk for aneuploidy should be offered amniocentesis or chorionic villus sampling (CVS). Counseling about the limitations and risks of these tests, as well as their psychologic implications, is necessary. Folic acid supplementation beginning in the preconception period and early pregnancy reduces the incidence of neural tube defects. Laboratory testing during the first prenatal visit consists of assessment of hemoglobin and hematocrit to identify anemia; blood D(Rh) type; serologic tests for syphilis, and rubella immunity; hepatitis B, and urinalysis. Testing for human immunodeficiency virus (HIV) infection should be offered and highly recommended because perinatal transmission can be decreased with appropriate medical intervention. During the pelvic examination, a Pap smear (if not done in past 6 months) as well as cultures for *Neisseria gonorrhoeae* and *Chlamydia* should be taken.

Follow-up Prenatal Visits

According to the report of the Expert Panel on Prenatal Care (Rosen et al., 1991), low-risk primigravid women should have at least 10 prenatal visits; low-risk multiparous women should have at least eight visits. Again, however, data suggest that antenatal visits could be reduced without adverse effect to the mother and child (Carroli et al., 2001). Women with psychosocial issues or pregnancy complications should be seen more frequently. In the first two trimesters, prenatal visits may be 5 to 6 weeks apart if no problems have been ascertained. Frequency of visits should increase after 30 weeks, with weekly visits after 37 weeks. Specific recommendations are noted in Table 21-4. Routine visits for low-risk women should be scheduled at times that recommended laboratory testing could be accomplished. Prenatal screening for chromosomal abnormalities is available in the first trimester between 10 weeks, 2 days and 13 weeks, 6 days. Structural defects of the fetus (in particular neural

[†]That week and each week thereafter.

‡For some.

HIV, Human immunodeficiency virus.

tube defects) and karyotypic abnormalities in the form of alpha-fetoprotein based tests (Quad screen, see below) can be obtained at 16 to 18 weeks. Screening for gestational diabetes is recommended at 26 to 28 weeks of gestation, as well as screening for anemia with a hemoglobin or hematocrit. Antibody screening, Rh₀(D) immune globulin (RhoGAM) prophylaxis for D-negative mothers, and repeat testing for infectious diseases for at-risk mothers are recommended at this time.

At 36 weeks' gestation, rectocervical cultures for group B streptococci (GBS) should be obtained. If cultures are positive, antibiotic prophylaxis during labor is given. For women without a penicillin allergy, penicillin (5 million units, then 2.5 million units IV every 4 hours) is administered during labor. If there is a penicillin allergy, sensitivities to clindamycin and erythromycin should be obtained and one of these agents used. If the organism is resistant to these antibiotics, women with a serious penicillin allergy should receive vancomycin; women with a minimal reaction from penicillin (e.g., rash) should receive a first-generation cephalosporin intravenously during labor (ACOG, 2002a, Schrag et al., 2002). Women with GBS bacteremia or a prior child affected with GBS sepsis should be treated during labor without screening cultures.

The clinical components of routine prenatal visits are controversial. Most guidelines recommend routine assessment with fundal height and maternal weight and blood pressure measurements, fetal heart auscultation, urine testing for protein and glucose, and questions about fetal movement. The assessment of uterine growth and size should be performed at every prenatal visit. Documentation of fetal heart tones is also recommended with each prenatal visit. Before 12 weeks' gestation, the size of the uterus is estimated by bimanual pelvic examination. The ability to assess the presence of fetal heart tones using Doppler ultrasound before 12 weeks is variable. After 12 weeks and before

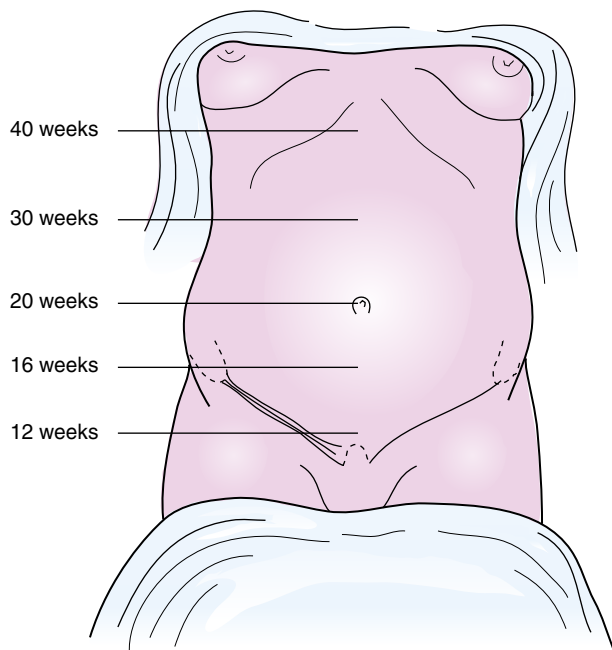

Figure 21-2 Fundal growth at various weeks of gestation.

20 weeks, adequate uterine growth is assessed by location of the uterine fundus in the lower abdomen (Fig. 21-2). Fetal heart tones should be reliably heard during this period. At 20 weeks of gestation, most women have a palpable fundus at the umbilicus. After 20 weeks, fundal height is measured using the distance from top of the symphysis pubis to top of the fundus. The number of completed weeks of gestation should equal this measurement in centimeters (± 2 cm). This measurement should be performed as accurately as possible. The most common reasons for inconsistency between menstrual age and fundal height is an inaccurate menstrual-age assignment and inaccurate measurements caused by maternal obesity. Larger-than-expected fundal height may also be caused by multiple gestation, uterine fibroids, polyhydramnios, or a large-for-gestational-age (LGA) fetus. Smaller-than-expected fundal height should warrant an exploration for etiologies such as oligohydramnios, IUGR, and fetal demise.

By 30 weeks' gestation, the fetus is large enough that it can be palpated through the maternal abdomen. Position of the fetus should be documented at this and subsequent visits. This is easily done in most women by Leopold's maneuvers (Fig. 21-3). The first maneuver involves palpation of the uterine fundus to identify the fetal part that is there. The palpating hands then glide downward laterally to perform the second maneuver, location of the fetal back. In the third maneuver the hands are cupped around the presenting part

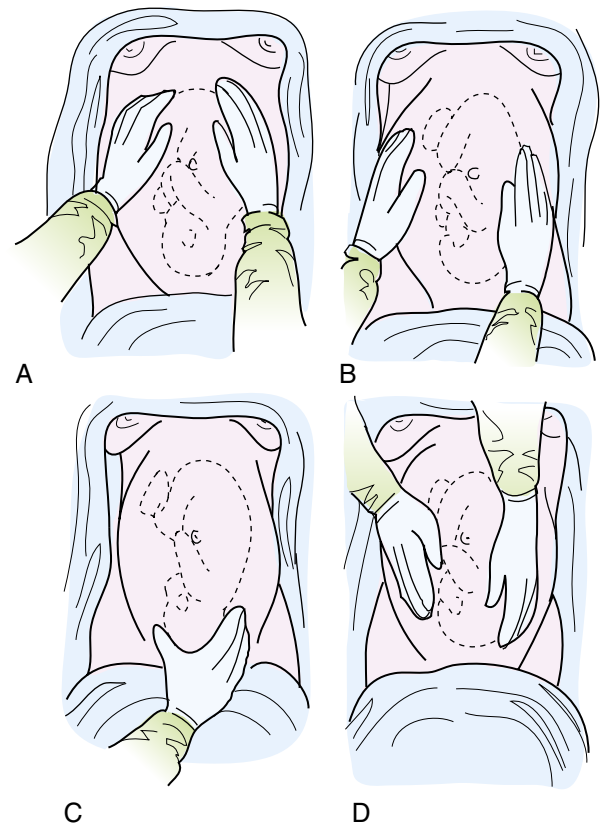

Figure 21-3 Leopold's maneuvers for determination of fetal position. **A**, First maneuver: palpation of the uterine fundus to identify the fetal part. **B**, Second maneuver: location of the fetal back. **C**, Third maneuver: cupped hands to determine the presenting part and station. **D**, Fourth maneuver: palpation of the cephalic prominence to determine the degree of flexion.

at the level of the symphysis pubis to determine the presenting part as well as its degree of descent into the pelvis. If the presenting part is cephalic, the fourth maneuver will determine its degree of flexion. The examiner now turns 180 degrees to face the mother's legs, and the cephalic prominence is palpated. Another aid in ascertaining the position of the fetal back is the location of the fetal heart tones by Doppler sonography or auscultation. These sounds are best heard through the fetal back; in the left lower uterus in left occiput anterior, transverse, and posterior positions of the fetal head; and the right lower uterus in right occiput positions. The evidence supporting the previous practices is variable but continues as the standard of care (Kirkham et al., 2005).

By the end of gestation, the practitioner as well as the woman should know the presentation of the fetus. This avoids emergent management when she presents in labor with a nonvertex presentation. Internal digital cervical examination can also verify presentation of the fetus and may be done when needed. Unless indicated, however, routine cervical examination to determine cervical readiness for labor need not be done until 41 weeks' gestation.

Prenatal Genetic Diagnostic Testing

If specific risk factors for fetal abnormalities are identified in the mother, appropriate counseling and specific diagnostic testing should be offered. The most common reason to offer prenatal genetic diagnosis is advanced maternal age; a somewhat linear increase in nondisjunction in meiosis increases the risk of a conception with aneuploidy (abnormal chromosome number). This is one reason why older women have a higher rate of spontaneous first-trimester miscarriage. It is also why older women are more likely to give birth to a child with a chromosomal abnormality, most often Down syndrome (trisomy 21).

Women of advanced maternal age are those 35 or older at the anticipated birth of their baby. This group of women should be given specific counseling and offered diagnostic testing in the form of amniocentesis or CVS to ascertain the well-being of their fetus.

Amniocentesis

Genetic amniocentesis is typically performed at 14 to 20 weeks of gestation but can also be done any time after 20 menstrual weeks. After ultrasound examination of the fetus and placenta, an area of skin overlying a pocket of amniotic fluid is cleaned with iodine solution. With ultrasound guidance throughout the procedure, a 22-gauge spinal needle is used to remove 20 mL of amniotic fluid. Special care is taken to avoid the fetus, umbilical cord, and the large placental vessels. In experienced hands, the pregnancy loss rate attributed to the procedure is about 1 in 300. The entire testing time for a chromosomal analysis is about 10 to 12 days. Alternately, the supernatant may be assayed for metabolites to diagnose other disorders that run in the family if identified on counseling. Earlier amniocentesis (at 11 to 13 weeks) has been successfully performed but is not recommended any longer because of the recent initial reports regarding a slightly higher rate of clubfoot in these newborns.

EVIDENCE-BASED SUMMARY

- Early amniocentesis performed before 14 completed weeks of gestation is not considered a safe alternative to second-trimester amniocentesis or chorionic villus sampling (CVS) (SOR: A).
- CVS should *not* be performed before 10 completed weeks of gestation (SOR: B).
- CVS should always be performed under direct ultrasound control (SOR: B).
- Third-trimester amniocentesis does not appear to be associated with significant risk of complications leading to emergency delivery (SOR: B).

Chorionic Villus Sampling

In CVS, another technique for obtaining fetal tissue for genetic evaluation, the chorionic villi, or placental cells, are aspirated. With ultrasound guidance, CVS can be performed at 10 to 13 menstrual weeks transabdominally with a spinal needle or transvaginally with a catheter designed and approved for this purpose. Chromosomal analysis of the villous cells can be completed in 7 days. Thus the advantage to CVS is the early gestational time of the procedure and availability of the results. The procedure-related fetal loss rate is approximately 1 in 125 tests (Jackson et al., 1992).

Maternal Biochemical Screening

Low-risk women can be offered screening for genetic abnormalities of the fetus by biochemical testing in the first or second trimester and ultrasound nuchal translucency screening (first trimester) and targeted ultrasound evaluation of fetal anatomy, best done at 18 to 20 weeks' gestation. The general consensus is that women of any age should have access to any screening or diagnostic testing (as previously described) if they choose to accept the underlying risks.

Biochemical testing is the measurement of certain chemicals in the mother's blood found to be predictive of fetal abnormality. The quadruple screen is a maternal blood test in which one maternal sample drawn at 15 to 20 weeks (but most sensitive at 16 to 18 weeks) is assayed for alpha fetoprotein, estriols, and beta subunit of human chorionic gonadotropin (hCG). Normal ranges vary for each gestational week. Maternal serum alpha-fetoprotein (MSAFP) elevations can result from open neural tube defects such as spina bifida or anencephaly, when the protein leaks from the fetal tissue into the amniotic fluid through the amniochorion and into the maternal system. A lower-than-expected MSAFP suggests Down syndrome. The addition of β subunit of hCG and estriols has improved sensitivity for the detection of chromosomal abnormalities (Table 21-5). This test should be offered to any pregnant women with appropriate counseling regarding sensitivity and specificity. Women with abnormal tests should be referred for targeted ultrasound and possibly amniocentesis.

First-trimester ultrasound and biochemical screening are now available for clinical use, specifically the "First Trimester Screen" performed between 10 weeks, 2 days and 13 weeks, 6 days of gestation. Testing involves an ultrasound measurement of the nuchal translucency (lymphatic fluid at fetal neck) (Fig. 21-4) and laboratory measurement of pregnancy-associated plasma protein A (PAPP-A) and β subunit

|--------------------------|-----------------------|---------------------|---------------------------|
| | Detection Sensitivity | False-Positive Rate | Positive Predictive Value |
| Down syndrome | 77%-79% | 3%-5% | 3.7% |
| Trisomy 18 | 60% | 2%-4% | 2.2% |
| Open neural tube defect* | 90% | 4.0% | 2.5% |

*Most sensitive at 16 to 18 weeks of gestation.
 **Not used for neural tube defect screening.
 HCG, Human chorionic gonadotropin.

of hCG. The First Trimester Screen has about 85% sensitivity for Down syndrome detection at 4% false-positive rate. Several tests are also available that combine a first-trimester screen with a second-trimester screen for even higher sensitivity. Physicians should become familiar with the sensitivity, specificity, and availability of the test most suitable for their practices.

EVIDENCE-BASED SUMMARY

- First-trimester screening using both nuchal translucency measurement and biochemical markers is an effective screening test for Down syndrome in the general population (SOR: A).
- Women found to have increased risk of aneuploidy with first-trimester screening should be offered genetic counseling and the option of chorionic villus sampling or second-trimester amniocentesis (SOR: A).

Drug and Chemical Exposures in Pregnancy

Pregnant women frequently ask about the effect of drug and other chemical exposures on the unborn infant, whether environmental, OTC, or prescription. Many of these are everyday exposures at the workplace, in the community, or as a result of medical treatment and management.

Figure 21-4 Transabdominal ultrasound assessment of nuchal translucency (NT). The measurement in this figure is normal. An increased measure (>3 mm) is associated with an increased risk of chromosomal abnormalities, complex congenital heart disease, and other genetic syndromes.

The consequences can range from the most innocuous to actually jeopardizing the pregnancy. The physician should be prepared to answer these pregnancy-related questions and advise their patients appropriately.

The consequences of a chemical exposure may be related to the nature of the agent and the timing, dose, and duration of the exposure. The effect can range from minor morphologic abnormalities and growth deficiency to severe malformation and loss of the pregnancy. Thalidomide has obvious effects on the fetus, causing a third of fetuses to have limb reduction defects. Furthermore, the effect of a drug may be subtle or delayed (Welch et al., 1993). Diethylstilbestrol (DES) is associated with the development of uterine structural abnormalities and clear cell carcinoma of the vagina in daughters whose mothers took this medication.

Much of the knowledge about chemical exposures and effects on reproduction and fetal development comes from research on experimental animals. This poses great uncertainty given genetic variability and species-specific responses. Given these limitations, the health care provider must carefully weigh the evidence before using a drug. To help the practitioner classify a drug for use, the U.S. Food and Drug Administration (FDA, 1980) developed a risk factors index. The abbreviated definitions of these categories are as follows: **Category A:** Controlled studies in women fail to demonstrate a risk to the fetus.

Category B: Animal reproduction studies have not demonstrated a fetal risk, but there are no controlled studies in pregnant women; or animal reproduction studies have shown adverse effect that was not confirmed in controlled human studies.

Category C: Studies in animals have revealed adverse effects on the fetus, and there are no controlled studies in women. Drugs should be given only if the potential benefit justifies the potential risk to the fetus.

Category D: There is positive evidence of human fetal risk, but the benefits from use in pregnant women may be acceptable.

Category X: Studies in animals or humans have demonstrated fetal abnormalities, or there is evidence of fetal risk based on human experience. The drug is contraindicated in women who are or who may become pregnant.

Table 21-6 Drugs and Exposures in Pregnancy

| Agent | Recommendation | Comments |
|-----------------------------------|---------------------------------|---|
| Antihistamines | Acceptable | Most are category B. |
| Decongestants | Acceptable | Pseudoephedrine preferred. |
| Cough medication with guaifenesin | Acceptable | — |
| Acetaminophen | Acceptable | Preferred analgesic and antipyretic. |
| Aspirin | Avoid | Increases risk of bleeding; no benefit in preeclampsia; may be prescribed in low doses for specific conditions. |
| NSAIDs | Avoid | Premature closure of ductus arteriosus. |
| Cephalosporins | Acceptable | — |
| Sulfonamides | Avoid in third trimester. | Kernicterus in newborn. |
| Tetracyclines | Avoid | Discoloration of teeth. |
| ACE inhibitors | Avoid | Stillborn, renal abnormalities, renal failure in newborn. |
| Immunizations | Avoid live, attenuated viruses. | Measles, mumps, rubella. |
| Allergy shots | Acceptable | Alteration in maintenance dose may be necessary. |

Modified from Hueston WJ, Eolers GM, King DE, McGlaughlin VG. Common questions patients ask during pregnancy. *Am Fam Physician* 1995;51:1465-1470. ACE, Angiotensin-converting enzyme; NSAIDs, nonsteroidal anti-inflammatory drugs.

This classification is an oversimplification, and the individual practitioner will need to weigh the available data in the management of the pregnant woman. Few absolutes are possible in the field of human teratology; however, current recommendations for common drug categories in pregnancy are summarized in Table 21-6. It is important to emphasize that it is difficult to demonstrate an actual cause-effect relationship between a specific drug and an adverse pregnancy outcome. At no time, however, should a drug be considered safe because no data exist.

Infections in Pregnancy

Although a woman is subject to many of the same infections during pregnancy as when not pregnant, specific infectious diseases have implications on fetal development and complications of pregnancy, such as premature labor and premature rupture of membranes. Certain infections in pregnancy can be teratogenic to the fetus, particularly if infections occur in the first trimester. These agents have been given the acronym of

TORCH for toxoplasmosis, other (e.g., syphilis), rubella, cytomegalovirus, and herpesvirus. Although not teratogenic, HIV may be transmitted to the fetus and may be lethal in the child.

Toxoplasmosis

The causative agent of toxoplasmosis is *Toxoplasma gondii*, a parasite that usually infects rodents. Based on serologic studies, approximately one third of reproductive-age women have had toxoplasmosis. In the United States, maternal infection is thought to occur in about 0.5%. Congenital toxoplasmosis can only occur when active infection occurs during pregnancy. Recognizable damage to newborns is estimated to occur in about 1 in 10,000 births; incidence of infected but asymptomatic newborns is unknown. Maternal infections that occur in the first trimester are more likely to cause abortion and significant fetal damage. Infections later in pregnancy tend to be asymptomatic at birth.

A pregnant woman can contract toxoplasmosis by eating raw meat containing the cysts of the organism or by fecal-oral transmission of the oocytes from an infected cat. Cats that are fed cooked or canned food are most often not infectious. Those that obtain rodents from the wild are more at risk. Pregnant women should avoid changing cat litter and handling cats, particularly those cats allowed to roam outdoors. Maternal toxoplasmosis may be asymptomatic or may present as a mononucleosis-like syndrome. Congenital disease ranges from overwhelming, including seizures, microcephaly or hydrocephaly, chorioretinitis, hepatosplenomegaly, jaundice, microphthalmia, and cataracts, to less symptomatic, which usually involves chorioretinitis. Prenatal ultrasound or postnatal brain scan can also show intracranial calcifications. The placenta should be examined pathologically for cysts of *T. gondii* (Beasley and Egerman, 1998).

The diagnosis of toxoplasmosis is serologic, looking for immunoglobulin G (IgG) and IgM by enzyme-linked immunosorbent assay (ELISA). Some assays have a high level of false-positive results. Laboratories well versed in performing these serologic tests should be used. Pyrimethamine and sulfadiazine can treat women who acquire the infection prenatally. Effectiveness of treatment protocols for prevention of congenital infection appears variable (Wallon et al., 1999). Screening of all pregnant women is not recommended at this time.

Syphilis

Syphilis is a treatable infection caused by *Treponema pallidum*, a motile spirochete. In the pregnant woman, infection is most often sexually transmitted. The infection is described in four stages: primary, secondary, latent, and tertiary or late. It is rare to see pregnant women in tertiary or late syphilis (Sheffield and Wendel, 1999).

Pregnancy has little effect on the course of syphilis, but syphilis has a substantial effect on pregnancy and the fetus. Stages with spirochetemia are the most deleterious for the fetus. This is most often seen in late primary syphilis and in secondary syphilis. An increase in miscarriage, hydrops fetalis, stillborn, and preterm delivery of an infected fetus can be seen. Penicillin is the only antibiotic currently recommended for syphilis treatment in pregnancy because of its safety, efficacy, and transplacental passage to treat

the fetus (CDC, 1999). Penicillin-allergic women should undergo desensitization first. Whenever treatment adequacy is questioned in pregnancy, repeat therapy should occur because congenital syphilis is a preventable disorder. All women with syphilis should be carefully evaluated for other STDs, in particular HIV, as the treatment and surveillance is different in co-infection and the possibility of neurosyphilis must be carefully evaluated.

Rubella

Congenital rubella was first recognized in 1941, when after a rubella epidemic, a large number of children born to infected mothers were noted to have cataracts. Immunization against the rubella virus in the United States, Canada, and many European countries has decreased maternal rubella and thus congenital rubella. In the United States, only a few cases of congenital rubella are reported per year. Attention is now directed at its eradication in developing countries (Banatvala, 1998).

Although maternal infection can be subclinical, it usually presents 14 to 21 days after exposure with a maculopapular rash that begins on the face and spreads to the neck, trunk, arms, and legs. It is associated with lymphadenopathy, malaise, arthralgias, and petechiae. There is no therapy other than supportive. Pregnant women found not to have immunity to rubella should be instructed to avoid individuals who have viral illnesses. Suspected infection should be documented by specific rubella IgG and IgM measurement or by viral culture of the mother.

Maternal rubella acquired in the first trimester of pregnancy has a high risk of conferring damage to the developing fetus, and documented cases should be counseled and pregnancy interruption offered. In congenital rubella syndrome, many abnormalities can be found, such as cataracts, chorioretinitis, microphthalmia, congenital heart disease, myocarditis, microcephaly, deafness, mental retardation, and bone lesions, as well as signs of systemic infection (pneumonitis, hepatosplenomegaly, hepatitis, thrombocytopenia) (Stamos and Rowley, 1994).

Cytomegalovirus

Two percent of pregnant women will develop primary cytomegalovirus (CMV) infection, obtained by direct contact or respiratory aerosol from an infected individual. They will most often be asymptomatic or have mild generalized symptoms such as fatigue, malaise, fever, lymphadenopathy, and pharyngitis. Approximately 50% of fetuses whose mothers seroconvert during pregnancy will develop CMV infection, but only 10 to 15% of these will have damage from the infection. Hearing loss is the most common manifestation.

Fetal infection and damage are more likely in the first and second trimesters. Although hearing loss is the most common presentation, congenital CMV can also present with microcephaly or hydrocephalus, microphthalmia, mental retardation, and brain calcifications. Overwhelming fetal infection at birth, known as cytomegalic inclusion disease, is uncommon, is most often caused by maternal primary infection late in gestation, and is often fatal.

Recurrent CMV infection in pregnancy can also cause infection of the fetus, but rarely fetal damage (Stagno, 1982).

Thus, documented immunity to CMV with serologic studies performed before a pregnancy can be reassuring to women at risk of exposure, such as child care providers or health care workers. General screening for CMV in pregnancy is not recommended at present. Suspected CMV infection should be documented by serology or cultures of the cervix, amniotic fluid, or maternal urine.

Herpesvirus

Herpes simplex virus type 2 (HSV-2) is the causative agent in most cases of genital herpes, with a few cases caused by HSV-1, which most often causes oropharyngeal herpes. Primary infection is most deleterious for both mother and fetus and can present as fever, malaise, inguinal lymphadenopathy, and urinary retention. At 2 to 10 days after exposure, vesicles containing numerous viral particles painfully erupt on the cervix, vagina, perineum, or rectum; ulcerate; and remain open 1 to 3 weeks. Herpetic lesions in recurrent disease last a shorter period and are most often not associated with systemic symptoms.

The fetus is most susceptible to herpesvirus infection and damage during viremia, which most often occurs in primary herpes. At that time, herpes-specific maternal IgG is not adequate for transplacental passage and protection of the fetus from serious disease. The fetus may also acquire a herpetic infection from delivery through an infected vaginal canal. If this occurs during a primary episode, the risk of congenital infection is about 50%; if during a recurrent infection, the risk is much less than 8%. Congenital herpes may be localized to skin, eyes, and oral cavity and may involve the central nervous system (CNS). Congenital infection may be disseminated and is often fatal or entirely asymptomatic (Riley, 1998).

Various surveillance protocols have been attempted to decrease perinatal transmission at delivery. At present, at labor and delivery, a careful evaluation of the genital tract for ulcers is performed. If any active lesions are found, the baby is delivered by cesarean section (Roberts et al., 1995). Prenatal use of acyclovir is controversial, but it has been used with informed consent in pregnant women with systemic disease or frequent episodes of recurrent disease.

Human Immunodeficiency Virus

Human immunodeficiency virus is a retrovirus transmitted through infected secretions, most often sexually. The most serious consequence of HIV infection in pregnancy is transmission to the fetus resulting in the birth of an HIV-congenitally infected newborn. Maternal HIV is not teratogenic or associated with increased fetal loss (except end-stage disease). The goal in pregnancy is identification of HIV disease and prevention of perinatal transmission. At-risk women include hemophiliacs, intravenous drug users, prostitutes, and female partners of infected men. Although most often seen in urban areas, HIV infection in women is rising throughout the United States.

Screening for HIV is recommended and should be offered to all pregnant women. At-risk women should be screened more than once during the pregnancy. Testing for IgG antibody with ELISA is the basis of screening for an HIV infection. Western blot or another, more specific test confirms all positive tests. If a pregnant woman is found to have HIV

infection, specific counseling should be given, often best done in a center familiar with its treatment and management. Interruption of pregnancy should be offered. In ongoing pregnancies, specific therapy should be instituted to prevent perinatal transmission.

Zidovudine administration in HIV-infected pregnant women from 14 to 34 weeks' gestation decreased perinatal HIV transmission from 25.5% to 8.3% (Connor et al., 1994). The regimen included antepartum zidovudine (100 mg orally five times daily), intrapartum zidovudine (2 mg/kg body weight intravenously over 1 hour, then 1 mg/kg/hr until delivery). Zidovudine is given to the newborn (2 mg/kg orally every 6 hours for 6 weeks). This therapeutic regimen is currently used in pregnancy. However, combination therapy, including reverse-transcriptase inhibitors, is recommended by some experts (Rose, 1998).

Pregnant women on zidovudine therapy must be followed for bone marrow suppression and liver toxicity on a monthly basis. Although long-term studies are not available, the drug appears safe for the fetus. The quantity of viral load (HIV-1 RNA) in the mother appears to be a significant risk factor to fetal infection (Mofenson et al., 1999). Mode of delivery is controversial, with many experts recommending cesarean section to those women with high viral load. During vaginal delivery, artificial rupture of membranes and placement of a scalp electrode onto the fetal head are contraindicated. Amniocentesis and breastfeeding are also contraindicated in HIV-infected women.

EVIDENCE-BASED SUMMARY

- Pregnant women should be offered screening for HIV infection early in pregnancy because appropriate antenatal interventions can reduce maternal-to-child transmission (SOR: A).
- Women diagnosed as HIV positive during pregnancy should be informed that interventions such as antiretroviral therapy, cesarean section, and avoidance of breastfeeding can reduce the risk of mother-to-child HIV transmission (SOR: A).
- Amniocentesis and breastfeeding are contraindicated in HIV-infected pregnant patients (SOR: A).

Influenza and Novel Influenza A (H1N1) Virus

The influenza virus poses a particular threat to the pregnant patient. The majority of pregnant women with novel influenza A (H1N1) or the regular seasonal influenza virus infection will present with typical acute upper respiratory, influenza-like illness (e.g., cough, sore throat, rhinorrhea) and fever. Other symptoms can include body aches, headache, fatigue, vomiting, and diarrhea. Most pregnant women have an uncomplicated disease course. However, pregnant women appear to be at higher risk for severe complications from influenza infection, and for some, illness might progress rapidly and may be complicated by secondary bacterial infections, including pneumonia and evidence of fetal distress. Case reports of adverse pregnancy outcomes and maternal deaths have been associated with severe illness and death. Ideally, pregnant women who have suspected novel influenza A (H1N1) virus infection should be tested for influenza, although commercially available rapid-testing kits have limited sensitivity.

Treatment should not be delayed pending results of testing or withheld in the absence of testing. Antiviral treatment is most effective when started as early as possible after the onset of symptoms (i.e. within first 2 days). The highest priority is to treat pregnant women with influenza-like symptoms as soon as possible. The currently novel influenza A (H1N1) virus is sensitive to the neuraminidase inhibitor antiviral medications zanamivir (Relenza) and oseltamivir (Tamiflu). Pregnancy should not be considered a contraindication to oseltamivir or zanamivir use. Because pregnant women may be at higher risk, the benefits of treatment or chemoprophylaxis with oseltamivir or zanamivir outweigh the theoretic risks of antiviral use. The Advisory Committee on Immunization Practices recommends that 2009/10 H1N1 monovalent flu and the seasonal flu vaccine be given to all pregnant women at any time during pregnancy. The American College of Obstetricians and Gynecologists (ACOG) and AAFP also recommend routine vaccination of all pregnant women. The nasal spray vaccine is not approved for use by pregnant women. Pregnant women should not receive nasal spray vaccine for either seasonal flu or 2009/10 H1N1 flu.

KEY TREATMENT

Pregnant women with confirmed, probable, or suspected novel influenza A (H1N1) infection should receive antiviral therapy with oseltamivir (Tamiflu) (CDC, 2009) (SOR: C).

Immunizations in Pregnancy

Immunizations that are not live, attenuated viruses are not contraindicated in pregnancy. Measles, mumps, and rubella (MMR) are the most common vaccines with live, attenuated viruses and should be avoided during pregnancy, although retrospective assessment of risks to the fetus has not documented a significant risk. Vaccines made of viral coat and not the complete virus are safe to administer in pregnancy; for example, influenza vaccinations are recommended. However, the pregnant woman should receive the injected vaccine and not the nasal spray, which is the live, attenuated virus.

Medical Disorders in Pregnancy

Many medical disorders can be seen in the pregnant woman; few are incompatible with pregnancy. In the management and care of the pregnant woman with a medical illness, it is important to understand the normal physiology of pregnancy and the effect of the disorder on the pregnancy, and vice versa. Common medical problems in pregnancy include anemia, asthma, hypertension, diabetes, and pyelonephritis. Women with moderate to severe preexisting medical illness should be referred for evaluation to a physician experienced in managing the disorder in pregnancy.

Anemia

Iron deficiency anemia during pregnancy has been associated with an increased risk of LBW, preterm delivery, and perinatal mortality. Normal physiologic changes in intravascular volume cause a physiologic anemia of pregnancy.

However, a severe anemia with maternal hemoglobin (Hgb, Hb) levels less than 6 g/dL has been associated with abnormal fetal oxygenation, resulting in nonreassuring fetal heart rate pattern, reduced amniotic fluid volume, fetal cerebral vasodilatation, and fetal death. In normal singleton pregnancy, blood volume increases approximately 36%, plasma volume 47%, and red blood cell (RBC) mass 17%, causing a relative hemodilution throughout pregnancy, but most pronounced after 28 weeks' gestation. Thus, Hb, hematocrit (Hct), and RBC count will be lower than normal, but RBC indices, specifically the mean corpuscular volume (MCV), mean corpuscular hemoglobin (MCH), and mean corpuscular hemoglobin concentration (MCHC), remain normal. Iron, iron-binding capacity, and ferritin remain unchanged. Hb less than 15 mg/dL and Hct less than 33% is generally considered nonphysiologic anemia in pregnancy.

The most common nonphysiologic anemia encountered in pregnancy is iron deficiency. *Iron deficiency anemia* is suspected when the RBC indices are low and there are microcytic, hypochromic RBCs on the peripheral blood smear. This anemia is confirmed by a low serum iron concentration, high total iron binding capacity, and low ferritin. Risk factors for iron deficiency anemia in otherwise healthy women include poor nutrition, menstrual loss, and short interconceptional period. Reproductive-age women have low-normal to abnormal iron stores for this reason. Iron requirements in pregnancy put an increased demand on maternal iron stores because iron is actively transported across the placenta to the fetus regardless of maternal stores. Iron supplementation decreases the prevalence of maternal anemia at delivery, and without iron supplementation in pregnancy, many women will become iron deficient. The recommendation is 30 mg of elemental iron in the form of simple salts such as ferrous sulfate, gluconate, or fumarate. Iron deficiency anemia should be treated with 60 to 120 mg of elemental iron in two or three divided doses daily, which can cause gastric irritation and constipation. More frequent administration has not been shown to improve absorption. Because iron demands in pregnancy are highest after 20 weeks' gestation, depending on the degree of anemia, full-dose iron therapy can be delayed until that time, when pregnancy-associated nausea and vomiting should have subsided. Dietary modifications or stool softeners may be required when pregnant women take large doses of iron.

The failure to respond to appropriate iron therapy should prompt further investigation and may suggest an incorrect diagnosis, coexisting disease, malabsorption (sometimes caused by enteric-coated tablets or concomitant antacids), patient noncompliance, or ongoing blood loss. Hypochromic, microcytic RBCs with an MCV of less than 80 suggest thalassemia. Hemoglobin electrophoresis should also be performed when evaluating hypochromic, microcytic anemia. Iron deficiency anemia and beta-thalassemia can coexist. Megaloblastic anemia from folic acid deficiency is unlikely in the pregnant woman because many reproductive-age women take at least 400 µg of folic acid daily. Any other anemia may occur in pregnancy. Its diagnosis and therapy should be prompt to ensure a healthy outcome for the fetus. Hereditary anemias have the additional implication of possible inheritance by the fetus that should be addressed with the pregnant woman.

EVIDENCE-BASED SUMMARY

- Iron supplementation decreases the prevalence of maternal anemia at delivery (SOR: A).
- Iron deficiency anemia during pregnancy has been associated with an increased risk of low birth weight, preterm delivery, and perinatal mortality (SOR: B).
- Severe anemia with maternal hemoglobin levels less than 6 g/dL has been associated with abnormal fetal oxygenation; thus maternal transfusion should be considered for fetal indications (SOR: B).

Data from ACOG, 2008a.

Asthma

Asthma is caused by reversible airway obstruction from bronchial smooth muscle contraction, excessive secretions, and edema in response to various stimuli, most often infectious or allergic. Airway obstruction is most severe in expiration, making breathing difficult and fatiguing. Asthma is a chronic illness with acute exacerbations.

Approximately 4% of pregnant women will have asthma with severity varying from mild to life threatening. One third of pregnant asthmatic patients will experience exacerbations of their disease (Stenius-Aarnaila et al., 1988). Women with severe asthma are more likely to have disease exacerbation while pregnant. Additionally, moderate to severe asthma can have a significant effect on pregnancy, including an increase in preterm labor, LBW, perinatal mortality, and preeclampsia.

In normal pregnancy, progesterone causes an increase in tidal volume and thus minute ventilation, to make more oxygen available for the fetus (Table 21-7). These changes result in a mild respiratory alkalosis that should be taken into account when interpreting blood gas values (Table 21-8).

Table 21-7 Pulmonary Function Changes in Pregnancy

| Parameter | Nonpregnant Value | Pregnant Value |
|--|-------------------|----------------|
| Tidal volume (V_T) (amount of air moved in one respiratory cycle) | 450 mL | 600 mL |
| Respiratory rate (breaths/min) | 16-18 | Same |
| Minute ventilation (volume of air moved/min) | 7.2 L | 9.6 L |
| Forced expiratory volume in 1 second (FEV ₁) | 80%-85% of VC | Same |
| Peak expiratory flow rate (PEFR) | 380-550 L/min | Same |
| Forced vital capacity (FVC) (largest amount of air that can be exhaled after maximum filling of lungs) | 3.5 L | Same |
| Residual volume (RV) (amount of air left in lungs after maximum expiration) | 1000 mL | 800 mL |

Modified from Cugell DW, Frank NR, Gaensler EA, Badger TL. Pulmonary function in pregnancy. I. Serial observations in normal women. *Am Rev Tuberc* 1953;67:568.

Evaluation and management of acute asthma should include objective assessment of maternal lung function and fetal well-being; avoidance or control of environmental precipitating factors; pharmacologic therapy; and patient education (Clark, 1993). The best respiratory parameter to measure for assessment of the degree of obstruction in asthmatic patients is FEV₁ (see Table 21-7). This requires formal pulmonary function testing, so it is not a practical tool for monitoring. However, this value can be estimated by measuring the peak expiratory flow rate (PEFR) using an inexpensive portable peak-flow meter. Women with moderate to severe asthma should monitor their PEFR several times daily while pregnant. Normal PEFR for pregnant as well as nonpregnant women is 380 to 550 L/min. PEFR can be used to diagnose an exacerbation early, as well as for evaluation of therapy.

Pharmacologic therapy in the pregnant asthmatic patient is similar to that in the nonpregnant woman. The main goal of therapy is to maintain adequate oxygenation for the mother and fetus. The arterial oxygen partial pressure (Pao₂) should be kept above 60 mm Hg and oxygen saturation (So₂) at least 95%. In acute exacerbations during pregnancy, the clinician should have a lower threshold for hospital admission and intubation. Women in the late second trimester and the third trimester should also have fetal monitoring.

Ultrasonography to detect IUGR of the fetus in the moderate to severe asthmatic patient is warranted. If IUGR is diagnosed, antenatal testing should be performed. During labor and delivery, the F-series prostaglandins, in particular prostaglandin F_{2α} (Hemabate), should be avoided because it stimulates bronchial smooth muscle to constrict. Instead, prostaglandin E₂ (Prostin E₂), which causes bronchodilation, should be used.

Chronic Hypertension

Historically, there have been many classifications of hypertension in pregnancy with no apparent consensus. In this chapter we use the now-accepted classification as developed by the National Institutes of Health (Report of the National High Blood Pressure Education Program Working Group on High Blood Pressure in Pregnancy). Hypertension during

pregnancy is categorized as (1) preeclampsia/eclampsia, (2) gestational hypertension, (3) chronic hypertension, or (4) preeclampsia superimposed on chronic hypertension (Box 21-5). These categories identify different disorders that at times overlap but with different epidemiologic characteristics, pathophysiology, and risks for mother and baby. Pregnancy-induced hypertensive disorder is an older, less specific term no longer in general use.

Preexisting hypertension often complicates pregnancy. A diagnosis of chronic hypertension is made when hypertension precedes pregnancy or is diagnosed before 20 weeks of gestation. In normal pregnancy, arterial blood pressure (BP) and peripheral vascular resistance (PVR) fall shortly after implantation of the conception. Normal first-trimester and early second-trimester BP ranges from 92 to 114 mm Hg systolic, 46 to 66 diastolic sitting, and 103 to 123 systolic, 47 to 67 diastolic supine. At 28 to 30 weeks' gestation, BP in normal pregnant women increases to near prepregnancy range. It is generally accepted that BP greater than 130/80 mm Hg at any time during pregnancy is abnormal.

Fetal effects of chronic or essential hypertension depend on severity of hypertension and range from none to IUGR, fetal distress, abruptio placentae, prematurity, and fetal death (Haddad and Sibai, 1999). Women with preexisting hypertension have approximately a 20% chance of developing superimposed preeclampsia. The maternal and fetal morbidity and mortality are higher in chronic hypertension with superimposed preeclampsia than in each disorder alone.

Most women with chronic hypertension will present at their first prenatal visit with the diagnosis. As many as one third of pregnant women with essential hypertension will become normotensive in the first half of pregnancy. Often, their antihypertensive medications can be discontinued and only restarted when elevations recur, typically after 28 weeks. Controversy exists as to whether medical treatment of essential hypertension in pregnancy improves fetal outcome or decreases the risk of superimposed preeclampsia. However, maternal complications can occur when diastolic BP is persistently elevated. Thus, it is generally accepted that therapy to decrease maternal BP be instituted or modified to keep maternal diastolic BP lower than 100 to 105 mm Hg. A profound drop in maternal BP over a short period should be avoided to prevent decreased cardiac output to the placenta and fetus.

Alpha-methyldopa (Aldomet), a central-acting, alpha-adrenergic, false neurotransmitter, is the drug of choice for treatment of chronic hypertension in pregnancy. The initial starting dose is 250 mg every 8 hours. This dose can be increased to 2 g/day if needed. If adequate control cannot be obtained, a second drug, most often nifedipine or hydralazine, can be added. Also, with its safety confirmed in pregnancy, labetalol is gaining popularity for use as first-line single-agent therapy. ACE inhibitors and diuretics for BP control are contraindicated in pregnancy (Witlin and Sibai, 1998).

Obstetric management includes baseline laboratory studies early in pregnancy that will later help in diagnosis of superimposed preeclampsia. Specifically, in addition to routine prenatal testing, this includes renal function studies, liver enzymes, platelets, uric acid, and 24-hour urine test for protein and creatinine clearance. If chronic hypertension is a new diagnosis, pheochromocytoma should be ruled out by catecholamine levels in serum or 24-hour urine (Keely, 1998). Early ultrasonography to confirm dating and intermittently to evaluate

Table 21-8 Normal Arterial Blood Gas Values in Pregnancy

| | pH | Pco ₂ (mm Hg) | Po ₂ (mm Hg) |

| Normal | 7.40 | 35-40 | 75-100 |
| Pregnancy | 7.45 | 27-32 | 90-108 |

Box 21-5 Classification of Hypertensive Disorders in Pregnancy

Chronic hypertension

Preeclampsia/eclampsia

Preeclampsia superimposed on chronic hypertension

Gestational hypertension

1. Transient hypertension of pregnancy if preeclampsia is not present at delivery and blood pressure returns to normal by 12 weeks postpartum.
2. Chronic hypertension if the elevation persists.

fetal growth will aid in the diagnosis of IUGR. Women with moderate to severe hypertension benefit from more frequent prenatal visits as well as home BP monitoring. Antenatal testing should be performed at least for women with superimposed preeclampsia or IUGR. Preterm delivery may occur.

KEY TREATMENT

Alpha-methyl dopa (Aldomet), a central-acting alpha-adrenergic, false neurotransmitter, is the drug of choice for treatment of chronic hypertension in pregnancy (SOR: C).

Gestational Diabetes

Gestational diabetes, or diabetes diagnosed in pregnancy, affects 3% to 5% of pregnant women. Pregnancy is a state of increasing insulin resistance predominantly caused by placentally produced hormones, in particular human placental lactogen, which increases with placental mass and gestational age. Although most women can compensate, a small subset of pregnant women cannot. Early impairment of glucose metabolism may have no maternal signs or symptoms, but can have fetal effects that include macrosomia, fetal distress, and fetal demise.

Screening for gestational diabetes by a glucose challenge is recommended at 26 to 28 weeks of gestation. There is little evidence supporting earlier screening. The U.S. Preventive Services Task Force (USPSTF), however, concludes that the current evidence is insufficient to assess the balance of benefits and harms of screening for gestational diabetes mellitus (GDM), either before or after 24 weeks' gestation and recommends that clinicians should discuss screening for GDM with their patients and make case-by-case decisions. Discussions should include information about the uncertainty of benefits and harms as well as the frequency of positive screening test results. Women who are obese, older than 25, have a family history of type 2 diabetes or gestational diabetes, or are members of certain ethnic groups, such as Hispanics, native Americans, Asians, and African Americans, are at increased risk for gestational diabetes.

The initial screening test is performed in a nonfasting state. The pregnant woman is asked to drink a mixture containing 50 g of glucose; 1 hour later a plasma glucose level is performed. If the result is 140 mg/dL or greater, the more definitive 100-g 3-hour glucose challenge is performed. The pregnant woman should have at least 3 days of adequate carbohydrate intake, fast the night before the test, and receive 100 g of glucose. Venous blood glucose is determined fasting and at 1, 2, and 3 hours after the glucose challenge. Two abnormal values make the diagnosis of gestational diabetes (Table 21-9). Different studies have various thresholds for making the diagnosis, and clinicians should review their institutional norms (Carpenter and Coustan, 1982) (Table 21-10). Women at high risk for gestational diabetes, such as those with glucosuria, prior gestational diabetes, obesity, or strong family history, should be screened earlier in pregnancy. If negative, testing should be repeated in the latter half. The evidence supporting this practice is variable.

Initial therapies of gestational diabetes are diet and, if not contraindicated in the pregnancy, exercise in the form of walking, as well as support from diabetes educators and nutritionists and increased surveillance in prenatal care. The daily recommendation is 30 to 35 kcal/kg lean body weight. If fasting blood sugar cannot be maintained below 105 and

OGTT, Oral glucose tolerance test.

2-hour postprandial blood sugars below 120 mg/dL, insulin therapy is begun. Hemoglobin A_{1c} can be performed every 4 to 6 weeks but will not be elevated unless there is fasting hyperglycemia. At least weekly evaluation of blood sugar is recommended because insulin resistance increases with advancing gestation. Ultrasonography to assess fetal size should be performed every 4 to 6 weeks. Women requiring insulin should have antenatal testing in the third trimester. Good blood sugar control is also important to decrease the incidence of metabolic newborn complications such as hypoglycemia, hypocalcemia, polycythemia, and hyperbilirubinemia.

The family physician should remember that women who have had gestational diabetes have a 30% to 60% chance of developing type 2 diabetes mellitus in their lifetime (O'Sullivan, 1979). Postpartum and yearly glucose tolerance testing is recommended in these women. Weight loss and exercise have been shown to decrease their risk.

EVIDENCE-BASED SUMMARY

- The current evidence is insufficient to assess the balance of benefits and harms of screening for gestational diabetes mellitus (GDM), either before or after 24 weeks gestation.
- Screen for GDM using risk factor analysis and, if appropriate, use of an oral glucose tolerance test (OGTT) (SOR: C).

Data from American Diabetes Association (ADA), 2008; and U.S. Preventive Services Task Force (USPSTF), 2008.

Pyelonephritis

Asymptomatic bacteriuria can be found in 3% to 5% of pregnant women and up to 10% of those with sickle cell trait. Asymptomatic bacteriuria is most often caused by *Escherichia coli*. Antibiotic therapy is similar to that in the nonpregnant state. Cephalosporins, ampicillin, and nitrofurantoin (Macro-dantin) are frequently used medications that are safe in pregnancy. It appears best to treat asymptomatic bacteriuria in pregnancy for 5 to 7 days. Untreated, 30% of women with asymptomatic bacteriuria will progress to pyelonephritis. Hormonal and anatomic changes of pregnancy causing hydronephrosis and hydroureter are responsible for the higher incidence of pyelonephritis in the pregnant woman. A urinary pathogen count of at least 100,000 colonies/mL is considered significant, although pyelonephritis also occurs at counts as low as 20,000 to 50,000 (Cunningham and Lucas, 1994). Periodic cultures for screening should be performed in women with sickle cell trait, recurrent urinary tract infection, recurrent asymptomatic bacteriuria, or urine dipstick suggesting bacterial growth, such as positive nitrite.

Pyelonephritis in pregnancy requires hospitalization because of frequently associated dehydration, nausea, vomiting, and premature labor, as well as the uncommon but serious risk of endotoxic shock and endotoxin damage of alveolocapillary membranes leading to pulmonary edema and a clinical picture of adult respiratory distress syndrome (Gurman et al., 1990). Pregnant women with pyelonephritis require hospitalization for aggressive hydration and parenteral antibiotics. Antibiotic treatment is similar to those of other-adult regimens. Intravenous antibiotic therapy with a cephalosporin or an extended-spectrum penicillin until symptoms improve and the fever has completely resolved is usually sufficient for initial therapy. Because 25% of patients with mild acute pyelonephritis who are pregnant have a recurrence, these patients should have monthly urine cultures or antimicrobial suppression with oral nitrofurantoin (Macro-dantin), 100 mg daily, until 4 to 6 weeks postpartum. Fluoroquinolones should be avoided because of concerns about their teratogenic effects on the fetus. Oral antibiotics are then prescribed for 7 to 10 additional days. For seriously ill women, the addition of an aminoglycoside at the onset of therapy may be warranted until sensitivities of the offending organism are available. Renal function as well as peak and trough aminoglycoside levels should be followed.

Complications of Early Pregnancy

Ectopic Pregnancy

An ectopic pregnancy occurs when the fertilized ovum implants on any tissue other than the endometrial lining of the uterus. Overall, 95% of all ectopic pregnancies are tubal, 1.5% abdominal, 0.5% ovarian, and 0.03% cervical (Breen, 1970). A *heterotopic pregnancy* is a coexisting intrauterine and extrauterine pregnancy. Historically, there is an increasing incidence reported in the literature to a current rate of about 1 in 4000 pregnancies. This increased rate is thought to be associated with the use of ovarian stimulation and with assisted reproductive technologies. Ectopic pregnancies are responsible for more than 10% of all maternal deaths in the United States (Koonin et al., 1997).

The rate of ectopic pregnancy in women with known history of pelvic inflammatory disease (PID) is 6 to 10 times higher than in women with no prior history. PID usually results from invasion by either gonorrhea or chlamydia from the cervix into the uterus and tubes. The infection in these tissues causes an intense inflammatory reaction. Bacteria, white blood cells, and other fluids fill the tubes as the body combats the infection. During the healing process, however, the delicate tubal mucosa is permanently scarred. The fimbriated end of the fallopian tube as well as the lumen may become partially or completely blocked with scar tissue. If PID is treated very early and aggressively with intravenous (IV) antibiotics, the tubal damage might be minimized and fertility preserved. Other conditions associated with ectopic pregnancies include progesterin-bearing intrauterine devices (IUDs), previous tubal surgery, and tubal ligation.

Diagnosis

A common clinical presentation of a woman with an ectopic pregnancy is the classic triad of amenorrhea, abdominal pain, and irregular vaginal bleeding. All women with these symptoms should be evaluated for possible ectopic gestation.

Serum quantitative hCG is often used to help identify those women with ectopic pregnancies. An isolated hCG level is not of much use unless it is above the threshold where one should visualize an intrauterine pregnancy with ultrasound. This threshold may vary depending upon type of hCG assay used and sonographic technique (Peisner and Timor-Tritsch, 1990). Two hCG levels drawn 48 hours apart are more informative. The general rule is a doubling of values in 48 hours. However, one must be careful to give pregnancies with a slow hCG rise every chance possible because they may turn out to be normal. A plateauing of hCG is consistent with an ectopic gestation or abnormal intrauterine pregnancy; ultrasound can be used to differentiate the two.

Serum progesterone levels are of some value in making the diagnosis of ectopic pregnancy (Stovall et al., 1989). A progesterone level less than 15 ng/mL is seen in 81% of ectopic, 93% of abnormal intrauterine, and 11% of normal intrauterine pregnancies. Less than 2% of ectopic pregnancies and less than about 4% of abnormal intrauterine pregnancies will have a progesterone level of 25 ng/mL or greater. Therefore a single progesterone value less than 15 ng/mL is probably an abnormal pregnancy and should prompt further evaluation. A single value greater than 25 ng/mL probably indicates a normal pregnancy.

Ultrasound

Key Point

- Routine screening ultrasound in low-risk pregnancies is not associated with a decrease in perinatal mortality, birth weight, or preterm birth.

With high-resolution vaginal sonography, a normal singleton pregnancy can be seen by 5½ to 6 weeks of pregnancy (1½ to 2 weeks after the missed period). By this time, the quantitative hCG level has reached the *discriminatory zone*, or the level above which a gestational sac is always visualized. The discriminatory zone may vary from institution to

institution because of differences in equipment and assays, but ranges from 800 to 1000 IU/L (Second International Standard), or 1000 to 2000 IU/L (First International Reference Preparation) (Nyberg et al., 1985; Peisner and Timor-Tritsch, 1990).

As many as 20% to 30% of ectopic gestations have no detectable sonographic abnormality. The typical ultrasound findings for ectopic pregnancy are a unilateral mass, fluid in the cul de sac, and no evidence of intrauterine pregnancy. Conclusive diagnosis of an ectopic gestation by sonography can only be made if a fetus or fetal cardiac motion is seen outside the uterus. With vaginal ultrasound, this only occurs in about 20% of ectopic pregnancies.

Management

Treatment for ectopic pregnancy can be medical or surgical. Methotrexate, a folate antagonist, is often used in the medical management of ectopic gestation. It inhibits the rapidly growing trophoblast cells of the early placenta. Several treatment protocols are accepted (Buster and Pisarska, 1999). Most side effects seen with low-dose methotrexate therapy are mild and transient. Resolution of the ectopic state has been reported in about 70% to 95% of cases treated, depending somewhat on selection criteria.

The surgical approaches for ectopic pregnancy include laparoscopy for both confirmation and treatment and occasionally, laparotomy. The procedure of choice is salpingostomy, reserving salpingectomy for women not wanting future fertility.

Spontaneous Abortion

First-trimester miscarriage is a common event. All women with clinically recognized pregnancies have approximately a 15% chance of spontaneous pregnancy loss in the first 3 months of pregnancy (Evans and Beischer, 1970). The risk is lower for younger women and higher for older mothers. Because women can present with symptoms of spontaneous miscarriage even before they are aware of pregnancy, all family physicians should be well versed in its assessment and management.

There are many causes of spontaneous pregnancy loss in the first trimester; sporadic chromosomal aneuploidy accounts for about 60%. The remaining 40% have various etiologies, including chronic maternal illness (e.g., diabetes, connective tissue disorder), uterine structural malformations, certain infections, inadequate progesterone production, and possibly other, less-well-understood causes such as immunologic "rejection" and environmental factors.

Diagnosis

First-trimester miscarriage can be further defined according to stage of pregnancy loss and associated symptoms.

Threatened abortion is diagnosed when the pregnant woman presents with vaginal bleeding, lower back discomfort, or midline pelvic cramping. On examination, the cervical os is closed, and the pregnancy is viable (by Doppler ultrasound). About 25% of women will have some degree of bleeding in the first trimester, about half of whom will miscarry. The remaining women may have a slightly higher risk

of perinatal complications, such as preterm labor and IUGR. The risk of congenital malformations is not increased.

Inevitable abortion occurs when there is profuse bleeding requiring surgical intervention or overt rupture of membranes. Although the cervical os may be initially closed and tissue has not passed, the miscarriage is inevitable.

Incomplete abortion is diagnosed when products of conception have passed the level of the cervical os. There is often heavy vaginal bleeding, midline cramping, and an open cervical os.

Complete abortion occurs when all the gestational products have passed. This is ascertained by examination of the passed products of conception, pelvic ultrasonography to ascertain emptiness of the uterus, and at times retrospectively with falling quantitative hCG levels.

"Missed abortion" is a poor term still in use to describe retention of a nonviable pregnancy for longer than 4 weeks. Ultrasound scans of these women provide a more specific and usually earlier diagnosis, such as empty sac or an embryonic gestation, or fetal demise.

Septic abortion is diagnosed when there is infection of the uterus and products of conception. This occurs most often with incomplete abortions. Fever, uterine tenderness, foul discharge, and leukocytosis should aid the practitioner in making this diagnosis.

Recurrent spontaneous abortion is reserved for those women who have had three or more first-trimester losses. This diagnosis should prompt further evaluation for etiology.

Management

The goal of management of early miscarriage is assurance of complete emptying of the uterus in the least traumatic manner, avoidance of excessive blood loss, prevention of infection, and administration of adequate emotional support. Women with threatened abortions are reassured somewhat that the loss is neither imminent nor inevitable. Bed rest is encouraged, but no evidence supports its value in prevention of miscarriage.

When there is profuse bleeding or sepsis, women with inevitable, incomplete, or septic abortions require prompt surgical treatment in the form of dilation and curettage (D&C), or in some, curettage alone. IV antibiotics should be used when appropriate. Rarely, blood transfusion is required. Certain women may benefit from oral antibiotics and methylergonovine (Methergine) on discharge.

When the diagnosis is missed abortion or incomplete abortion without hemorrhage or infection, the choice is surgical intervention versus natural spontaneous completion of the miscarriage. In well-selected women, no convincing evidence suggests one method is preferable. Many practitioners give these patients the option of D&C or spontaneous resolution. D&C has risks of anesthesia, cervical trauma, uterine scarring, and perforation; spontaneous resolution has risks of infection and hemorrhage. If products of conception for karyotype analysis are required for the evaluation of recurrent losses, surgical approach is more successful in producing uncontaminated tissue for culture.

Those women who are Rh(D)-negative and less than 13 weeks' gestation should receive 50 µg of D immune globulin intramuscularly when the abortion is diagnosed, to prevent sensitization. If beyond 13 weeks, 300 µg is used.

This treatment can be omitted if the father is known to be D-negative as well. Iron therapy should be given to women when heavy bleeding occurs or is anticipated.

Molar Pregnancy

A molar pregnancy, or *hydatidiform mole*, is uncommon. A *gestational trophoblastic disease* (GTD), it occurs predominantly in older women. In the United States, molar pregnancy occurs in about 1 in 1800 pregnancies (Grimes, 1984). Molar pregnancy can be classified as complete or incomplete, which are two distinct entities etiologically and pathologically. A *complete* or *hydatidiform mole* has no fetal components, consists entirely of hydropic placental villi, is frequently associated with medical complications, and has a 15% to 20% risk of GTD (Jones, 1987). In an *incomplete mole*, a fetus, usually abnormal, is often present. The placenta may be hydropic or small, and there is a 5% to 10% risk of GTD.

A hydatidiform mole is most often diagnosed in the first trimester because of symptoms of excessive nausea and vomiting, vaginal bleeding, uterine size larger than expected, and sonographic findings of no fetus but a large placenta with numerous small cysts. These findings should prompt quantitative hCG evaluation, which is often elevated. Evacuation of the uterus with careful attention to levels of hCG postevacuation is important to detect GTD, usually invasive mole, occasionally choriocarcinoma. Pregnancy is avoided for 1 year after a complete mole.

An incomplete mole is most often diagnosed in the second trimester and occasionally the third trimester. There may be an abnormal placenta, fetal growth and structural abnormalities, or signs and symptoms of preeclampsia.

Complications of Late Pregnancy

Preterm Labor

Preterm labor is defined as uterine contractions occurring before 37 weeks of gestation that cause cervical change. Cervical change can be diagnosed if an initial examination reveals a cervix that is at least 2 cm dilated or 80% effaced, or if interval cervical examinations document progression of effacement or dilation. Preterm contractions without cervical advancement can also occur; these do not require intervention. The distinction may be difficult, in particular at the onset of contractions.

Certain women are at higher risk of developing preterm labor (Box 21-6). These women should be assessed more frequently in the prenatal period and instructed on signs and symptoms of premature labor. While many tests to identify women at risk of preterm labor have been proposed and evaluated, only ultrasound for cervical length and fetal fibronectin have been shown to be effective (ACOG, 2001; Iams et al., 1996). A short cervix by transvaginal ultrasound and positive cervicovaginal fetal fibronectin test is predictive of an increased risk of preterm delivery in the index pregnancy.

Assessment of patients thought to be in premature labor involves monitoring for premature contractions as well as fetal heart rate while they are in the right or left lateral recumbent position. Complete history and physical exam should be performed to find any treatable causes

Box 21-6 Risk Factors for Preterm Labor

- Low socioeconomic status
- Uterine anomalies
- African American ethnic group
- Uterine leiomyoma
- Poor nutritional state
- Bacterial vaginosis
- Low maternal weight (less than 50 Kg)
- Multiple gestation
- Poor pregnancy weight gain
- Bacteriuria or urinary tract infection
- Prior preterm labor
- Placenta previa or abruptio
- Cocaine use
- Polyhydramnios
- Nicotine use
- Poor prenatal care

of premature labor as well as any contraindications to tocolytic therapy. Urinalysis, as well as culture, is obtained and antibiotic therapy instituted if the urinalysis is suspicious. If there is a possibility of rupture of membranes, a sterile speculum examination of the cervix should be performed and vaginal fluid for nitrazine and ferning obtained. Cultures for GBS, *Chlamydia*, and possibly herpesvirus and *Neisseria gonorrhoeae* are often performed in this setting. If there is no historical or physical evidence of rupture of membranes, digital examination of the cervix with careful assessment of consistency as well as dilation and effacement is performed. Chorioamnionitis should be ruled out by assessing degree of uterine tenderness, leukocytosis, maternal fever, and fetal well-being.

In a woman at 22 to 35 weeks' gestation, before digital examination, assessment of the presence of fetal fibronectin can be determined. *Fetal fibronectin* is released from the interface of the chorion and decidua in women likely to deliver preterm. Fetal fibronectin can be determined in 1 hour by most hospital laboratories and is used predominantly for its high negative predictive value. Thus, if a fetal fibronectin is negative, the woman will likely not deliver for at least 7 to 10 days; if positive, closer surveillance or treatment is warranted.

Management

Hydration appears to decrease the frequency of preterm contractions, but it does not decrease the rate of preterm birth. Intermittent digital cervical examinations should be performed either to confirm the diagnosis of preterm labor or to monitor progression. The frequency of these examinations has not been established and should be based on the clinical situation. However, a digital examination should always be performed at discharge to assess any cervical change.

If preterm delivery is a possibility, antibiotic prophylaxis for group B streptococci should be administered (ACOG, 2002a). Betamethasone is also recommended, 12 mg intramuscularly every 24 hours for two doses to accelerate fetal lung maturity in patients between 24 and 34 weeks of gestation (Liggins and Howie, 1972).

If a diagnosis of preterm labor is made and contractions do not subside with bed rest and hydration, pharmacologic therapy is considered. Contraindications to stopping labor include chorioamnionitis, abruptio placentae, heavy vaginal bleeding, severe or chronic hypertension, and fetal demise. Although many tocolytic drugs are available, terbutaline and magnesium sulfate are used often.

Terbutaline at 0.25 mg can be administered subcutaneously every 20 to 30 minutes for three doses. If this is successful, oral therapy can be instituted at doses of 2.5 to 5.0 mg every 2 to 6 hours. Doses should be individualized, allowing maximal efficacy and low side effects. Through beta-1 receptors, beta agonists increase heart rate and thus stroke volume, increase fat breakdown, drive intravascular potassium into cells, and decrease gastrointestinal motility. Through beta-2 receptors, bronchial and uterine smooth muscle relaxation and glycogenolysis occurs. Certain maternal cardiac disorders are a contraindication to this therapy. Women taking beta-adrenergic agonists experience tachycardia, jitteriness, and occasionally nausea and vomiting. Maternal heart rate of 120 beats/min or greater is a contraindication for further dosing, and the interval or quantity may need modification. Fetal heart rate elevations can also be seen.

Intravenous magnesium sulfate therapy can also be used for preterm labor. There is no clear-cut greater efficacy of one tocolytic versus another. Magnesium sulfate relaxes uterine smooth muscle by competitive inhibition of the action of calcium. The dose should be adjusted so that contractions are decreased or abolished but maternal toxicity is not reached. This can be done by frequent examination of deep tendon reflexes, which should be present but depressed. Complete loss of deep tendon reflexes can herald further toxicity, and dosing should be decreased. Plasma magnesium levels can also be performed and should be kept between 5 and 8 mg/dL. Because it is excreted predominantly by the kidney, the plasma magnesium level is influenced by urine output as

well as infusion rate. Calcium gluconate should be readily available in case of magnesium toxicity. Women receiving IV magnesium experience warmth, flushing, and poor muscle tone; some develop diplopia, nausea, and vomiting. The majority of these side effects occur with the loading dose. Magnesium sulfate therapy is typically used for 24 hours, then discontinued. Long-term tocolytic therapy has not been shown to be efficacious.

Intrauterine Growth Restriction

Fetuses with IUGR are those that fall below the 10th percentile for weight for a given gestational age. IUGR occurs when a fetus does not meet its growth potential (Vandenbosche and Kirchner, 1998). Some below-10th-percentile fetuses are not growth-restricted but constitutionally small, have reached their growth potential, and are healthy. Often, it is difficult to differentiate the two states.

Although mild growth abnormalities are generally tolerated well by the fetus, more severe growth abnormalities can be associated with poor outcome, including fetal distress, fetal demise, and postnatal developmental abnormalities (Botero and Lifshitz, 1999). The growth-restricted fetus should be identified so that appropriate management can be instituted to ensure the best outcome. Factors that influence fetal growth can be divided into the following three categories:

1. Maternal factors affecting nutrient availability to the fetus, such as poor nutrition and cigarette smoking (Chomitz et al., 1995),
2. Maternal factors influencing placental growth and function, such as maternal hypertension, diabetes with vascular involvement, and connective tissue disorders.
3. Fetal factors interfering with adequate utilization of nutrients despite their availability, such as fetal infection or genetic disorder.

Growth restriction has also been described as asymmetric and symmetric. *Asymmetric* or "head-sparing" IUGR occurs because of fetal autoregulation of blood flow. The initial response to lack of adequate delivery of oxygen and nutrients to the fetus results in shunting of blood flow to important organs such as the brain and adrenal glands. Muscle and other viscera such as kidneys are somewhat underperfused, resulting in smaller body than head, smaller muscle mass, and oligohydramnios due to underperfusion of the fetal kidneys and decreased fetal urine output. If inadequate delivery of oxygen and nutrients is early, persistent, or profound, all organs and tissues of the body will be affected and *symmetric* IUGR ensues. IUGR from fetal infection or genetic disorder is often symmetric as well because all the tissues of the body are often affected.

Diagnosis

The physician can suspect IUGR based on lack of appropriate growth of the uterine fundus. Poor fundal growth with or without risk factors for IUGR should prompt ultrasound evaluation. Women at risk for IUGR should have early sonography to confirm their estimated day of delivery to aid in diagnosis. For example, a woman at 30 weeks' gestation has her first ultrasound for possible IUGR. The fetus is found to be 27 weeks by all parameters measured. It would be

EVIDENCE-BASED SUMMARY

- There are no clear "first-line" tocolytic drugs to manage preterm labor; clinical circumstances and physician preferences should dictate treatment (SOR: A).
- Antibiotics do not appear to prolong gestation and should be reserved for group B streptococcal prophylaxis in patients in whom delivery is imminent (SOR: A).
- Neither maintenance treatment with tocolytic drugs nor repeated acute tocolysis improves perinatal outcome; neither should be undertaken as a general practice (SOR: A).
- Tocolytic drugs may prolong pregnancy for 2 to 7 days, which may allow for administration of steroids to improve fetal lung maturity and consideration of maternal transport to a tertiary care facility (SOR: A).
- Cervical ultrasound examination and fetal fibronectin testing have good negative predictive value; thus, either approach or both combined may be helpful in determining which patients do not need tocolysis (SOR: B).
- Amniocentesis may be used in women in preterm labor to assess fetal lung maturity and intra-amniotic infection (SOR: B).
- Bed rest, hydration, and pelvic rest do not appear to improve the rate of preterm birth and should not be routinely recommended (SOR: B).

Data from ACOG, 2003.

difficult to decide if the fetus is symmetrically growth-restricted or just due 3 weeks later. Overall, ultrasound for diagnosis of IUGR is 80% to 90% sensitive, depending on the measurements used. The abdominal circumference, a soft tissue measurement, is the first routinely measured parameter to fall behind normal growth in IUGR. Estimation of fetal weight, calculated using the abdominal circumference, can be plotted on fetal growth curves to evaluate its percentile for a specific gestational age.

Management

The only treatment modality thought to be of benefit for IUGR is bed rest in a lateral recumbent position. This position prevents vena caval compression by the gravid uterus and allows maximal venous return to the heart, maximizing cardiac output and uteroplacental perfusion. Certain fetuses with growth restriction caused by significant maternal illness may benefit from improvement of the maternal condition. Antenatal testing is recommended for IUGR fetuses. If antenatal testing is abnormal or persistent oligohydramnios is present, delivery may be warranted before term. Otherwise, these fetuses are delivered at 38 to 40 weeks, depending on the degree of growth restriction.

Preeclampsia

Preeclampsia is one of the most common causes of perinatal morbidity and mortality. The etiology for preeclampsia remains unknown. However, placental dysfunction may initiate systemic vasospasm, ischemia, and thrombosis that eventually damages maternal organs and causes placental infarction, IUGR, and death. Preeclampsia complicates 5% to 10% of all pregnancies. It occurs at both extremes of reproductive age but is greatest in women younger than 20. Risk factors for preeclampsia include extremes of maternal age, nulliparity, African American race, multiple gestation, molar pregnancy, preexisting medical conditions (hypertension, diabetes, renal disease, connective tissue disorders, vascular disease), and prior or family history of preeclampsia or eclampsia.

The disorder is typically suspected in the presence of hypertension and proteinuria in the pregnant woman without history of preexisting chronic hypertension. Edema is no longer considered a reliable clinical sign and is often seen after the 20th week of gestation without signs of a hypertensive disorder. Historically, mild preeclampsia was diagnosed with a systolic BP rise of 30 mm Hg or diastolic BP rise of 15 mm Hg. Consensus statements now describe mild preeclampsia as an absolute reading of 140/90 mm Hg or greater in a pregnant woman with proteinuria greater than 0.3 g in a 24-hour urine collection. Again, nondependent edema is no longer considered a diagnostic criterion. Severe preeclampsia consists of a systolic BP greater than 160 mm Hg or diastolic BP greater than 110 mm Hg, complicated by significant proteinuria (>5.0 g/day) and evidence of end-organ damage. Signs and symptoms indicating severe preeclampsia include headache, visual disturbances, confusion, right upper quadrant (RUQ) or epigastric pain, impaired liver function, proteinuria, oliguria (<500 mL/24 hr), pulmonary edema, microangiopathic hemolytic anemia, thrombocytopenia, oligohydramnios, and IUGR.

Pregnant women with hypertension documented before pregnancy may develop preeclampsia. Chronic hypertension with superimposed preeclampsia is responsible for 15% to 30% of hypertensive disease in pregnancy. Treatment for mild preeclampsia involves bed rest and surveillance to assess development of complications. Delivery is carefully delayed until fetal maturity, development of severe preeclampsia, or other complications occur. In most cases, treatment of severe preeclampsia is delivery.

During labor and delivery, women with preeclampsia should receive IV magnesium sulfate for seizure prophylaxis, with a loading dose of 4 g infused over 15 to 20 minutes, then continuous infusion at 2 g/hr, similar to the preterm-labor magnesium therapy protocol (Box 21-7). Blood pressure should be carefully evaluated and treated with IV hydralazine if levels are persistently above 110 mm Hg diastolic. Severe preeclamptic women should generally deliver within 24 hours. Postpartum therapy with magnesium sulfate is recommended for 12 to 24 hours depending on degree of severity.

HELLP Syndrome

If unrecognized, preeclampsia can progress to a syndrome of hemolysis, elevated liver enzymes, and low platelets (HELLP syndrome). This is another complication in seemingly stable patients. The HELLP syndrome is noted in 5% to 10% of patients with preeclamptic symptoms. Such patients often present with RUQ and epigastric pain and a peripheral blood smear consistent with a microangiopathic hemolytic anemia. There may be decrements in the platelet count and increments in the transaminase (AST, ALT) and lactic acid dehydrogenase (LDH) enzymes. This is a life-threatening emergency that requires prompt delivery of the baby.

Eclampsia

Another serious complication of preeclampsia is development of seizures or coma. This is known as eclampsia. Eclampsia occurs in approximately 0.2% of pregnancies and

Box 21-7 Magnesium Sulfate Protocol for Preterm Labor

1. Continuous electronic fetal and contraction monitoring.
2. Patient in lateral recumbent position.
3. Nothing by mouth initially; then clear liquids if muscle tone adequate to prevent aspiration.
4. Intravenous fluids begun with lactated Ringer's 5% dextrose solution.
5. Four grams (range, 2-6) of $MgSO_4 \cdot 7H_2O$ in 500 mL of 5% dextrose administered over 15 minutes as loading dose.
6. Continuous infusion of 1 to 3 g/hr of $MgSO_4 \cdot 7H_2O$ after initial load.
7. Calcium gluconate readily available.
8. Accurate intake and output.
9. Frequent assessment of deep tendon reflexes.
10. Frequent examination of lungs for early signs of pulmonary edema.
11. Plasma magnesium levels monitored as clinically indicated.
12. Continue protocol for 24 hours. Change to oral beta-adrenergic agent if needed.

terminates 1 in 1000 pregnancies. The seizures and mental status changes of eclampsia are thought to result from hypertensive encephalopathy. Perinatal mortality is 2.0% to 8.6% (Sibai et al., 1981). Maternal mortality is less than 2%, with intracranial hemorrhage the major cause.

Gestational Hypertension

Gestational hypertension is defined as systolic BP of 140 mm Hg or greater and/or a diastolic BP of 90 mm Hg or greater, in the absence of proteinuria, in a previously normotensive pregnant woman at or after 20 weeks of gestation. Gestational hypertension is considered severe with sustained elevations in systolic BP of 160 and/or diastolic of 110 mm Hg or greater. Women with BP greater than 140/90 mm Hg without proteinuria or end-organ damage may ultimately develop preeclampsia. These initially normotensive women usually become hypertensive late in pregnancy, during labor, or within 24 hours postpartum and note a return to normal BP within 10 days postpartum. If preeclampsia does not develop, the diagnosis of gestational hypertension is made. The diagnosis of gestational hypertension is a temporary one and should be used during pregnancy only in women who do not meet criteria for preeclampsia or chronic hypertension.

Abruptio Placentae

Abruptio placentae (placental abruption) refers to separation of a normally located placenta before birth of the fetus. This event occurs in 1 in 129 births. Severe abruption results in a fetal mortality of 0.2%. Bleeding into the decidua basalis leads to separation of the placenta. Hematoma formation further separates the placenta from the uterine wall and compresses these structures, compromising the blood supply to the fetus leading to increased intrauterine pressure, uterine tenderness, frequent uterine contractions, fetal distress, and demise. The severity of fetal distress correlates with the degree of placental separation.

When the abruption is extensive, retroplacental blood may penetrate the thickness of the uterine wall into the peritoneal cavity because of increased intrauterine pressure. This phenomenon is called "couvelaire uterus." The myometrium becomes weakened and rarely may rupture, leading immediately to a life-threatening obstetric emergency. In near-complete or complete abruption, fetal death is inevitable unless immediate delivery by cesarean section is performed. Abruptio placentae received renewed awareness with the causal relationship to cocaine (Kline, 1997).

Abruptio placentae is a clinical diagnosis. Painful vaginal bleeding in the third trimester is the hallmark. Because ultrasound for this disorder has a high false-negative rate, this complication is diagnosed primarily on the findings of vaginal bleeding, abdominal pain, uterine tenderness, uterine contractions, and fetal distress. In one prospective study, almost 80% of patients with abruptio placentae presented with vaginal bleeding, 66% with uterine or back pain, and 60% with fetal distress (Hurd et al., 1983). Other evidence of abruptio placentae can include idiopathic preterm labor, uterine hypertonicity, and fetal demise. The monitoring of uterine contractions may reveal a high baseline pressure with concurrent contractions often 1 to 2 minutes apart.

Etiology

From 40% to 50% of women with abruptio placentae have underlying hypertension. Maternal trauma is the cause in 1.5% to 9.4%. The remainder can be associated with excessive alcohol consumption, cocaine use, sudden decompression of the uterus (as in delivery of first twin), retroplacental bleeding from needle puncture after amniocentesis, and possibly tobacco use. In a small group, no underlying association is found; abnormalities of uterine blood vessels and decidua likely exist in this idiopathic group.

Management

The management of abruptio placentae is primarily supportive and entails both aggressive hydration and monitoring of maternal and fetal well-being, with the expeditious delivery of the fetus if indicated (Turner, 1994). Maternal and fetal death may result from hemorrhage and coagulopathy. Coagulation studies should be performed to look for disseminated intravascular coagulation (DIC). Packed RBCs should be typed and held. If the fetus appears viable but compromised, urgent cesarean delivery should be considered. Recommended laboratory testing includes complete blood count with platelets, prothrombin and partial thromboplastin time, fibrinogen, fibrin degradation products, D-dimer, blood type, and Kleihauer-Betke acid elution. D(Rh)-negative mothers benefit from administration of D immune globulin (Pearlman et al., 1990).

Placenta Previa

Placenta previa is a life-threatening condition that presents in three forms (Fig. 21-5). When the cervical os is completely covered with placenta, it is classified as a *complete* or *total* placenta previa. *Partial* placenta previa occurs when the placenta covers a portion of the cervical os. A *marginal* placenta previa is one that extends just to the edge of the cervix. Placental implantation in the lower uterine segment is termed *low-lying placenta*. The incidence of placenta previa is about 1 in 200 to 250 pregnancies and is associated with potentially serious consequences from hemorrhage, separation of the placenta, or emergency cesarean delivery (Iyasu et al., 1993).

Placenta previa is usually diagnosed when the patient complains of painless vaginal bleeding in the third trimester. A smaller number of patients present with excessive bleeding in labor. Usually the initial bleeding is not profuse enough to be fatal and spontaneously ceases, only to recur later. The average first bleed occurs at 27 to 32 weeks of gestation. Women with a centrally implanted placenta previa tend to have earlier episodes of bleeding, which are more severe. Another suspicious aspect of the history includes an abnormal lie, in particular transverse or breech presentation.

Risk Factors

There are a few predisposing factors for placenta previa. They include advanced maternal age, increased parity, uterine abnormalities, multiple gestation, tobacco abuse, prior placenta previa, and previous uterine surgery.

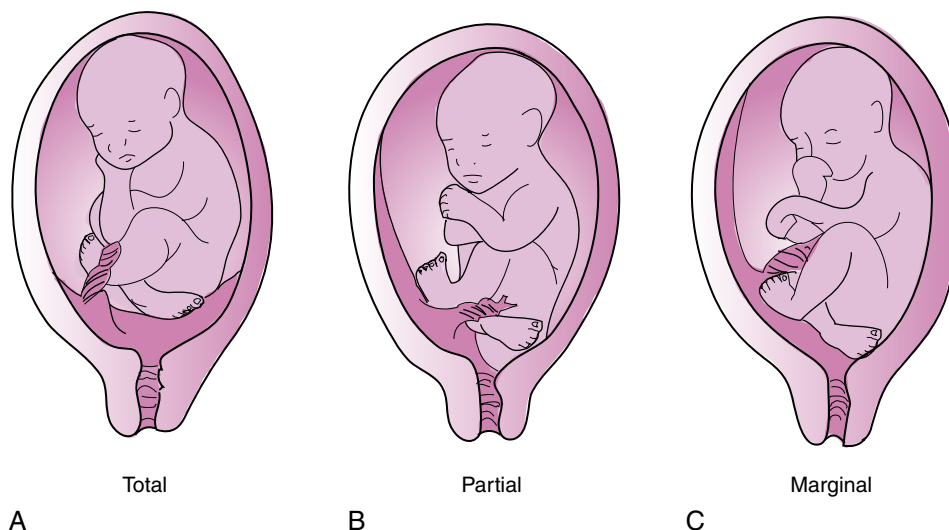

Figure 21-5 Various types of placenta previa. **A**, Cervical os is completely covered by the placenta. **B**, Cervical os is partially covered by the placenta. **C**, Placenta extends to the edge of the cervical os.

Ultrasound

Transabdominal ultrasound is a simple, precise, and safe method to visualize the placenta. It has an accuracy of 93% to 98% (Bowie et al., 1978). False-positive results can result from focal uterine contractions or bladder distention. The accurate assessment of placental position can also be difficult with a placenta implanted on the posterior uterine wall. In the patient whose placental edge is not well visualized and is not actively bleeding, the transvaginal approach may be used. The bladder should be empty, and initially the vaginal transducer should be inserted into the vagina to visualize the cervix. Once the closed cervix is visualized, deeper insertion of the probe will aid in visualization of the placenta. The use of the vaginal approach is safe and accurate in diagnosis of a placenta previa.

During routine second-trimester sonography, placenta previa is frequently diagnosed. Typically at 16 weeks' gestation, the placenta occupies 25% to 50% of the uterine surface area. As the third trimester approaches, growth of the lower uterine segment outflanks growth of the placenta, allowing apparent "migration" of the placenta (placental migration) away from the cervical os. For this reason, although 5% of pregnancies are diagnosed with complete previa by second-trimester ultrasound, 90% of these resolve by term (Rizos et al., 1979). When second-trimester sonography suggests a placenta previa, transvaginal ultrasound can be helpful in making a more accurate diagnosis before term.

Vasa Previa

Vasa previa is a rarely reported condition in which fetal blood vessels unsupported by the umbilical cord or placental tissue traverses the fetal membranes below the presenting part, covering the cervical os. It almost always coexists with a velamentous insertion of the umbilical cord. Vasa previa leads to fetal exsanguination from tearing of the large-caliber fetal vessels when the membranes rupture spontaneously or

artificially. This event has an associated fetal mortality of 33% to 100% (Bright and Becker, 1991).

When pulsatile vessels are palpated preceding the fetal vertex during digital examination, vasa previa should be considered along with cord presentation. Vasa previa must be included in the differential diagnosis of all cases of third-trimester bleeding. The blood that is lost can be tested for the presence of fetal hemoglobin, but often there is insufficient time to accomplish this. Vasa previa is often a retrospective diagnosis made after emergent cesarean delivery for fetal distress. Fetal mortality and morbidity from vasa previa may be reduced if there is a high index of suspicion, reliable method of diagnosis, and prompt surgical intervention (Messer et al., 1987).

Placenta Accreta, Increta, and Percreta

These three conditions are forms of abnormal placental attachment in which the trophoblasts invade beyond the normal location into the uterine muscle to varying degrees. Abnormal blood supply to the inner lining of the uterus and prior trauma to both the endometrium and myometrium (the muscle layer) appear to alter lower uterine physiology and influence placental implantation. The most common risk factor is a previous cesarean delivery or prior uterine surgery.

The risk of maternal death is 3%. In cases of bladder involvement with a placenta percreta, the risk of maternal death increases to 20%. The leading immediate causes of death are uterine bleeding and DIC. Placenta accreta, increta, or percreta is often the etiology of retained placenta (Breen et al., 1997). During manual extraction, the placenta fragments without complete separation, resulting in uncontrolled hemorrhage.

The major factor affecting outcome is the degree of placental invasion. A minimally invasive placenta (accreta) can often be removed manually or by curettage. Invasion deeper in the myometrium (increta) or through the myometrium (percreta) more often requires hysterectomy. The increased rate of cesarean deliveries is making abnormalities of placental

attachment more frequent, particularly if the placenta is attached in the area of the prior uterine incision.

Multiple Gestation

At least 1 in 80 births is a twin gestation. With assisted reproductive technologies, this rate has now increased to almost 1 in 50 to 60. Approximately two thirds to three quarters of twins are dizygotic.

Twin gestation presents unique challenges. Monozygotic twins have twice the anomaly rate of dizygotic twins or singletons. Women with a twin gestation are more likely to miscarry early in gestation and more likely to deliver prematurely. Half of mothers of twins experience premature labor. Bed rest is often recommended after 5 months of gestation to aid in preterm-labor prevention. Education regarding associated signs and symptoms is important in this group. The average gestational age of delivery for a twin gestation is 36 menstrual weeks.

Women with a twin gestation are also at higher risk for chronic hypertension, pyelonephritis, gestational diabetes, and placenta previa. They should take supplemental iron, particularly in the latter trimesters, even if they are not iron deficient. Growth discordance can also occur, from twin-twin transfusion syndrome or more often simply from different placental implantation and different accessibility to nutrients. Serial ultrasound studies for growth approximately every 6 weeks is recommended. Twin fetuses with growth discordance should have antenatal testing.

The majority of twins will present both head first, cephalic-cephalic (Fig. 21-6, A), or first one cephalic, second one breech (cephalic-breech, 21-6, B). Any other combination can be seen, although cephalic-transverse (21-6, C), and breech-cephalic are the most likely in this remaining group. Once well into the third trimester, the first presenting fetus most often stays in its position; the second fetus often changes position, occasionally even during early labor. Twins who are cephalic-cephalic can be delivered vaginally. Those who are cephalic-breech and cephalic-transverse can also be attempted vaginally by skilled operators in carefully chosen women. When the first fetus is presenting other than cephalic, delivery is often best accomplished by cesarean section. Breastfeeding has been successful in many women with twins and should be encouraged.

Antepartum Fetal Surveillance

The three most common methods used to evaluate fetal well-being in utero are the nonstress test, contraction stress test, and biophysical profile (Babbitt, 1996). Vibroacoustic stimulation and fetal movement counts are also useful adjunctive tools in the evaluation of fetal well-being.

The indications for antepartum fetal surveillance are multiple and reflect conditions that are associated with increased fetal morbidity and mortality (Smith-Levitin et al., 1997). Conditions that lead to fetal hypoxia, uteroplacental insufficiency, and death are all indications for increased fetal surveillance. There are no absolute protocols for increased fetal surveillance, but there are certain accepted practices for given maternal-fetal risks. For example, weekly antenatal testing beginning the 32nd week of gestation is often performed in women with low to moderate risk (e.g., gestational diabetes, chronic hypertension, mild preeclampsia). For women with higher risk of abnormal outcome, earlier and more frequent antenatal testing is indicated, requiring an individualized approach.

Nonstress Test

Most often the nonstress test (NST) is used as the primary tool in antepartum fetal surveillance. It has been used to document second-trimester and third-trimester fetal well-being for the past 40 years. It serves as a surrogate measure of the developing fetal autonomic nervous system and the adequacy of the uteroplacental function (Myrick and Harper, 1996).

The NST is more specific than sensitive and thus a better indicator of fetal health than fetal illness. The test itself is read as reactive or nonreactive and may be repeated at intervals as a screen for high-risk maternal conditions. A reactive or reassuring NST is defined as one with at least two accelerations above baseline fetal heart rate of 15 beats/min for 15 seconds, in a 20-minute period. If a reactive pattern is not present at the end of the first 20 minutes, attempts may be made to arouse the fetus. Fetal rest periods, reportedly 30 to 40 minutes in duration, must be excluded for the fetus to demonstrate a reactive NST. Because fetuses can have normal sleep cycles lasting up to 40 minutes, NST might require over an hour to complete

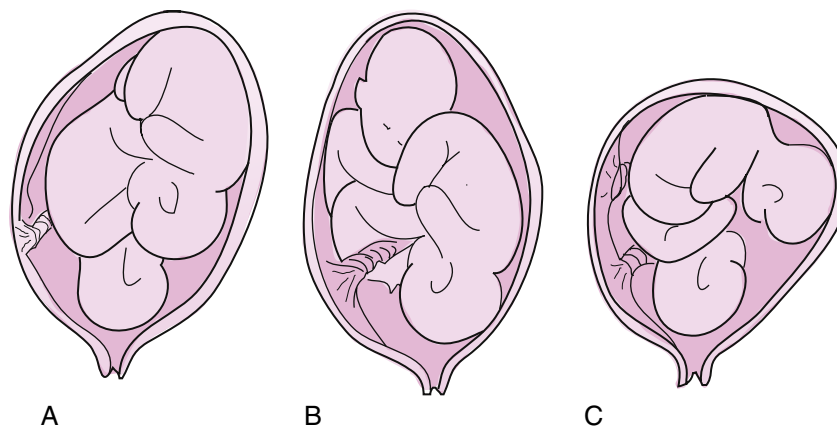

Figure 21-6 Three common twin presentations: **A**, cephalic-cephalic; **B**, cephalic-breech; **C**, cephalic-transverse.

if it is initially nonreactive. It is important to differentiate whether a nonreactive tracing truly represents a compromised fetus versus a temporary behavioral state (Knuppel et al., 1982).

The absence of fetal accelerations with the exclusion of a fetal sleep state denotes a nonreactive test. There are no contraindications to the NST as a primary screening tool, and it is easily reproducible, relatively inexpensive, and acceptable to most patients. Maternal narcotics, extreme prematurity, and fetal cardiac or CNS anomalies may also be responsible for a nonreactive NST. A nonreactive NST does not indicate fetal jeopardy but should be viewed as an indication for further evaluation. This evaluation may take the form of a biophysical profile or contraction stress test.

Biophysical Profile

The biophysical profile (BPP) is an ultrasound assessment of fetal well-being. It was originally designed to mimic the Apgar score for postnatal assessment. The BPP is technically more difficult to perform and interpret but provides a greater degree of certainty of fetal well-being. During a 30-minute examination, certain behavioral patterns associated with a healthy fetus are documented. The test is scored with five components, each worth 2 points (Table 21-11). Indicators such as amniotic fluid volume, fetal breathing, fetal heart rate, movement, and tone are evaluated. A score of 8 or 10 is reassuring; a score of 6 is suspicious and indicates a need for further evaluation; and a score of 4 or less is ominous, indicating the need for immediate intervention. A low score may also reflect the fetus's behavioral state during the test, such as normal sleep or sedation from maternal use of narcotics or CNS depressants. However, a decreasing score has been well correlated with poor outcome and with increasing degrees of fetal acidemia.

Modified Biophysical Profile

The modified BPP consists of the NST and the amniotic fluid index. It has proved to be an excellent means of fetal surveillance and identifies a group of patients at increased risk for poor perinatal outcome and small-for-gestational-age (SGA) infants. It has proved to be as effective as a full BPP in assessing fetal well-being.

Contraction Stress Test

With the increasing popularity of the NST, the contraction stress test (CST), also known as the *oxytocin challenge test* (OCT), is most often used as a supplementary tool in fetal surveillance. The CST is more cumbersome to perform, is difficult to interpret, and has several contraindications. This test is used to assess the reserve of the marginally compromised fetus when subjected to the stress of several uterine contractions (Collea and Holls, 1982; Lagrew, 1995). The goal of CST/OCT is to achieve three contractions in a 10-minute period through oxytocin infusion or nipple stimulation and look for late decelerations.

The CST is considered to be negative if no late decelerations are noted. A negative (normal) CST is a good indication of adequate fetal well-being as judged by fetal distress in labor, Apgar scores, and absence of meconium. The CST

Table 21-11 Components of the Biophysical Profile*

| Parameter | Normal (score = 2) | Abnormal (score = 0) |
|---------------------------|--|--|
| Nonstress test | Two or more accelerations of at least 15 beats/min above baseline for at least 15 seconds. | Less than two accelerations of sufficient height and duration. |
| Amniotic fluid volume | At least one amniotic fluid pocket is 2 × 2 cm or greater in perpendicular plane. | No 2 × 2-cm pockets, or AFI less than 5.0. |
| Fetal breathing movements | Sustained fetal breathing for at least 30 seconds. | Less than 30 seconds of fetal breathing |
| Fetal body movements | At least three limb or gross body movements. | Less than three limb or body movements. |
| Fetal tone | Extremities in flexion at rest and at least one episode of extension of extremity or spine with return to flexion. | Extension at rest or no return to flexion after movement. |

Modified from Norman LA, Karp LE. Biophysical profile for antepartum fetal assessment. *Am J Fam Physician* 1986;34:83-89.

*Scoring of latter four components is done sonographically in 30-minute observation period. Total score of 8 to 10 is reassuring; score of 6 is suspicious; and score of 4 or less is ominous.

AFI, Amniotic fluid index (sum of largest vertical pocket in each of four quadrants of uterus).

is considered positive if late decelerations accompany 50% or more of contractions. A positive CST is predictive of fetal compromise and distress in labor in up to 80% of cases and in specific clinical situations indicates need for delivery of the fetus. The presence of fewer decelerations indicates a suspicious study. The latter two conditions mandate need for further evaluation. Contraindications to a CST include risk of preterm labor, placenta previa, classic uterine scar or full thickness scar from previous uterine surgery, incompetent cervix, and multiple gestation (Babbitt, 1996).

Vibroacoustic Stimulation

Vibroacoustic stimulation is an artificial burst of noise produced by a handheld battery-powered artificial larynx (Birnholtz and Benacerraf, 1983). This device is portable and easy to apply to the maternal abdomen and provides a stimulation that combines both sound and vibration. The goal is to alter the fetal behavioral state, waken a sleeping fetus, and provoke accelerations in the heart rate. Use of this device is associated with a significant increase in the number of reactive NSTs and a significant decrease in overall testing time. The use of vibroacoustic stimulation in achieving fetal heart rate accelerations has been found to be equally predictive of a favorable fetal outcome as

spontaneously generated fetal heart rate accelerations (Smith et al., 1986).

Normal Labor and Delivery

Labor, whether preterm or term, is defined as the presence of sufficient uterine contractions in frequency, intensity, and duration to bring about effacement and dilation of the cervix. Control of normal labor is complex and, despite advances in medical science, poorly understood. Evidence supports prostaglandin (PG) involvement, in particular PGE₂ and PGF_{2α}, as well as other mediators (Ulmsten, 1997).

Before the onset of labor, the fetal head may descend into the pelvis, and the height of the fundus will diminish. This lightening may occur acutely and may be very obvious to the pregnant woman, or it may occur over several weeks. An increase in pelvic pressure is experienced at this time. *False labor*, or irregular, short contractions that occur often before true labor, may in fact aid in cervical effacement and shortening of the cervical canal that begins as funneling at the internal cervical os. With impending true labor, cervical effacement and early dilation may allow the passage of a blood-tinged mucous termed “bloody show.” Most women go into true labor within 3 days of a bloody show. Bleeding described as “heavy as the beginning of a menstrual period” may be pathologic, and the pregnant woman should be evaluated for placenta previa, abruptio placentae, or other causes of vaginal bleeding.

Contractions of active labor most often occur every 2 to 3 minutes, last about 1 minute, and have a mean of 40 mm Hg in intensity. However, some women successfully deliver babies with less frequent and intense uterine contractions. Frequent contractions of 1 to 2 minutes apart may be a sign of the increased intrauterine pressure associated with abruptio placentae. Adequate relaxation between contractions is imperative to allow oxygenated blood to enter the intravillous spaces and transfer to the fetal compartment. During the course of labor, uterine contractions cause cervical effacement and then dilation to a full 10 cm to allow passage of the fetal head, the largest diameter of the fetus to pass through the birth canal.

Progress of Labor

The degree and rate of cervical dilation measures the progress of labor. Labor can be divided into stages that are somewhat predictable in the nulliparous and multiparous woman (Table 21-12 and Fig. 21-7). The first stage of the labor course can be subdivided into the latent phase and the active phase.

First Stage of Labor

Latent Phase

The latent phase of the first stage of labor is variable in length, but usually less than 20 hours for a nullipara and 14 hours for a multipara. Little cervical dilation is seen, but cervical preparation for labor occurs with changes in consistency caused by changes in collagen and connective tissue. An increase in effacement as well as the anterior positioning of the cervix is also noted. Conduction anesthesia given in this phase may prolong or arrest progress. In normal pregnant women, latent-phase labor is best experienced at home. Clear liquids instead of heavy meals are encouraged during this time.

Table 21-12 Stages of Labor

| Stage | Onset | Completion |
