The underfill theory suggests that fluid is collected in the splanchnic vascular bed. The kidneys then act upon a perceived decrease in intravascular volume, resulting in sodium and water retention. The overflow theory proposes that the primary abnormality is in the kidneys. It is hypothesized that despite a normal intravascular volume, the kidneys retain sodium and water (62). The arterial vasodilation hypothesis is based upon hemodynamic findings in cirrhotic patients. Both the systemic vascular resistance (SVR) and mean arterial pressure (MAP) are decreased, whereas their cardiac output ( $\dot{Q}$ ) is increased (63). Vasodilation of the splanchnic circulation is likely responsible for these pressure changes (64). Several mechanisms of vasodilation have been proposed. Opening of portosystemic collaterals may contribute to decreases in SVR, as well as the presence of multiple circulating vasodilators (65). Agents such as glucagon, vasoactive intestinal peptide, substance P, platelet-activating factor, prostaglandins, prostacyclin, and NO have all been studied (61,66). The vasodilation results in an apparent hypovolemia, activating the renin-angiotensin system, the sympathetic nervous system, and the release of antidiuretic hormone (67). This results in sodium and water retention. Renal sodium excretion may fall to less than 10 meq/day and may result in an increased total body sodium with a dilutional hyponatremia (68).

Additional factors that may play a role in ascites development include increased central sympathetic outflow, increased hydrostatic pressures within the splanchnic capillary bed and hypoalbuminemia from decreased synthesis with reduced plasma oncotic pressure.

## Treatment

☞ **The mainstays of ascites management consist of dietary sodium restriction and diuretics.** ☞ When dietary sodium intake exceeds urinary sodium output, total body sodium, and water may further increase resulting in worsening ascites and peripheral edema. A diet with ~88 meq, or 2000 mg, of sodium each day is a practical initial goal. Reducing dietary intake to 44 to 66 meq/day may be necessary to manage ascites in up to 10% of patients (69).

When pharmacologic intervention is necessary, the most successful diuretic regimen consists of spironolactone and furosemide. Spironolactone 100 mg a day and furosemide 40 mg a day is a common initial dose (70). However, these doses may be doubled if there is no obvious response after several days. Spironolactone inhibits the sodium-potassium exchange in the distal tubule, thereby increasing sodium excretion. Furosemide will potentiate this effect by blocking the Na-K-2Cl cotransport in the loop of Henle. Furosemide alone will deliver more sodium to the distal tubule and typically should not be used as a sole agent to manage ascites (69). The maximum recommended doses are spironolactone 400 mg/day and furosemide 160 mg/day (71).

Ten to twenty percent of patients with ascites will be refractory to diet and diuretic therapy. One therapeutic option in these patients is large volume paracentesis. The removal of five or more liters as often as necessary is an effective means of ascites management. Controversy exists regarding the necessity to administer albumin with paracenteses that remove more than 5 L. Several studies have shown more stable renin and aldosterone levels after large volume paracentesis with the addition of albumin, with concomitant decreases in morbidity or mortality (69).

Distal surgical portosystemic shunts are an option for individuals with ascites who are refractory to diuretic therapy, and those with recurrent variceal hemorrhage. There is a high incidence of hepatic encephalopathy, and a high mortality following portosystemic shunts. Furthermore, central portosystemic shunts should be avoided if the possibility of liver transplantation exists. Another effective shunting procedure is the transjugular intrahepatic portosystemic shunt (TIPS). These procedures reduce sinusoidal pressure and increase the effective arterial blood volume by diverting blood from the liver, and reducing ascites formation. The major complications of the TIPS procedure include hepatic encephalopathy and liver failure (69).

## Complications

### Spontaneous Bacterial Peritonitis

☞ **SBP is an infection of ascitic fluid without a recognizable secondary cause of bacterial peritonitis. About 10% to 25% of patients with cirrhosis and ascites admitted to the hospital will have SBP.** ☞

Classically, SBP is a monobacterial infection, with aerobic Gram-negative organisms accounting for up to 80% of cases. *Escherichia coli* accounts for 50% of cases. Gram-positive cocci may also be involved, with *Streptococcus pneumoniae* being the most common.

Clinical features include fever, leukocytosis, abdominal pain, and mental status changes. Although these signs and symptoms may be helpful, an abdominal paracentesis must be performed to make the diagnosis. An ascitic fluid absolute neutrophil count greater than 250 cells/mm<sup>3</sup> is sufficient for a presumptive diagnosis (72). Cultures and a gram stain should be performed. Inoculating blood culture

bottles at the bedside can enhance the likelihood of obtaining a positive culture (73). Decreased ascitic fluid total protein, glucose, and lactate dehydrogenase may prove helpful in confirming the presence of SBP.

Empiric therapy with cefotaxime, or a similar third-generation cephalosporin, should be started as soon as possible as initial treatment (72). As the culture results become available, the antibiotic coverage should be tailored based upon the specific organism present. Based on a single study (74) in which patients who received intravenous albumin (1.5 g/kg initially followed by 1 g/kg on day 3) were significantly less likely to develop renal impairment, many authorities advocate its use as part of the treatment of SBP. Antibiotic prophylaxis should be considered in patients at high risk for SBP such as those with a prior episode of SBP, ascitic fluid total protein concentration of less than 1.0 g/dL, or cirrhotic patients with gastrointestinal bleeding (75,76). The two currently recommended prophylactic regimens are either ciprofloxacin, 750 mg once a week, or trimethoprim-sulfamethoxazole, one double-strength tablet (sulfamethoxazole 800 mg and trimethoprim 160 mg) five days a week (69).

### Hepatorenal Syndrome

HRS, a potential complication of portal hypertension, is defined as renal failure associated with severe liver disease in the absence of an intrinsic kidney abnormality. ⚡ **The severe splanchnic vasodilatation with a reduced effective arterial blood volume seen in end-stage cirrhosis can result in extreme renal artery vasoconstriction and renal failure.** ⚡ The risk of HRS in patients with ascites is ~27% at one year and ~40% at five years. Renal failure of other etiologies must also be considered in patients with deteriorating renal function (Volume 2, Chapters 40 and 41). Patients with HRS have a very poor prognosis and liver transplantation remains a suitable therapy. The use of TIPS may be of some benefit, but further trials are needed (69). In critically ill patients, particularly those who are candidates for liver transplantation, early continuous renal replacement therapy is an important option (Volume 2, Chapter 43).

### Hepatopulmonary Syndrome

⚡ **Hepatopulmonary syndrome (HPS) is a condition that consists of a triad of (i) liver dysfunction, (ii) hypoxemia with an increased alveolar-arterial (A-a) gradient, and (iii) intrapulmonary vascular dilatation.** ⚡ Although cirrhotic patients may be mildly hypoxic due to diaphragmatic excursion from ascites, severe hypoxemia ( $\text{PaO}_2 < 50$  mmHg) in the absence of cardiopulmonary disease in a cirrhotic patient suggests the presence of HPS. Individuals with HPS are frequently dyspneic, and may also display platypnea (increased dyspnea when upright and relieved with recumbency) or orthodeoxia (desaturation when upright and relieved with recumbency) (77). Key points of HPS are summarized in Table 5.

The precise mechanism of HPS is unclear, although it is believed that the intrapulmonary vascular dilatation is largely caused by failure of the cirrhotic liver to clear NO. Patients may benefit from supplemental oxygen. Other therapies have been tried unsuccessfully. Mortality has been estimated at 41% in patients who have been followed for over 2.5 years (2,77,78). At present, liver transplantation appears to be the most effective treatment for HPS in patients with severe hypoxemia.

**Table 5** Summary Findings in Hepatopulmonary Syndrome

Hepatopulmonary syndrome triad	
Liver dysfunction	
Hypoxemia with wide A-a gradient	
Intrapulmonary vascular dilatation	
Severe hypoxemia in the absence of cardiopulmonary disease suggests HPS	
Clinical signs consistent with the degree of HPS	
Platypnea = increased dyspnea when upright and relieved when supine	
Orthodeoxia = desaturation when upright and relieved when supine	

### Hyponatremia

Hyponatremia is a common problem in advanced cirrhosis. The reduction in SVR and MAP in cirrhosis leads to activation of the renin-angiotensin system and the sympathetic nervous system and increases levels of antidiuretic hormone. This results in renal sodium and water retention (38). This inability to excrete water results in dilutional hyponatremia (58,79). ⚡ **The severity of the hyponatremia is proportional to the degree of cirrhosis and is of prognostic value (60).** ⚡

The standard therapy in nontrauma or surgical patients is restriction of water intake to create a negative water balance. Providing oral or parenteral salt is only indicated if the hyponatremia is symptomatic. However, in trauma or critically ill postsurgical patients, salt-containing fluids often need to be administered to replete lost fluids and guard against further deletion of intravascular volume.

## HEPATIC ENCEPHALOPATHY

Hepatic encephalopathy or portosystemic encephalopathy is a spectrum of neuropsychiatric abnormalities occurring in patients with advanced liver failure.

### Pathogenesis

⚡ **Although the precise mechanisms of hepatic encephalopathy are unknown, there are several theories regarding the pathogenesis. Ammonia, metabolic changes, cerebral edema, impaired perfusion, and changes in neurotransmitter systems may all be involved.** ⚡

Ammonia acts as a neurotoxin in hepatic encephalopathy. It is produced by urease splitting colonic bacteria from nitrogenous sources such as protein, blood following upper GI hemorrhage, and by enterocytes from glutamine. Normally, the liver clears almost all the ammonia in the portal vein by converting it into glutamine. The arterial concentration of ammonia is increased in about 90% of patients with hepatic encephalopathy (80). Hyperammonemia can increase the cerebral concentration of neutral amino acids which may affect the synthesis of several neurotransmitters (81). Cerebral edema is also seen during hyperammonemia. This may be secondary to increased glutamine production from the metabolism of ammonia resulting in an increase in intracellular osmolarity (82). Ammonia may also directly affect neuronal electrical activity by inhibiting postsynaptic potentials (83–85).

Another metabolite that may be involved in the development of hepatic encephalopathy is oxindole. It is created by bacteria in the intestines and is a product of tryptophan with neurodepressant effects. It can cause sedation, weakness, hypotension, and coma. Greatly increased plasma concentrations of oxindole have been found in patients with hepatic encephalopathy (86).

Impaired neurotransmission may be a component in the pathogenesis of hepatic encephalopathy. Both the Gamma-aminobutyric acid-benzodiazepine and glutamatergic neurotransmission systems have been studied. Astrocytic benzodiazepine receptors may be increased in patients with hepatic encephalopathy resulting in accumulation of cholesterol and neurosteroids (87). Astrocytes appear to have a reduced ability to reuptake neuronally released glutamate during hepatic encephalopathy and may play a role in its pathogenesis (88,89).

Several catecholamines may also be implicated in hepatic encephalopathy. Reduced norepinephrine concentrations in the brain are routinely found in liver failure. Significantly increased levels of the serotonin metabolite, 5-hydroxyindoleacetic acid, are a consistent finding in hepatic encephalopathy (90). Additionally, alterations in the blood-brain barrier, as well as changes in cerebral energy metabolism may prove to be important in the pathogenesis, but require more study (91,92).

### Signs and Symptoms

Patients with hepatic encephalopathy usually have advanced liver disease and will likely display many of the signs and symptoms associated with hepatic dysfunction.

The changes in mentation seen in hepatic encephalopathy are often preceded by sleep disturbances. This may be either insomnia or hypersomnia. Changes in cognition, personality, intellectual function, behavior, and eventually consciousness may then develop (45). A commonly used grading system for hepatic encephalopathy uses these changes to place patients into stages, from I to IV (Table 6) (93). This may be useful to follow the course of the illness and its response to therapy. Other clinical signs include the presence of asterixis, hyperactive deep tendon reflexes, and even focal neurologic deficits.

The diagnosis of hepatic encephalopathy is one of exclusion. Other causes of a change in mental status, such

as electrolyte disturbances, drugs, infarction, uremia, and infection must first be excluded. There is no laboratory or radiologic test that is diagnostic of hepatic encephalopathy. Although ammonia may be involved in the pathogenesis, neither venous nor arterial serum levels are appropriate screening tests (94). Likewise, serum  $\text{NH}_3$  levels have not been shown to correlate with the severity of clinical symptoms. The electroencephalogram may be used to evaluate the degree of encephalopathy. Although not specific, a bilaterally synchronous decrease in wave frequency and an increase in wave amplitude may be seen in hepatic encephalopathy (95).

### Treatment

In managing the patient with hepatic encephalopathy, potential precipitating causes, such as gastrointestinal bleeding, high protein intake, infection, and benzodiazepine use, must first be identified and treated.

Many therapies target ammonia production or absorption. Reducing dietary protein to less than 70 g/day is an effective way to decrease ammoniogenic substrates (96). Oral and rectal lactulose are a mainstay of treatment. The bacterial flora in the gastrointestinal tract convert lactulose into a short-chain fatty acid which lowers the intestinal pH. This favors the conversion of ammonia to a nonabsorbable form, ammonium. The dose should be titrated to cause two to three stools each day (97). Lactitol, another synthetic disaccharide, appears to be as effective as lactulose and may have fewer side effects (98–100). The use of antibiotics has also been studied as a means to inhibit ammonia production. The poorly absorbed aminoglycoside neomycin has been shown to be effective, but ototoxicity and nephrotoxicity limit its use as a long-term treatment. Additionally, oral enterococcus faecium SF68, which may alter the gastrointestinal flora to a more urease-negative form, was shown to be as effective as lactulose in a small, randomized study (101). More recently, the minimally absorbed antibiotic rifaximin shows promise for its safety and efficacy in treating hepatic encephalopathy (102). Agents such as ornithine-aspartate, which may increase ammonia removal by stimulating glutamine synthesis, and sodium benzoate, which may increase urinary ammonia excretion, may prove useful, but need more study (103). Studies on branched-chain amino acid infusions, as well as agents that target the neurotransmitter systems (e.g., flumazenil),

**Table 6** West Haven Staging for Hepatic Encephalopathy

Stage	Mental status	Intellectual function	Asterixis/reflexes	EEG
I	Euphoria or depression, mild confusion, slurred speech, disordered sleep	Short attention	+Tremor and incoordination +Mild astrexis	Usually normal
II	Lethargy, moderate confusion	Disoriented	+Hyperreflexia ++Astrexis	Abnormal Triphasic slowing (5 cps)
III	Marked confusion, incoherent speech, sleeping but arousable	Loss of meaningful communication	++Hyperreflexia +++Astrexis	Abnormal Triphasic slowing (5cps) Abnormal
IV	Coma; initially responsive to noxious stimuli, later unresponsive	Absent	+++ (Ankle clonus) +Decerebrate +Babinski	Very slow (2–3 cps) (delta waves)

may be involved in hepatic encephalopathy and have yielded conflicting results (104,105).

**ESOPHAGEAL VARICES AND UPPER GI BLEED**

Esophageal variceal hemorrhage, a major complication of portal hypertension from cirrhosis, accounts for significant morbidity and mortality in the cirrhotic patient. This condition accounts for 10% to 30% of all upper gastrointestinal hemorrhages, but accounts for nearly 80% to 90% of bleeding episodes in patients with cirrhosis. **Variceal hemorrhage occurs in approximately one-third of patients with cirrhosis. Thirty to fifty percent of these bleeds are fatal.** Slightly more than two-thirds of those that do survive the first bleed are likely to have a recurrence, with an increased mortality as high as 50% (106,107).

In managing a cirrhotic patient with a variceal hemorrhage, it is important to consider four principal areas: prediction of the at-risk patient, prophylaxis, treatment of the acute bleed, and secondary prevention.

**Predicting the Risk of Variceal Hemorrhage**

Varices form in response to the increased obstruction of the portal vein outflow caused by the cirrhotic liver. **The formation of varices occurs when the portal vein to hepatic vein pressure gradient exceeds 12 mmHg (108).** Although this measurement may not be routinely performed, there are clinical and endoscopic factors that are useful for predicting which patients with cirrhosis are at highest risk for variceal hemorrhage (Table 7).

**Clinical Factors**

A greater degree of liver dysfunction, as measured by the Child–Pugh classification (Table 8), is associated with a greater risk of ruptured varices. In addition, a previous variceal bleed predicts a 70% likelihood of a second bleeding episode. The risk of rebleeding is greatest within the first six weeks of the initial bleeding episode. Approximately, 50% of rebleeds occur within the first 48 hours. Other clinical risk factors include presence of ascites and continued alcohol consumption (109).

**Endoscopic Factors**

Varices can develop anywhere along the gastrointestinal tract, but are most often identified in the esophagus. However, gastric and rectal varices can be found in cirrhotic patients. In the esophagus, varices which develop in the submucosa become more superficial and have less connective tissue in the distal aspect of the esophagus

**Table 7** Risk Factors for Variceal Hemorrhage

Increased portal pressure (>12 mmHg)
Recent bleed (within 48 hr to 6 wk)
Severity of initial bleed
Size of varix
Erythema or “red wales”
Continued alcohol abuse
Active bleeding seen on endoscopy
Location of varices near the gastroesophageal junction
High Child–Pugh score (Table 8)

**Table 8** Modified Child–Pugh Classification of the Severity of Cirrhosis

Variable	Score		
	1	2	3
Ascites	None	Mild	Moderate–severe
T-bili (mg/dL)	<2	2–3	>3
Albumin (g/dL)	>3.5	2.8–3.5	<2.8
INR	<1.7	1.8–2.3	>2.3
Encephalopathy <sup>a</sup>	None	Grade 1–2	Grade 3–4
Classification	Total score	1 yr survival	2 yr survival
A	5–6	100	85
B	7–9	80	60
C	10–15	45	35

<sup>a</sup>Encephalopathy grade refers to West Haven hepatic encephalopathy score (Table 6).

Abbreviations: INR, international normalization ratio; T-bili, total bilirubin. Source: From Ref. 108.

(Fig. 4A). Therefore, varices near the gastroesophageal junction are more likely to rupture. Varices may also develop in the stomach. Gastric varices tend to bleed less frequently, but can bleed more severely (110). Rectal varices can also develop and may bleed. Laplace’s Law suggests that a small increase in the vessel wall radius results in a significant increase in the wall tension and supports the finding that larger varices are at an increased risk of rupturing (106). Endoscopic identification of erythema, red spots, or red streaks (so called “red wales”) can independently predict a higher likelihood of hemorrhage (110).

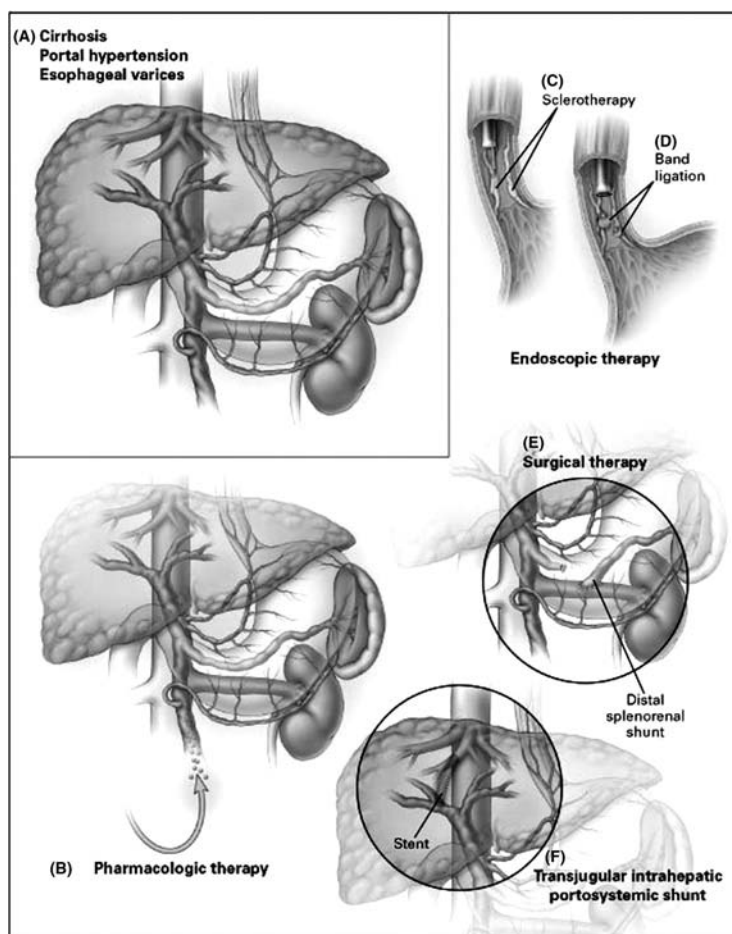

**Prophylaxis**

Portal hypertension results from increased portal venous inflow and/or increased resistance to portal outflow. Pharmacologic prophylaxis is aimed at reducing the inflow (Fig. 4B). Nonselective  $\beta$ -blockers (e.g., propranolol or nadolol) result in unopposed  $\alpha$ -mediated vasoconstriction of the splanchnic arteries, thereby decreasing portal inflow. The  $\beta$ -blocker should be titrated to achieve a 25% decrease in resting heart rate or a pulse of 50 to 60 beats/min (Table 9) (106).

The potential side effects of blockers (especially the noncardioselective ones) include hypotension and bronchoconstriction which may limit the use of these agents in select patients. Although nitrates can decrease portal pressure, this class of drug is not recommended as single-agent prophylaxis because of concerns of an increased mortality in those over 50 years of age (111).

Combined therapy of  $\beta$ -blocker and a long-acting nitrate (e.g., isosorbide mononitrate) can be considered in patients who cannot achieve the desired pulse or response to  $\beta$ -blockers alone. In patients who can tolerate the combination of  $\beta$ -blockers and nitrates, the combination appears to offer greater benefit than  $\beta$ -blockers alone and without an increase in mortality (112). In patients who cannot tolerate pharmacologic prophylaxis, endoscopic sclerotherapy, or band ligation is a clinically effective means of prophylaxis

**Figure 4** Pictorial representations. (A) Overview of cirrhosis, portal hypertension, and esophageal varices. (B) Pharmacologic therapy. (C) Sclerotherapy. (D) Band ligation. (E) Surgical therapy. (F) TIPS. *Abbreviation:* TIPS, transjugular intrahepatic portostemic shunt. *Source:* From Ref. 105.

(113). These procedures have typically been reserved for individuals who have already experienced an episode of bleeding. Although currently the standard practice, further studies are needed to determine whether endoscopic intervention should be advocated for use as a primary prevention.

**Management of Variceal Hemorrhage**

Variceal hemorrhage typically presents as severe acute hematemesis. Individuals typically require intensive care management. Pharmacologic therapy, endoscopic intervention, balloon tamponade, and TIPS are often used in the management of variceal bleeding (Table 10) (106).

**Table 9** Variceal Hemorrhage Prophylaxis

Nonselective B-blocker titrated to pulse 50–60 or 25% decrease of resting heart rate
Nonselective B-blocker plus long-acting nitrate
Band ligation

**Pharmacotherapy**

Intravenous vasopressin constricts splanchnic arterioles and reduces portal pressure. Although this agent can achieve hemostasis, the benefit is limited by extrasplanchnic vasoconstriction that can result in myocardial and mesenteric ischemia. In addition, intracranial pressure can be increased in cirrhotics with cerebral edema and increased cerebral blood flow due to vasopressin-induced hypertension. The concurrent use of intravenous nitroglycerine results in improved hemostasis and a reduction in complications (114).

Somatostatin, or the synthetic longer acting octreotide, can reduce portal pressure via inhibition of vasoactive peptides. Somatostatin is approximately twice as effective in

**Table 10** Management of Active Variceal Hemorrhage

Octreotide
Sclerotherapy
Band ligation
Balloon tamponade
Transjugular intrahepatic portosystemic shunt
Surgery

achieving initial hemostasis than vasopressin. Side effects can include mild hyperglycemia and abdominal cramping, but it is generally well tolerated (115).

**Endoscopic Therapy**

☞ Endoscopic therapy is the preferred treatment for active variceal hemorrhage. Sclerotherapy or band ligation can result in a cessation of bleeding in 80% to 90% of patients. This is an important change to make because band ligation is actually preferred over sclerotherapy because of band ligations fewer complications. Sclerotherapy is rarely done in this country any more. (Fig. 4C). ☞ Its advantages include its wide availability, ease of use, and low cost. Its disadvantages include complications such as perforation, ulceration, and stricture formation (106).

Endoscopic variceal band ligation, involving the placement of an elastic band around the varices, is equally as effective as sclerotherapy with fewer reported complications, and is therefore in favor. Frequently individuals will require a combination of pharmacologic and endoscopic therapy (Fig. 4D) (116).

**Balloon Tamponade**

In situations where pharmacotherapy and endoscopic therapy have failed to control bleeding, balloon tamponade can be utilized to stabilize a patient during acute hemorrhage. An inflatable balloon attached to a nasogastric tube applies direct pressure to the bleeding site. The risk of rebleeding is high, once the balloon is deflated. However, this technique can be an effective method to achieve rapid, short-term hemostasis until more definitive treatment can be instituted. The patient should be intubated to protect the airway when this procedure is used for management of varices because of the increased risk of aspiration and tube migration. In addition, balloon tamponade has been associated with lethal complications

including esophageal rupture (106). The benefits and disadvantages of the various nonoperative techniques for treatment of variceal hemorrhage are summarized in Table 11.

**Transjugular Intrahepatic Portosystemic Shunt**

☞ TIPS creates a low-resistance pathway between the hepatic and portal veins by angiographic insertion of a metal stent in liver parenchyma (Fig. 4E). ☞ This procedure can be performed when pharmacologic and endoscopic treatments are unsuccessful, which can occur in 10% to 20% of cases. TIPS has been shown to markedly improve short-term survival (117). Potential complications of TIPS include stent stenosis, encephalopathy, hemolytic anemia, and infection (118).

**Surgical Therapy**

The reported morbidity associated with surgical shunting and TIPS are comparable. However, the complications of surgery appear to be more immediate than the complications of TIPS placement. The decision to perform surgery or use TIPS is primarily based upon the experience and skills of available physicians (106,119).

**Secondary Prevention**

Approximately one-third of patients with esophageal varices will experience an episode of rebleeding within six weeks. One-third of individuals who have variceal bleeding will experience recurrent variceal bleeding with a 50% mortality at six weeks (119,120). Secondary prevention, using pharmacologic, endoscopic, or surgical intervention, is frequently employed to decrease the incidence of recurrent variceal bleeding with a potential reduction in morbidity and mortality in cirrhotic patients.

**Table 11** Benefits and Disadvantages of Various Nonoperative Techniques for the Control of Variceal Hemorrhage

Therapy	Advantages	Disadvantages
Sclerotherapy	Effective Widely available Inexpensive	Perforation Ulceration Stricture formation
Band ligation	Equally or more effective Fewer complications	More challenging procedure Better visibility required
Balloon tamponade	Effective Quick	Esophageal rupture possible Temporary Frequently rebleeds when removed Intubation required
TIPS	An option when all else fails  Improves short term survival	In stent stenosis Encephalopathy Hemolytic anemia Infection

Abbreviation: TIPS, transjugular intrahepatic portosystemic shunt.

**HEMOSTASIS**

Numerous elements in the coagulation system are dysfunctional in the cirrhotic patient, including platelet number and function, increased fibrinolysis, and deficiencies in clotting factors (Table 12). The common causes and treatments for each of these abnormalities are discussed below.

**Table 12** Coagulation System Abnormalities and Cirrhosis

Abnormality	Laboratory finding	Treatment
Thrombocytopenia	Platelet count <100,000 $\mu\text{L}^{-1}$	Platelet transfusion, splenic embolization
Platelet dysfunction	Bleeding time >10 min, impaired aggregation	Platelet transfusion, desmopressin
Increased fibrinolysis	Normal or low fibrinogen, increased fibrin split products, increased D-dimer	Supportive care, correct underlying abnormalities

### Abnormal Platelet Number or Function

☞ **The severity of cirrhosis is directly related to the extent of thrombocytopenia and platelet dysfunction.** ☞ Approximately 40% of cirrhotic patients are thrombocytopenic with platelet counts of less than  $100,000 \text{ mm}^{-3}$  or have abnormal platelet function with a bleeding time of greater than 10 minutes (121,122). Thrombocytopenia can be explained by portal hypertension induced splenomegaly that causes sequestration of platelets from the circulation (121). Platelet-associated IgG in cirrhotic patients can play a role in immunologic platelet destruction (123). In addition, the cirrhotic liver may synthesize less thrombopoietin, a peptide that is responsible for platelet production (124). Cirrhosis is also independently associated with worsening of platelet function (122).

In the critical care setting, thrombocytopenia and thrombocytopenia are typically managed with platelet transfusion. Desmopressin may be helpful for management of prolonged bleeding times. Splenic embolization has been used to control the platelet sequestration and immunologic destruction. However, the use of splenic embolization to decrease morbidity associated with thrombocytopenia has declined with the increasing availability of transplantation (121).

### Increased Fibrinolysis

Although the mechanisms are not clear, there appears to be an increase in fibrinolysis in cirrhotic patients. This is evidenced by increased levels of fibrin split products, D-dimers, and tissue plasminogen activator. Impaired clearance of tissue plasminogen activators and impaired synthesis of fibrinolytic inhibitors have been implicated. Severe dysfibrinogenemia can lead to disseminated intravascular coagulopathy (DIC). Treatment of this condition is challenging and largely aimed at supportive care and correcting other underlying abnormalities. At present, use of antifibrinolytic drugs is not recommended except in cases of intraoperative bleeding or liver transplantation (121).

### Deficient Synthesis of Clotting Factors

The liver parenchyma cells produce most of the factors involved in the coagulation cascade. Individuals with cirrhosis can have progressive decrease in hepatocyte synthetic function. The production of vitamin K-dependent factors II, VII, IX, X, and proteins S and C can be significantly decreased. This results in impaired coagulation of the intrinsic and extrinsic coagulation pathways. The short four to seven hours half-life of factor VII results in early impairment of PT (120).

☞ **Urgent treatment of coagulopathy in the cirrhotic patient consists of administration of fresh frozen plasma (FFP).** ☞ This may need to be administered every 6 to 12 hours because of its short half-life. Additionally, vitamin K should be given to ensure optimization of carboxylation of the vitamin-K dependent clotting factors, although the effect will not be seen for at least six hours (121,125).

## HEPATOCELLULAR CARCINOMA

Hepatocellular carcinoma (HCC) is a malignant tumor derived from hepatocytes. It is most frequently associated with chronic liver disease with cirrhosis (126). ☞ **The occurrence of hepatocellular carcinoma should be considered in patients with longstanding and recently**

**decompensated chronic liver disease.** ☞ The association between hepatitis B and HCC is clearly established, with newer evidence suggesting that the relative risk of HCC is correlated with the serum level of hepatitis B virus DNA (HBV DNA) (127). This is in contrast to hepatitis C whereby HCC occurs almost exclusively in those with cirrhosis (27,128). The combination of HCV and HBV infections increases the relative risk of HCC. HCC is one reason for the interest in the continued improvement of the efficacy and tolerability of medical therapy for chronic viral hepatitis.

### Epidemiology

Primary hepatocellular carcinoma results in between 250,000 and one million deaths globally per year. It is by far the most common primary malignancy of the liver, accounting for over 80% of these tumors. Its incidence varies widely according to geographic location, ethnicity, and sex. High incidence regions include sub-Saharan Africa, China, Hong Kong, and Taiwan. Low incidence areas include North and South America, most of Europe and Australia, but the incidence has been increasing in the United States (129). Men are more likely to develop hepatocellular carcinoma compared with females, with a ratio of 3:1 (126). The majority of cases occur in patients with chronic liver disease and cirrhosis. The mean age at presentation is between 50 and 60 years of age (129).

### Etiology

A variety of risk factors have been identified for the development of hepatocellular carcinoma. Patients with chronic liver disease of any etiology have an increased incidence of hepatocellular carcinoma. Compensated cirrhotics have a 3% to 4% annual incidence of hepatocellular carcinoma (130,131). ☞ **Chronic hepatitis C infection, chronic hepatitis B and the carrier state, aflatoxins, and liver cirrhosis of any etiology are the most frequently reported etiologies of hepatocellular carcinoma.** ☞ Other less common associations that have been reported include AAT deficiency, hemochromatosis, oral contraceptives, and porphyria (126). Cigarette smoking appears to be an additional independent risk factor for hepatocellular carcinoma development. The role of alcohol may only be in the development of cirrhosis and not directly in the pathogenesis of hepatocellular carcinoma (130).

### Clinical Features

☞ **Decompensation of a previously compensated cirrhotic patient is suspicious for malignancy.** ☞ The signs and symptoms of hepatocellular carcinoma are often similar to those caused by chronic liver disease and cirrhosis. General malaise, upper abdominal pain, anorexia, abdominal fullness, weight loss, ascites, nausea, vomiting, jaundice, and wasting may all be presenting symptoms (126). This may represent invasion of the hepatic or portal veins or arteriovenous shunting induced by the tumor (132). Severe abdominal pain with or without hypotension may be indicative of intraperitoneal bleeding secondary to tumor rupture (126). Watery diarrhea has been shown to be significantly more common among cirrhotics with hepatocellular carcinoma than those without (133).

### Diagnosis

Several serum markers have been investigated for use in the diagnosis of hepatocellular carcinoma. Alpha-fetoprotein

(AFP) is a glycoprotein whose serum concentration is often elevated in patients with hepatocellular carcinoma. Levels do not correlate with tumor size, stage, or prognosis. AFP levels greater than 500 g/L (normal, 10–20 g/L) in a high-risk patient is essentially diagnostic of hepatocellular carcinoma (134). Des-gamma-carboxy prothrombin has also been evaluated as a potential marker in the diagnosis of hepatocellular carcinoma. Elevated levels are common in patients with hepatocellular carcinoma, but much less frequently with tumors less than 3 cm in size (135).

Ultrasound, computed tomography (CT), and magnetic resonance imaging (MRI) are all commonly used to help diagnose hepatocellular carcinoma. Ultrasound is noninvasive and can assess for vascular invasion, but cannot distinguish various types of solid tumors (136). Multiple studies have placed its sensitivity from 40% to 75% (137–139). Helical CT scan has greatly improved the sensitivity of this test. Hypervascular tumors as small as 3 mm may be detected with this method. Current sensitivity estimates are as high as 90% (140). MRI has a similar sensitivity as the helical CT scan in detection of hepatocellular carcinoma. Hepatocellular carcinoma has high density on T2-weighted images and low intensity on T1-weighted images (126). MRI is often used in patients with renal insufficiency, contrast allergies, and those with an inconclusive CT scan (141).

An ultrasound or CT-guided biopsy can be performed in patients with a lesion in whom the diagnosis is uncertain. The histology of the tumor can vary from well-differentiated to poorly differentiated lesions with large multinucleate anaplastic giant cells. The risks of biopsy should be considered before the procedure and include bleeding and seeding of the tumor along the needle track (142).

## Treatment

Treatment of hepatocellular carcinoma can include hepatic resection, orthotopic liver transplantation, percutaneous ethanol injection, transarterial chemoembolization, radiofrequency thermal energy, and chemotherapy.

Partial hepatectomy is the mainstay treatment for those patients with preserved hepatic function, no evidence of portal hypertension, and a solitary lesion (143). Unfortunately, most patients do not meet these criteria. Tumors greater than 5 cm in diameter are not resected due to an increased likelihood of distant metastasis. Notably, patients who undergo surgical resection have recurrence rates ranging from 38% to 68% (44). Postoperative systemic chemotherapy evaluated with a meta-analysis has shown no improvement in survival and potentially an increase in mortality in patients with underlying cirrhosis (144).

Orthotopic liver transplantation may be appropriate and effective in certain patients (Volume 2, Chapter 36). Patients had a greater than 90% four-year survival after transplantation if there is a single lesion less than 5 cm in diameter or no more than three lesions that are less than 3 cm in diameter. Liver transplantation cannot be performed if there is evidence of vessel, node, or extrahepatic involvement (145). A primary concern with transplantation in patients with hepatocellular carcinoma is the prolonged waiting period that may result in the progression of the disease and disqualify the patient for transplantation. Percutaneous 95% ethanol injections into lesions are typically reserved for patients with small tumors who are not surgical candidates. This procedure can cause tumor shrinkage, necrosis, and may improve survival (146). The major side

effects are intraperitoneal hemorrhage and hepatic or renal failure, which can occur in less than 5% of individuals (147). Transarterial chemoembolization involves the injection of chemotherapy into the hepatic artery and is often followed by occlusion of the artery. Lipiodol (iodized poppy seed oil) may be included to help tumor retention of the chemotherapy. In patients with large, unresectable lesions, using chemoembolization may reduce tumor size, but it has not been shown to improve survival (148). The use of radiofrequency thermal energy to induce tumor necrosis has received mixed reviews. While achieving similar success rates when compared with percutaneous ethanol injections, side effects are more common and may include death, hemorrhage, and tumor seeding (149). Most studies involving various combinations of systemic chemotherapy have yielded poor results. Agents such as doxorubicin, 5-fluorouracil, and gemcitabine have all been studied and shown minimal response with very short response durations (150–152).

## THE CIRRHOTIC TRAUMA PATIENT

☞ **The cirrhotic patient with the same Injury Severity Score as a noncirrhotic patient has a fourfold increase in mortality and a higher mortality than predicted by scoring systems such as the APACHE II.** ☞ In the individual with cirrhosis who experiences trauma, there is little time for optimization of the hepatic function prior to the performance of potentially life-saving procedures or surgeries. Clinical outcome is correlated with the extent of the operation required to correct the sustained injury, with worse outcomes occurring in cirrhotic patients who have injuries that involve the abdomen. The pretrauma medical condition correlates with clinical outcome. The American College of Surgeons has recommended that prehospital providers transport a cirrhotic patient experiencing a traumatic emergency directly to a major trauma center (3,153).

It is specifically worth noting that hemoperitoneum is a commonly occurring complication of blunt traumatic injury in the cirrhotic patient. ☞ **Acute traumatic hemoperitoneum in a cirrhotic patient is a life-threatening condition and warrants the need for prompt surgical exploration (154).** ☞ Spontaneous hemoperitoneum can occur in 5% of cirrhotics. But hemoperitoneum is much more common after a trauma involving the liver or the often enlarged spleen. Occasionally, hemoperitoneum can develop insidiously without hemodynamic instability. When an adequate history may be unattainable, this insidious development of hemoperitoneum can go unrecognized without a high index of suspicion. Blood may only be a minor peritoneal irritant in this circumstance, resulting in the absence of peritoneal signs. The degree of abdominal pain in an individual with hemoperitoneum is related to the extent and rapidity of blood extravasation.

The diagnosis of hemoperitoneum is confirmed by an abdominal paracentesis revealing hemorrhagic (>50,000 RBC/mL or a hematocrit of  $\geq 0.5\%$ ) ascitic fluid. It has been suggested that a second paracentesis be performed at another site to exclude the possibility of having punctured a dilated vessel during the first procedure. Hemorrhagic ascitic fluid should not be removed even in tense ascites as this may be acting to tamponade active bleeding. An abdominal CT scan is a sensitive and specific ( $\geq 95\%$ ) test to locate the site of bleeding (154). However, clinical

evaluation rather than radiologic findings should determine the need for surgical exploration.

## PREOPERATIVE EVALUATION AND RISK ASSESSMENT

Cirrhotic patients who require surgery are at an increased risk for complications depending on the severity of liver disease and type of surgery and anesthesia required.

A number of preoperative morbidities are associated with increased complications. Cirrhotic patients should be assessed for conditions that can complicate perioperative management. The coexisting diseases that may significantly impact upon clinical outcomes include chronic renal insufficiency, chronic obstructive pulmonary disease, pneumonia, congestive heart failure, ischemic heart disease, insulin-dependent diabetes mellitus, infection, and upper gastrointestinal tract bleeding. One study documented a perioperative complication rate of 30% in individuals with cirrhosis with significant comorbidities (155). However, cirrhosis by itself results in a higher perioperative morbidity.

Additional risk factors for perioperative complications are male gender, high Child–Pugh score, elevated PT, low serum albumin, elevated creatinine, presence of ascites, presence of varices, and an etiology of cirrhosis other than primary biliary cirrhosis. Postoperative complications in the cirrhotic patient, in order of frequency, include pneumonia, ventilatory dependence, infection, worsened ascites, and dysrhythmias.

The type of surgery required by a cirrhotic patient has an important role in determining the degree of postoperative hepatic dysfunction. ⚡ **Several studies have documented an approximately 5 to 20 times higher perioperative mortality risk associated with cirrhotic patients undergoing various surgical procedures (155–159).** ⚡ Procedures associated with more postoperative complications include: (i) emergent surgeries; (ii) laparotomy or other intra-abdominal procedures requiring significant abdominal traction; (iii) procedures associated with significant blood loss, making the risk of hepatic ischemia more likely; (iv) surgery that encounters vascular adhesions from prior procedures which can bleed extensively; (v) extensive cardiac surgery for patients with a Child–Pugh class B or greater.

Risk factors for complications concerning anesthesia management include a high American Society of Anesthesiologists (ASA) physical status classification, emergency surgery, intraoperative hypotension, and general anesthesia (155).

## INTRAOPERATIVE MANAGEMENT CONSIDERATIONS

Hepatic blood flow is altered during anesthesia and surgery. ⚡ **Compromise in hepatic blood flow can result in significant postoperative hepatic insufficiency and a potential increase in mortality in patients with cirrhosis.** ⚡ The liver receives approximately half of its oxygen supply from the hepatic artery and half from the portal vein. During periods of reduced portal inflow, the hepatic artery is able to provide additional oxygenation (“reciprocity of flow”) by vasodilating. Intraoperative changes in blood pressure or cardiac output, as well as surgical manipulation can result in decreased portal inflow. However, the hepatic artery’s ability to vasodilate can be blunted by certain

anesthetics or high anesthetic concentrations (155). One study documented a 16% reduction in hepatic blood flow associated with anesthesia and mechanical ventilation (160). This can be identified by transient elevations of liver associated enzymes. ⚡ **In the cirrhotic patient, the reciprocity of flow between the hepatic artery and portal vein is disturbed, making the cirrhotic liver more prone to ischemia, with potential release of inflammatory mediators, and multiorgan system failure (155).** ⚡ There is no evidence that cirrhosis is a predisposing factor to anesthesia induced hepatotoxicity. However, cirrhotic livers are at greater risk of ischemic injury from low perfusion (hypotension, hypovolemia) states as frequently occur following trauma, some surgical procedures, and critical illness.

## Mechanical Ventilation

⚡ **Cirrhotic patients may have respiratory failure for a number of reasons including atelectasis, pleural effusions, pulmonary hypertension, or HPS.** ⚡ Hypercarbia should be avoided as it decreases portal blood flow by sympathetically stimulating splanchnic circulation—resulting in vasoconstriction (161). One should also exercise caution with the use of positive end expiratory pressure (PEEP) in the patient with cirrhosis because it can potentially decrease hepatic blood flow as a result of impaired venous return. It is theorized that the decrease in hepatic blood flow related to PEEP may be further exacerbated by preportal venoconstriction (160).

## Medications

Patients with liver dysfunction have an unpredictable response to medications. Altered response to medications can be the result of altered pharmacokinetics relating to alterations in drug plasma binding, volume of distribution, liver blood flow, drug metabolism, and degree of liver dysfunction. All medications should be administered with caution in patients with cirrhosis. The effects of specific classes of medications have been studied in patients with cirrhosis. Barbiturates, benzodiazepines, narcotics, propofol, neuromuscular blocking agents, ketamine, dopamine, dobutamine, and sodium nitroprusside will be discussed.

The safety of barbiturates in patients with hepatic dysfunction is well studied. Barbiturate-related rise in cytochrome P450 may result in increased toxic metabolites. Thiopental and methohexital have preserved clearance in cirrhotics, however, dosages should be decreased in cirrhotic patients with low albumin to account for a decrease in volume of distribution and protein binding.

Benzodiazepines can have prolonged effects in patients with liver dysfunction owing to their low hepatic clearance rate. Dosages of benzodiazepines need to be adjusted according to the degree of hepatic compromise. Narcotics may have potentiated effects in cirrhotic patients. Morphine has been reported to have both unaltered as well as reduced clearance in cirrhotics. Although its clearance is dependent on blood flow, extrahepatic conjugation may aid in its elimination. Hypoalbuminemia and hyperbilirubinemia, however, decrease protein binding of morphine, making more free drugs available for neurological side effects. Fentanyl, on the other hand, has the least effect on hepatic hemodynamics, and is thus the narcotic of choice in patients with liver dysfunction (160).

The metabolism of propofol is unchanged in uncomplicated cirrhotics. However, the effect of propofol upon systemic pressure may impact the hepatic blood flow. In

general, propofol has been well tolerated when used on compensated cirrhotic patients (160,162). Neuromuscular blocking agents may have prolonged effects in cirrhotic patients based upon a decrease in excretion and an increase in the volume of distribution. Ketamine does not affect portal or hepatic flow, although it does decrease oxygen transport by increasing oxygen consumption of preportal organs. It is well-tolerated in cirrhotic patients (160).

Dobutamine causes increased total hepatic and portal venous blood flow. However, the improved hepatic oxygen delivery is counteracted by an increase in hepatic oxygen uptake. This results in no improvement in hepatic oxygen supply–uptake ratio. Dopamine and norepinephrine increase hepatic venous oxygen saturation. Sodium nitroprusside does not result in a change in hepatic portal flow despite a significant reduction in blood pressure, as long as the cardiac index is maintained (160). High antidiuretic hormone concentrations are usually seen in patients with decompensated cirrhosis, presumably reflecting vasodilatation and reduced effective intravascular volume. Vasopressin reduces portal blood flow via splanchnic vasoconstriction; however, this medication is not used to control variceal bleeding due to its side effect profile, which includes an increased risk of myocardial infarction and mesenteric ischemia (163).

### Volatile Anesthetics

Volatile anesthetics reduce hepatic blood flow in a dose-dependent fashion via their effect on cardiac output and blood pressure.

Halothane significantly reduces cardiac function and thus results in impaired hepatic circulation. One animal study demonstrated that a 30% reduction in systolic blood pressure resulted in a 50% reduction in hepatic blood flow in addition to an increased oxygen extraction. Additionally fulminant hepatic failure can occur in patients receiving repeated doses of halothane. For equipotent doses, enflurane reduces hepatic blood flow to a lesser degree than halothane. **Isoflurane maintains the reciprocity of liver blood flow and can preserve hepatic perfusion, making it a preferred agent in patients with liver disease.** Nitrous oxide has also been used in patients with liver disease and has not been shown to have to contribute to worsening function (160).

### POSTOPERATIVE MANAGEMENT

The postoperative management of a cirrhotic patient requires an understanding of the altered hepatic physiology, complications that can result from hepatic dysfunction, and the potential impact of coexisting disorders. In patients with cirrhosis, there can be postoperative worsening of ascites or the development of anasarca following the receipt of intraoperative intravenous fluid. The sodium content of all intravenous fluids should be closely monitored. Treatment of an infection or prophylaxis against SBP may be necessary in the postoperative cirrhotic patient. Careful consideration of the sodium content of intravenous fluids used for antibiotic administration is also necessary. Serum creatinine should be monitored to assess for worsening renal function and the potential development of HRS. Coagulopathy and bleeding tendency of the patient with cirrhosis should be considered throughout the perioperative period. It is important to consider the altered pharmacologic effects in the patient with compromised hepatic function.

Significant proportions of individuals with cirrhosis are malnourished. **Malnourishment in patients with chronic liver disease or cirrhosis can be the result of a combination of poor diet, malabsorption, maldigestion, increased catabolism, decreased protein synthesis, or a product of medication side effects (164).** It is no longer recommended that cirrhotic patients be protein restricted; rather an intake of 1 to 1.5 g/kg protein is advised in the nonencephalopathic patient. A minimum of 0.5 to 0.7 g/kg protein is suggested in the encephalopathic patient, with upward titration as tolerated (164,165). In addition, cirrhotic patients typically have an increased caloric need and perioperatively may require significant nutritional support (163). It is recommended that 25 to 40 kcal/kg body weight a day be administered to the critically ill patient, depending upon clinical status. A diet with 2 g of sodium/day is typically recommended in effort to balance a low-sodium diet with the need to offer a diet that is palatable. If adequate intake cannot be achieved orally, perioperative tube-feeding or parenteral feeding should be considered (164). Notably, percutaneous endoscopic gastrostomy tube is contraindicated in patients with ascites.

Nutritional support has been shown to be particularly beneficial in cirrhotic patients undergoing hepatectomy or liver transplantation, and is generally used both pre- and postoperatively. It aims to preserve protein synthesis, prevent hepatocellular dysfunction, and optimize hepatocyte repair and regeneration (164,166). The role of perioperative nutritional support targeted to liver dysfunction is an area of continued research.

### EYE TO THE FUTURE

Liver biopsy is currently the gold standard for diagnosis of cirrhosis, but is inexact and invasive. Less invasive, more rapid, and reproducible diagnostic tools are in development to accurately evaluate the spectrum of hepatic fibrosis and cirrhosis. Transient elastography (FibroScan<sup>®</sup>, Echosens, France) is one example, in which ultrasound is used to measure the velocity of an induced low-amplitude, low-velocity vibratory elastic shear wave transmitted through the liver. The ultrasound follows the propagation of the wave and therein measures the liver's "stiffness." The greater the fibrosis, the stiffer the tissue, and the faster the wave propagates. Although further validation is needed, the device appears to perform well for advanced fibrosis, but is limited by a patient's obesity and ascites (167).

Understanding the fibrogenic process has led to the development of noninvasive tests (e.g., FibroTest–ActiTest<sup>®</sup>, Biopredictive, Paris, France) for the measurement of numerous matrix proteins, enzymes, and cytokines involved in the process. Although we may be nearing a time when serum biomarkers are integral to the assessment of patients with chronic liver disease, the current ability of these assays to differentiate the stages of fibrosis is less than that clinically required (168).

With the significant progress made in recent years in the understanding of fibrosis/cirrhosis, a field dedicated to therapeutic antifibrotics has emerged. The principal event in fibrogenesis appears to be activation of hepatic stellate cells; accordingly, recent efforts have focused on the hepatic stellate cell and its role in matrix deposition and the cascade of events with liver injury. A recent concept is that the fibrosis is dynamic and may be reversible. Although

current therapy focuses on the removal of the underlying disease process (e.g., virus in hepatitis B, obesity in NASH), the future will likely include therapies targeted directly at the fibrotic lesion—likely directed at the stellate cell (169).

Owing to an inadequate supply of donors to meet the growing need, at least one-third of patients are dying while waiting for a liver transplant (170). Moreover, the critically ill patient often has a comorbid relative contraindication for transplantation. For this reason, there continues to be research into liver support systems. These can be categorized into: (i) noncell-based systems, which include plasmapheresis and charcoal-based hemoadsorption and (ii) systems with living hepatocytes, the so-called bioartificial support systems (171). Although these techniques are currently not indicated for routine clinical use, as we improve our understanding of the requirements of a liver support system, these may offer an alternative to acute liver transplantation in the future.

There is a need for improved stratification of surgical risk in patients with cirrhosis (especially in management of blunt abdominal trauma, as well as more routine surgical procedures) (172). In addition, as the frequency of hepatic infarction may be increasing because of more widespread use of laparoscopic surgery, hepatic artery chemoembolization, liver transplantation, and the hypoperfused cirrhotic patient, further research into augmenting hepatic perfusion is indicated. Finally, as we face the pandemic of obesity, we must be prepared for the growing challenges of caring for the morbidly obese cirrhotic patient (173).

## SUMMARY

Cirrhosis represents the irreversible final common pathway of chronic progressive liver disease, and is a costly condition with a high morbidity and mortality. There are numerous etiologies for cirrhosis including infections, metabolic diseases, genetic conditions, drugs, and toxins. The therapy and outcomes vary according to the etiology and comorbidities.

A thorough history and physical examination can be helpful in patients suspected of being cirrhotic. Laboratory evaluation can also be suggestive of cirrhosis, although definitive diagnosis is currently made only by liver biopsy. Newer diagnostic modalities may allow earlier diagnosis.

As the end stage of progressive hepatic fibrosis, the complications of cirrhosis can include ascites, SBP, hepatic encephalopathy, HRS, HPS, varices, poor hemostasis, and hemorrhage. Individuals with cirrhosis are also at an increased risk for hepatocellular carcinoma.

The individual with cirrhosis who experiences trauma has a higher perioperative morbidity and mortality risk than noncirrhotic individuals. There is seldom time for optimization of the hepatic function prior to the performance of potentially life-saving procedures or surgeries in the cirrhotic trauma patient. Yet these patients have additional considerations beyond the normal trauma patient. Particular focus is given to: (i) repletion of coagulation factors with FFP, and platelet transfusions to correct thrombocytopenia; (ii) close intraoperative monitoring of follow-up coagulation studies; (iii) alterations in hemodynamic response due to the baseline peripheral vasodilation and impaired ability to compensate for hemorrhage and third spacing; (iv) understanding of splanchnic hypoperfusion and the particular vulnerability of the cirrhotic patient, emphasizing the need for vigorous fluid repletion and invasive monitoring; (v) and baseline metabolic alterations imposed by liver

dysfunction (e.g., hyponatremia, hypoalbuminemia, and impaired lactate clearance ability) all serve to exacerbate the severity of trauma shock in these patients.

The response to medications can be the result of altered pharmacokinetics relating to alterations in drug plasma binding, volume of distribution, liver blood flow, drug metabolism, and degree of liver dysfunction. Various factors, including the Child–Pugh score, can be helpful in predicting clinical outcomes for the individual with cirrhosis. It is critical that the management of the cirrhotic patient be adjusted to encompass the altered hepatic physiology.

## KEY POINTS

- ✎ The fibrotic tissue in cirrhosis consists of extracellular matrix molecules, collagen types I and III, sulfated proteoglycans, and glycoproteins.
- ✎ The development of cirrhosis is most often silent until complications of significant hepatic dysfunction occurs.
- ✎ The mainstays of ascites management consist of dietary sodium restriction and diuretics.
- ✎ SBP is an infection of ascitic fluid without a recognizable secondary cause of bacterial peritonitis. About 10% to 25% of patients with cirrhosis and ascites admitted to the hospital will have SBP.
- ✎ The severe splanchnic vasodilatation with a reduced effective arterial blood volume seen in end-stage cirrhosis can result in extreme renal artery vasoconstriction and renal failure.
- ✎ Hepatopulmonary syndrome (HPS) is a condition that consists of a triad of (i) liver dysfunction, (ii) hypoxemia with an increased alveolar-arterial (A-a) gradient, and (iii) intrapulmonary vascular dilatation.
- ✎ The severity of the hyponatremia is proportional to the degree of cirrhosis and is of prognostic value.
- ✎ Although the precise mechanisms of hepatic encephalopathy are unknown, there are several theories regarding the pathogenesis. Ammonia, metabolic changes, cerebral edema, impaired perfusion, and changes in neurotransmitter systems may all be involved.
- ✎ Variceal hemorrhage occurs in approximately one-third of patients with cirrhosis. Thirty to fifty percent of these bleeds are fatal.
- ✎ The formation of varices occurs when the portal vein to hepatic vein pressure gradient exceeds 12 mmHg.
- ✎ Endoscopic therapy is the preferred treatment for active variceal hemorrhage. Sclerotherapy or band ligation can result in a cessation of bleeding in 80% to 90% of patients. This is an important change to make because band ligation is actually preferred over sclerotherapy because of band ligations fewer complications. Sclerotherapy is rarely done in this country any more. (Fig. 4C)
- ✎ TIPS creates a low-resistance pathway between the hepatic and portal veins by angiographic insertion of a metal stent in liver parenchyma (Fig. 4E).
- ✎ The severity of cirrhosis is directly related to the extent of thrombocytopenia and platelet dysfunction.
- ✎ Urgent treatment of coagulopathy in the cirrhotic patient consists of administration of fresh frozen plasma (FFP).
- ✎ The occurrence of hepatocellular carcinoma should be considered in patients with longstanding and recently decompensated chronic liver disease.

- 9 Chronic hepatitis C infection, chronic hepatitis B and the hepatitis B carrier state, aflatoxins, and liver cirrhosis of any etiology are the most frequently reported etiologies of hepatocellular carcinoma.
- 9 Decompensation of a previously compensated cirrhotic patient is suspicious for malignancy.
- 9 The cirrhotic patient with the same Injury Severity Score as a noncirrhotic patient has a fourfold increase in mortality and a higher mortality than predicted by scoring systems such as the APACHE II.
- 9 Acute traumatic hemoperitoneum in a cirrhotic patient is a life-threatening condition and warrants the need for prompt surgical exploration.
- 9 Several studies have documented an approximately 5 to 20 times higher perioperative mortality risk associated with cirrhotic patients undergoing various surgical procedures.
- 9 Compromise in hepatic blood flow can result in significant postoperative hepatic insufficiency and a potential increase in mortality in patients with cirrhosis.
- 9 In the cirrhotic patient, the reciprocity of flow between the hepatic artery and portal vein is disturbed, making the cirrhotic liver more prone to ischemia, with potential release of inflammatory mediators, and multiorgan system failure.
- 9 Cirrhotic patients may have respiratory failure for a number of reasons including atelectasis, pleural effusions, pulmonary hypertension, or HPS.
- 9 Isoflurane maintains the reciprocity of liver blood flow and can preserve hepatic perfusion, making it a preferred agent in patients with liver disease.
- 9 Malnourishment in patients with chronic liver disease or cirrhosis can be the result of a combination of poor diet, malabsorption, maldigestion, increased catabolism, decreased protein synthesis, or a product of medication side effects.

### INTRODUCTION

Blood purification techniques have been used to supplement the treatment of hepatic failure for 50 years. However, a suitable complete liver replacement device remains elusive. This is mainly due to the complex anatomy, physiology, and biometabolic properties of the liver. The devices that have been employed are capable of providing certain functions but not all. Investigators and clinicians are still struggling to provide a system that supplies the full gamut of liver functions required to keep a patient with liver failure alive (1).

Liver Support Devices must not only remove toxic metabolites (e.g., ammonia, lactate, and toxins), but also provide metabolic functions (e.g., carbohydrate metabolism), immunologic support (e.g., production of complement, and serve as a filter system with its kupffer cells, etc.), a synthetic system for carrier proteins, albumin, and coagulation factors, finally the biliary functions of the liver need to be replicated as well (2).

Extracorporeal liver support systems usually process the blood of the patient using artificial filters and sieves, but to provide full replacement function will need to perform all activities of a hepatocyte. If the system does not contain active cells, it is classified as a nonbiological device; however, if the system contains active cells or tissue that provide some metabolic functions, they are classified as biological devices. In vivo hepatocyte transplantation can be considered as another method to support a failing liver, although they are not considered "classical" liver support systems (3).

This chapter reviews, briefly, the anatomy and physiology of the liver, the definition of liver failure, and the conventional support therapies as a refresher for the novice. Next, the early approaches to blood purification are reviewed, and a survey of current therapies is provided. The basic concepts of various techniques being studied to form a bioartificial liver are provided along with the current hurdles and successes. Finally, the reader is provided a glimpse into current research techniques in the "Eye to the Future" section.

### REVIEW OF LIVER ANATOMY AND PHYSIOLOGY

#### Organ and Segmental Anatomy

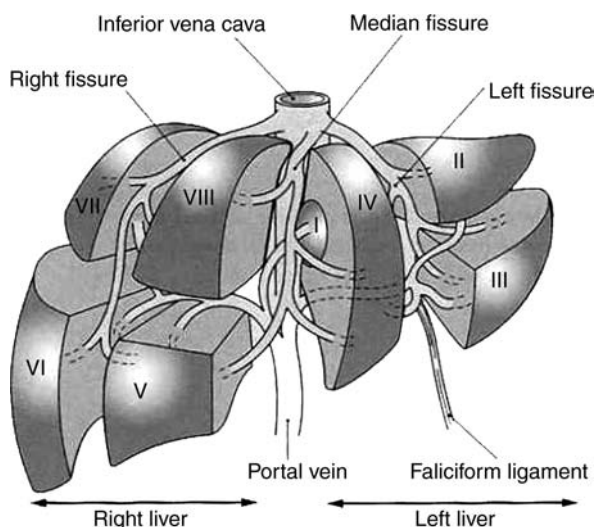

The liver is the largest solid organ in the body. It weighs 1600 g in men and around 1400 g in women. The liver receives blood through the portal vein (75%) and the hepatic artery (25%). It drains bile through the biliary system into the duodenum. The liver has eight functional segments based on its vascular distribution (Fig. 1). Venous drainage is through the hepatic veins into the inferior vena cava. The caudate lobe of the liver has its own vascular supply and drainage. The liver has a complicated structure, which allows both hepatic and portal blood to reach the hepatocytes.

The functional unit of the liver is the hepatic lobule (Fig. 2) in which the central venule is in the center of the lobule and the portal tracts are in the corners. Accordingly, hepatocytes are described to be centrilobular around the central vein (zone 3), or perilobular around the portal tracts (zone 1) (4).

#### Hepatocytes

The liver cell (hepatocyte) occupies 80% to 90% of the total liver volume in humans. Cells are arranged in plates with their sinusoidal (basolateral) surface projecting into the presinusoidal Space of Disse in direct contact with plasma, and the lateral wall opens in an intercellular canalicular space formed with the adjacent cells. Other cells in the liver include nonparenchymal cells, which account for 20% to 30% of the total number of liver cells (5).

Hepatocytes residing in zone 1 of the liver have large mitochondria, as this is the dominant region for gluconeogenesis, beta-oxidation of fatty acids, amino acid catabolism, urea and cholesterol syntheses, and bile excretion. Whereas hepatocytes residing in zone 3 have more endoplasmic reticulum and large nuclei, it is the dominant region for glycolysis, lipogenesis, biotransformation of drugs, detoxification, and clearance of ammonia.

**Figure 1** Functional segments of the liver. The eight hepatic functional segments are based on vascular distribution. *Source:* From Ref. 4.

#### ☞ Certain hepatic injuries affect specific zones. ☞

Acetaminophen toxicity predominantly induces zone 3 necrosis. Iron deposition diseases such as hemochromatosis are predominately manifested in zone 1. Viral hepatitis tends to present with spotty necrosis in all zones. Hypotension and systemic hypoperfusion classically produce zone 3 necrosis, while in disseminated intravascular coagulation (DIC, Volume 2, Chapter 58), fibrin deposition occurs in the sinusoids of zone 1 hepatocytes, causing ischemic injury to these cells.

#### Nonparenchymal Cells

Other nonparenchymal cells residing within the liver include the endothelial cells, kupffer cells, stellate cells (fat-storing cells or Ito cells), and liver-associated lymphocytes (Pit cells). These cells are all directly in contact with blood in the

**Figure 2** Hepatic lobule. The central venule is the core of the hepatic lobule, portal tracts comprise the corners. *Source:* O'Grady JG, Lake JR, Howdle PD. *Comprehensive Clinical Hepatology* 2000; Chapter 1, p 1.7.

sinusoids. Endothelial cells line the sinusoids forming a barrier between the blood and the hepatocytes. Only plasma proteins leak through the fenestrae of the endothelial cells and get in contact with parenchymal cells in the Space of Disse. Endothelial cells have endocytotic activities and can secrete a wide variety of proteins, including interleukins, interferons, TNF- $\alpha$ , and others. Some of these cytokines play a role in the defense mechanism of the liver.

Kupffer cells are the macrophages of the liver. Kupffer cells are attached to the endothelial cells by long cytoplasmic processes. They spread along the sinusoids. They remove particles, toxins, foreign substances, immune complexes, and endotoxins from the blood. They produce vasoactive mediators, and are the main defensive cells of the liver.

Stellate cells (fat-storing cells), are located in the Space of Disse in contact with the parenchymal cells, contain vitamin A rich lipids, and are considered fibroblasts. In liver disease, the cells start proliferating actively, lose their lipid droplets and acquire the morphology of myofibroblast, synthesize and secrete extracellular matrix proteins, which play a major role in liver fibrosis (6).

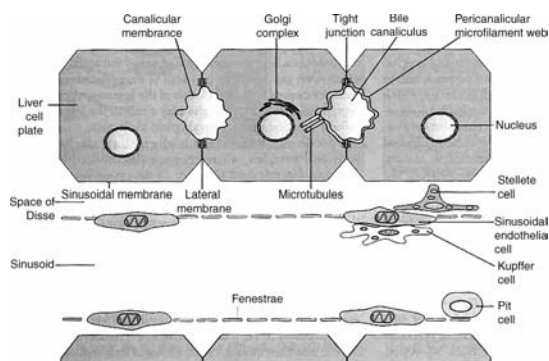

Liver-associated lymphocytes (Pit cells) are recruited from the blood to the sinusoids to be activated into natural killer cells. These "Pit cells" reside within the sinusoids, and possess strong cytotoxic and antiviral activities, and support differentiation of liver cells (Fig. 3) (7).

#### Functions of the Liver

☞ The liver is a complex metabolic factory (biochemical reactor) and performs a number of other functions including protein synthesis, immuno protection, and bile formation-related tasks. ☞ The functions of the liver originate from the functions of its cells. It includes regulation of solutes in blood that affect the performance of other systems of the human body; neurological (brain, nerves), cardiovascular (heart, vessels), musculoskeletal (muscles, bones), and excretory systems (biliary, kidneys). The functions involve uptake, metabolism, biotransformation, storage, synthesis, and secretion, in addition to its role in support of the immune system.

#### Metabolic Functions

The liver is essential for the metabolism of lipids, carbohydrates, and proteins. It plays a major role in biotransformation of drugs, which subsequently are excreted in the urine or bile. Its role in ammonia metabolism is central. Ammonia

**Figure 3** Pit cells. Liver-associated lymphocytes ("pit cells") reside within the hepatic sinusoids serving immunoprotective functions, and also serving to support hepatic cellular differentiation. *Source:* O'Grady JG, Lake JR, Howdle PD. *Comprehensive Clinical Hepatology* 2000; Chapter 3, p 3.1.

and nitrogenous compounds are removed from the circulation and metabolized into urea via the Krebs cycle in the periportal hepatocytes or glutamine in the perivenular hepatocytes.

### Synthetic Functions

The liver synthesizes albumin (12 g/day), which is critical in the maintenance of plasma, oncotic pressure, and is a binder and transporter of many drugs and hormones. Other important synthetic products of the liver include the coagulation factors, antithrombin III, and protein C and S, which maintains the normal balance between blood coagulation and fibrinolysis without the deleterious occurrence of spontaneous thrombosis.

### Immunologic Functions

The liver is exposed to influxes of nutrients, particulates, bacteria, viruses, parasites, endotoxins, and others. Both Kupffer cells and pit cells constitute the main defense line of the liver against infection. In their role to defend the host, these cells become activated by different stimuli and induce their effects through the production of cytokines, eicosanoids, reactive oxygen intermediaries, extracellular matrix component, nitric oxide among others (8).

### Role of Bile Formation

The liver forms bile (500 mL/day), which is composed of water, inorganic electrolytes, proteins, amino acids, lipids, steroids, vitamins, heavy metals, drugs, and toxins. Bile secretion is a complex metabolic process, which is essential for eliminating toxic lipophilic compounds, the excretion of cholesterol, and also facilitates the digestion and absorption of fats and fat-soluble vitamins in the intestine (9).

## LIVER FAILURE: DEFINITION AND CONVENTIONAL THERAPIES

Liver failure is a process in which the different functions of the liver fall below the level required to maintain body homeostasis. It is termed acute if it occurs within days to weeks (<24 weeks) in a previously normal liver and is termed acute-on-chronic if it occurs in a patient with pre-existing chronic liver disease. Liver failure presents clinically as hepatic encephalopathy, hemodynamic instability, electrolyte and renal dysfunction (hepato-renal syndrome), severe coagulopathy, bleeding, and frequently results in sepsis and death from brain edema or multi-organ dysfunction syndrome (MODS).

Liver failure can result from numerous etiologies.

☞ **The most common cause of acute liver failure is drug-related hepatotoxicity, which comprises more than 50% of acute cases.** ☞ Acute liver failure occurs in approximately 2000 cases per year in the United States (10). However, death from chronic liver disease is estimated to occur in over 30,000 patients per year. The majority of these cases are due to acute events resulting in decompensation of the liver function in patients with pre-existing chronic liver disease and cirrhosis. In these situations, correcting the precipitating events responsible for the acute decompensation is the mainstay of therapy to give the liver an opportunity to regain its functions (11).

There are few toxin-specific treatment options for particular etiologies of liver failure. These options offer improvement in the liver's detoxification abilities, such as *N*-acetylcysteine in patients with acetaminophen toxicity and silymarin for patients with mushroom poison-

ing. Unfortunately, complications arising from the acute insult to liver functions compromise liver regeneration and recovery and result in patient death, unless the liver functions are replaced by performing a liver transplant.

Liver transplantation survival has improved, and remains the gold standard for treating patients with liver failure. However, liver grafts are not readily available. Waiting for a liver transplant can extend over a period of days to weeks. During that time, most patients die from complications of liver failure, or become inappropriate candidates for liver transplantation. Therefore, the goal of managing patients with liver failure is to keep them in a stable condition that could support liver regeneration and recovery, or maintain their transplant candidacy until a liver graft becomes available (12).

Coagulopathy and bleeding resulting from liver failure are controlled by plasma and platelet transfusions and replacement of deficient clotting factors, such as recombinant factor VII. Endoscopy and sclerotherapy or band ligation of varices and transjugular intrahepatic portosystemic shunt (TIPS) control variceal bleeding. Antibiotics and antifungals help in reducing the risk of systemic infection and sepsis. Renal therapies and ventilatory support help to regulate electrolyte and pH disturbances. However, accumulation of toxins resulting from the necrosis of hepatic cells and failure of the detoxification powers of the liver exacerbate and prolong the syndrome of liver failure. Approaches directed toward detoxification of the blood are the main goal of liver support systems.

☞ **Liver failure is associated with a significant compromise of metabolic regulation, protein synthesis, detoxification, and immunological defense mechanisms executed by the liver.** ☞ The clinically predominant consequences of lacking metabolic regulation are hypoglycemia and lactic acidosis. Predominant consequences of lacking protein synthesis are coagulopathy, hypoalbuminemia, and complement factor deficiencies. Insufficient detoxification results in the endogenous accumulation of toxic molecules, producing hepatic coma, hemodynamic instability, renal failure, blood cell and bone marrow toxicity, suppression of regeneration, and progression of hepatocyte apoptosis and necrosis. The immunological disturbances associated with liver failure include reduced clearance of microorganisms and their fragments and the subsequent increased exposure of the systemic circulation to infection and bacterial toxins emanating from the splanchnic bed and the portal venous drainage (11).

## EARLY APPROACHES TO BLOOD PURIFICATION Exchange Transfusions

In 1957, Lee and Tink treated a 13-year-old child with hepatic coma with a whole blood exchange transfusion. After two exchange transfusions with an exchange volume of 3 L each, the patient recovered from hepatic coma (13). Nine years later, in 1966, Trey et al. (14) reported 11 exchanges in patients with hepatic coma with seven survivors. Since then, this technique has been used widely. The advantages are toxin removal from the circulation and substitution by fresh blood and plasma components including coagulation factors. The best results were seen if direct transfusion from a donor to a recipient was performed. However, this is not a practical solution as several donors with the same blood group would be needed for every treatment. Thus citrated or heparinized blood has to be used which results in acidosis, hyperkalemia, high citrate levels, and

hyperammonemia in patients with failing livers. The initial optimism concerning the effect on survival in liver failure was replaced by more realistic estimates as the results of larger patient data sets became available, indicating a survival rate below 25% (15,16). Thus no significant increase of survival could be demonstrated using exchange transfusion, and the main cause of death often reported was brain edema (17).

### Therapeutic Plasma Exchange

In therapeutic plasma exchange (TPE), the blood of the patient is either centrifuged or filtered to separate the blood cells from the plasma. The patient's plasma is then replaced by fresh frozen plasma (FFP) of healthy donors and then both the blood cells and the plasma are transfused back to the patient. The goal is to remove toxic plasma compounds and supply plasma factors. An advantage over exchange transfusion is that FFP is easier to obtain and handle than whole blood. It can be performed daily and for a longer period of time. Moreover, larger plasma volumes can be exchanged (up to 2 L/hr) (18). Since the first report of successful use of TPE in hepatic coma by Cree and Berger in 1968, total survival rates differed extensively between the many groups that performed TPE studies (19). Buckner et al. reported in a study of TPE for acute liver failure, survival of 41 patients out of 138 patients (29.7%). Decisive for the poor outcome was the high complication rate of bacterial infections, lung edema and hemorrhage, and acute respiratory distress syndrome (ARDS) (18). One of the concerns of TPE is the removal of growth factors (HGF, IGF, EGF, TGF) produced by the injured liver and other tissues such as the pancreas, intestinal tract, and platelets during the process of plasma exchange (20,21). Yamazaki et al. reported survival rates of 34% in patients with FHF, who were treated with repeated 5 L plasma exchange compared with 14% survival in control patients (22). However, his study was not randomized and not controlled with respect to etiology and severity of FHF.

### High-Volume Plasmapheresis

High-volume plasmapheresis involves exchange of large plasma volumes of (9.9 L per treatment) to remove toxins distributed throughout the body and not only in the plasma pool. Investigators have reported successfully bridging patients to transplantation using this approach (23).

### Total Body Washout

The total body washout method was first attempted by Klebanoff et al. (24) in 1972 for a case with hepatic coma. The patient's blood was totally washed out of the body and continuously replaced by Ringer's lactate solution over 40 minutes while the core temperature was maintained around 21°C. The system was driven by a heart-lung machine with a flow rate of 2200 to 2300 mL/min. Then the circulation was filled with whole blood again. The patient regained consciousness and abnormal serum parameters returned to normal. Liver biopsy taken days after the treatment showed marked histological improvement. However, days later the patient died from respiratory failure and gram-negative sepsis.

In another trial the same group added albumin to the substitution fluid and reported better survival. Nine patients survived out of 13 treated for hepatic coma (25). Tobias and Isom (26) confirmed the success of total body washout in the treatment of hepatic coma secondary to fulminant viral

hepatitis (2 long-term survivors out of 3 treated). However, this approach had not been pursued any further.

### Hemoperfusion over Activated Charcoal and/or Resins

♂ Hemoperfusion using activated charcoal was shown to have beneficial effects in patients with severe poisoning (8). ♂ Chang (27) in 1972, reported the first clinical use of this technique in hepatic coma. In 1974, Gazzard et al. (28) treated 31 patients with grade III hepatic coma due to paracetamol-induced hepatic failure with coated charcoal columns. He achieved long-term survival in 11 patients. Using hemoperfusion over activated charcoal the outcome seems to be greatly influenced by the etiology of hepatic failure. The best survival was reported in patients with fulminant hepatic failure from acute hepatitis A infection (67%), followed by acetaminophen toxicity (53%), and was the lowest in acute hepatitis B infection (20%), and halothane and other drug induced acute liver failure (12%) (29).

Ion exchange resins can attract protein bound substances and, therefore, are of interest in the treatment of hepatic failure (30,31). Its clinical use was hampered by bioincompatibility which could only be avoided by isolated plasma (plasmapheresis) over the resins following plasma separation (32). However, the main disadvantages of hemoperfusion are the lack of selectivity with the adsorption of hormones, vitamins, immunoglobulins, drugs, and other important plasma components to the resins. It can also cause activation of the complement cascade, thrombocytopenia, and leukocyte margination. The approach of coating the charcoal particles could mitigate hemocompatibility.

### High-Flux Dialysis

Hemodialysis had been used in treatment of hepatic failure, but was abandoned because of failure to improve survival (33). The introduction of large-pore dialysis membranes improved the results of hemodialysis in hepatic failure patients. Opolon et al. treated 39 patients with FHF and coma with 164 hemodialysis sessions using the high-flux membrane AN69 (polyacrylonitrile) and a closed loop dialysate circuit containing sterile acetate buffered dialysate. Recovery of consciousness was reported in 18% of the patients dialyzed versus 0% in the comparable group that was not dialyzed. Total survival was 23% in the dialysis group versus 18% in the undialyzed group. Silk and Williams (34) had long-term survival of 31% in 65 patients with hepatic failure treated with the same method. The initial rationale for the use of polyacrylonitrile membranes was the removal of middle molecular weight molecules up to 5000 Da. Indeed some of the "middle molecules" and substances known to accumulate in liver failure like ammonia and phenol-acids are partially removable by high-flux dialysis. Although this technique might improve hepatic encephalopathy, it does not promote liver regeneration or survival (35). High-flux dialysis cannot remove hydrophobic and/or protein-bound substances like short- and middle-chain fatty acids, mercaptans, or bilirubin.

### Hemofiltration

Long-term hemofiltration was used in the treatment of fulminant hepatic failure. Opolon (36) reported hemofiltration in 10 patients with hepatic failure. The mean duration of treatment was 92 hours with a total hemofiltrate of 248 L. Five patients survived. In a further study, which included the following nine patients, he reported 10% survival in patients over 30 years of age, whereas with

patients under 30 years of age, their survival was 25% with conventional intensive care, 35% with high-flux dialysis, and 57% with long-term hemofiltration.

## CURRENT THERAPIES

### Hemodiadsorption

☞ Hemodiadsorption is “a process during which blood passes through dialysis membrane packages surrounded by a suspension of fine sorbent particle” (37). ☞ Hemodiadsorption combines sieving (dialysis) and adsorption to remove toxins normally metabolized by the liver. Ash et al. (38) used a sorbent suspension dialysis system where a cellulosic flat membrane dialyzer is perfused by the patient’s blood on one side and by a dialysate containing a mixture of charcoal and anion-exchange resin particles on the other. Employing a clamp mechanism, the entire system is driven by pumps on the dialysate side only, thus diminishing mechanical stress on the blood cells. The system has been available for several years in the United States and is FDA approved. Pilot trials showed its efficacy in improving hepatic encephalopathy in a subgroup of patients with liver failure. In a study of 15 patients with liver failure and hepatic encephalopathy grade III/IV, five patients survived; one of them had a liver transplant following treatment with the device. Improvement of neurological status occurred in 13 of the patients. In a randomized controlled trial of 10 patients with FHF and hepatic coma, only one patient survived in the device group versus three in the control group (39). Konstantin et al. (40) used hydrophobic polysulfone hollow-fiber membranes that were filled with paraffin oil. Blood was passed through the hollow fiber. An alkaline acceptor solution (NaOH) was recirculated along the dialysate side of the membranes. Although removal of otherwise non-dialyzable toxins (e.g., mercaptans) could be demonstrated in vivo, no improvement in survival was shown (41).

### Extracorporeal Albumin Dialysis

☞ A number of extracorporeal albumin dialysis (ECAD) devices have been introduced in the last decade, and preliminary data demonstrate that these can be used as support systems for the failing liver or as a bridge to transplantation in selected patients. ☞ The various ECAD devices do clean the blood from different toxins. These devices do not provide the metabolic functions of the liver, but do provide detoxification of the blood. The two commercially available devices with the greatest degree of research data are presented subsequently.

### Molecular Adsorbent Recirculating System

Molecular adsorbent recirculating system (MARS) is another modification of hemodiadsorption which uses a new type of highly permeable hollow-fiber dialyzer. The MARS dialyzers are capable of loosening the albumin-toxin binding by physiochemical interaction. It also provides a closed-loop dialysate circuit containing standard dialysate with 15% to 20% human serum albumin, which acts as a molecular adsorbent. The on-line purified dialysate albumin accepts albumin-bound toxins (ABTs) from the blood side (e.g., free fatty acids, aromatic amino acids, bile acids, and bilirubin). It is then perfused over a charcoal and a resin column to remove albumin bound toxins from the albumin and dialyzed through a regular dialysis membrane to remove

water-soluble toxins (urea, ammonia) (42). The MARS system is available in Europe and Asia, and was recently approved by the FDA for use in drug poisoning. The concept of extracorporeal albumin dialysis using the MARS device is currently in a multi-center trial in the United States for hepatic encephalopathy and its role on survival is being investigated in Europe in patients with fulminant hepatic failure and in patients with acute liver decompensation complicating end-stage liver disease (Fig. 4)

### Fractional Plasma Separation and Adsorption

☞ Fractional plasma separation and adsorption (FPSA) is a form of albumin dialysis in which a filter with a cutoff of 250,000 Dalton (250KD) is used. ☞ This technique was first introduced by Falkenhagen et al. in 1999 (43). Albumin and protein bound toxins pass through the membrane from the blood side into a secondary circuit. The filtered albumin-rich plasma flows through two adsorbers in a row where toxins are directly adsorbed. The purified plasma then returns to the blood side of the albumin filter, back to the patient via a conventional high-flux dialyzer to eliminate water-soluble toxins. A commercial version of this device is called “Prometheus®.” A recent study by Rifai et al. (44) showed that Prometheus® is a safe supportive therapy for patients with liver failure. Randomized controlled trial using the Prometheus® device is underway.

### Biological Liver Support Systems

In parallel to the developments of devices, biological liver support systems have been in development and testing. Biologicals combine synthetic components (an apparatus, a polymer membrane, etc.) with biologically active cells, tissue slices or liver lobules in a bioreactor aiming to provide most functions of the liver if possible. However, until today, the ideal biological liver replacement is a human liver transplant. But, as transplants are not readily available, extracorporeal liver support systems could provide enough liver function to keep the patients alive until recovery of their liver injury or until they get a liver transplant. This concept started as early as the 1960s when Burnell et al. performed the homologous blood cross circulation between a liver failure patient and a healthy “donor” with identical blood group, thus providing metabolic support for the patient given by a healthy individual with a healthy liver (45,46). Because that concept did not improve the survival rates but was accompanied with

**Figure 4** MARS device. The molecular adsorbent recirculating system (MARS) is a form of extracorporeal albumin dialysis, which can serve as a temporary bridge to transplantation. *Source:* From Ref. 139.

**Figure 5** Bioartificial liver devices currently available. Cellular based extracorporeal devices perfuse the patient's blood through bioreactors containing hepatocytes, such as immortalized human cell lines that have been transplanted directly or implanted on scaffolds. Transgenic animals have also been raised to harvest humanized livers. *Source:* Allen JW, Hassanein T, Bhatia SN. *Advances in bioartificial liver devices.* *Hepatology* 2001; 34(3):447–455.

immunological complications and hazards for the healthy “donor,” it was abandoned (47,48). To eliminate the disadvantage of risks for a healthy human donor several efforts were made to replace that donor by baboons (49–51). In that concept, a total blood exchange in the animals was performed against human blood in the hope to subsequently prevent immunological risks for the patient (48). However, because of the difficulty of the method and ethical aspects regarding the use of primates on the one hand and poor survival rates on the other, that concept was also abandoned.

The first generation of the bioartificial liver, as we know it today, is the extracorporeal isolated liver perfusion, which has been performed with pig and bovine livers with poor results (52,53). However, when primate livers were perfused, better survival rates were achieved (47,54,55). In the last decade, highly sophisticated bioreactors have been developed, which are populated by different cell lines. A discussion of these systems and its components will follow.

## BIOARTIFICIAL LIVERS

Just as with dialytic therapies for renal failure, techniques for supporting liver failure are continuing to undergo evolution with ongoing research and development. Renal failure patients can have their blood cleansed three times a week, and receive supplemental medications to help deal with some of the problems that are not directly addressed by dialysis (e.g., erythropoietin administration to assist with anemia). Similar efforts are likely to occur with liver failure (i.e., we may be able to supplement clotting factors, albumin, etc.—but this is expensive). This section reviews the currently available techniques.

## Basic Concepts of Currently Available Techniques

☞ The most common cell-based liver support designs incorporate hepatocytes in hollow fiber cartridges borrowed from hemodialysis (1). ☞ Hollow fiber membranes provide a scaffold for cell attachment, immunoisolation, and are well characterized in a clinical setting but may not provide adequate nutrient transport or the proper environmental cues for long-term hepatocyte stabilization. In attempts to improve the hepatocyte microenvironment, investigators have used microcarriers (56), gel entrapment both intralumenally (57) and in the extracapillary space (58), multi-compartment interwoven fibers (59), and multi-coaxial configurations (60).

## Cellular Components

The full complement of cellular functions required in bioartificial liver devices to affect positive clinical outcomes has not been determined. To address this problem, “surrogate” markers of each class of liver-specific functions typically are characterized, including: synthetic, metabolic, detoxification (phase I and II pathways), and biliary excretion. The implicit assumption is that hepatocytes capable of a wide array of known functions will also express those unmeasured (or unknown) functions that are central to their metabolic role. Table 1 describes cell types that have been used and are currently being evaluated for use in cell-based systems. Each of these—primary hepatocytes, cell lines, and stem cells—should be evaluated on the basis of availability, potential adverse interactions, and efficacy in providing liver-specific function.

Primary porcine hepatocytes are most commonly used in devices undergoing preclinical and clinical evaluation. Studies have also been conducted with cells isolated from rabbit (61), canine (62), and rodent species (63). In general, primary hepatocytes are well known to require specific microenvironmental cues to maintain the hepatic phenotype *in vitro*, and it is likely that a more detailed investigation of culture conditions will improve the stability of porcine hepatocytes *in vitro* as has been the case for rodent hepatocytes.

Primary human cells would be ideal, but like whole organs, they are in limited supply. They have been used for bioartificial liver application (Gerlach, personal communication), as well as for hepatocyte transplantation (64). A persistent paradox of human hepatocytes is their facile proliferation *in vivo* but static nature in culture, despite significant progress in stimulating DNA synthesis of rodent hepatocytes in culture (65–67). Recent reports regarding underlying differences in telomerase expression in humans and rodents may play a role in this phenomenon (68).

The growth limitations of primary cells has spurred attempts to develop cell lines that can proliferate in culture while maintaining liver-specific functions. Many cell lines have been established by retroviral transduction or lipofection of the simian virus 40 tumor antigen gene (SV40Tag) whose gene product binds to cell cycle regulator proteins Rb and p53. Spontaneous immortalization has been documented as a result of collagen gel sandwich cultures or co-cultures (69). Cell lines derived from hepatic tumors, such as C3A (a subclone of Hep G2), have already been used in clinical trials (70). The risk of transmitting oncogenic substances or cells into the patient's circulation remains a concern. Efforts to improve the control and safety of cell-based therapies with immortalized cells has resulted in the use of temperature-sensitive SV40Tag (71),

**Table 1** Cell Sources for Liver Therapies

Cell source	Critical issues
Primary Human, xenogenic	Sourcing, expansion, safety (PERV), phenotypic stability, immunogenicity
Immortalized SV40, telomerase, tumor-derived, spontaneously immortalized	Safety (suicide genes, tumorigenicity) function, efficacy
Stem cells liver progenitor, embryonic, transdifferentiation (HSC, pancreas)	Sourcing (cadaveric), differentiation, screening, phenotypic stability, safety (tumorigenicity), immunogenicity

*Abbreviations:* HSC, hematopoietic stem cells; PERV, porcine endogenous retrovirus; SV40, simian virus 40.

Cre-loxP-mediated oncogene excision (72), and integration of suicide genes such as HSV-tk. (73). In the case of tumor-derived cell lines, filters preventing transmission have been implemented in the bioartificial liver design as an extra precaution. Finally, stem cells are being considered for therapy of liver disease. Potential sources include embryonic stem cells, adult liver progenitors, and transdifferentiated nonhepatic cells (58,74–82).

### Stabilization of Primary Hepatocytes

✎ Although primary hepatocytes represent the most direct approach to replacing liver function in hepatic failure, they are anchorage-dependent cells and notoriously difficult to maintain *in vitro*. ✎

When enzymatically isolated from the liver and cultured in monolayer or suspension cultures, they rapidly lose adult liver morphology and differentiated functions. Typical approaches to stabilizing liver-specific functions involve manipulation of the extracellular matrix environment, media composition, or promotion of cell–cell interaction (both homotypic and heterotypic). Extracellular matrix (ECM) modulation has included both variations in composition and topology (83–90). Sandwich culture (87) was designed to mimic the microenvironment of the adult hepatocyte where cells are sandwiched by extracellular matrix in the Space of Disse. Cells in the configuration stably express many liver-specific functions; however, attempts to scale-up this culture method have been met with limited success thus far.

Modifications such as hormonally defined media (80,91) and addition of low concentrations of dimethyl sulfoxide (92) or dexamethasone (93) are known to help stabilize hepatocyte morphology, survival, and liver-specific functions. However, these approaches are inapplicable to bioartificial liver designs because of systemic exposure of patients to these specialized and nonphysiological media components.

Finally, liver-specific functions are stabilized in hepatocytes that are cocultured with nonparenchymal cells (“heterotypic interaction”—see Bhatia et al., 1999 for review) (94). Although the precise molecular mechanisms that underlie the “coculture” effect are not known, it is likely that a highly conserved signaling pathway is involved.

While this concept has not been applied to a bioartificial liver device, it merits consideration.

### Bioreactor Designs

Continued innovation in engineering and material science has contributed greatly to the development of an extracorporeal liver-assist device. Coupled with new discoveries in cell sourcing and hepatocyte stabilization, bioartificial liver devices tailored for use with hepatocytes are becoming a reality. Table 2 summarizes the bioreactor designs that have been proposed and studied. ✎ There are four main types of hepatic bioreactors, each with inherent advantages and disadvantages: hollow fiber, flat plate and monolayer, perfused beds or scaffolds, and beds with encapsulated or suspended cells. ✎ A successful and clinically effective bi-device should satisfy a few key criteria: adequate bidirectional mass transport, maintained cell viability and function, and potential for scale-up to therapeutic levels.

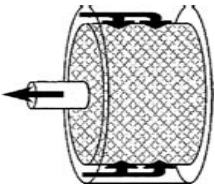

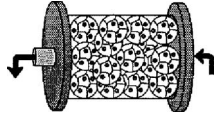

### Bidirectional Mass Transfer

In bioartificial liver devices, bidirectional mass transfer is needed to provide nutrients to sustain cell viability and allow export of therapeutic cell products. Although most device designs address this, there are important limitations involving the use of membranes, diffusivity of key solutes, and spatial uniformity.

Semi-permeable membranes provide selectivity for the size of biological molecules that will be exchanged between the patient and the device. They are inherent in hollow-fiber devices but have been used also in flat-plate and perfusion systems (95,96). In many hollow-fiber devices, the membrane must simultaneously function as a perm-selective barrier and as a scaffold for cell attachment. As noted earlier, the interaction of the hepatocyte with its microenvironment dramatically affects stability and function. Therefore, this design may not allow for optimization of both function and transport. Conversely, hollow-fiber designs provide a larger surface area-to-volume ratio than flat designs thus improving metabolite transport and minimizing dead volume.

The membrane in a bioartificial liver device is typically characterized by its molecular weight cutoff (MWCO), which is selected both to prevent the exposure of bioreactor cells to components of the immune system and to block the transport of larger xenogenic substances into the circulation. The aim of allowing free transport of larger carrier proteins such as albumin (~60 kDa) while preventing transport of immunoglobulins (~150 kDa), complement (>200 kDa) or viruses has led most groups to choose a membrane MWCO of 100 to 150 kDa. Membranes also prevent the migration of cells into the patient’s circulation, although case reports of cellular translocation exist. Although transport in bioartificial liver devices is a combination of convective and diffusional phenomena, mass transfer limitations of key nutrients to and from the cellular compartment often arise due to diffusion resistances. In contrast, transport in the liver is achieved primarily by convection along the sinusoid with short diffusion distances (<5  $\mu\text{m}$ ) across the Space of Disse. Barriers to diffusive transport include membranes, collagen gels, and nonviable cells. Some designs use encapsulated cells in perfusion systems, which provide immunoisolation, but also increases diffusion resistance (56,57,97). Packed bed reactors offer improved mass transfer by allowing direct contact of cells on microcarriers or packing material with the perfusing media (59,60,62,98).

### **Biliary Excretion Consideration**

☞ **A continuing conundrum in current bioartificial liver designs is the universal absence of functional biliary excretion into an isolated compartment.** ☞ In current configurations, even primary hepatocytes that regain polarity *in vitro* (e.g., spheroids, coculture) excrete biliary constituents into the surrounding fluid, which then recirculate continuously. In this regard, addition of a nonbiological adjunct such as an albumin dialysis module may complement many existing bioartificial liver devices. In the long term, culture environments that promote a separate functional biliary compartment will greatly improve the design of these devices.

Oxygenation is key to hepatocyte function and may be suboptimal in current bioartificial liver devices (99–104). Hollow fiber compartments (100) or nonwoven fabric scaffolds (101) with fibers for gas delivery (102) may improve oxygen delivery. Geometric constraints also may affect mass transport in a bioartificial liver. Cell distribution and flow should be uniform. A single monolayer culture is easily perfused, but a series of stacked plates may introduce “shunting” through regions of low resistance. Hollow fiber devices present difficulty in achieving homogeneous cell distribution during inoculation through the tight matrix of capillaries. Uniform perfusion of packed-bed reactors is a classic engineering problem. Distribution of fluid flow is greatly dependent on the characteristic of the packing material. Larger, rigid particles will yield well-distributed flow but a decreased surface area for cells, while smaller, porous packing will result in clogging and fluid channeling (105). A packed bed reactor built around a microchanneled scaffold is an example of one designed explicitly to reduce heterogeneous perfusion and improve the transport characteristics of the devices (98).

### **Cell Viability and Function**

☞ **One of the major obstacles to bioartificial liver offering long-term treatment is the inability to maintain highly functional hepatocytes *in vitro*.** ☞ Current device designs do very little to integrate an appropriate microenvironment for hepatocytes. Gel entrapment and use of spheroidal aggregates has been introduced into various membrane-based systems to provide chemical and topological ECM cues or cell–cell interaction; however, this introduces an additional diffusion barrier (56,89,106–108). Single cell suspensions, used in some devices because of their desirable transport properties, quickly lose metabolic capacity (109). Some packed bed designs (59,60) and one hollow-fiber device (110) seed cells on microcarriers before device assembly. While microcarriers provide a substrate for anchorage, data from hepatocyte cell culture suggests that these cells will likely detach in a few days and die as they do in monolayers. Along with providing adequate attachment, future devices should consider integrating engineering strategies for efficient transport with environments that optimize cell–ECM interactions, cell–cell interactions, and integrate relevant chemical stimuli.

### **Scale-Up**

In order for a device to become a clinical reality, it must be scaled to a size that provides effective therapy. Studies indicate that between 10% and 30% of normal liver mass is needed to sustain life, which in adults, corresponds to 150 to 450 g of cells. Clinically tested devices incorporate between 1 g and 500 g of hepatocyte mass. The current solution for scaling up hollow fiber devices involves increasing

cartridge size 101 and using multiple cartridges (112). Systems using spheroids or microcarriers are easily scaled to the needed cell mass but may entrain a considerable dead volume (“priming volume”). Flat or stacked plate designs raise similar concerns as well as the problem of heterogeneous flow distribution and channeling upon scale up.

### **Review of Recent Trials Evaluating Liver Support Systems**

Experimental devices using suspended primary hepatocytes were some of the first to be used with human patients in the late 1980s, but have met with limited success (112,113). Presently, several hollow-fiber devices are under evaluation in clinical trials (Table 3). The most extensively tested device, the HepatAssist System from Circe Biomedical, recently completed phase II/III trials. The trial was the first prospective, randomized, controlled trial of a biological liver support system in patients with liver failure. It included 171 patients with either fulminant or subfulminant hepatic failure and primary graft nonfunction following liver transplantation. Eighty-five patients received bioartificial liver while 86 patients were controls. Their results showed 30-day survival of 71% for bioartificial liver versus 62% for control ( $p = 0.26$ ). When survival was analyzed after accounting for the confounding factors (such as liver transplantation, time to transplant, disease etiology, disease severity, and treatment site), there was no difference between the two groups. However, survival in the fulminant/subfulminant liver failure patients was significantly higher in the bioartificial liver group compared with the control ( $p = 0.048$ ). Though an examination of study subpopulations and secondary endpoints shows moderate benefit, a conclusive measure of efficacy is confounded by factors such as transplantation, disease etiology, and stage of encephalopathy. Critical evaluation of the complete results of the HepatAssist trial should provide valuable insight for future large-scale clinical studies (114). Careful consideration needs to be given to treatment indications, clinical end points, and device regulation in clinical trial design so that clear evidence of treatment efficacy may be established. Ongoing clinical experience with extracorporeal support will likely play a key role in the improvement of next generation devices.

### **EYE TO THE FUTURE**

A difficulty that arises when examining the current clinical data is the inability to determine the role of live, functional hepatocytes as opposed to extracorporeal perfusion itself, given that some bioartificial liver designs incorporate charcoal filtration. Ideally, a protective comparison should be made between charcoal filtration alone, dead or nonhepatocyte cells, and live hepatocytes given that nonhepatocytes and dead hepatocytes provided survival benefit in some animal models of ALF (115).

Also inherent in the present data are a number of practical issues: Are the cells fresh or frozen? Should the device be perfused with plasma or whole blood? What is the role of heparin versus citrate anticoagulation? These issues are critical both for patient well-being and for survival of hepatocytes in the device. The limited function of cryopreserved hepatocytes has been well-documented, yet

**Table 3** Current Clinical Trials of Extracorporeal Support Devices

Company	Indication—no. of patients	% Recovery <sup>a</sup>	Average bridge—hours <sup>b</sup>	Device	Phase	Comments
<b>Biological devices</b>						
Vaital Therapies (ELAD)	FHF (25)	Dbd			Chinese Trials 2006 US III 2006 I/II multicenter	C3A cell line, continuous treatment up to 10 days, ultrafiltrate perfusion, 150–300 mL/min, heparin, 4 replicable cartridges, cell mass: 4 × 200 g (70, 29, 130, 138)

ryopreservation offers flexibility in timing and scheduling of therapies (117).

The use of whole blood has the advantage of erythrocytes as oxygen-delivery vehicles for the bioartificial liver, although leukocyte activation and cell damage may occur. Conversely, plasmapheresis and plasma perfusion preserve the viability of hematopoietic cells, yet the solubility of oxygen in plasma is very low. Similarly, heparin anticoagulation has been shown in some studies to cause lipid accumulation and deleterious effect on otherwise phenotypically stable hepatocytes (117). Each group has grappled with these trade-offs, and the outcome remains to be seen. Even if these trials do not prove the efficacy of bioartificial liver devices, the knowledge gained along with future improvements in cell sourcing and stability will positively impact the next generation of devices.

In a recent review of all published data by the Cochrane Group, it was concluded that artificial support systems reduce mortality in acute-on-chronic liver failure compared with standard medical therapy; however, artificial and bioartificial support systems so far did not appear to affect mortality in acute liver failure. Hence, randomized trials on artificial or bioartificial support systems versus standard medical therapy for liver failure are still required (118).

Recently the ELAD<sup>®</sup> (Extracorporeal Liver Assist Device<sup>®</sup>)—Vital Therapies, Inc (San Diego, CA, USA) received US Federal Drug Administration (FDA) approval to ship units to China for clinical trials beginning in early 2006. The ELAD<sup>®</sup> system comprises four cartridges containing cloned human hepatocytes of the C3A cell line. Each of the four cartridges serves as a hollow fiber membrane bioreactor.

These cells function like normal human liver cells metabolizing toxins, removing waste products, and producing essential proteins that enter the plasma. The cartridges are incorporated into a blood pumping system and provide continuous treatment for up to 12 days.

Vital Therapies Inc. has completed phase I & II trails in the US and will start phase III trials in the US in 2007 after the clinical trails commencing in China (138).

## SUMMARY

The liver is an essential organ that cannot currently be supported for long when failure occurs. The numerous roles of the liver including synthetic, metabolic, detoxification, and biliary excretion constitute one hurdle in developing a viable artificial liver. Other hurdles are technical in nature and relate to maintaining hepatocytes stabilized within artificial perfusion chambers ensuring viability of cells and the ongoing bidirectional mass transfer of nutrients and hepatocyte products, as well as the ability to handle bile production and excretion. Although numerous obstacles remain, solutions to these problems are being approached in numerous research laboratories around the globe.

Our prediction is that the next decade will see bioartificial liver therapies becoming more commonplace, though the solution to total compatibility and portability is still sometime off into the future.

## ACKNOWLEDGMENTS

SNB thanks Jared Allen for his contribution to the review of cell-based systems and NIDDK for financial support.

## KEY POINTS

- ☞ Certain hepatic injuries affect specific zones.
- ☞ The liver is a complex metabolic factory (biochemical reactor) and performs a number of other functions including protein synthesis, immuno protection and bile formation related tasks.
- ☞ The most common cause of acute liver failure is drug-related hepatotoxicity, which comprises more than 50% of acute cases.
- ☞ Liver failure is associated with a significant compromise of metabolic regulation, protein synthesis, detoxification and immunological defense mechanisms executed by the liver.
- ☞ Hemoperfusion using activated charcoal was shown to have beneficial effects in patients with severe poisoning.
- ☞ Hemodiadsorption is “a process during which blood passes through dialysis membrane packages surrounded by a suspension of fine sorbent particles.”
- ☞ A number of Extra-Corporeal Albumin Dialysis (ECAD) devices have been introduced in the last decade, and preliminary data demonstrate that these can be used as support systems for the failing liver or as a bridge to transplantation in selected patients.
- ☞ Fractional plasma separation and adsorption (FPSA) is a form of albumin dialysis in which a filter with a cutoff of 250,000 Dalton (250KD) is used.
- ☞ The most common cell-based liver support design incorporates hepatocytes in hollow fiber cartridges borrowed from hemodialysis.
- ☞ Although primary hepatocytes represent the most direct approach to replacing liver function in hepatic failure, they are anchorage-dependent cells and notoriously difficult to maintain in vitro.
- ☞ There are four main types of hepatic bioreactors, each with inherent advantages and disadvantages: hollow fiber, flat plate and monolayer, perfused beds or scaffolds, and beds with encapsulated or suspended cells.
- ☞ A continuing conundrum in current bioartificial liver designs is the universal absence of functional biliary excretion into an isolated compartment.
- ☞ One of the major obstacles to bioartificial liver offering long-term treatment is the inability to maintain highly functional hepatocytes in vitro.

## Acute Pancreatitis and Pancreatic Injuries

Matthew H. Katz, A. R. Moossa, and Michael Bouvet

Department of Surgery, UC San Diego Medical Center, San Diego, California, U.S.A.

### INTRODUCTION

Acute pancreatitis and trauma to the pancreas can result in varying degrees of secondary injuries due to pancreatic and peripancreatic inflammatory processes. Patients with acute pancreatitis may have a mild form of the disease, which is associated with minimal organ dysfunction, and they typically undergo a rapid, uneventful recovery. Others may acquire a severe, necrotizing pancreatitis characterized by glandular necrosis and infection in association with failure of multiple organ systems, requiring weeks of treatment in the intensive care unit (ICU). Similarly, patients with pancreatic trauma may have a simple pancreatic contusion, which can be treated nonoperatively, or a severe pancreatic ductal disruption with associated injury to the duodenum or other vital structures requiring immediate surgery and prolonged hospitalization. While mild pancreatic inflammation and injury are easily treated and carry a low rate of morbidity and mortality, fulminant pancreatic disease can be catastrophic and is associated with mortality rates up to 50% despite maximal medical and surgical therapy. It is an essential clinical challenge, therefore, not only to diagnose patients with these diseases, but also to rapidly identify that subset of patients with severe disease that will require management in the ICU and/or surgical treatment.

### PANCREATIC ANATOMY AND BASIC PHYSIOLOGY

#### Anatomy

##### *Surgical Anatomy and Related Structures*

The pancreas is a soft, tan gland that weighs from 60 to 100 grams and measures approximately 12 to 15 centimeters long (1). It lies transversely in the retroperitoneum of the upper abdomen, at approximately the level of vertebrae L1 to L3, and has some of the most complex anatomical relationships in the human body. These relationships account for many of the symptoms and signs of pancreatic trauma and benign pancreatic disease, and are responsible for the technically demanding surgical operations which may be required for the treatment of patients with these problems.

Located directly behind the parietal peritoneum of the lesser sac, the pancreas is intimately related to several vital intra-abdominal organs. Lying to the right of the superior mesenteric vessels, the pancreatic head is cradled by the first three segments of the duodenum, and comes in contact with the right kidney, the vena cava, and the distal common bile duct. The posterior portion of the head may give rise to an uncinata process, which passes behind the superior mesenteric vessels along the third portion of the duodenum, directly anterior to the aorta and vena cava.

The neck of the pancreas overlies the superior mesenteric vessels and is intimately related to the portal confluence, wherein the portal vein is established from the superior mesenteric and splenic veins. The pancreatic body lies to the left of the superior mesenteric vessels, crossing transversely across the floor of the omental bursa. The root of the transverse mesocolon is attached at its inferior border. Posterior, it is associated with the renal vessels, left kidney and left adrenal gland. The body is arbitrarily divided from the tail, which is associated with the splenic flexure of the colon and the spleen.

#### *Pancreaticobiliary Ductal Anatomy*

The secretions of the exocrine pancreas are drained into the duodenum by two major ducts that are variable in their anatomy. The main pancreatic duct runs transversely through the length of the gland, turning inferiorly in the pancreatic head to open into the duodenum at the ampulla of Vater along with the distal common bile duct. The main pancreatic duct routinely drains the body, tail and uncinata body of the gland. The accessory pancreatic duct, which typically drains the pancreatic head, is more variable (2).

The ampulla of Vater (3) is a common pancreaticobiliary channel which lies on the posteromedial wall of the second portion of the duodenum and receives drainage from both the common bile duct and the main pancreatic duct. The ampulla surrounds a complex of sphincter muscles, the sphincter of Oddi (4), which regulates flow from these ducts into the small intestine, and prevents reflux of secretions from one system into another. In approximately one-third of patients, a true common channel is formed by the junction of the pancreatic and biliary ducts within the duodenal wall; other variations of distal ductal anatomy are common but rarely clinically relevant.

#### *Arterial Supply and Venous Drainage*

The pancreas receives its arterial supply from both the celiac and the superior mesenteric arteries. The head of the gland is supplied mainly from the pancreaticoduodenal arcades, the superior branches of which are derived from the celiac trunk via the gastroduodenal artery, and the inferior branches which receive flow from the superior mesenteric artery. The arcades course along the groove between the duodenal C-loop and the pancreatic head, and support a rich network of vessels, which are the predominant blood supply to both of these entities. The shared blood supply of the pancreatic head and the second and third portions of the duodenum imply that simultaneous surgical resection of both is compulsory.

The body and tail of the gland are mainly supported by branches of the splenic artery. This vessel travels transversely along the superior aspect of the pancreas, and gives rise to up to 10 branches which course inferiorly through the pancreatic parenchyma and anastomose with the transverse pancreatic artery running transversely over the inferoposterior surface of the gland.

The venous drainage of the pancreas is to the portal vein. This occurs via the splenic vein, the superior mesenteric vein and the inferior mesenteric vein. The portal confluence is located posterior to the neck of the pancreas and is created by the union of the superior mesenteric and splenic veins.

### **Surgical Access to the Pancreas**

☞ **Three surgical maneuvers must be performed to completely evaluate the pancreas: (i) entry into the lesser sac via the gastrocolic ligament, (ii) division of the leiorenal ligament with full mobilization of the pancreatic tail, and (iii) mobilization of the duodenum and pancreatic head with a Kocher maneuver.** ☞ Because of the retroperitoneal location of the pancreas and its complex anatomical relationships with adjacent vital organs and blood vessels, surgical access to, and resection of the gland is technically demanding. Access to the pancreatic body may be achieved through the omental bursa by incising the gastrocolic omentum along the greater curvature of the stomach just distal to the gastroepiploic vessels, or along the avascular plane found between the posterior leaf of the gastrocolic omentum and its insertion on the transverse colon. The stomach is then retracted superiorly, while the transverse colon is retracted inferiorly, yielding an unobstructed view of the anterior surface of the gland. Inspection of the posterior aspect of the body and tail requires division of the leiorenal ligament and full mobilization of the spleen and pancreatic tail. To adequately visualize and palpate the anterior and posterior aspects of the head of the pancreas, a Kocher maneuver may be performed by mobilizing the right colon at its lateral border and then retracting the hepatic flexure inferomedially. The peritoneum overlying the second portion of the duodenum can then be incised. Blunt dissection is used to separate the head of the pancreas and duodenum from underlying structures.

### **Basic Pancreatic Physiology**

Functionally and histologically, the pancreas is divided into endocrine and exocrine components. Of these, the exocrine component predominates, accounting for over 90% of the gland by weight. The functional unit of the exocrine pancreas is the acinus, composed of multiple acinar cells arranged around a central lumen, which empties into the pancreatic ductal system. The acinar cells are responsible for both production and secretion of pancreatic digestive enzymes, including amylases, lipases and proteases, which facilitate digestion of carbohydrates, fats, and proteins. Another component of the pancreatic acinus, the centroacinar cells, secrete bicarbonate and other electrolytes into a fluid that carries the digestive enzymes to their site of action in the duodenum.

Secretion of pancreatic digestive enzymes occurs primarily upon stimulation by cholecystokinin, which is released by the small intestine in response to an intraluminal meal. Acetylcholine release from vagal fibers also induces stimulation. With the exception of amylase, pancreatic digestive enzymes are secreted into the pancreatic ducts in an

inactive form, and require subsequent activation by the protease trypsin to perform their digestive functions. This activation occurs in the duodenum and is accelerated by the presence of the duodenal enzyme enterokinase and a fall in the pH below 7.0. Within the substance of the pancreas, premature activation of digestive enzymes is prevented by a system of antiproteolytic enzymes also secreted by the acinar cells as well as by the presence of the bicarbonate-rich fluid secreted by the pancreatic centroacinar cells and ductal epithelium which maintains an alkaline pH in the pancreatic ducts.

The endocrine functions of the pancreas are performed by so-called islets of cells which are dispersed throughout the pancreatic parenchyma. These islets contain four types of cells, A, B, D, and F, which produce and secrete glucagon, insulin, somatostatin and pancreatic polypeptide, respectively. These hormones are responsible for maintaining intravascular and intracellular glucose levels and regulating gastric, pancreatic, and biliary secretions. Their functions are important to keep in mind, because major destruction of the pancreas, as may occur with severe pancreatitis or traumatic injury, may disrupt the homeostasis established by each of these endocrine mechanisms.

### **ACUTE PANCREATITIS IN THE CRITICALLY ILL PATIENT**

Acute pancreatitis is defined as an acute inflammatory process of the pancreas, with variable involvement of other regional tissues or remote organ systems (5). The disease is characterized by the presence of varying degrees of pancreatic and peripancreatic inflammation, autodigestion and necrosis. Of the 185,000 patients newly diagnosed and hospitalized with acute pancreatitis in the United States each year (6), most will have a mild form of the disease which may be treated successfully with simple, conservative measures. In this subset of patients, pancreatic necrosis is minimal and the disease is typically self-limiting over two to five days, with a mortality rate less than one percent. In contrast, approximately 15% to 20% of patients develop severe acute pancreatitis, associated with widespread pancreatic necrosis, failure of multiple organ systems, and serious local and systemic complications. These patients will require a protracted course of therapy in the ICU and may need one or more surgical operations to eliminate necrotic and potentially infected pancreatic debris.

### **Etiology**

☞ **The two leading causes for acute pancreatitis are biliary tract stones and alcohol abuse, which together account for over 90% of cases.** ☞ Hypotheses of the mechanisms by which gallstones induce pancreatitis center on the anatomic confluence of the common bile duct and the main pancreatic duct at the ampulla of Vater (7). Gallstones impacted at this site could induce pancreatic ductal obstruction and subsequent hypertension, leading to premature activation of digestive enzymes in the acinar cell. Ampullary inflammation and edema caused during the passage of a stone from the bile duct into the duodenum could cause similar effects; this is likely the more frequent mechanism (8).

Alcohol is the primary cause of acute pancreatitis in many parts of the world, including the United States. It has been suggested that alcohol exerts its toxic effects on the pancreas through the production of protein precipitates that block small pancreatic ducts and induce pancreatic

**Table 1** Etiologies of Pancreatitis

Major causes	Subcategories
Biliary stone disease	
Alcohol	
Drugs	Salicylates Sulfa-containing agents Diuretics Didanosine (DDI)
Trauma	Blunt Penetrating Iatrogenic (ERCP)
Metabolic abnormalities	Hyperlipidemia Hypercalcemia
Infections	
Periampullary tumors	
Hereditary/congenital	Hereditary pancreatitis Cystic fibrosis Pancreas divisum
Idiopathic	Autoimmune

Many etiologies for acute pancreatitis exist. Alcohol and biliary tract disease account for approximately 90% of cases.

*Abbreviations:* DDI, diuretics didanosine; ERCP, endoscopic retrograde cholangiopancreatography.

ductal hypertension. This effect may be aggravated by the spasmogenic effects of alcohol on the sphincter of Oddi. Alcohol, its metabolites and metabolic by-products also appear to have a direct toxic effect on the enzyme-secreting acinar cells. Whatever the etiology, the incidence of pancreatitis caused by alcohol is proportional to the level of alcohol consumption, suggesting that the effects of alcohol on the pancreas are cumulative and dose related (9).

While gallstones and alcohol are responsible for the majority of cases of acute pancreatitis, several less frequent etiologies are well described (Table 1). Pancreatitis can be associated with congenital or hereditary conditions such as pancreas divisum or cystic fibrosis (10). Penetrating and blunt abdominal trauma are associated with acute pancreatitis in approximately 2% of cases, due to direct injury to the pancreatic parenchyma and ducts and to the premature release of activated digestive enzymes. Periampullary tumors may incite pancreatitis by obstructing the main pancreatic duct. Several drugs can induce pancreatitis, as can infection with certain parasites and the venom of rare varieties of scorpions and spiders. Often, a specific precipitating factor cannot be identified.

One final cause of pancreatitis deserves special mention. Iatrogenic injury to the pancreas may occur as a complication of several therapeutic interventions. It is well known that endoscopic retrograde cholangiopancreatography (ERCP) (11) carries a predictable risk of pancreatitis of approximately 5% overall (12). Pancreatitis in this setting is due to direct manipulation of the gland and pancreaticobiliary ducts; evidence suggests that this complication is more frequent when ERCP is performed by inexperienced operators (13). Severe pancreatic inflammation may also occur after other surgical procedures and interventions that do not involve the gland directly, such as cardiac (14) or aortic (15) operations, percutaneous liver biopsy (16), and gastric surgery. The mechanism by

which pancreatitis occurs in these settings is not always evident.

### Pathophysiology and Natural History

Whatever its cause, the inflammatory process of pancreatitis is initiated by the final common pathway of premature and inappropriate activation of trypsin and other digestive enzymes, which subsequently induce autodigestion of the pancreas and peripancreatic tissues (17). Normally, the pancreas is protected from autodigestion by trypsin-inhibiting enzymes such as pancreatic secretory trypsin inhibitor, and trypsinogen-degrading enzymes such as mesotrypsin. Additionally, the bicarbonate-rich secretions of the exocrine pancreas typically prevent inappropriate enzyme activation by maintaining an alkaline pH. In pancreatitis, these protective mechanisms appear to be disrupted and overwhelmed, and activation of enzymatic proteases occurs. As pancreatic acinar cells are damaged by this initial insult, they discharge their enzymes, further exacerbating local injury.

For approximately 75% of patients, locoregional injury to the pancreas and peripancreatic tissues is the only manifestation of their disease. These patients may be described to have mild acute pancreatitis, as classified by the Atlanta Convention in 1992 (5). The predominant histological feature of this process is interstitial edema; microscopic areas of necrosis in the pancreatic parenchyma are occasionally found, but widespread pancreatic necrosis is conspicuously absent. Distant organ failure does not occur.

**✎ Treatment of patients with mild acute pancreatitis can be accomplished on a general medical or surgical ward, and the disease is typically self-limiting, resulting in an uneventful recovery. ✎**

Progressive injury to the pancreatic acini induces the overexpression of inflammatory mediators which may exacerbate both local and systemic injury. TNF- $\alpha$  is one of the most active of these mediators. Derived predominantly from activated macrophages, expression of this protein increases rapidly over the first several hours of pancreatitis (18) and induces an inflammatory syndrome clinically indistinguishable from that of shock. The inflammatory effects of TNF- $\alpha$  are exacerbated by IL-1 (19), which is also involved in the activation of leukocytes and in the upregulation of endothelial adhesion factors. Combined with mediators such as IL-6, the complement cascade and platelet activating factor (PAF), these agents are responsible for both the local and systemic manifestations of severe disease, which result from the effects of impaired microcirculatory perfusion of organs and capillary endothelial leak.

Severe acute pancreatitis is the clinical manifestation of local pancreatic and peripancreatic destruction, combined with distant organ failure and complications due to systemic cytokine release. Histologically, the pancreas shows evidence of parenchymal and peripancreatic necrosis, which may be widespread; a direct correlation exists between the amount of necrosis present and patient prognosis. Necrosis typically involves the acinar cells, islet cells and ductal system. Hemorrhage in these tissues is variable, but not uncommon. Systemic features of the disease include the cytokine-induced multiple organ dysfunction syndrome (MODS), with distant organ systems such as the kidneys, lungs and heart involved. Superinfection of the pancreatic necrosis is variable, but devastating.

As could be predicted, the course of patients with severe disease is protracted, and these are the patients who will require care in the ICU. The natural history of their

disease can be described as having two stages (20). The first two weeks of hospitalization reflect the early local and systemic inflammatory response, and is characterized by cytokine release, systemic inflammation and injury, and failure of multiple organ systems. Patients who survive this initial insult often develop superinfection of their pancreatic necrosis in the second and third weeks, with associated sepsis and the potential for further decompensation.

Because the natural history of acute pancreatitis in the general population varies so widely, particular emphasis must be placed on the early identification of individual patients with severe disease, so that proper therapeutic interventions can be performed.

### Diagnosis

While diagnosing this disease, the clinician should attempt to determine the following: (i) a clear diagnosis of pancreatitis, (ii) its etiology, and (iii) an individual assessment of disease severity. Accurate determination of all three of these may be difficult, even using all of the following diagnostic tools.

### Clinical History and Physical Findings

The patient with acute pancreatitis may have several complaints, none of which is specific to this disease. Upper abdominal pain, which may radiate to the back, is the most common symptom. The pain is variable in severity, ranging from mild discomfort to severe pain that may be confused with peritonitis. Nausea and vomiting frequently occur. Fever is a part of the clinical presentation of over half of all the patients, but neither its presence nor magnitude correlate with severity of the disease (21). Other nonspecific complaints such as anorexia or lethargy may or may not be present.

The initial physical exam of patients with pancreatitis is also characteristically nonspecific. Patients may be febrile, tachycardic and in extremis, or may be hemodynamically stable. Abdominal findings are variable. Periumbilical and flank bruising (Cullen's and Grey Turner's signs) are often touted as evidence of severe pancreatitis, but these are very rare and can be seen in any hemorrhagic abdominal disorders. It is important to emphasize that the signs and symptoms of pancreatitis are variable, nonspecific, and may mimic other abdominal problems. Additional data must be accumulated to definitively diagnose the disease and to establish its severity.

### Biochemical Studies

#### Amylase

Serum amylase is used universally in the diagnosis of acute pancreatitis (22). This pancreatic digestive enzyme is normally secreted by pancreatic acini; large amounts are released into the systemic circulation in states in which disruption or dysfunction of the pancreatic ductal system occurs. The serum amylase level typically rises steadily over the first 12 hours of an attack of pancreatitis, returning to normal over the next five days (23). Its peak may usually be measured within the first 48 hours. If a patient presents to the hospital late in the course of the disease, this peak may have passed and the amylase level may be normal (24). Normoamylasemia in the presence of pancreatitis may also occur in patients with an alcoholic etiology for their disease (25), and in states of chronic or severe necrotizing pancreatitis in which widespread acinar cell destruction has occurred.

While fairly sensitive, an elevated serum amylase is not specific to the diagnosis of acute pancreatitis. Serum amylase may rise in response to several other abdominal disorders, including trauma, appendicitis, perforated bowel and mesenteric ischemia. Similarly, salivary isoforms of the enzyme may lead to false positive elevations when patients present with inflammation of the salivary glands. Finally, because amylase is in large part cleared from the circulation by the kidneys, renal insufficiency may lead to an elevated amylase level.

Nonetheless, measurement of serum amylase is key to the diagnosis of acute pancreatitis. Differentiation from other extrapancreatic conditions can typically be made if the serum amylase is greater than five times normal, which rarely occurs when hyperamylasemia occurs from a nonpancreatic source. Though not routinely performed, salivary and pancreatic amylase isoforms may be measured in certain situations. Calculation of the fractional renal clearance of amylase, in which renal clearance of the enzyme is compared to that of creatinine, may be useful to confirm the diagnosis. A fractional clearance in excess of 4% is suggestive of acute pancreatitis.

It should be noted that no correlation has been found between the level of amylase elevation and magnitude of disease. ⚡ **Serum amylase and lipase are used to diagnose pancreatitis, but their magnitudes are not predictive of disease severity.** ⚡

#### Lipase

The serum lipase level may also be used to assist in the diagnosis of acute pancreatitis, and may be a more specific test than amylase (26,27), particularly if elevated greater than three times normal. Concentrations of the enzyme in serum increase within the first eight hours after the onset of symptoms, peak within the first 24 hours, and return to baseline over the following two weeks (28). Lipase concentrations may therefore be elevated long after serum amylase levels have returned to normal. Nonetheless, an increase in lipolytic activity is not specific to pancreatitis, and elevations can be seen in other conditions such as trauma, intestinal obstruction, cholecystitis, and esophagitis. As with amylase, the level of lipase elevation cannot be used to assess the severity of disease.

⚡ **Whether amylase or lipase is more accurate in the diagnosis of pancreatitis is debatable; in clinical practice, serum levels of both are typically ordered. Concomitant elevation of both enzymes is good evidence for the diagnosis, especially in conjunction with a consistent history and physical examination.** ⚡

#### Other Diagnostic Laboratory Tests

Other laboratory markers, such as trypsin, elastase, phospholipase A-2, trypsinogen-2, pancreas, associated peptide (PAP), and C-reactive protein (CRP) have been reported as possible adjuncts to the laboratory diagnosis of acute pancreatitis (29,30). None of these has been studied as thoroughly as CRP. CRP is an acute phase protein, produced in the liver upon inflammatory stimuli by cytokines (31), such as occurs in the early stages of acute pancreatitis. Unlike other markers of pancreatitis, CRP has been shown to reliably differentiate mild from severe acute pancreatitis with a high degree of specificity (32). Unfortunately, the clinical utility of CRP is undermined by the fact that its levels in serum do not spike until two to four days after the onset of the disease (33) and thus it cannot be used on admission, when its value would be most appreciated. The

marker is thus rarely used in the diagnosis and staging of acute pancreatitis in the United States.

#### Associated Biochemical Findings

Other laboratory findings consistent with a diagnosis of acute pancreatitis include hyperglycemia, hypocalcemia, hyperlipidemia, leukocytosis, an elevation in hepatic transaminases, elevated hematocrit, and derangements in the arterial blood gas. None of these markers can be used either to diagnose the disease or to assess its severity.

#### Imaging Studies

##### Ultrasound and Endoscopic Ultrasound

Transabdominal ultrasound (US) plays little role in the detection or grading of pancreatic necrosis. The gland is poorly visualized in up to 25% of cases, often due to the effects of intestinal ileus and superimposed bowel gas (34). Moreover, ultrasound cannot reliably distinguish between necrotic pancreatic parenchyma and surrounding tissues, and is unable to accurately identify pancreatic infection. Nonetheless, transabdominal ultrasound is generally recommended as an initial imaging study in patients suspected of having acute pancreatitis. Because of its excellent ability to assess the biliary tract and gallbladder, the primary role of US is identification or exclusion of biliary tract disease as a causal factor (35). It is also useful to demonstrate fluid collections and identify extrapancreatic spread of inflammation (36). **✎ Ultrasound may also be used to assess complications of acute pancreatitis, such as pseudocyst and aneurysm formation. ✎**

The role of endoscopic US (EUS) is not yet well established (Fig. 1). This modality appears to be more sensitive than either transabdominal ultrasound or computed tomography (CT) scan, and as sensitive as ERCP, in the identification of both cholelithiasis and choledocholithiasis (37,38). Because it is less invasive than ERCP, it has been suggested that EUS be performed early for diagnosis of acute biliary pancreatitis, relegating ERCP to a purely therapeutic role (39). Nonetheless, no large studies have definitively established its role in the diagnosis or staging of acute pancreatitis. At present, its use must be viewed as experimental.

**Figure 1** Endoscopic ultrasonography demonstrating choledocholithiasis. Two gallstones are visualized in the common bile duct using endoscopic ultrasonography. Information regarding the presence or amount of pancreatic necrosis is not provided, using this imaging modality.

**Figure 2** Computed tomography demonstrating pancreatic necrosis. Baseline contrast-enhanced computed tomography scan performed on admission of a 34-year-old male diagnosed with severe acute pancreatitis. Impaired perfusion reflects widespread pancreatic necrosis.

##### Computed Tomography

A contrast enhanced CT scan is the imaging modality of choice for both the diagnosis of severe acute pancreatitis and for the assessment of the severity of disease (40). Poorly perfused areas of pancreatic necrosis are easily identified on CT as areas of nonenhancement during the arterial phase of intravenous contrast administration (Fig. 2). The unperfused areas of pancreatic tissue seen on CT scan are detected with an overall accuracy of up to 90%, as confirmed by surgical exploration (41,42). Other possible CT findings in pancreatitis include diffuse or partial pancreatic enlargement, fluid collections, and obliteration of the peripancreatic fat planes.

Due to its ability to accurately identify and quantify pancreatic necrosis, and because pancreatic necrosis is one of the most important determinants of prognosis for patients with the disease, CT staging of disease severity has gained widespread acceptance. Several scoring systems, such as Balthazar's CT severity index (43) have been established; such systems have enabled accurate prediction of a patient's prognosis using CT findings alone. CT scanning is the diagnostic modality of choice, and a good baseline CT scan is therefore recommended upon admission to the ICU in all patients suspected of having severe disease. **✎ Subsequent imaging may be performed later in the patient's hospital course to follow the course of treatment. ✎**

##### Endoscopic Retrograde Cholangiopancreatography

While ERCP may be used successfully to treat patients with choledocholithiasis and cholangitis, its role in the diagnosis and treatment of acute pancreatitis without biliary obstruction is, at best, controversial (44). ERCP is unable to assess or quantify pancreatic necrosis, and is therefore unsuitable for the diagnosis and staging of the disease. Several large studies have examined the outcomes of patients with pancreatitis treated with early ERCP and sphincterotomy compared with patients treated conservatively, with conflicting results (45,46). These results must be balanced with the known complications associated with ERCP, which include trauma to the ampulla of Vater, contamination of the main pancreatic duct and exacerbation of pancreatitis. The

routine use of ERCP therefore cannot be justified in either the diagnosis or the treatment of acute pancreatitis. In cases where it is appropriate, such as in the presence of a gallstone clearly impacted at the ampulla of Vater, ERCP should be performed by an experienced endoscopist.

#### **Magnetic Resonance Cholangiopancreatography**

Accumulating evidence suggests that, like EUS, noninvasive MR imaging of the pancreas may eventually obviate the use of diagnostic ERCP. Magnetic resonance cholangiopancreatography (MRCP) (47) appears to be a safe imaging modality that gives reliable information about the patency of the pancreaticobiliary ductal system (48–50), and may therefore be useful in selecting out those few patients who truly require therapeutic ERCP. MRCP is able to differentiate pancreatic and peripancreatic necrosis from adjacent viable tissue, and may be as good as contrast-enhanced CT in this regard (51). It can also accurately identify peripancreatic fluid collections, and may be superior to CT in determining their contents and identifying their suitability for radiological drainage (52). At present, however, CT is more widely accessible, less expensive to perform, and should be regarded as the imaging modality of choice.

#### **Fine Needle Aspiration for the Diagnosis of Infected Necrosis**

✎ **Distinguishing between sterile and infected necrosis is imperative.** ✎ Typically, patients with severe but sterile necrotizing pancreatitis can be managed conservatively in the ICU, while patients with contaminated necrosis will ultimately require surgery (discussed subsequently). Many groups prefer to take a nonaggressive approach, and use clinical evidence of sepsis as an indicator of the presence of pancreatic contamination (53). Fine Needle Aspiration (FNA) may also be used to establish a definitive diagnosis, and has been generally accepted as safe and effective. Using ultrasound or CT guidance, a needle is inserted into the pancreatic parenchyma. Aspirated tissue may be sent for culture, yielding a sensitivity of detection of infected necrosis up to 90% (54). It must be remembered, however, that FNA is an invasive technique, and is associated with morbidity and mortality including bowel perforation, pancreatitis and hemorrhage. Clinical judgment must therefore be used in its application.

#### **Assessment of Severity**

Because the natural history of acute pancreatitis in those patients with mild disease is so different from that in patients with necrotizing pancreatitis, the early identification of patients who will develop severe disease is crucial. Unfortunately, staging of the severity of acute pancreatitis is notoriously difficult; using clinical data alone, even experienced examiners can predict patients' prognosis in only 39% of cases (55). Multifactorial scoring systems to predict the natural history of acute pancreatitis have therefore been established, the first of which was developed by Ranson in 1974 (Table 2) (56). In this system, five laboratory and clinical parameters are measured on admission, and six more are assessed over the course of the first 48 hours of hospitalization to estimate a likelihood of ultimate mortality. Validated by the Atlanta Convention, severe disease is frequently associated with three or more positive Ranson findings, and studies have confirmed an acceptable sensitivity for diagnosing severe disease (57). Unfortunately, the criteria require a full 48 hours to establish, and thus are not useful for diagnosis in the most crucial early hours.

**Table 2** Ranson Criteria

On admission
Age >55 years
White blood cell count >16,000 mm <sup>3</sup>
Serum glucose >200 mg/dL
Lactate dehydrogenase (LDH) >350 IU/dL
Aspartate aminotransferase (AST) >250 IU/L
Within 48 hours
Hematocrit decrease >10%
Blood urea nitrogen (BUN) increase >5 mg/dL
Serum calcium <8 mg/dL
Arterial pO <sub>2</sub> <60 mmHg
Base deficit >4 mmol/L
Fluid sequestration >6L

Ranson's criteria for the assessment of severity in acute pancreatitis. The presence of three of the above criteria is associated with severe disease according to the Atlanta Convention. If less than three criteria are present, the likelihood of mortality is approximately 1%. The original report focused on alcohol-induced pancreatitis; slight modifications have been adopted for patients with biliary etiology. *Source:* From Ref. 56

The acute physiology and chronic health evaluation (APACHE) II, (Table 3) (58), and more recently III (59) scores can be used to measure the severity of a variety of critical illnesses, and have the advantage that they may be used earlier in a patient's hospital course than the Ranson system (60) to predict prognosis in an attack of acute pancreatitis. While the system is able to predict severe disease with an overall accuracy approaching 90% within the first 24 hours, it is complicated to use in the clinical setting. No advantages to the use of APACHE III over APACHE II have yet been demonstrated.

Because of the cumbersome nature of these multifactorial systems, attempts have been made to estimate prognosis using a single clinical or laboratory indicator. The most successful of these attempts has been with CT scanning. By assessing the degree of pancreatic and peripancreatic inflammation, the presence of associated fluid collections and the presence and degree of pancreatic necrosis, scoring systems such as the Balthazar CT severity index (Table 4) can be used to reliably predict disease severity with an accuracy equal to, or even greater than, the previously described multifactorial systems (57,61).

#### **Nonoperative Management Guidelines**

##### **Resuscitation**

Initial therapy for patients diagnosed with severe acute pancreatitis has two aims: (i) to provide cardiocirculatory support and (ii) to prevent and to minimize the complications of multi-organ system failure (62). Patients identified as having severe disease should be admitted to the ICU and continuously monitored. ✎ **Fluid resuscitation with crystalloid solutions is the cornerstone of management, because immense volume shifts can lead to depletion of the intravascular volume.** ✎ Pulse, blood pressure, urine output and the base deficit determined by arterial blood gas can serve as markers of resuscitation in many patients; in the elderly or more tenuous patients a central venous catheter or pulmonary artery catheter should be inserted so that central venous pressure, pulmonary artery wedge pressure, cardiac output and systemic vascular resistance can be recorded. Electrolyte levels should be continuously monitored throughout the resuscitation.

**Table 3** The Acute Physiology and Chronic Health Evaluation II Scoring System

Physiologic variables	Method of scoring	Reference range
	Score 0–4 points according to deviation of value from normal reference range unless otherwise stated	
Rectal temperature (°C)		36.0–38.4
Mean arterial pressure (mmHg)		70–109
Heart rate (beats/min)		70–109
Respiratory rate (breaths/min)		12–24
Oxygenation (mmHg)		PaO <sub>2</sub> >70 and FiO <sub>2</sub> <0.5 or (A-a)O <sub>2</sub> <200 and FiO <sub>2</sub> >0.5
Arterial pH		7.33–7.49
Serum sodium (mmol/L)		130–149
Serum potassium (mmol/L)		3.5–5.4
Serum creatinine (mg/dL)	Score doubled if patient in renal failure	0.6–1.4
Hematocrit		30–45.9
Leukocyte count (×10 <sup>9</sup> /L)		3–14.9
Glasgow Coma Scale (GCS)	Subtract GCS from total score	
Age	Score 0 if age ≤44 Score 2 if age 45–54 Score 3 if age 55–64 Score 5 if age 65–74 Score 6 if age ≥75	
Operative status and chronic health	Score 0–5 depending on operative status (nonoperative, emergency postoperative, felective postoperative) and presence of severe organ insufficiency	

Factors measured in the APACHE II Scoring System, which may be applied to many critical illnesses including pancreatitis. Up to four points are ascribed to each physiologic variable listed according to its most abnormal value within the first 24 hours of hospitalization. Additional points are given for older age, history of previously diagnosed medical conditions and surgical status. The magnitude of the APACHE index, from 0–71, correlates with an increased severity of disease and a greater risk of in-hospital death.

*Abbreviation:* APACHE, acute physiology and chronic health evaluation computed tomography.

*Source:* From Ref. 58.

The systemic cytokine release in the early stages of the disease, combined with the effects of massive fluid shifts, frequently lead to dysfunction of other organ systems. Renal failure is a frequent complication of severe disease (63) that carries a particularly poor prognosis (64). Continuous hemodialysis may be required. Acute lung injury and ARDS, found in up to one-third of patients with severe acute pancreatitis, account for 60% of deaths within the first week of diagnosis (65,66). Endotracheal intubation and respiratory support should be provided early in the face of impending respiratory failure. Routine strategies such as the use of low tidal volume mechanical ventilation, permissive hypercapnia, and proning may be used in patients with severe lung disease.

Despite maximal supportive therapy, the prognosis of patients with severe acute pancreatitis who develop multiple organ failure is poor (67). It is incumbent upon the clinician, therefore, to practice an aggressive policy of prevention and early detection.

### Nutritional Support

Over the past two decades, the traditional tenets of restricting enteral nutrition and decompressing the stomachs of patients with severe acute pancreatitis have been challenged and largely discounted. Nasogastric decompression in

**Table 4** The Balthazar Computed Tomography Severity Score

	Score	CT appearance
<i>CT grade</i>		
A	0	Normal
B	1	Pancreatic enlargement
C	2	Peripancreatic inflammation
D	3	Single fluid collection
E	4	Multiple fluid collections
<i>Gland necrosis</i>		
None	0	Normal pancreatic enhancement
<30%	2	Nonenhancement of <30% of pancreas
30%–50%	4	Nonenhancement of 30%–50% of pancreas
>50%	6	Nonenhancement of >50% of pancreas

Balthazar's index predicts severe pancreatitis based on an assessment of peripancreatic inflammation, associated fluid collections, and degree of pancreatic necrosis as seen on the admission computed tomography scan. Scores range from 0 to 10; patients with scores <3 have a 2% morbidity and essentially 0% mortality, while those with a score greater than 7 have a 17% mortality and a complication rate of 92%.

*Source:* From Ref. 43.

particular has been shown to have no positive effect on the clinical course of these patients (68,69), and may in fact have contradictory effects in terms of perceived pain, resumption of bowel function and length of hospital stay. ⚡ **Nasogastric suction should not be used routinely, and is limited to those patients who have a high risk of aspiration, or who suffer from a concomitant ileus or bowel obstruction.** ⚡

In contrast, the use of aggressive nutritional support is a fundamental part of treatment that should be provided to each patient with severe disease. The cytokine release initiated by pancreatic inflammation induces a metabolic state similar to that of sepsis, characterized by hypermetabolism, catabolism, and negative nitrogen balance. Patients' resting energy expenditures may reach 150% of normal as predicted by the Harris-Benedict equations (70,71), with catabolism contributing to nitrogen losses up to 40 g/day (72). Untreated, these metabolic derangements will lead to loss of lean body mass and malnutrition.

In the past, nutritional replacement has been accomplished using total parenteral nutrition (TPN) (73). The parenteral route was justified by the belief that enteral feeding would stimulate proteolytic pancreatic secretions and thus exacerbate pancreatic autodigestion and inflammation. Initial studies suggested that patients receiving TPN early in their hospital course for severe acute pancreatitis could enjoy a reduction in complications and a survival advantage compared to controls. Nonetheless, several disadvantages to its use were identified. First administration of concentrated dextrose solutions requires the introduction of a central venous catheter, which is itself associated with complications such as pneumothorax and catheter-related sepsis (74). Parenteral administration may lead to electrolyte imbalances and may exacerbate metabolic disturbances. Finally, neglect of the alimentary tract may lead to mucosal atrophy, increased intestinal permeability, and bacterial translocation (75). This may lead to contamination of pancreatic and peripancreatic necrosis or outright sepsis.

The use of enteral feeding for nutritional support for patients with severe pancreatitis has been justified by several recent studies, and has now replaced parenteral nutrition as the primary method of nutritional replacement for patients with this disease. Enteral feedings are typically performed through a nasojejunal feeding tube, the tip of which is endoscopically or radiographically placed beyond the ligament of Treitz, although recent studies suggest that intragastric feeding may also be acceptable (76). Use of the enteral route is safe and well tolerated by patients, and is not associated with an increase in pancreatic inflammation or necrosis, as previously supposed. In fact, enteral feeding appears to be associated with an improvement in disease severity, a decrease in the rate of complications, sepsis and organ failure, and a reduction in the length of ICU hospitalization compared to parenteral nutrition (77–79). Moreover, enteral feeding does not induce the atrophy and adverse functional changes in intestinal mucosa seen in patients treated with parenteral nutrition (80). This likely contributes to a reduction in the frequency of gut-derived systemic toxicity, a phenomenon seen both clinically and experimentally (81). Finally, enteral nutrition is also far less expensive to administer than TPN. For these reasons, current recommendations include the early use of enteral nutrition for patients with severe acute pancreatitis. ⚡ **The use of TPN should be relegated to the small subset of patients who do not tolerate enteral feedings.** ⚡

### **Prophylactic Antibiotics**

Due to advances in critical care methods and care, the mortality rate from multiorgan system failure in the first stages of severe pancreatic illness has fallen. Septic complications, typically occurring later in the patients' hospital course, now account for approximately 80% of deaths from severe acute pancreatitis (20,82). Infection of pancreatic and peripancreatic necrosis, in particular, is recognized as the most important risk factor for death from the disease (83). Unfortunately, infections occur in up to 40% of patients who have over 30% necrosis of the pancreas. Prevention and diagnosis of infection are thus of utmost importance in the treatment of critically ill patients with acute pancreatitis.

Bacterial contamination of pancreatic necrosis can occur through several routes (84). The use of central venous catheters, endotracheal tubes, indwelling urinary catheters and nasogastric tubes can introduce bacteria into the bloodstream. Reflux of contaminated bile into the pancreatic duct may occur. Uncommonly, microorganisms can also ascend into the main pancreatic duct from the duodenum. The most important portal of entry, however, appears to be the colon, across which bacteria and endotoxins can translocate into the systemic circulation through an injured and hyperpermeable mucosal barrier (85). Injury to the mucosa may occur by several mechanisms, including hypoperfusion and ischemia, reperfusion injury, and bacterial overgrowth. Mucosal atrophy, as occurs during prolonged use of parenteral feeding, can contribute to the problem, as can mechanical injury to the bowel that may occur concomitantly with blunt or penetrating pancreatic trauma. Once the function of the mucosal barrier has failed, bacteria may translocate to intra-abdominal ascites, the systemic circulation, or to the pancreatic necrosis directly (84).

The theory of gut-derived sepsis in acute pancreatitis is supported by several lines of evidence. Experimental evidence has clearly demonstrated that splanchnic hypoperfusion during the early stages of pancreatitis can lead to gut barrier dysfunction (86). This dysfunction is associated with an increase in the permeability of enteric mucosa to bacteria and macromolecules such as bacterial endotoxin, which have been identified in high levels in the blood of patients during severe pancreatic attacks (87). Perhaps most compelling, prior to widespread use of antibiotics, gram-negative and other enteric bacteria such as *Escherichia coli*, *Enterobacter* spp, *Pseudomonas* spp, and *Bacteroides* spp were the most common organisms recovered from pancreatic necrosis; these organisms are still all too prevalent in patients with severe disease, particularly when due to biliary stones (88).

The use of prophylactic broad-spectrum antibiotics in patients with severe pancreatitis to reduce pancreatic contamination from the gut and other sources is now well established. The agents imipenem and ciprofloxacin have satisfactory efficacy against enteric organisms, and have been shown to achieve high levels in pancreatic secretions and peripancreatic tissues. These agents have been demonstrated to reduce both the frequency of complications and the rate of mortality in patients with severe disease (89,90).

⚡ **Current recommendations now support the early administration of prophylactic imipenem (or ciprofloxacin) in patients with severe pancreatitis and high levels of pancreatic necrosis. Because the rate of pancreatic infection in patients with minimal necrosis is very low, the use of prophylactic agents in patients with mild pancreatitis is not warranted.** ⚡

The prophylactic use of broad spectrum antibiotics has been shown to be associated with fungal infections, and therefore the administration of these agents must not be taken lightly. Several studies have demonstrated not only a strong association between the protracted use of prophylactic antibiotics and the occurrence of fungal contamination of pancreatic necrosis, but also an increased mortality rate in patients with this complication (91–94). No data yet support the routine use of prophylactic fluconazole in the treatment regimen for patients with severe disease, but this agent may be administered upon suspicion or diagnosis of fungal infection.

### **Somatostatin and Octreotide**

For the last two decades, the role of somatostatin in the treatment of acute pancreatitis has been controversial. First described as a potential treatment for severe pancreatitis in 1980 (95), somatostatin is an endogenously produced antisecretory hormone secreted by D cells of the pancreatic islets. Octreotide, a somatostatin analog, was subsequently evaluated for use in these patients. While early studies demonstrated conflicting results in terms of the efficacy of these agents (96–98), recent studies suggest that no benefits exist (99). The use of somatostatin and octreotide therefore cannot be recommended for routine use in the treatment of patients with acute pancreatitis.

Several recent reports have also suggested that prophylactic somatostatin might play a role in reducing the incidence of pancreatitis after ERCP; results have been contradictory (100,101), and therefore their routine use is not recommended in this setting, either.

## **Surgical Treatment**

### **Indications and Timing of Surgical Intervention**

☞ **Three established indications for surgical intervention in severe pancreatitis exist: (i) the presence of infected pancreatic necrosis, (ii) failure to improve after a long period of conservative management, and (iii) acute abdominal catastrophe.** ☞

Infection of pancreatic necrosis occurs in up to 70% of patients with severe necrotizing pancreatitis (83), and its frequency correlates with the duration of the disease as well as the amount of necrotic tissue present. Left untreated, infected necrosis carries a high mortality rate approaching 100% (84,102) due to sepsis-induced organ failure initiated by the necrotic focus of infection. With appropriate surgical management, these patients fare better, with mortality rates in the order of 20% (103,104). The presence of infected pancreatic necrosis is therefore universally accepted as an absolute indication for surgical intervention.

Sterile necrosis, in contrast, is typically not an indication for surgery (105), and can be managed successfully using the nonoperative methods described in III.D.1. Several reports have validated the use of nonoperative therapy in these patients (104,106). In addition to conferring no benefit in the majority of these cases, operative manipulation of the sterile necrosis may actually contaminate it, leading to higher mortality rates.

In the case of infected necrosis, operation should be delayed as long as possible, with broad spectrum antibiotics used in the period of conservative management. Improved outcomes have been achieved with late compared to early surgical intervention (107,108). This phenomenon is attributed to the clear demarcation between viable and nonviable pancreatic tissues that occurs over time, enabling precise

necrosectomy when performed later in the disease course. Moreover, by waiting, patient stability can be maximized using nonoperative interventions. In cases of early operation, patients are frequently unstable, and the identification at laparotomy of truly necrotic tissues in the pancreatic bed is difficult, leading to unnecessary removal of potentially viable tissue. These drawbacks of early intervention appear to outweigh any advantages achieved by the early removal of the septic focus.

The second indication for surgical intervention in acute pancreatitis is failure of a patient to improve despite continued support for a prolonged period, typically three to four weeks. Often, these patients will demonstrate signs of increasing toxicity in the absence of proven infection; failure of multiple organ systems is a frequent complication. Evidence suggests that operating in these cases may be beneficial (109,110). Unfortunately, the timing of surgery in these patients is not clear; good surgical judgment remains the only way to select that subset of patients who will benefit from surgical management.

The final indication for operative management in patients with acute pancreatitis is in the presence of an acute abdominal catastrophe, such as rupture of a peripancreatic fluid collection or intra-abdominal bleeding from erosion of a major vessel (2). In these unusual cases, the surgeon may be forced to operate immediately.

Although these indications for operation serve as a guide, the following advice of the eminent pancreatic surgeon Dr. Kenneth Warren remains instructive: “the two most common mistakes made in the treatment of acute pancreatitis are to operate too early and do too much and to operate to late and do too little.” The underlying wisdom of these remarks derive from the recognition that choosing the right operative path is based upon careful and repetitive examinations of the patient, and re-evaluation of all data (i.e., CT scans, amylase, etc.) in the setting of an optimally resuscitated patient.

### **Operative Techniques**

#### **Necrosectomy**

The preferred surgical treatment for necrotizing pancreatitis involves necrosectomy, in which devitalized pancreatic parenchyma and peripancreatic tissues are debrided from the retroperitoneum (111). The abdomen is opened according to the preference of the surgeon, typically through a vertical upper abdominal or bilateral subcostal incision to facilitate exposure. Access to the pancreatic bed is achieved through the maneuvers described previously. Removal of necrotic tissue can then be accomplished using blunt finger dissection and irrigation with a balloon syringe. A sample of tissue should be sent for culture. All peripancreatic fluid collections are gently opened and drained. Perioperative oozing, which may be copious, is controlled by pressure with moist laparotomy pads.

Once the necrotic debris is entirely removed, the residual cavity must be drained in order to remove serum, blood, and pancreatic secretions. This may be accomplished using a closed technique in which saline is irrigated daily into the pancreatic bed through a series of catheters and then removed through another set of drains (103,112). Other authors perform a closed technique in which the residual cavity is packed with penrose drains stuffed with gauze, which are subsequently withdrawn over time (113). If the residual cavity is very large, or contains extensive necrosis, open drainage may be performed (114). In such methods, laparotomy pads are placed into the lesser sac and the

abdominal wound is loosely approximated in a temporary closure. Daily packing changes can be performed using sterile technique in the operating room until the wound begins to granulate. With any of these methods, complete necrosectomy may require multiple explorations. These may be scheduled or may be performed on an as-needed basis dictated by the clinical condition of the patient.

The choice of technique depends in large part on the choice and comfort of the surgeon. Satisfactory results have been demonstrated using all of the above methods in which successful debridement and drainage of the lesser sac are effected.

#### *Percutaneous Drainage*

As experience with interventional radiology has grown, so too has interest in using percutaneous techniques in the treatment of acute pancreatitis. While percutaneous drainage clearly has a role in the treatment of peripancreatic fluid collections (115), abscesses (116), and pseudocysts (117), such techniques have not yet proven useful in the removal of pancreatic necrosis. **Open surgery remains the primary approach for pancreatic necrosis; interventional radiological techniques may subsequently be used successfully to drain residual fluid collections.**

#### **Late Complications and Sequelae**

Although they are relatively common, the late complications and sequelae of acute pancreatitis and its treatment typically occur weeks after the acute event. They are therefore infrequently part of the course of treatment of patients with acute pancreatitis during their ICU hospitalization.

Pancreatic pseudocysts are cystic lesions that arise secondary to disruption of the pancreatic ductal system with subsequent leakage of pancreatic fluid and enzymes into surrounding tissues (Fig. 3). These lesions form over a protracted four to six weeks course after an initial attack, and can be diagnosed by their appearance on CT scan and their absence of an epithelial lining on histological analysis.

**Figure 3** Computed tomography demonstrating a pancreatic pseudocyst. Computed tomography scan of the same patient as seen in Figure 2, performed seven weeks after the onset of symptoms. A large pancreatic pseudocyst was identified, which was subsequently treated by operative internal drainage into the stomach.

Pseudocysts occur in approximately 6% of cases of acute pancreatitis (20), and are more common in severe cases. Most cases resolve spontaneously, particularly when less than 6 cm in diameter. Drainage can be performed for large or symptomatic lesions, using surgical, endoscopic or percutaneous techniques.

Less common, yet more concerning, is the development of a pancreatic abscess (118). Like pseudocysts, these lesions occur late in the course of disease, but differ in that their contents are highly purulent. They are typically not associated with active pancreatic necrosis. Although drainage may be successfully accomplished percutaneously in a subset of patients, many patients will benefit from definitive surgical management (119).

Fistulas originating from the pancreas may occur despite therapy for acute pancreatitis, and typically communicate externally to the skin (120). Initial treatment for this complication is conservative, with endoscopic management or surgical treatment used only in cases that are unresponsive.

## **PANCREATIC INJURIES**

Although relatively uncommon, the incidence of pancreatic trauma has risen over the past several decades due to an increase in the frequency of automobile accidents and major gunshot wounds. The considerable morbidity and mortality associated with pancreatic trauma is due in large part to the frequency with which it is associated with other severe intra-abdominal injuries. Nonetheless, pancreatic injuries run the gamut of severity from minor contusions and lacerations to major ductal disruptions. Left untreated, these injuries can lead to devastating sequelae and complications. This is further complicated by the fact that identification of pancreatic injury is often delayed, particularly when associated with a blunt abdominal trauma in the otherwise stable patient.

### **Etiology**

Pancreatic injury may occur as a result of either blunt or penetrating mechanisms, and is a component of up to 12% of major abdominal injuries (121). Stab wounds and gunshot injuries are common penetrating etiologies of pancreatic injury, and occur as a result of direct mechanical disruption to the gland. In contrast, blunt injuries resulting in pancreatic injury are typically the result of high-energy transfer, in which the gland is compressed posteriorly against the spinal column. In adults, up to 60% of these injuries occur in automobile accidents, as a result of compression of the steering wheel against the anterior abdomen (122). In children, blunt pancreatic trauma is attributed to bicycle handlebar injuries in as many as 75% of cases (123).

### **Diagnosis**

Isolated penetrating pancreatic injuries are uncommon (124) because of the gland's retroperitoneal location in close proximity to major blood vessels and other vital organs (Table 5). Penetrating pancreatic trauma is therefore typically identified intraoperatively upon laparotomy performed for other indications, such as evidence of hemorrhage or peritonitis, or identification of a stab wound which is found on digital examination to penetrate the anterior abdominal fascia. Gunshot wounds to the abdomen are themselves an indication for operation in most centers. Rarely, if ever, is emergent laparotomy performed because of isolated

**Table 5** Intra-abdominal Injuries Associated with Pancreatic Trauma

Intra-abdominal organ	Percent of injuries (%)

Source: From Ref. 124.

concern for pancreatic injury (125). Patients requiring laparotomy for the treatment of penetrating abdominal trauma require no additional preoperative evaluation for the specific detection of pancreatic injury. **Pancreatic injuries secondary to penetrating abdominal trauma are best diagnosed within the critical first six hours of injury.**

For the same reasons, identification of pancreatic injury in the unstable patient with blunt abdominal trauma is routinely made in the operating room. In contrast, the diagnosis of blunt pancreatic trauma in the relatively stable patient with no immediate indication for exploration is more difficult, frequently leading to significant delays in definitive diagnosis and treatment. Several factors contribute to this difficulty. First, clinical findings and laboratory values in cases of blunt pancreatic injury are nonspecific. Patients frequently present with abdominal pain, but this is common in trauma patients. Pain out of proportion to physical exam has been suggested as a clue to retroperitoneal injury; this finding is nonspecific and unreliable. Serum hyperamylasemia may be present, but amylase may be normal in as high as 34% of patients with blunt abdominal injury (125). In addition, random elevations in both serum amylase and lipase are frequently found in patients with blunt abdominal trauma but no pancreatic injury (126). Although additional sensitivity may be achieved by performing serial abdominal exams and measuring serial serum amylase levels, this implies a diagnostic and therapeutic delay.

Another factor contributing to a difficulty in diagnosing blunt pancreatic injury is the retroperitoneal location of the gland. Massive retroperitoneal injury may be present in the face of a normal diagnostic peritoneal lavage, which is most suitable for the diagnosis of intraperitoneal injury (127). Likewise, trauma ultrasound is typically used to identify free fluid in the intraperitoneal cavity; it is not as sensitive in the diagnosis of retroperitoneal injury (128).

For these reasons, blunt pancreatic trauma is frequently diagnosed using CT scan, which has a sensitivity of upwards of 80% in the diagnosis of these injuries. Findings suggestive of pancreatic injury on CT include the presence of a parenchymal laceration, peripancreatic fluid collections and hematoma, hemorrhage into the peripancreatic tissues, and focal or diffuse enlargement of the gland

(121). Nonetheless, the use of CT is associated with certain caveats.

**Although CT scans are crucial to the early diagnosis of pancreatic injuries, the scans of patients with significant pancreatic injury may be entirely normal, particularly within the first 12 hours of injury.** As concerning, CT scan is notoriously inaccurate in its ability to diagnose major ductal injuries, and therefore often understages pancreatic injuries compared to findings made at laparotomy (121,129). CT scan should thus be viewed as a valuable tool in the diagnosis of pancreatic trauma, but should not be a substitute for clinical judgment and frequent physical examinations.

### Classification and Assessment of Severity

Commonly used systems of classification of pancreatic injuries reflect the mechanism of an injury, its anatomic location, and its extent, and therefore both facilitate estimation of the severity of injury and help to guide its treatment. The classification system in most widespread use is that of the American Association for the Surgery of Trauma (AAST) (130), in which injuries are graded as follows (Table 6). Grade I injuries consist of minor pancreatic contusions or superficial lacerations without evidence of ductal injury. Grade II injuries represent major contusions or lacerations without ductal injury or substantial loss of tissue. Grade III injuries are those that involve distal transection or major parenchymal injuries that involve the pancreatic ducts. Transections of the gland that are more proximal are named Grade IV injuries, as are major parenchymal injuries that involve the ampulla of Vater. Massive disruptions of the pancreatic head are Grade V.

### Treatment

Up to 75% of trauma victims who die with a pancreatic injury do so within the first 48 hours, often due to exsanguination from associated vascular injuries. Moreover, less than 10% of deaths in patients with pancreatic injury can be attributed directly to the pancreatic injury itself (122). Treatment of patients with abdominal trauma should therefore be initiated with proper resuscitation using standard Advanced Trauma Life Support® (ATLS®) protocols. Surgical procedures should likewise have, as their initial focus, the

**Table 6** American Association for the Surgery of Trauma Classification of Pancreatic Injuries

Grade	Type	Description
I	Hematoma	Minor contusion without duct injury
	Laceration	Superficial laceration without duct injury
II	Hematoma	Major contusion without duct injury or significant tissue loss
	Laceration	Major laceration without duct injury or significant tissue loss
III	Laceration	Distal transection or parenchymal injury with duct involved
IV	Laceration	Proximal transection or parenchymal injury involving ampulla of Vater
V	Laceration	Massive disruption of the pancreatic head

Classification of pancreatic injuries based on mechanism, location of injury, and involvement of the pancreatic duct or ampulla of Vater. In general, a higher score is associated with a higher magnitude of severity.

Source: From Ref. 130.

identification and treatment of associated life-threatening injuries to the vasculature and other solid organs. Control of contamination from intestinal injuries is also of paramount importance. On occasion, this may require a damage control approach, wherein the patient's bleeding is controlled in a first operation and definitive treatment is accomplished in a second operation, performed after hypothermia, acidosis and coagulopathy are corrected in the ICU (131). **Only after the patient is stabilized should attention be turned to the pancreas.**

Patients in whom pancreatic injury is suspected should undergo a complete surgical assessment of the gland, using the surgical maneuvers described above. Careful attention should be paid to the possibility of injury to the pancreatic duct, as its presence has an impact on both morbidity and surgical technique. In general, patients with class I and II injuries which do not disrupt the pancreatic duct require only external drainage, typically to closed suction Jackson Pratt-type drains. Injuries that involve the pancreatic duct, in contrast, may require additional procedures, which are dictated by the location of the injury. Injuries to the left of the superior mesenteric vessels, that is, those in the body or tail of the gland, may be treated successfully by distal pancreatectomy. Although splenic salvage can be attempted in these cases, undue effort should not be used to save the spleen in the unstable patient. If pancreatic duct injury is suspected but cannot be grossly identified, transduodenal pancreatography can be performed, but some authors prefer instead to assume a duct injury exists, because the morbidity of distal pancreatectomy is low and the morbidity of a duodenotomy can be substantial.

In cases in which injuries to the pancreatic head cause disruptions of the main pancreatic duct to the right of the superior mesenteric vessels, treatment may consist of pyloric exclusion or duodenal diverticulization, if the injury is associated with duodenal trauma. These procedures need not be performed for isolated injury to the pancreatic head, for which aggressive external drainage is the favored therapeutic technique. ERCP and stent placement may be used postoperatively to provide proximal drainage of pancreatic secretions. Only in rare circumstances must formal resection of the pancreatic head and duodenum, the "Trauma Whipple," be performed.

Overall, appropriate treatment of pancreatic trauma is associated with satisfactory results (124,132). **The most common complication following operative management of pancreatic trauma is the formation of a pancreatic fistula, which emphasizes the fundamental need for external drainage as part of any surgical operation on the gland.** Even despite such treatment, pancreatic fistula may occur in up to 25% of patients postoperatively. Treatment of this complication is typically conservative, although the use of ERCP for decompression has been successful in decreasing fistula output. Octreotide does not appear to play a role in management (133). Peripancreatic pseudocyst may also occur as a result of inadequate drainage. Abscess formation, pancreatitis, and pancreatic hemorrhage are other less common complications.

## EYE TO THE FUTURE

Evolution in the care of patients with severe acute pancreatitis and pancreatic trauma is ongoing. Major advances in the fields can be grouped into those pertaining to the

diagnosis of these diseases and those dealing with their medical and surgical treatment.

In both pancreatitis and pancreatic trauma, novel diagnostic modalities that could reliably diagnose and predict the severity of disease would be most welcome. To this end, current research is looking at early inflammatory mediators as potential markers for pancreatic inflammation, necrosis, and infection. Elevations in procalcitonin and IL-6 have been recently identified as having a predictive value for the ultimate occurrence of infected necrosis in severe acute pancreatitis (134). Measurement of urinary trypsin activation peptide (TAP), which is released upon activation of trypsinogen to trypsin, has also been shown to be an effective predictor of severe disease, and can be applied within the first 24 hours after its onset (135,136). Assays to measure these and other potential early indicators of severe disease are at present costly and require specialists to both perform and interpret. As experience grows, their acceptance and use should become more widespread.

Similar advances are also being made in the field of pancreatic imaging. MRCP appears to hold particular promise in the diagnosis of benign pancreatic disease. Currently, the use of MRCP is limited due to artifacts that compromise image quality, but improvements in technology should eliminate these problems. While the technique has questionable utility in the care of the acute trauma patient, similar advances in ultrasound and CT diagnostics will likely enable more rapid and definitive diagnosis of patients with pancreatic injury (137).

That these diagnostic advances may improve outcomes of patient's with severe acute pancreatitis, and pancreatic injury is unquestioned. It remains to be seen if advances in surgical technique will likewise have an effect on morbidity and survival. Laparoscopic necrosectomy (138,139), as performed using transgastrocolic or transgastric approaches, has been performed in small groups of patients, in an attempt to successfully debride the pancreas and create effective drainage without the morbidity of a laparotomy. Early results are enticing, but further studies are needed to perfect the procedures and to definitively identify a subgroup of patients for whom this minimally-invasive approach would be beneficial. Laparoscopic abdominal exploration in trauma is also gaining popularity in certain situations, with use of laparoscopy in the diagnosis and definitive treatment of injuries to the pancreas in its infancy (140).

Finally, elucidation of the pathogenic mechanisms behind acute pancreatitis and its effects on distant organ systems has driven investigation into the ability of immunomodulatory therapies, such as the platelet activating factor antagonist lexipafant (141), and drotrecogin alfa (recombinant human activated protein C) (142), to prevent catastrophic local and systemic complications. While no such therapies are currently in use, they represent potentially important novel strategies in the critical care management of pancreatitis.

## SUMMARY

Acute pancreatitis ranges in severity from very mild to catastrophically severe. Patients with severe disease must be identified early. Although measurements such as the APACHE II score can be used for this purpose, the identification of widespread necrosis on an initial CT scan is just as reliable, and thus all patients suspected of having severe disease should receive a baseline CT scan on admission.

Those patients found to have a poor prognosis should be triaged to the ICU. Initial treatment is medical, and should focus on cardiopulmonary support and the prevention of injury to other organ systems. Patients that survive this first phase of treatment frequently develop superinfected pancreatic necrosis and must undergo an operation designed to remove the infected focus and drain the residual cavity. Although late sequelae are not uncommon, long-term morbidity and mortality have been reduced to acceptable levels using this course of therapy.

Morbidity from pancreatic injuries may likewise be substantial. While these injuries may be detected upon laparotomy performed for other indications, the diagnosis of pancreatic trauma is frequently difficult. A high level of suspicion should be maintained. If diagnosed, treatment depends on the severity and location of the injury, as well as on the presence or absence of involvement of the main pancreatic duct. In all cases, aggressive drainage is required to prevent complications such as fistula or pseudocyst formation.

## KEY POINTS

- ☞ Three surgical maneuvers must be performed to completely evaluate the pancreas: (1) entry into the lesser sac via the gastrocolic ligament, (2) division of the leiorenal ligament with full mobilization of the pancreatic tail, (3) mobilization of the duodenum and pancreatic head with a Kocher maneuver.
- ☞ The two leading causes for acute pancreatitis are biliary tract stones and alcohol abuse, which together account for over 90% of cases.
- ☞ Treatment of patients with mild acute pancreatitis can be accomplished on a general medical or surgical ward, and the disease is typically self-limiting, resulting in an uneventful recovery.
- ☞ Serum amylase and lipase are used to diagnose pancreatitis, but their magnitudes are not predictive of disease severity.
- ☞ Whether amylase or lipase is more accurate in the diagnosis of pancreatitis is debatable; in clinical practice, serum levels of both are typically ordered. Concomitant elevation of both enzymes is good evidence for the diagnosis, especially in conjunction with a consistent history and physical examination.
- ☞ Ultrasound may be used to assess complications of acute pancreatitis, such as pseudocyst and aneurysm formation.
- ☞ CT scanning is the diagnostic modality of choice, and a good baseline CT scan is therefore recommended upon admission to the ICU in all patients suspected of having severe disease.
- ☞ Distinguishing between sterile and infected necrosis is imperative.
- ☞ Fluid resuscitation with crystalloid solutions is the cornerstone of management, because immense volume shifts may lead to a depletion of the intravascular volume.
- ☞ Nasogastric suction should not be used routinely, and is limited to those patients who have a high risk of aspiration, or who suffer from a concomitant ileus or bowel obstruction.
- ☞ The use of TPN should be relegated to the small subset of patients who do not tolerate enteral feedings.
- ☞ Current recommendations now support the early administration of prophylactic imipenem (or

ciprofloxacin) in patients with severe pancreatitis and high levels of pancreatic necrosis. Because the rate of pancreatic infection in patients with minimal necrosis is very low, the use of prophylactic agents in patients with mild pancreatitis is not warranted.

- ☞ Three established indications for surgical intervention in severe pancreatitis exist: (1) the presence of infected pancreatic necrosis, (2) failure to improve after a long period of conservative management, (3) acute abdominal catastrophe.
- ☞ Open surgery remains the primary approach for pancreatic necrosis; interventional radiological techniques may subsequently be used successfully to drain residual fluid collections.
- ☞ Pancreatic injuries secondary to penetrating abdominal trauma are best diagnosed within the critical first six hours of injury.
- ☞ Although CT scans are pivotal in the early diagnosis of pancreatic injuries, the scans of patients with significant pancreatic injury may be entirely normal, particularly within the first 12 hours of injury.
- ☞ Only after the patient is stabilized should attention be turned to the pancreas.
- ☞ The most common complication following operative management of pancreatic trauma is the formation of a pancreatic fistula, which emphasizes the fundamental need for external drainage as part of any surgical operation on the gland.

### INTRODUCTION

“All we really know for certain about the kidney is that it produces urine” (1). This statement by the eminent twentieth century renal physiologist and philosopher, Homer Smith, epitomizes the complexity of urine formation. Clinicians often rely on adequate urine output as a sign of tissue perfusion and renal function. Normal urine production (about 1–2 L per day) is the result of a delicate balance between renal and extrarenal factors. This balance is frequently disrupted in patients following trauma and critical illness, which leads to decreased urinary output, or oliguria (oligio = few, small, or little).

Oliguria may be one of the first clinical clues heralding inadequate renal perfusion in trauma and critically ill patients. Understanding the definition, verification process, differential diagnosis and treatment priorities for oliguria constitutes essential fundamental knowledge required of all trauma intensivists. Because oliguria is a normal compensatory response to acute hypovolemia, it has been deemed by some as a sign of renal success rather than renal failure (2).

In the past, oliguria associated with a disease process was viewed by many as a primary renal event that heralded a dysfunctional kidney (renal failure); thus, therapy usually was directed towards restoration of normal urinary output. The concept that during illness or trauma, oliguria may also represent an adaptive mechanism by the kidney in its efforts to restore homeostasis (renal success) was introduced later (2,3).

However, there is a narrow window (approximately 30–60 minutes) between the onset of the protective compensation (renal conservation of sodium and water, resulting in oliguria), and the initiation of ischemic acute tubular necrosis (ATN) in the setting of severe renal hypoperfusion.

Because of the short time span following hypoperfusion of the kidneys and progression to ATN, especially in the setting of pre-existing renal insufficiency, or concomitant toxic exposure, other (indirect) but earlier indicators of renal perfusion (or underperfusion) must be relied upon in order to protect patients and their kidneys from perioperative renal doom.

✎ **Oliguria is often an early sign of renal compromise, representing either a compensatory mechanism for hypoperfusion (hypovolemia and/or hypotension) or an acute renal insult.** ✎ Renal compensatory mechanisms are

limited and progression to overt renal insufficiency can occur over a short period of time (minutes to hours), thus providing a small window for therapeutic intervention (4,5).

This chapter provides an overview of oliguria along with the background knowledge required to understand and promote renal viability following trauma and critical illness. Identifiable factors known to increase the risk for renal insufficiency, and the maneuvers that should be taken to limit renal injury in these susceptible patients are reviewed. The physiology of urine formation, and the pathogenesis of ARF are described.

The appropriate evaluation and treatment of the oliguric patient requires an understanding of the mechanisms involved in urine production, the risk factors, and the pathophysiological entities responsible for oliguria and ARF. An organized approach to the diagnosis and treatment of reversible causes of oliguria must be initiated expeditiously, in order to prevent the poor prognosis of acute renal failure (6,7).

### DEFINITION AND CLASSIFICATION

#### Definition of Oliguria

The standard definition of oliguria in an adult is a urine output <400 mL/day (approximately 15 mL/hr) (8). This volume is based on the amount of maximally concentrated urine required to excrete the normal daily solute load including nitrogenous waste products. In certain clinical conditions (e.g., administration of osmotic diuretics, severe hyperglycemia), a patient may be considered oliguric despite a higher urinary output. Similarly, patients with pre-existing renal dysfunction may be unable to effectively concentrate the urine and thus require a higher urinary output to maintain homeostasis.

#### Definition of Acute Tubular Necrosis

Acute tubular necrosis (ATN) is the death of tubular cells as occurs following prolonged ischemia (hypotension and hypovolemia chiefly) or exposure to toxins (rhabdomyolysis, IV contrast, aminoglycosides, etc.). The pathophysiology of ATN is not completely understood, but a recent review by Gill is recommended (8).

#### Classification of Acute Renal Failure

Traditionally acute renal failure (ARF) has been separated into three major categories: Prerenal, intrinsic renal, and

**Table 1** Major Categories of Oliguria in Trauma and Critical Care

Class	Cause	Examples/comments
Prerenal	Hypovolemia	Blood loss, fluid loss, third space sequestration
	Hepatorenal syndrome	Liver failure and decreased effective intravascular volume
	Cardiac and cardiovascular failure	Infarction, tamponade, arrhythmia, sepsis, anaphylaxis
	Vascular obstruction	Thrombosis (arterial or venous), embolus, aneurysm, amyloidosis
Renal	Hemolysis	Transfusion and immune reactions, malaria
	Rhabdomyolysis	Trauma, muscle damage, heat stroke, malignant hyperthermia
	Nephrotoxins	Radiocontrast, aminoglycosides
	Vasculitis acute, diffuse	Periarthritis
	Pyelonephritis antibiotics	
Postrenal	Obstruction	Catheterized patients: kinked catheter, clot obstruction, false passage Non-catheterized patients: calculi, stricture, neoplasms
	Extravasation	Bladder rupture

postrenal (Table 1) (9,10). This is an incomplete classification system because prerenal oliguria initially is reversible, but when hypoperfusion is allowed to persist for too long, intrinsic renal injury in the form of ATN will occur. Post (or obstructive) renal failure is also initially reversible but when prolonged can cause intrinsic renal injury and failure. Nephrotoxic drugs and pre-existing renal disease can increase the risk of ATN with all these entities. A wide variety of medical conditions not unique to trauma or critical care can also cause renal failure.

## PATHOPHYSIOLOGY

☞ **When the kidneys sense abnormalities in extracellular fluid volume or osmolality, they respond by increasing or decreasing the amount of urine excreted.** ☞ Marked reduction or cessation of urinary output in a trauma or critically ill patient can occur suddenly or over a period of several hours to days. Oliguria may be the harbinger of ATN. Correct diagnosis and treatment are paramount to prevent significant morbidity and mortality.

If oliguria is associated with a prerenal state, a measurable decrease in urine output is present and blood urea nitrogen (BUN) rises to a greater degree than does the serum creatinine, as the kidneys produce concentrated urine to conserve intravascular volume. As renal conservation mechanisms become exhausted, renal failure supervenes, function deteriorates and abnormal serum biochemical values develop. ☞ **Significant oliguria implies a state of renal dysfunction, since a urine output of  $\leq 400$  mL/day is inadequate for excretion of the daily solute load of 650 to 750 mOsm (normal diet) in a maximally concentrated urine (1.2 mOsm/mL).** ☞ Since renal failure also may be associated with a high urine output, both oliguric and polyuric states represent the extremes of a continuum. Thus, a diagnosis of renal failure must take into account the quality of urine excreted as well as the quantity produced.

## Physiology of Urine Formation

160 to 180 L of water, each containing approximately 300 mOsm of solute, are filtered daily through the glomeruli of a healthy adult in a 24-hour period. As the filtrate passes through the proximal convoluted tubules, sodium is actively resorbed into the renal cortical interstitium, chloride follows passively, and water is reabsorbed by osmosis. Ions and

water deposited in the interstitium are rapidly removed by blood perfusing the cortical capillaries, thereby reducing the fluid volume in the proximal tubules by approximately 75%. However, the osmolar concentration remains unchanged.

As fluid flows through the thin, descending limbs of Henle's loops, water diffuses out into the hypertonic interstitium of the medulla and papilla, and sodium and chloride diffuse in. The volume of tubular fluid decreases, and the osmotic pressure progressively increases. In the thick part of the ascending limb of Henle's loops, chloride is extruded into the interstitium. Since water cannot pass through the ascending limbs, the osmolar concentration of the tubular fluid is reduced.

Fluid entering the distal convoluted tubules is hypotonic compared to the surrounding cortical interstitial fluid, and its volume is reduced to 15% of the original glomerular filtrate. Tubular fluid is isotonic with cortical interstitial fluid when it reaches the middle of the distal segment. Active extrusion of sodium and passive osmotic diffusion of water are resumed in the distal tubule, and the volume of tubular fluid volume entering the collecting duct is reduced to approximately 1% of the original glomerular filtrate. Collecting duct fluid, which initially is iso-osmotic, becomes progressively concentrated as it descends through the hypertonic medullary and papillary interstitium.

As water diffuses out of the descending limbs of Henle's loops and the collecting ducts, it is removed by blood flow through the vasa recti of the medulla and papilla. These vessels reduce the loss of osmotically active solutes from the medulla and papilla. Once urine exits the kidney, it is transported to the bladder via ureteral peristalsis, initiated in pacemaker sites located at the junction of the ureter and the renal pelvis.

## Renal Perfusion

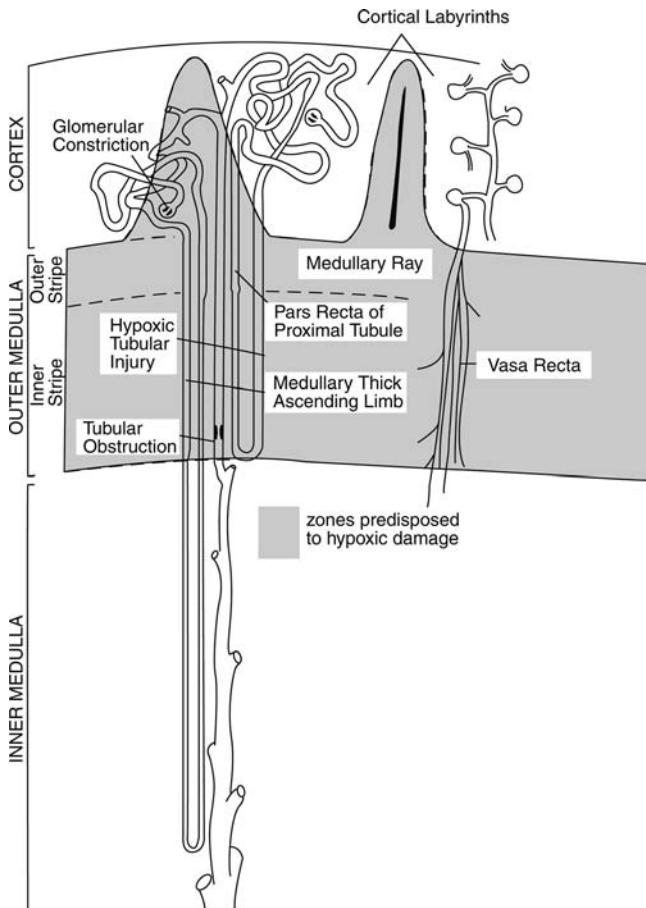

The kidneys receive approximately one-fifth the total resting cardiac output ( $\dot{Q}$ ). However, their oxygen consumption ( $\dot{V}O_2$ ) is rather low (about 10% of total body  $\dot{V}O_2$ ) (11). The three main determinants of renal blood flow are: (i)  $\dot{Q}$ , (ii) renal perfusion pressure, and (iii) local hemodynamic factors such as afferent versus efferent arteriolar tone.

Renal blood flow is preferentially directed to the cortex (90–95%), where most glomeruli are located, in order to optimize filtration and reabsorption. Unlike the cortex,

the medulla receives only a fraction of flow (5–10%), to preserve the osmotic gradient required to concentrate the urine (12). Medullary cells (particularly those on the ascending limb) have a higher oxygen extraction than cortical cells (80% vs. 20%) (13). ⚡ **The high metabolic rate in combination with a lower blood supply places the medullary tubular cells at a higher risk for hypoxic damage, despite what would be perceived as adequate renal blood flow.** (Fig. 1). ⚡

Renal blood flow is constant over a wide range of mean arterial pressures (MAPs) (Fig. 2). The predominant mechanism involves changes in glomerular arteriolar tone with consequent variations in renal vascular resistance. Decreased renal perfusion may occur with low  $Q$  (e.g., hypovolemia), decreased perfusion pressure (MAP) despite adequate  $Q$  (e.g., sepsis), or due to local redistribution of blood flow (as occurs with hepatorenal syndrome). Hypotension due to hypovolemia causes a greater reduction in renal blood flow than hypotension (of a similar magnitude) due to impaired left ventricular (LV) function (14). This difference is caused by the release of atrial and brain natriuretic peptides from the left atrial and ventricular endocardium in response to increased filling pressures (15). These protective endogenous peptides are important renal vasodilators, which also increase GFR and sodium excretion.

The response to renal hypoperfusion is complex and multifactorial, as the kidneys “attempt” to preserve GFR.

**Figure 1** Anatomy of intrarenal zones predisposed to hypoxic injury in acute renal failure. *Source:* From Ref. 136.

**Figure 2** Autoregulation of glomerular filtration rate (GFR) and renal blood flow (RBF), based on the original data of Shipley and Study, GFR and RBF remain constant between a renal arterial pressures of 80 to 180 mmHg. *Source:* From Ref. 137.

Both neurohormonal and hemodynamic factors (local and systemic) are involved (16–18) and include: (i) afferent arteriolar dilatation that, when combined with efferent arteriolar constriction, increases filtration fraction; and (ii) activation of the renin-angiotensin aldosterone (RAA) axis, with increased sodium reabsorption and efferent arteriolar resistance. A low cardiac output will trigger the release of ADH with consequent reabsorption of water in the collecting duct (19). The accompanying sympathetic response produces a further increase in arteriolar resistance.

Intrarenal production of prostaglandins  $E_2$ ,  $D_2$ , and  $I_2$ , each play an important role in local autoregulation of blood flow by acting as renal vasodilators. In the presence of decreased renal blood flow, the release of  $PGE_2$  counteracts the renal vasoconstrictive effects of angiotensin and norepinephrine to preserve renal blood flow (20). Certain nonsteroidal anti-inflammatory agents (NSAIDs) decrease the synthesis of  $PGE_2$  by inhibiting the activity of cyclooxygenase, thereby increasing the risk of renal ischemia in susceptible patients (21).

⚡ **Oliguria in response to hypoperfusion is the result of the kidneys’ self-preservation to circumvent renal failure.** ⚡ Unless the primary insult is corrected, however, these mechanisms eventually become overwhelmed, and tubular necrosis occurs.

## DIFFERENTIAL DIAGNOSIS

### Prerenal Oliguria

Oliguria in trauma and postsurgical patients is most commonly associated with inadequate renal perfusion, stemming from hypotension and inadequate *circulating blood volume secondary to hemorrhage* and/or shift of third space fluids. Other contributors, including nephrotoxic drugs, cardiac failure or preexisting diseases can also be involved, especially during the critical illness. The abdominal compartment syndrome can also play an important role (Chapter 34). When renal blood flow is minimally or moderately depressed, a compensatory increase in filtration fraction occurs, and GFR and urine formulation remain relatively unaffected. However, when depression of renal

blood flow is marked, GFR, urine formation, and electrolyte excretion also are significantly reduced.

Oliguria caused by blood loss, sequestration of fluid into a surgical third space, dehydration, or gastrointestinal loss is a complex problem. If hypovolemia is severe and persistent enough to cause renal ischemia, functional lesions acquire a renal morphological component. In extreme cases, simple prerenal oliguria is transformed into oliguric renal failure (22).

Extravasation of urine outside the bladder following pelvic trauma (Volume I, Chapter 28), may be associated with oliguria. Pelvic fractures are associated with 9% to 15% incidence of a ruptured bladder (23). The uterers are rarely injured, except from direct trauma during surgery.

### **Intrinsic Renal Disease (Acute Tubular Necrosis)**

Renal causes of oliguria are also known as intrinsic renal failure, implying a nonprerenal etiology. This is not necessarily true in trauma patients. Indeed, renal oliguria in trauma and postsurgical patients usually results from uncorrected renal hypoperfusion, leading to ATN. Although primary renal oliguria is not usually associated with trauma and surgery, in certain clinical conditions, oliguria occurs as a result of a toxic insult to the kidney despite adequate renal perfusion.

### **Ischemia**

Prolonged prerenal state, hypotension, hypovolemia, and hypoxia are all common conditions in the critically ill trauma patient and all can cause ATN. Many disparate etiologies, including various nephrotoxins, can lead to ATN via a mechanism involving reduced total or segmental renal blood flow with resultant ischemic injury.

The mortality associated with this syndrome has remained high despite 50 years of improvements in management. This is largely because modern resuscitation practices now prevent ATN in less severely ill patients, and saves the lives of those critically ill patients who formerly would have died. Thus ATN is seen in a progressively sicker subset of patients.

Ischemia causes changes in tubular cell polarity; loss of integrity of the tubular epithelial barrier; necrotic and apoptotic cell death; loss of both viable and nonviable cells, which lift off the basement membrane; and expression of genes characteristic of the embryonic kidney mesenchyme (24,25). The damaged kidney epithelium, however, in contrast to heart or brain, can be completely restored in structure and function.

The kidney possesses a remarkable regenerative capacity after acute ischemic and/or toxic injury. This regenerative capacity manifests itself by proliferation and migration of poorly differentiated cells along the denuded basement membrane of injured tubular segments within a few days after ischemic insult (26). In animal models of repair following ischemic injury, proliferation is observed to be maximal in the straight segment of the proximal tubule located in the outer medulla, where damage is most apparent. The damaged areas of the nephron are repopulated initially by poorly differentiated proliferating cells that have features of epithelial precursors, such as a less well-developed brush border, downregulation of the transcription factor *kid-1* (27), and expression of the intermediate filament protein vimentin, which is normally undetectable in the adult proximal tubule epithelium but is expressed in the embryonic metanephric mesenchyme (26). There are several possibilities for the origin of these regenerating epithelial

cells: (i) epithelial cells may dedifferentiate, proliferate, then redifferentiate into mature tubular cells, as a survival response to injury; (ii) bone marrow stem cells (BMSCs) may home to the injured epithelium, where local cues trigger differentiation; or (iii) a population of renal mesenchymal stem cells exists that may replenish the epithelial cell population after injury.

In addition to tubular cell injury, the peritubular vasculature undergoes changes in response to ischemia associated with ATN. These changes range from activation of inflammatory genes, cell swelling, and disruption of endothelial junctions to detachment of live and dead cells from the basement membrane (28). These endothelial changes, together with persistent, inappropriate vasoconstriction, lead to reduction of peritubular blood flow, which contributes to extension of the initial ischemic insult (29). Although replacement of the lost tubular cells is essential for nephron regeneration, the return of blood flow, which is dependent upon endothelial cell integrity, is also essential for recovery. Recently, it has been suggested that cells repopulating the ischemically injured tubule derive from bone marrow stem cells. More recently Duffield et al. (30–34), showed that these bone marrow-derived cells do not make a significant contribution to the restoration of epithelial integrity after an ischemic insult (30). It is likely that intrinsic tubular cell proliferation accounts for functionally significant replenishment of the tubular epithelium after ischemia.

### **Nephrotoxic Drugs**

Intravenous contrast agents (ionic worse than nonionic) are common causes of ATN. The agents are used in digital vascular imaging and selective renal angiography (31,32). Contrast induced nephropathy is classically oliguric and occurs within 24 hours of use. NSAIDs such as phenylbutazone, ibuprofen, and indomethacin (33,34), and aminoglycoside antibiotics may lead to oliguria and renal insufficiency. The latter agents account for 5% to 10% of all hospital-acquired acute renal failure (35), but ATN does not usually occur with these drugs until >5–7 days of use.

### **Myoglobin and Stroma-Free Hemoglobin**

**♣ Reduction of the GFR rather than tubular obstruction appears to be the primary event leading to oliguric renal failure when stroma-free hemoglobin or myoglobin enters the glomeruli (36,37).** ♣ Also, the transfusion of incompatible blood leads to disseminated intravascular coagulation, with deposition of fibrin in renal tubules. Red cell membranes are thought to initiate the coagulation process, ultimately leading to a decrease in platelets, fibrinogen, and factors II, V, and VII (38). Rhabdomyolysis and Myoglobinuria following extensive, crushing-type muscle injuries also may lead to oliguric renal failure (38,39). The mechanism is probably similar as that for stroma-free hemoglobin.

Oliguria and azotemia have occurred after captopril therapy (40,41) or following treatment with amphotericin B. In the latter situation, renal vasoconstriction is thought to occur concomitantly with nephrotoxicity. Acute oliguria can also occur from thrombosis of the glomerular afferent arterioles following chemotherapy with vinblastine, bleomycin, or cisplatin (42).

Although degradation of sevoflurane to a compound (compound A) that is nephrotoxic in rats has been demonstrated (43), low-flow isoflurane and sevoflurane do not appear to alter renal function in patients with preexisting stable renal disease (44). With the exception of methoxyflurane

(no longer used), anesthetic-induced changes of renal function are readily reversed when administration of the agent is discontinued (45–48).

Intratubular obstruction and backflow of filtrate into damaged tubules may be causative factors (36). Most common in the pathogenesis of ATN is the suppression of glomerular filtration (37). However, light and electron microscopic studies of glomeruli generally failed to reveal structural abnormalities; thus the likelihood is that reduced glomerular filtration is caused by vasomotor phenomena (49).

### Postrenal Oliguria

Obstruction of normal urinary outflow is the most significant disorder in this category. It leads to an increase in hydrostatic pressure in the urinary tract proximal to the obstruction and, ultimately, a marked decrease in GFR. Morphologic damage to the renal parenchyma is related to the degree and duration of obstruction and related factors such as the virulence of associated pyelonephritis, which may develop as a result of urinary stasis.

Extrinsic obstruction can result from the abdominal compartment syndrome (50), retroperitoneal malignancies, rapidly growing cervical carcinomas, massive uterine fibromyomata, complete bilateral ureteral obstruction owing to lymphomatous or leukemic involvement of the lymph nodes (51), giant intra-abdominal cysts (52), and inadvertent ligation of or trauma to the ureters. The latter mishaps occur in 0.1% to 0.25% of patients undergoing gynecologic surgery (53,54).

♣ **Approximately 20% to 25% of ureteral injuries are bilateral, resulting in immediate anuria.** ♣ Fecal impaction in elderly patients can produce obstructive uropathy and oliguria.

Intrinsic obstruction results from blood clots, calculi, prostatic obstruction, neoplasms, fungus balls, bilharziasis, amyloidosis, and benign prostatic enlargement in older patients following operations around the groin or rectum (55–61). Intermittent anuria or oliguria may occur in patients with bladder stones if the calculus acts as a ball valve. Kidney transplant recipients also may develop obstructive uropathy with oliguria (60).

### RISK FACTORS FOR ACUTE RENAL FAILURE

Appropriate management for high-risk patients depends on identifying and minimizing important risk factors for complications, and quickly treating problems when they occur. Accordingly, the first step is to identify the patient at high risk for ARF. Next, evaluate the intravascular volume status and optimize management of preexisting medical conditions (particularly cardiovascular disease). Finally, employ a review of medications and a strict avoidance of any nonessential medications associated with renal insufficiency.

In a recent meta-analysis of preoperative risk factors for postoperative renal failure (involving 28 studies and 10,865 patients), preexisting renal disease emerges as the most important preoperative risk factor for the development of postoperative ARF. Unfortunately, few studies use the same criteria for ARF, and there is a lack of consistent criteria for establishing risk factors. Furthermore, the literature provides little quantitative information concerning the degree of risk associated with most risk factors. However, certain systemic diseases, several known nephrotoxic

drugs, and certain surgical procedures or conditions are associated with an increased risk of renal failure (Table 2).

### Clinical Assessment

In the majority of trauma and postsurgical patients, oliguria signifies renal hypoperfusion often due to either decreased effective circulating blood volume, renal perfusion pressure, or both. At present, no true monitor of renal perfusion exists for clinical use, although some authors have demonstrated that intrarenal blood flow can be evaluated with esophageal Doppler ultrasound (62) (Fig. 3). In practice, one must rely on evaluation of effective circulating blood volume as an indirect surrogate of renal perfusion by measuring arterial blood pressure, LV preload, and  $\dot{Q}$ .

### Mean Arterial Pressure

♣ **The MAP provides an estimate of renal perfusion pressure, whereas the systolic blood pressure variation (SPV) during positive-pressure ventilation may provide information on effective circulating volume (63).** ♣

### Left Ventricular Preload

Because a reliable method to determine intravascular volume is not currently available, clinicians must depend on measurements of cardiac filling pressures or LV size to estimate effective circulating volume. Central venous pressure (CVP) provides an estimate of right ventricular (RV) preload. In the presence of normal left heart function, one can expect a reasonable correlation between CVP and left atrial pressure. This relationship is lost when there is significant LV dysfunction, mitral valve disease, or pulmonary hypertension. Pulmonary artery catheterization can provide indirect estimates of LV filling by measuring pulmonary artery occlusion pressure (PAOP), while cardiac output can be measured intermittently or continuously to determine the response to treatment. Several investigators, however, have shown a poor correlation in critically ill patients between PAOP (as a surrogate of LV diastolic pressure) and direct measurement of LV diastolic volume (64–66). This observation results from changes in ventricular compliance that affects the LV end-diastolic pressure/volume relationship.

Echocardiography can provide visual estimates of ventricular preload and global and regional function. Transthoracic echocardiography (TTE) in the perioperative period is confined to the ICU environment, although the inability to obtain useful acoustic windows (e.g., chest tubes, dressings) significantly limits its usefulness (67,68). Transesophageal echocardiography (TEE), although more invasive, is the technique of choice, particularly in intubated patients. Once the transducer is inserted, evaluation of ventricular function can be performed rapidly and expeditiously (Chapter 21). Additionally, Doppler technology allows measurement of  $\dot{Q}$  and estimates of filling pressures (69,70). While the role of TEE as a continuous monitor in the operating room is well established, the discomfort associated with the large size gastroscope limits its current use as a diagnostic tool in the ICU unless patients are heavily sedated.

### Cardiac Output

♣ **Measurement of  $\dot{Q}$  in combination with MAP determinations is, at present, the most reliable way to evaluate renal perfusion clinically.** ♣ Thermodilution  $\dot{Q}$  obtained via a pulmonary artery catheter is considered the gold standard; however, it is an invasive technique, and its use is

**Table 2** Risk Factors for Perioperative Acute Renal Failure

Category	Disorder/drug/procedure/comments
Pre-existing renal insufficiency	↓'d GFR, ↓'d renal reserve (likely more sensitive to all renal insults)
Prolonged hypovolemia or hypotension during resusc.	Prolonged hypotension or hypovolemia can cause ARF in normal patients, and exacerbates the renal effects of all the above conditions
Procedures associated with ARF	Biliary surgery Burns/trauma Cardiac surgery Genitourinary/obstetric Transplant Vascular surgery (especially suprarenal x-clamp)
Systemic diseases associated with chronic renal failure	CAD, congestive heart failure Diabetes Hypertension (especially renovascular hypertension) Liver failure, jaundice Peripheral vascular disease, Polycystic kidney disease Scleroderma SLE Rheumatoid arthritis Wegner's granulomatosis
Nephrotoxic drug exposure	Acetaminophen (usually with hepatotoxicity) ACE II inhibitors (impairs renal autoregulation) Allopurinol Aminoglycosides (proximal tubule necrosis) Amphotericin B (GN and ATN) Asparaginase Cephalosporins (especially with aminoglycosides) Cisplatin (ATN) Cimetidine, ranitidine (interstitial nephritis) Cyclosporin-A, tacrolimus IV radiocontrast (oliguria within 24 hrs) Methotrexate Metoclopramide (inhibits renal D <sub>2</sub> receptors) Nitrosoureas NSAIDs (especially phenacetin, indomethacin, toradol) [less with selective cyclooxygenase <sub>2</sub> (cox <sub>2</sub> ) inhibitors] Penicillins, sulfonamides, (interstitial nephritis)

*Abbreviations:* ↓'d, decreased; GFR, glomerular filtration rate; ARF, acute renal failure; x-clamp, cross clamp; CAD, coronary artery disease; SLE, systemic lupus erythematosus; GN, glomerulonephritis; ATN, acute tubular necrosis; IV, intravenous; NSAIDs, nonsteroidal anti inflammatory drugs.

associated with complications. Recently, less invasive methods have been developed which utilize CO<sub>2</sub> rebreathing (71,72), esophageal Doppler (73), or arterial thermodilution (74). Early results have shown that these techniques compare favorably with pulmonary arterial thermodilution and may be considered a viable alternative in certain patient populations (75–77).

## Laboratory Data

### Blood Urea Nitrogen and Creatinine

Large amounts of protein, catabolic states, anabolic steroids, and blood in the gut increase urea nitrogen production. Urea nitrogen is freely filterable by the kidneys and is both secreted and reabsorbed by the tubules. In general, an inverse relationship between GFR and BUN exists. ⚡ **Oliguria,**

### hypercatabolism, and blood in the gut may increase the BUN independent of a decrease in GFR. ⚡

Serum creatinine is also inversely proportional to GFR. Creatinine is produced by muscle, and its rates of production and release are related to muscle mass. Creatinine is freely filtered by the glomeruli, a small amount is also secreted by the tubules. Serum creatinine × GFR is a constant in steady state conditions; if GFR is halved, serum creatinine doubles (Table 3). If GFR ceases, the serum creatinine rises about 0.5 to 1.0 mg/dL/day. The increase is much greater following severe trauma with resultant muscle damage, or in rhabdomyolysis. Because creatinine production is related to muscle mass, loss of muscle tissue with renal failure may result in a deceptively low serum creatinine level. In this setting, BUN and serum creatinine values do not accurately reflect acute changes in GFR.

**Figure 3** Pulsed-wave Doppler spectral array of the left renal artery. The negative orientation of the waveform velocities indicates flow away from the transducer. The area within the trace is used to calculate mean velocity. Peak systolic and diastolic values are obtained to calculate pulsatility index (peak systolic velocity – diastolic velocity/mean velocity) and resistive index (peak systolic velocity–diastolic velocity/peak systolic velocity).

Table 4 shows conditions associated with acute elevations in BUN and creatinine.

**Urinalysis**

Complete anuria is unusual (78). Causes include cortical necrosis, vascular accident, glomerulitides, vasculitides, and severe intra-abdominal hypertension. Urinary tract obstruction may result in anuria, but is usually incomplete as the obstructing body changes position. Urine composition may be helpful to distinguish prerenal oliguria from that due to established acute tubular necrosis.

**Urinary Composition**

Amber color urine with a high specific gravity ( $\geq 1.030$ ) suggests preservation of the concentrating ability of the kidney and points towards a prerenal cause. Similarly, urinary indices, such as a low fraction excretion of sodium and high osmolar clearance, suggest a prerenal etiology (Table 5), with the exception of hepatorenal syndrome. This form of renal failure is due to local redistribution of blood flow and is invariably associated with a very low urinary sodium concentration.

The fractional excretion of sodium, the renal failure index, and other urinary indices for differentiating prerenal

failure from acute tubular necrosis are of limited clinical value in the operating room. In the ICU, these indices are often useful, particularly when a nephrology consultation is being obtained. Urine and plasma samples for analysis must be collected before any diuretic agents are administered. Similarly, the diagnostic utility of urinary indices is diminished in the presence of preexisting renal dysfunction or chronic diuretic use.

**☞ In the absence of lower urinary tract trauma, a positive heme result on a dipstick suggests the presence of free hemoglobin or myoglobin in the urine. The latter is characterized by the absence of red cells on urinalysis. ☞**

**Urinary Sediment**

Hyaline and finely granular casts are common in prerenal oliguria; coarse and cellular casts are rarely seen. Oliguria associated with acute tubular necrosis is characterized by dirty, brown cellular casts and numerous epithelial cells and casts. A paucity of formed elements suggests obstruction.

**Imaging Studies**

Supine abdominal radiographs help to determine kidney size and to visualize calcified stones. Further differentiation usually requires more specialized techniques. Urographic studies are used to exclude obstruction and, with modern techniques, are reasonably safe even in acute oliguric renal failure (31,79).

Intravenous pyelography will reveal an immediate, dense, and persistent nephrogram in patients with acute tubular necrosis and pyelonephritis, but not with other forms of oliguria. In prerenal oliguria, the pyelogram is normal; in established oliguric renal failure, the pyelogram is not seen, but the nephrogram may be dense enough to

**Table 5** Urinary Indices and Oliguria

Parameter	Prerenal	Renal

*Abbreviations:* U/P Osm, ratio of urinary and plasma osmolarity; U/P Cr, ratio of urinary/plasma creatinine; C H<sub>2</sub>O, (free water clearance; mL/min), U/P Osm, X urinary volume; U Na<sup>+</sup>, urine Na<sup>+</sup> (mEq/L); FENa<sup>+</sup>, fraction of excretion of sodium, [(U<sub>Na+</sub> · P<sub>Cr</sub>)/(P<sub>Na+</sub> · U<sub>Cr</sub>)] × 100; RFI, renal failure index, U Na<sup>+</sup>/(U<sub>Cr</sub>/P<sub>Cr</sub>).

demonstrate filling defects (retrograde urography may be necessary for precise localization).

Sonography and computed tomography are integral to the evaluation of oliguria (80). Radionuclide studies are useful in the diagnosis of renal artery stenosis, chronic pyelonephritis, and lymphomatous infiltration of the kidney. These studies also may provide functional information for each kidney without resorting to invasive measures (81).

## TREATMENT

### Repletion of Intravascular Volume

☞ Maintenance or prompt restoration of adequate renal perfusion is paramount to minimize the risk of ATN. ☞ In patients at risk for contrast nephropathy, appropriate hydration is necessary in order to minimize the renal effects of the contrast material. In addition, several other measures have been tested with varying success (Table 6). Recently, *N*-acetylcystine has been shown to prevent renal failure in high risk those with preexisting renal insufficiency (82,83).

### Restoration of Circulating Blood Volume

Restoration of circulating blood volume to values as near normal as possible is a major goal in hypovolemic patients, regardless of the etiology of the deficit. During surgery, additional fluid losses may occur owing to hemorrhage, formation of a surgical third space, or evaporative loss from exposed intestinal surfaces. Postoperative hypovolemia should be avoided as carefully as during the preoperative or intraoperative periods.

As a general rule, replacement fluid should match the type of fluid that has been lost. The importance of intravascular volume replacement in surgery, shock, and trauma is obvious. Exsanguination necessitates blood volume replacement. When blood loss is less severe, or when hypovolemia has been present for a prolonged period, options other than blood replacement alone should be considered.

Hypertonic solutions are beneficial in resuscitation from shock and trauma. Compared to isotonic solutions, the lesser volumes required are associated with equivalent or

improved systemic blood pressure, cardiac output, and survival in experimental animals. A positive cardiac inotropic effect results, as well as a decrease in systemic vascular resistance. Restoration of normal cellular transmembrane potential is enhanced, indicating a reversal of the cellular abnormalities induced by hemorrhagic shock. As long as 24 hours after the shock episode, blood pressure is maintained more efficiently than with Ringer's lactate alone or a combination of Ringer's lactate with added mannitol.

7.5% saline has been shown to be more beneficial with respect to survival than 0.9%, 5% or 10% saline solutions. Improved tissue perfusion occurs, as indicated by reduced lactate values. An early increase in urine output, decreased fluid retention, and improved late pulmonary function are also demonstrable. Currently, only 3% solutions are available "off-the-shelf" in the United States.

RescueFlow<sup>®</sup> (BioPhausia, Knivsta, Sweden) is a 250 mL solution containing 7.5% sodium chloride and 6% dextran 70. It represents a "new concept" drug for "Small Volume Resuscitation," is currently registered in 14 European countries, and is recommended as a volume substitution solution in trauma. However, this is not a new concept (as claimed by the manufacturer), having been promulgated in the early 1970s for burn therapy. Nevertheless, a prepackaged resuscitation solution combining the advantages of crystalloid and colloid is certainly convenient and probably useful. The increased intravascular volume provided by 250 mL of RescueFlow<sup>®</sup> is alleged to be two to three times the infused volume, equivalent to the increase in volume resulting from intravenous administration of 3 L of crystalloid solution. Treatment benefits have been observed in patients with severe injuries such as penetrating injury requiring surgery and for patients requiring intensive care (84). Application for FDA approval in the United States has been submitted.

More recently hypertonic saline (HS) along with the phosphodiesterase inhibitor HPX has shown less organ damage in gut and lung (Volume 1, Chapter 11) (85). However, the effect on renal function has not yet been studied.

Although the administration of hypertonic crystalloid solutions can produce hypernatremia, this condition will not have an adverse effect on renal function and oliguria as long

**Table 6** Preventive Strategies During Administration of Contrast Dye

#	Strategy	Rationale
1	Vigorous hydration before, during, and after the procedure	Decrease osmotic stress; Nephrol Clin Pract 2003; 93: C29–C34
2	Prevention of hypotension	Prevent renal hypoperfusion; <counteracts #1 above>
3	Use of low contrast volume (<5 ml/kg ÷ [Cr])	Decrease toxic load; Am J Cardiol 2002; 90:1068–1073
4	Low osmolality contrast	Radiology 1993; 188:171–178
5	<i>N</i> -acetyl cystine 600 mg orally every 12–48 hrs	Antioxidant and vaso dilation effects; Nephrol 2004; 15:251–260
6	Consider alkalization of urine	Decreasing pH dependent free radicals; JAMA 2004; 291:2328–2334
7	Avoidance of mannitol and loop diuretics in the presence of renal dysfunction	Can counteract (1–3)
8	Peri procedure hemofiltration	N Engl J Med 2003; 349:1333–1340
9	Administration of DAI receptor agonists (e.g., fenoldopam)	Not proven to help but probably won't hurt

Abbreviations: Cr, creatinine, DAI, dopaminergic type 1.

as the serum osmolality stays  $<330$  mosm/dl. ⚡ **Conversely, if hypotonic solutions are administered in large amounts (as frequently happens following resuscitation when 0.45% saline or dextrose solution is ordered), the resultant hyponatremia and water intoxication may essentially “shut down” the kidneys.** ⚡ This situation was clearly described in 1951 (86). Earlier, in 1944, the surgical admonition was to avoid the use of any saline-containing solutions on the day of surgery and the first two postoperative days (87). It was felt that major surgery and anesthesia altered renal function so severely that the kidneys could not tolerate a salt and water load (Table 7). Indeed, the postoperative oliguria noted seemed, superficially, to support this concept. However, the changes, which at that time were thought to represent potential cardiac decompensation, actually reflected the water intoxication syndrome subsequently described by Bristol (Table 8) (86).

Finally, bear in mind that relative hypovolemia in conditions such as the abdominal compartment syndrome (Chapter 34) can play a role in the patient's problem. Emergency decompression may be necessary in order to restore renal blood flow (88).

### Drugs that Increase Renal Perfusion

There are a series of clinically available drugs that increase renal perfusion. These do not necessarily increase renal function or systemic perfusion, and have not been shown to improve outcomes or decrease the rate of renal failure. None of these drugs should be contemplated in the hypovolemic patient. After restoration of intravascular volume and systemic perfusion, some of these drugs may ultimately be found to be beneficial (as of yet this has not been shown).

### Dopaminergic Agents

#### Dopamine

It is generally accepted that Dopamine in doses between 1 and 5  $\mu\text{g}/\text{kg}/\text{min}$  causes renal and splanchnic vasodilation from stimulation of dopaminergic type 1 (DA1) receptors (89–91). In animals and healthy humans, as well as those with severe LV dysfunction, infusion of dopamine at doses  $<5$   $\mu\text{g}/\text{kg}$  is associated with diuresis, increased renal blood flow and GFR. ⚡ **Although it has been used for many years to improve renal perfusion and facilitate diuresis, no convincing evidence has yet shown “renal dose” dopamine to be renal protective.** ⚡ Recent reviews of the published literature in oliguric critically ill patients suggest a lack of benefit and possibly harmful effects associated with dopamine administration (92,93). Possible reasons include the greater variability of dopamine levels (94), which may induce renal vasoconstriction from stimulation of vascular

$\alpha$  receptors (94,95); the lack of efficacy with high renin levels (95); and the development of tolerance to the drug (96).

#### Dopexamine

Dopexamine is a dopamine analog with predominant affinity for DA1 and  $\beta$ -2 receptors (97,98). Its overall effects include systemic vasodilatation, mild inotropy, and increased cardiac output. In healthy volunteers, dopexamine was shown to increase renal blood flow, independent of systemic hemodynamic effects (99). Doses between 1 and 4  $\mu\text{g}/\text{kg}$  are associated with a proportional reduction in renal vascular resistance up to 30% (100). In surgical patients, the evidence of a direct renal effect is mixed (101,102).

#### Fenoldopam

Fenoldopam is a synthetic catecholamine with selective affinity for the DA1 receptor (103,104). At low doses (0.03  $\mu\text{g}/\text{kg}/\text{min}$ ), fenoldopam acts as a renal vasodilator, whereas higher doses (0.1 to 0.3  $\mu\text{g}/\text{kg}/\text{min}$ ) decrease venous capacitance and modestly reduces systemic vascular resistance with a concomitant increase in cardiac output (105). Fenoldopam also increases GFR and diuresis. Increase in renal blood flow occurs in the absence of systemic hemodynamic effects, thus confirming fenoldopam's direct effects on the renal vasculature (106,107).

### Natriuretic Peptides

#### Atrial Natriuretic Peptide

Atrial natriuretic peptide (ANP) is a polypeptide hormone found mainly in the left atrium. It is released in response to atrial stretching, and thus to elevated blood pressure (108). ANP reduces blood pressure by stimulating the rapid excretion of sodium and water in the kidneys (reducing blood volume), relaxing vascular smooth muscle (causing vasodilation), and through actions on the brain and adrenal glands. It appears to inhibit renin secretion, decrease aldosterone release, and may have a mutually antagonistic interaction with endothelin (109).

Administration of ANP increases GFR and may reverse renovascular hypertension. Animal studies suggest that it decreases azotemia and renal histologic damage in renal failure (110,111). A recent study in critically ill patients demonstrated improved renal function and increased dialysis-free periods in patients with oliguria who were treated with ANP; however, a followup study failed to demonstrate any difference (112). Blood pressure is less affected in oliguric renal failure than in nonoliguric states.

**Brain Natriuretic Peptide**

Peptide plasma brain natriuretic peptide (BNP) is a 32-amino acid polypeptide. The cardiac ventricles are the major source of plasma BNP. This circulating peptide has been used as a marker to assist in the diagnosis of congestive heart failure (113). In general, plasma BNP levels correlate positively with the degree of LV dysfunction, but they are sensitive to other biological factors such as age, sex, and diastolic dysfunction. Plasma BNP levels greater than 100 mg per mL are reported to support a diagnosis of abnormal or symptomatic heart failure. The pharmacological actions of BNP include vasodilation, increased GFR (due to afferent arteriolar vasodilation and efferent arteriolar vasoconstriction), decreased secretion of aldosterone, and inhibition of tubular reabsorption of sodium (114,115).

Synthetic BNP (Nesiritide) is available for clinical use in the treatment of decompensated congestive heart failure. Diuretic effects are seen at doses ranging from 0.015  $\mu\text{g}/\text{kg}/\text{min}$  to 0.3  $\mu\text{g}/\text{kg}/\text{min}$  (116). To date, no studies have been performed in oliguric critically ill patients.

**Diuretics**

As with drugs (discussed above) that increase renal perfusion, diuretics should never be administered to patients, who are prerenal (i.e., hypovolemic). The efficacy of diuretics in the treatment of critically ill patients with oliguria is variable. Because these agents are potentially harmful, their mechanisms of action must be understood if they are to be employed in the treatment of oliguria. These drugs should only be administered in patients who are intravascularly replete. A common error occurs when clinicians note that a patient is total body fluid overloaded but fail to recognize that the patient is also intravascularly depleted. When these patients are treated with diuretics, they can trigger conversion from prerenal oliguria to ATN and hence renal failure.

**Loop Diuretics**

☞ **Loop diuretics such as furosemide, bumetanide, and indapamide are commonly used in an effort to “convert” an oliguric patient to a nonoliguric state. Loop diuretics block sodium reabsorption in the loops of Henle and distal**

**convoluted tubules.** ☞ Furosemide is also a modest vasodilator of the renal vasculature (117), thus contributing to redistribution of intrarenal blood flow independent of the action of prostaglandin  $E_2$  (118). It may modulate renin secretion by the macula densa, thereby preventing the harmful effects of vasoconstriction on the glomerular apparatus.

If diuretics are not completely effective, they still may improve the clinical situation by converting oliguric renal failure to high output renal failure. The latter condition seems to be more easily managed than the former, although data supporting this concept are questionable. In addition, there appears to be no difference in outcome (119).

**Osmotic Diuretics**

☞ **Drugs such as mannitol produce diuresis because they are filtered by the glomerulus but not reabsorbed in the renal tubule; thus, they obligate the excretion of water.** ☞

Besides inducing an osmotic diuresis, other renal actions of mannitol include: (i) decreased renovascular resistance with consequent increase in blood flow, (ii) increased GFR, (iii) diuresis and natriuresis due to inhibition of tubular reabsorption of salt and water, (iv) decreased medullary hypertonicity with impairment of urinary concentration, (v) increased renal interstitial and intratubular pressure, (vi) release of ANP and renal prostaglandins, and (vii) scavenging of  $O_2$  radicals (120,121). Because of the accompanying increase in blood volume, osmotic diuretics are contraindicated in patients with oliguria and congestive heart failure.

**Distal Tubule Diuretics**

The use of distal tubule diuretics such as thiazides and metolazone is reserved to provide synergism to loop diuretics. These agents can only be administered orally, and thus their absorption may be unpredictable in some patients. Features of various diuretics utilized in the treatment of oliguria are shown in Table 9.

**Table 9** Classification of Diuretic Agents

Class	Examples	Site of action	Mechanisms	FENa	K	$HCO_3^-$
Loop diuretics	Furosemide, ethacrynic acid, bumetanide	MTAL	Inhibits Na-2K-2Cl symporter	20–25%	+	–
Thiazides	Chlorothiazide, hydrochlorothiazide, metolazone	Early distal tubule	Inhibit NaCl uptake	5–8%	++	+/-
Plasma-sparing	Triamterene, amiloride	Late distal tubule, collecting ducts	Inhibit Na uptake	<5%	–	–
	Spironolactone	Late distal tubule, collecting ducts	Aldosterone antagonism	<5%	–	–
Carbonic anhydrase inhibitors	Acetazolamide	Proximal tubule	Decreased intracellular $H^+$ formation (bicarbonate loss)	<5%	+	+++
Osmotic diuresis	Mannitol	Throughout tubule	Osmotic pressure: prevention of $H_2O$ absorption by permeable segments of the nephron	<5%	+	+/-

*Abbreviations:* +, increased urinary loss; –, decreased or no urinary loss; Cl, chloride; FENa, fractional excretion of sodium (sodium clearance/creatinine clearance  $\times$  100%);  $H^+$ , hydrogen ion;  $HCO_3^-$ , bicarbonate; K, potassium; mTAL, medullary thick ascending loop of Henle; Na, sodium.

*Source:* From Ref. 139.

### Spironolactone

In the hepatorenal syndrome, the effects of diuretic agents are variable, depending upon the degree of disease (110). In the earliest stages of cirrhosis, urinary sodium excretion is plentiful, and salt balance can be controlled by adjusting dietary intake. As the disease progresses, increased salt retention accompanies a progressive decline in renal function. Eventually, the filtered load of sodium becomes completely reabsorbed by the tubules, and the final urine becomes virtually devoid of salt.

When the filtered load is completely reabsorbed proximal to the thick ascending limb of Henle, the patient is resistant to the effects of diuretics and requires more invasive procedures such as repetitive large volume paracentesis or AV hemofiltration to remain in salt balance. However, mortality and hepatic regeneration do not appear to be affected by such interventions (111). In the terminal stages, the GFR falls to such a degree that oliguria, azotemia, and eventually uremia lead to the diagnosis of hepatorenal syndrome. Renal vasoconstriction at this point is severe and irreversible. Only after a successful liver transplant can restoration of near normal renal function be obtained.

### Diuretic Resistant Oliguria

Lack of response following incremental doses of diuretics characterizes this abnormality (122,123). The most common condition in the acute setting is renal hypoperfusion due to decreased circulating volume, leading to increased sodium and water reabsorption from the renal tubules. This condition is not uncommon in critically ill patients.

Diuretic resistance can also be seen in patients receiving long term diuretics due to hypertrophy of the cells of the medullary ascending limb (124). In patients with chronic failure of the heart, liver or kidneys, a lack of response may be seen due to decreased renal perfusion (ACE inhibitors and diuretics), decreased delivery of either sodium or diuretic to the limb cells, or impaired cellular function (125).

The following therapeutic strategy is suggested: (i) Restore renal perfusion by optimizing hemodynamic function and intravascular volume, (ii) Administer a high dose of diuretic (furosemide, 100–200 mg or bumetanide, 4–5 mg) once and observe for response (126). The lack of response may indicate a severe renal insult, and further doses must be avoided to prevent toxic side effects. Alternatively, a continuous infusion (furosemide 5–20 mg/hr) may achieve better results by maintaining a steady concentration and delivery of the drug to the kidney (127,128), (iii) Concomitant administration of diuretics with different mechanisms of action. The purpose of this strategy is to block the various segments of the nephron engaged in tubular reabsorption. A popular combination is the administration of Metolazone (blocks the reabsorption of sodium in the distal tubule) with a loop diuretic. Acetazolamide (proximal tubular blocker) and spironolactone are not routinely used because they can exacerbate acidosis and hyperkalemia, (iv) Patients with liver disease may benefit from the concomitant administration of albumin and furosemide due to increased delivery of the drug to the kidney (129), (v) A trial of fenoldopam or nesiritide by infusion may be indicated. Increased diuresis is usually seen after a couple of hours. The infusion probably should be stopped if no measurable response is seen after six hours.

### Miscellaneous Agents

Despite salutary effects associated with the use of some diuretics and renal vasodilators, their effects on outcome have been disappointing. Thus, the search for newer agents continues. ⚡ **Since the pathogenesis of acute oliguria is multifactorial, a targeted approach involving drugs with various mechanisms of action may be indicated.** ⚡ Adenosine receptor antagonists, calcium channel blockers, endothelin antagonists, and phosphodiesterase inhibitors conceivably can improve renal flow (130–133). Lazaroids and antioxidants (e.g., acetylcysteine) may prevent and decrease reperfusion injury (134). Small peptides such as arginine-aspartate-glycine decrease cell adhesion and may decrease tubular obstruction (135). Although animal models and small clinical trials have shown some promising results, their future clinical use must await the results of well-conducted clinical outcome studies.

### Relief of Renal Obstruction

In the treatment of postobstructive uropathy, prompt intervention is essential, because prolonged ureteral obstruction may result in irreversible loss of renal function. The degree of renal damage is related to the degree of obstruction, its duration, and the presence or absence of infection (31).

### Bladder Catheterization

If the patient is in severe pain, or if the bladder appears to be overdistended, a single in-and-out catheterization is appropriate. If too much time is permitted to elapse before the first postoperative voiding, the bladder becomes grossly overdistended and atonic. In this situation, an indwelling catheter should be inserted for five to seven days.

### Surgical Considerations

Complicated cases of postrenal oliguria often require surgical intervention. Percutaneous nephrostomy may be necessary in high obstruction, while suprapubic cystostomy may be satisfactory for bladder obstruction. ⚡ **Massive diuresis occasionally follows relief of obstruction, and thus signs of hypovolemia and electrolyte imbalance must be monitored in these patients.** ⚡ Hypotension sometimes follows rapid decompression of an over-distended bladder.

### EYE TO THE FUTURE

Our understanding of the mechanisms that lead to perioperative oliguria and renal failure has increased significantly. Although initial enthusiasm for new agents has been tempered by rather unimpressive results, new approaches continue to be examined. Similarly, the widespread use of time-honored techniques (e.g., dopamine, loop diuretics) may be limited to special circumstances due to a lack of overall efficacy and possible harm.

The importance of risk factors for acute oliguria and renal failure, such as renal medullary hypoperfusion and renal atheroembolism, is now increasingly recognized. The role of esophageal ultrasonography as a real-time monitor of renal blood flow is beginning to be evaluated. Since the etiology of perioperative oliguria is more often multifactorial, it is not surprising that a multifaceted approach will be necessary in order to show a benefit in outcome.

## SUMMARY

Acute oliguria is a common finding in patients undergoing major surgery or after significant trauma. Identifying risk factors and understanding the mechanisms of urine formation are essential steps in the prevention and management of oliguric patients.

In the majority of surgical patients, renal hypoperfusion and nephrotoxins play a significant role. Thus, prompt restoration of adequate renal perfusion and limiting the effects of toxins on the nephron are essential components of therapy that should be carried out before irreversible damage occurs. Since a reliable monitor for renal perfusion is not widely available, the clinician must rely on frequent evaluation of hemodynamic status and indirect measures of renal function for the prevention and timely management of oliguria.

Similarly, knowledge of the mechanism of action of the various pharmacological agents is necessary in order to maximize renal protection while minimizing side effects. Strategies such as the indiscriminate use of diuretics to convert patients to a nonoliguric state or the use of low-dose dopamine, have failed to demonstrate a favorable outcome. Conversely, osmotic diuretics and DA1 receptor agonists may help to preserve renal function in some patients. At present, avoidance of hypovolemia and maintenance of adequate renal perfusion are the cornerstones of therapy to preserve renal function in high-risk patients.

## KEY POINTS

- ✂ Oliguria is often an early sign of renal compromise, representing either a compensatory mechanism for hypoperfusion (hypovolemia and/or hypotension) or an acute renal insult.
- ✂ When the kidneys sense abnormalities in extracellular fluid volume or osmolality, they respond by increasing or decreasing the amount of urine excreted.
- ✂ Significant oliguria implies a state of renal dysfunction, since a urine output of  $\leq 400$  mL/day is inadequate for excretion of the daily solute load of 650 to 750 mOsm (normal diet) in a maximally concentrated urine (1.2 mOsm/mL).
- ✂ The high metabolic rate in combination with a lower blood supply, places the medullary tubular cells at a higher risk for hypoxic damage, despite what would be perceived as adequate renal blood flow.
- ✂ Oliguria in response to hypoperfusion is the result of the kidneys' self-preservation to circumvent renal failure.
- ✂ Reduction of the GFR rather than tubular obstruction appears to be the primary event leading to oliguric renal failure when stroma-free hemoglobin or myoglobin enters the glomeruli (32,33).
- ✂ Approximately 20% to 25% of ureteral injuries are bilateral, resulting in immediate anuria.
- ✂ The MAP provides an estimate of renal perfusion pressure, whereas the systolic blood pressure variation (SPV) during positive-pressure ventilation may provide information on effective circulating volume (63).
- ✂ Measurement of  $\dot{Q}$  in combination with MAP determinations is, at present, the most reliable way to evaluate renal perfusion clinically.
- ✂ Oliguria, hypercatabolism, and blood in the gut may increase the BUN independent of a decrease in GFR.

- ✂ In the absence of lower urinary tract trauma, a positive heme result on a dipstick suggests the presence of free hemoglobin or myoglobin in the urine. The latter is characterized by the absence of red cells on urinalysis.
- ✂ Maintenance or prompt restoration of adequate renal perfusion is paramount to minimize the risk of ATN.
- ✂ Conversely, if hypotonic solutions are administered in large amounts (as frequently happens following resuscitation when 0.45% saline or dextrose solution is ordered), the resultant hyponatremia and water intoxication may essentially "shut down" the kidneys.
- ✂ Although it has been used for many years to improve renal perfusion and facilitate diuresis, no convincing evidence has yet shown "renal dose" dopamine to be renal protective.
- ✂ Loop diuretics such as furosemide, bumetanide, and indapamide are commonly used in an effort to "convert" an oliguric patient to a nonoliguric state.
- ✂ Drugs such as mannitol produce diuresis because they are filtered by the glomerulus but not reabsorbed in the renal tubule; thus, they obligate the excretion of water.
- ✂ Since the pathogenesis of acute oliguria is multifactorial, a targeted approach involving drugs with various mechanisms of action may be indicated.
- ✂ Massive diuresis occasionally follows relief of obstruction, and thus signs of hypovolemia and electrolyte imbalance must be monitored in these patients.

### INTRODUCTION

Acute renal failure (ARF) is a syndrome characterized by the rapid (hours to days) loss of glomerular filtration and the accumulation of nitrogenous waste products (1). Unlike the acute respiratory distress syndrome (ARDS), which has a clinical consensus definition (2), ARF continues to be defined differently by various investigators. For this reason, the precise incidence of ARF is unknown; however, amongst the published studies, using a variety of definitions, the estimated incidence of ARF in critically ill patients ranges between 15% and 30%, and portends an increased mortality in affected patients by as much as 40% to 60% (3–6). Recently, a group of international nephrology leaders have been meeting to develop a consensus definition of ARF amongst other issues, and it is likely that standards for the diagnosis of ARF will soon be in place (7), and the term acute kidney injury (AKI) may become used in place of ARF.

The etiology of ARF is often multi-factorial, and aside from renal replacement therapy and improved general supportive care there is yet to be an effective therapy introduced which significantly alters the morbidity or mortality of ARF. Numerous drug interventions, including dopamine, insulin-like growth factor, and anaritide (synthetic atrial natriuretic peptide), have failed to show significant benefit (see Chapter 42) (8–10). Renal replacement therapies and transplantation are associated with a number of comorbidities, and are imperfect solutions. Thus, prevention of ARF and early recognition of renal insufficiency are the most important goals of renal management (11).

Over the past couple of decades, multiple organ dysfunction syndrome (MODS) has become a common pathway toward death for critically ill patients, including those who are septic (12,13). The kidney is nearly always one of the organs that fail in MODS. **Recent studies indicate that an increased relative risk of death is associated with kidney failure when adjusted for a wide range of covariates (14,15). Accordingly, early and accurate indicators of renal insufficiency or failure are essential to the management of critically ill patients.**

This chapter briefly surveys the pathogenesis of acute tubular necrosis (ATN), which is the chief cause of ARF in trauma and critically ill patients, and emphasizes the role of the prerenal state. Next, the role of various renal toxins are reviewed, followed by a summary of the basic diagnostic approach. Both direct and indirect measures of renal

function are clinically useful, and these are emphasized. Finally, specific renal failure scenarios of significance for trauma and critical care are reviewed in order to highlight the diagnostic clues, which assist in early recognition and treatment. The “Eye to the Future” section emphasizes newer diagnostic tests, which may become useful in the diagnosis of ARF and in the monitoring of renal well-being.

### PATHOGENESIS: ROLE OF HYPOPERFUSION

Of the numerous mechanisms of renal compromise that can lead to ARF, the most prominent is hypoperfusion. Indeed, hypoperfusion is a frequent element in two of the three major classes of ARF.

Those three traditional categories of ARF are prerenal, intrarenal, and postrenal. When clearance is limited by factors that decrease renal perfusion, the syndrome is classified as “prerenal failure” or “prerenal azotemia.” When dysfunction is due to damage within the kidney itself (e.g. ATN), it is termed “intrarenal” or “intrinsic” renal failure. If renal dysfunction occurs as a consequence of obstruction of the urinary outflow tract, then it is classified as “postrenal failure.” Obstructive uropathy is rarely the etiology of ARF following trauma or critical injury, unless there has been disruption of the ureters.

**Intrinsic or intrarenal ARF has many causes, but in trauma and critical care settings, the great majority of cases are due to acute tubular necrosis (ATN) following on from a prerenal hypoperfusion state.**

Initially the underperfused kidney is still capable of physiologic adaptation, conserving salt and water to create a urine of high osmolality and low sodium content. This is the picture typical of the prerenal state. As hypoperfusion continues, however, the renal tubular cell mass, which has a high metabolic requirement, begins to fail in its tasks of urinary concentration and sodium reabsorption. Thus the urine osmolality begins to fall; initially during this phase, correction of prerenal deficits still has a good chance of restoring renal function. But with further progression, the urine osmolality falls further, approaching that of the plasma (“isosthenuria”), signifying serious tubular damage and the onset of ATN. Additional factors, such as tubular obstruction from sloughed renal tubular cells, and inhibition of glomerular filtration by the tubuloglomerular feedback system, then come in to play, reducing

the glomerular filtration rate (GFR) further. The kidney then cannot even reabsorb sodium effectively, leading to the established picture of ATN, with high fractional excretion of sodium, low urine osmolality, and usually oliguria (16). Established ATN begins to heal only when good renal perfusion is reestablished, and usually takes a period of many days to weeks to recover. Prerenal causes are responsible for more than 90% of perioperative ARF (17). This is why perioperative renal function monitoring, and early treatment of oliguria (Chapter 40) are paramount clinically.

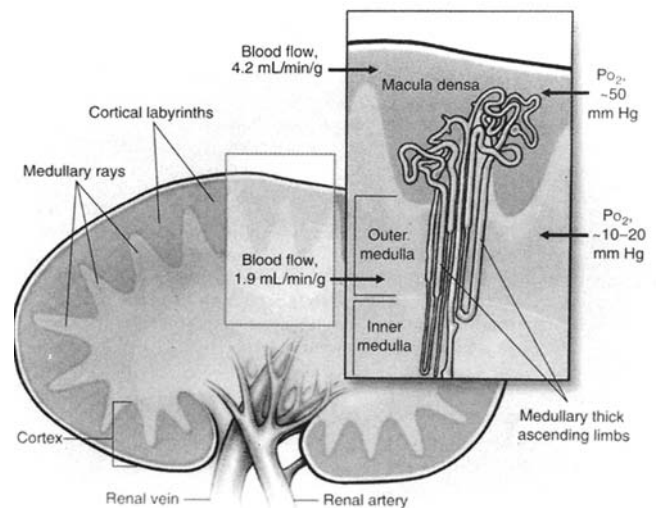

In trauma and critically ill patients with inadequate blood flow (prerenal), injury is often triggered by an additional assault on the nephron from harmful drugs (altering intrarenal distribution of blood flow by abnormal hemodynamics) or by pre-existing disease (e.g., diabetes) (18). Patients with pre-existing renal insufficiency, for example, are especially prone to develop ARF during cardiovascular surgery. Patients with diabetes mellitus and renal insufficiency are especially vulnerable to radiocontrast agents (19). Intrinsic renal causes that result in ARF are described according to the primary lesion (i.e., tubules, interstitium, vessels, or glomerulus). Tubular injury is the most common type seen in trauma and post-surgical patients (20).

Normally, the RBF is about 20% to 25% of the total cardiac output. The amount of blood the kidneys receive in the resting state (1000–1250 mL/min) far exceeds that needed to provide their intrinsic oxygen requirement. Essentially, all blood passes through glomeruli, and about 10% of RBF is filtered (resulting in a GFR of approximately 125 mL/min in the normal adult). The basal normal blood flow is 3 to 5 mL/min/g of tissue. This average primarily reflects blood flow in the cortical glomeruli, because perfusion to the inner medulla and papilla is only about one tenth of the total flow (21).

Renal clearance is determined by the delivery of waste products to the kidney (i.e., RBF) and the kidney's ability to extract them (GFR). When RBF is decreased (hypotension, hypovolemia), a series of systemic and renal compensatory responses are activated initially to preserve ultrafiltration and renal clearance. **The hallmark that underscores experimental models of hemodynamically mediated ARF is a reduction of RBF (injury generally results when RBF is reduced by more than 50%) for at least 40 to 60 minutes.** Once a decrease in renal perfusion is established, then glomerular filtration is disproportionately depressed, compared with the decrease in blood flow. Indeed, it has been observed that when RBF is decreased sufficiently to cause depression of glomerular filtration to less than 5% of normal, blood flow may only be depressed 25% to 50% of normal (20). Hence, although decreased RBF is the initiating event, most of the time other factors (e.g., tubular pathology) can sustain abnormal filtration, besides decreased RBF.

The renal cortex contains most of the glomeruli and receives the majority of the RBF, optimizing glomerular filtration and solute reabsorption. In contrast, blood flow to the medulla is lower, and this relationship helps to preserve the osmotic gradient required to maximally concentrate the urine.

During ischemic hypoxia, the renal cortical structures can become injured, particularly the pars recta portion of the proximal tubules. However, it is the medullary thick ascending limb (mTAL) of the Loop of Henley that is at greatest risk of hypoxic injury. This is because the mTAL cells are the most rapidly metabolizing cells in the nephron, and because they exist in an environment, which teeters on the

**Figure 1** Anatomical and physiologic features of the renal cortex and medulla. The cortex receives ample blood supply, optimizing glomerular filtration. Accordingly, it is generally well oxygenated (except for the medullary-ray areas, which are devoid of glomeruli and are supplied by venous blood ascending from the medulla). The medulla possesses a meager blood supply and is poorly oxygenated. Medullary hypoxia results both from countercurrent exchange of oxygen within the recta and from the consumption of oxygen by the medullary thick ascending limbs. Renal medullary hypoxia is an obligatory consequence of the process of urinary concentration. *Abbreviation:* PO<sub>2</sub>, partial pressure of oxygen. *Source:* From Ref. 26.

verge of hypoxia at baseline (Fig. 1). Thus, heterogeneity of intrarenal blood flow and cellular metabolic rate contribute to the pathophysiology of ischemic acute renal failure.

Furthermore, an imbalance between the intrarenal vasodilators [nitric oxide, prostaglandin-E<sub>1</sub> (PGE<sub>1</sub>), prostaglandin-E<sub>2</sub> (PGE<sub>2</sub>), and adenosine] (22) and the vasoconstrictors (endothelin, angiotensin II, vasopressin, etc.) can also impair medullary blood flow and contribute to tubular-cell damage (23). In the outer medulla, where the high oxygen consuming mTAL cells reside, ischemia causes swelling of tubular and endothelial cells as well as adherence of neutrophils to capillaries and venules (24,25). The resultant vascular congestion and reduced blood flow further impairs the balance between oxygen supply and demand. The role of renal medullary hypoxia in ATN has been recently reviewed by Brezis and Rosen (26).

In general, the response to renal hypoperfusion involves three major regulatory mechanisms that support renal function in the setting of decreased RBF: afferent arteriolar dilation increases the proportion of cardiac output that perfuses the kidney; efferent arteriolar resistance increases the filtration fraction; and hormonal and neural responses improve renal perfusion pressure by increasing intravascular volume, thereby indirectly increasing cardiac output (27). The afferent arterioles react to reductions in perfusion pressure by relaxing their smooth muscle elements to decrease renal vascular resistance. This property represents a relaxation response or myogenic reflex to reduced transmural pressure across the arteriolar wall.

The kidney also possesses a tubuloglomerular feedback system, which maintains the homeostasis of salt and water excretion. Decreased solute delivery to the macula

densa in the cortical portion of the thick ascending loop of Henle results in relaxation of the juxtaposed afferent arteriolar smooth muscle cells, thus improving glomerular perfusion and filtration. The macula densa also increases renin release from the granular cells of juxtaglomerular apparatus in response to reduced sodium delivery.

A selective increase in efferent arteriole resistance decreases glomerular plasma flow, thereby preserving GFR. Glomerular filtration is augmented because capillary pressure upstream from the site of vasoconstriction tends to increase. This mechanism enables the kidney to offer high organ vascular resistance, thereby contributing to the maintenance of systemic blood pressure (BP) without compromising its function of filtration. Studies using specific inhibitors of angiotensin II have shown that efferent arteriolar resistance is largely caused by the action of angiotensin II. At low concentrations, norepinephrine has a vasoconstrictive effect on efferent arterioles, indicating that the adrenergic system may also be important for maintaining the renal compensatory response.

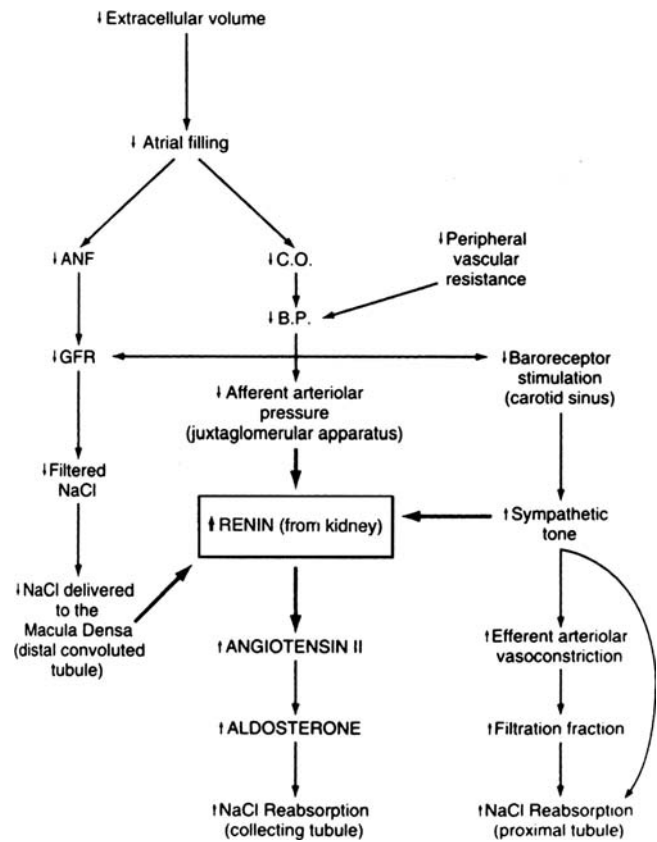

There is abundant evidence to support the notion that reductions in cardiac output are also accompanied by the release of vasopressin and by an increase in activity of the sympathetic nervous system and the renin-angiotensin-aldosterone (RAA) system (Fig. 2).

High concentrations of aldosterone stimulate reabsorption of sodium and water, primarily in the distal tubule and collecting ducts. Aldosterone is produced by the adrenal cortex in response to the feedback from the RAA system. Reduced delivery of sodium of the macula densa causes release of renin from the granular cells of the juxtaglomerular apparatus. Renin, in turn, catalyzes the release of angiotensin I from angiotensinogen. Angiotensin I then is transformed into angiotensin II in the lungs, catalyzed by angiotensin-converting enzyme (ACE). Angiotensin II stimulates the production of aldosterone (Fig. 2).

Antidiuretic hormone (ADH), or vasopressin, acts primarily on the collecting ducts to increase water reabsorption. An elevated level of ADH results in the excretion of small volumes of concentrated urine. The ADH is released from the posterior pituitary gland in response to increased blood osmolality, which stimulates osmoreceptors in the hypothalamus (28). The ADH is inhibited by stimulation of the atrial baroreceptors or increased atrial volume. The ADH release is also increased by stress, pain, fear, and increased PaCO<sub>2</sub>. However, plasma osmolality is the most potent regulator. The common denominator of these regulatory mechanisms to preserve RBF is salt and water conservation.

The control of blood delivery to the kidney, the fraction of plasma filtered, and the amount of volume returned to the systemic circulation are all determined by regulatory mechanisms within the kidney that attempt to preserve filtration function during compromised circulation. However, these compensatory mechanisms have limits. Excess vasoconstrictive forces may eventually induce a decrease in filtration function (29). If left unabated, the mechanisms that influence efferent vasoconstriction ultimately will overwhelm the system and cause afferent arteriolar vasoconstriction as well. The resulting decrease in filtration fraction is the hallmark of ischemic ARF.

Early cell changes following ischemia are reversible, such as the swelling of cell organelles, especially in the mitochondria. As ischemia progresses, lack of adenosine triphosphate interferes with the sodium pump mechanism, causing water and sodium to accumulate in the endoplasmic reticulum of tubular cells, and the cells themselves begin to swell (24).

**Figure 2** Mechanism of renal sodium and volume regulation. The regulation of intravascular volume and tonicity involves the complex interaction of atrial volume receptors, carotid and aortic body receptors, which stimulates the elaboration of renin. Renin promotes the conversion of angiotensinogen into angiotensin I (not shown). Angiotensin I is converted into angiotensin II in the liver, which increases blood pressure and aldosterone production. Aldosterone increases sodium reabsorption, potassium excretion, and hydrogen ion excretion. An additional mechanism regulating osmolality (not shown) involves the elaboration of antidiuretic hormone when osmoreceptors detect an elevated osmolality, which leads to water retention until the target osmolality is reached. *Abbreviations:* ANF, atrial natriuretic factor; BP, blood pressure; CO, cardiac output; GFR, glomerular filtration rate; NaCl, sodium chloride. *Source:* From Ref. 166.

The time of onset for tubular damage in experimental models of ARF is usually within 25 minutes of ischemia, as the microvilli of the proximal tubular cell brush borders begin to change. Within an hour, they slough off into the tubular lumen, and membrane bullae protrude into the straight portion of the proximal tubule. After a few hours, intratubular pressure increases and tubular fluid passively flows backward. Within 24 hours, obstructing casts appear in the distal tubular lumen. Even when RBF is completely restored after 60 to 120 minutes of ischemia, GFR may not immediately improve. Ischemic tubular damage may eventually be exacerbated further by an imbalance between oxygen supply and demand. Most vulnerable to the imbalance are the mTAL cells (26). In ischemia-induced ARF, lesions are unevenly distributed among the nephrons, probably reflecting variability in blood flow (27). **Urine output is not always the best measure of renal wellbeing. Rather,**

**indirect measures are at times more reliable during resuscitation of a trauma patient (i.e., mean arterial pressure, preload, and cardiac output).** ⚡

In the clinical setting of hypotension, the kidney appears to have a distinct susceptibility to injury. The reason for this susceptibility is not apparent when reviewing RBF alone. Indeed, total RBF is normally high and oxygen supply far exceeds the requirements for oxygen utilization, even in moderate hypovolemia. The kidneys receive nearly one quarter of the cardiac output and extract relatively little oxygen (thus the discrepancy between cortical and medullary blood flow) and oxygen consumption is marked (30). The apparent overabundance of blood flow to the cortex maximizes flow-dependent functions, such as glomerular filtration and tubular reabsorption. In the medulla, blood flow and oxygen supply are restricted by a tubular vascular anatomy specifically designed for urinary concentration. Normally, approximately 90% to 95% of blood flow is delivered to the cortex compared with 5% to 10% delivered to the medulla. Average blood flow is 5.0 and 0.03 mL/g/min for the cortex and medulla, respectively, whereas the oxygen extraction ratio (i.e.,  $O_2$  consumption  $[\dot{V}O_2] \div O_2$  delivery  $[DO_2]$ ) is 0.18 and 0.79 for the cortex and medulla, respectively. Normally, the  $PO_2$  is approximately 55 mmHg in the cortex and 8 to 15 mmHg in the medulla, making the mTAL cells the most vulnerable to tissue hypoxia (26).

Therefore, severe hypoxia may easily develop in the medulla with what otherwise would seem to be adequate total RBF. The initial response to decrease RBF is increased sodium absorption in the ascending loop of Henle, which coincidentally increases oxygen demand in the region most vulnerable to decreased oxygen delivery. To compensate for this, sympathoadrenal mechanisms promote cortical vasoconstriction and oliguria, which tend to redistribute blood flow away from the outer cortex to the inner cortex and medulla.

At the same time, decreased sodium delivery to the macula densa causes afferent arterial constriction. With afferent arterial vasoconstriction, glomerular filtration decreases, and consequently, solute reabsorption in the loop of Henle and oxygen consumption are also reduced. The severity of cellular injury appears to be related to the degree of imbalance between cellular oxygen supply and demand. In the hypoperfused-kidney preparation, oxygen-enriched perfusion reduces cellular damage, hypoxic perfusion increases it, and complete cessation of perfusion (glomerular filtration zero, preventing ultrafiltration) is associated with less cellular injury than hypoxic perfusion. Afferent arterial vasoconstriction and consequent oliguria may be a normal protector response to acute tubular injury. By reducing ultrafiltration, energy-dependent ischemic injury to medullary tubular cells is prevented, even at the cost of retaining nitrogenous waste.

When RBF is compromised, blood flow and glomerular filtration in the outer cortical nephrons decline first because of the redistribution of blood toward the inner cortical and medullary regions. This cortical-to-medullary redistribution of RBF protects the vulnerable medullary oxygen balance (26). Decreased glomerular filtration during compromised flow thus appears to be protective, because decreased urine delivery to the tubules requires less reabsorptive work and prevents further oxygen supply-demand imbalance. Modulation by various drugs or compensatory mechanisms can reduce tubular workload and prevent medullary hypoxic cellular injury. Among the

compensatory mechanisms that reduce cellular injury is reduced tubular transport of glomerular filtration. Thus, temporarily, the oliguria may protect against ARF.

⚡ **Ischemic ATN is typically seen after a prolonged episode of hypotension, particularly when the blood flow to the kidney is interrupted (e.g., aortic crossclamp) (31–34).** ⚡ Experimental models of ATN indicate that ischemia damages the medullary tubular segments of the nephron, causing intratubular obstruction, consequent back-leak, and increased intramedullary vascular resistance (35,36). The aggregate effect of this cascade is a profound reduction in GFR and a sustained maintenance phase of ARF after the ischemic injury (37). Despite the severe decrement in glomerular filtration, the kidney is quite resilient, and in the absence of further insults, usually recovers function within 7 to 21 days (27).

## **PATHOGENESIS: ROLE OF RENAL TOXINS**

Nephrotoxic ARF is commonly encountered in trauma and critically ill postsurgical patients. The kidney is responsible for clearing a vast number of drugs and toxins. Many of these drugs have nephrotoxic properties themselves, while others become injurious when used in combination with other drugs. The mechanism by which nephrotoxins injure the renal parenchyma include intra-arterial vasoconstriction [e.g., contrast media, catecholamines, and nonsteroidal anti-inflammatory drugs (NSAIDs)], direct tubular injury (e.g., aminoglycosides and amphotericin), and intratubular obstruction (e.g., acyclovir and sulfonamides) (38–41). As in ischemic ATN, if the offending insult is removed and further insults are avoided in a previously healthy kidney, normalization of renal function is the rule after a maintenance phase (37).

The natural history of ATN is triphasic, and interpretation of urine output requires knowledge of these phases. It begins with an insult or initiation phase followed by a maintenance phase, which is typically oliguric (though not always), followed by a diuretic or recovery phase. The maintenance phase lasts between 7 to 21 days, but in rare circumstances, it can last as long as 11 to 12 months before recovery. The diuretic phase continues, until tubular function is restored and the kidney regains its concentrating ability. Ischemic ATN follows this paradigm more consistently, whereas nephrotoxic ATN is more variable depending on the duration and severity of nephrotoxic exposure (37,42,43).

In addition to a wide range of compounds that are nephrotoxic, there are also a large number of agents that can cause interstitial nephritis (44–46). Drugs or toxins generally induce acute interstitial nephritis (AIN), but various infectious agents can also cause AIN (47). The AIN can cause modest renal insufficiency, which is clinically silent, or can progress to ARF. Edema and interstitial infiltrate mark the resultant lesion seen in AIN. Clinically, fever, skin rash, rising creatinine, pyuria, and white cell casts are a typical presentation (47,48). Eosinophiluria, which are seen in most but not all patients, is a common finding, but the diagnostic value of this test in isolation is uncertain (49,50). An abbreviated list of medications commonly used in the ICU that can cause AIN is provided in Table 1. AIN ordinarily occurs within three to five days of initiation of the medication, and withdrawal of the offending agent is often adequate therapy (51). However, in some cases, AIN can lead to ARF of sustained duration (52).

### PATHOGENESIS: OTHER CAUSES

Occlusion of the renal arterial or venous vasculature is an uncommon cause of ARF, but any process that compromises the arterial supply (e.g., aortic dissection, vasculitis, atheroemboli, thromboembolism, microangiopathic hemolytic anemia (MAHA), malignant hypertension, and hyper-viscosity syndromes) can rapidly cause ARF (53,54). Renal vein thrombosis is rare, primarily occurring in patients suffering from severe nephrotic syndrome, hypercoagulable state (e.g., cancer), or trauma where the kidney suffers direct trauma or a torsion injury (55–59). In order for there to be a significant clinical effect causing ARF from a vascular injury, there must be an underlying renal disease, both kidneys must be involved, or else one kidney must have been damaged previous to the new insult to the contralateral kidney (60).

Glomerular disease is an uncommon cause of ARF in the SICU, usually presenting over a more chronic course. Glomerular disease is invariably marked by significant proteinuria (>1 g/day) and hypertension. The major exception to this chronic course is rapidly progressive glomerular nephritis (RPGN), which can present with multi-system disease and can cause a brisk decline in GFR. Causes of RPGN that require ICU admission include but are not limited to Goodpasture's disease, Churg-Strauss disease, Wegner's granulomatosis, endocarditis, polyarteritis nodosa (PAN), and severe systemic lupus erythematosus (SLE). Identification of RPGN is explained in more detail subsequently.

Obstruction is an uncommon cause of ARF, but is seen more frequently in postoperative patients and trauma patients than medical patients in the ICU. In order for obstruction to cause ARF, the obstruction must be distal to the bladder neck (e.g., prostatic hypertrophy), involve some aspect of both ureters, or create unilateral obstruction with the contralateral kidney previously damaged or dysfunctional. If the obstruction is not chronic (<2 weeks), relieving the obstruction restores function promptly. As the duration of the obstruction lengthens, so does the delay in return of function and increases the amount of post obstructive tubular dysfunction.

### GENERAL DIAGNOSTIC APPROACH

Although a consensus definition for ARF does not exist, **most nephrologists would agree that doubling of the**

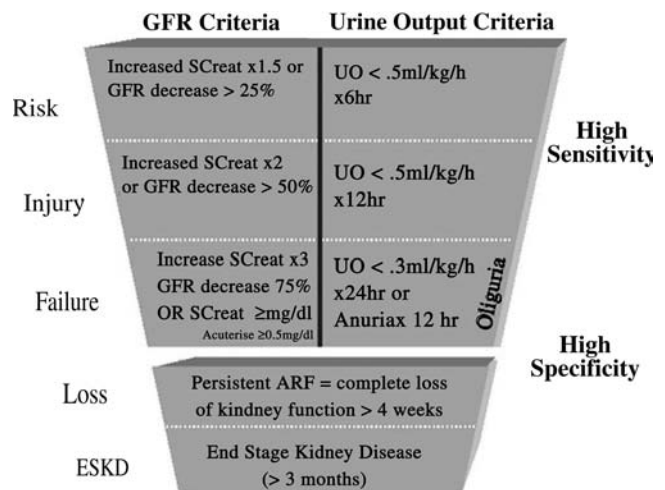

**Table 2** Definitions of Acute Renal Failure

Increase in serum creatinine of 1.0 mg/dL with clinical scenario consistent with ATN
Oliguria or elevated serum creatinine
Sudden rise in serum creatinine of greater than 2.0 mg/dL or greater than 50% in patients with baseline serum creatinine of 3.0 mg/dL

Abbreviation: ATN, acute tubular necrosis.

Source: From Refs. 8, 9, 124.

**serum creatinine or the rising of serum creatinine of 1.0 mg/dL per day over two to three days would constitute a patient in ARF (Table 2).** A recent categorization ("Rifle" system) has been proposed (Fig. 3). For purposes of this discussion, any rise of serum creatinine or indication of insufficient or unexpectedly poor clearance (e.g., elevated serum phosphorus and an elevated trough level of a renally excreted antibiotic that was dosed correctly) of a renally

**Figure 3** RIFLE (Risk, Injury, Failure, Loss, End-stage kidney Disease) criteria for acute renal failure. Proposed classification scheme for acute renal failure. The acronym RIFLE derives from the first letter of the following phrases: Risk of renal dysfunction; Injury to the kidney; Failure of kidney function; Loss of kidney function; End-stage kidney disease. The classification system includes separate criteria for creatinine and urine output (UO). A patient can fulfil the criteria through changes in serum creatinine (SCreat) or changes in urine output, or both. The criteria that lead to the worst possible classification should be used. Note that the F component of RIFLE "Failure of kidney function" is present even if the increase in serum creatinine is under three-fold, as long as the new serum creatinine is greater than 4.0 mg/dL (350 μmol/L) in the setting of an acute increase of at least 0.5 mg/dL (44 μmol/L). The designation RIFLE-F should be used in this case to denote "acute-on-chronic" disease. Similarly, when the RIFLE-F classification is achieved by urine output criteria, a designation of RIFLE-F O should be used to denote oliguria. The shape of the figure denotes the fact that more patients (high sensitivity) will be included in the mild category, including some without actually having renal failure (less specificity). In contrast, at the bottom of the figure, the criteria are strict and therefore specific, but some patients will be missed. Abbreviations: ARF, acute renal failure; GFR, glomerular filtration rate.

**Figure 4** The glomerular filtration rate (GFR) creatinine graph. Steady-state relationship between the plasma creatinine concentration ( $P_{cr}$ ), blood urea nitrogen, and the GFR. *Abbreviation:* GFR, glomerular filtration rate.

excreted substance should raise concern. If these abnormalities are not explained upon re-examination of the clinical picture, a formal diagnostic evaluation should begin.

Most clinicians use the blood urea nitrogen (BUN) and serum creatinine as their markers of renal function. However, these are both late markers of decreased GFR. Figure 4 shows the relationship between GFR decline and the rise of serum creatinine. As the figure illustrates, rise in serum creatinine is a late marker for the decrement in GFR. BUN is similarly unreliable due to its tendency to rise in conditions where the kidney is functioning adequately (e.g., hypermetabolic state, gastrointestinal bleeding, and high protein diet). Whenever the serum creatinine doubles within a 24-hour period, and the patient becomes oliguric, renal replacement therapy is often required, as the creatine cannot increase much faster and the value during this nonsteady state is no longer predictive of GFR.

Once ARF is suspected or in progress, the assessment of the cause of ARF should begin in a systematic fashion. Many clinicians rule out prerenal and postrenal (obstructive) etiologies and then begin to assess for renal causes of ARF. This approach does not work as well in the ICU; patient's disease processes evolve too fast to wait for investigative tests to be done. Like the shock/systemic inflammatory response syndrome (SIRS) mode or trauma model, treatment and diagnosis in critical illness must often occur simultaneously. Because prerenal and postrenal etiologies are the easiest to reverse, they should be assessed and immediately corrected if they are found (similar to the initial survey taken for a trauma patient) while other etiologies are evaluated.

Immediate interventions include correction of volume deficits, correction of hypotension or relative hypotension (for patients who have a normal mean arterial pressure (MAP), but are normally hypertensive), placement of Foley catheter, and cessation of known nephrotoxins (if clinically feasible) and basic urine and serum studies should be sent [i.e., urinalysis, urine electrolytes, urine protein, urine creatinine, urine eosinophils, urine osmolarity, and complete blood count with differential and serum creatine

**Table 3** Initial Survey

Complete blood count with differential
Urine electrolytes (sodium, potassium, and chloride)
Urine creatinine, urine protein, and urine eosinophils

Foley catheter placement, intra-abdominal pressure measurement
Renal U/S (assess kidney size and presence of obstruction)
Serum CPK, serum albumin
Correction of hypovolemia and hypotension
Discontinuation of any obvious nephrotoxic drugs (especially NSAIDs)

*Abbreviations:* CPK, creatine phosphokinase; NSAIDs, nonsteroidal anti-inflammatory drugs.

phosphokinase (CPK) level]. Table 3 lists the initial steps that should be taken during the initial survey.

While these lab tests are drawn and sent, the next step is to play detective and "round up the usual suspects" of clinical disorders and agents that are often implicated in ARF. These agents are contrast media, NSAIDs, and angiotensin converting enzyme inhibitors (ACEi). The nephrotoxicity seen with all of these agents is potentiated by hypovolemia, and the typical course of events is that the patient is exposed to one or more of these agents while hypovolemic.

Other medications that often cause ARF via ATN or AIN include, antibiotics, antifungal, and antiviral agents. Penicillins, cephalosporins, aminoglycosides, vancomycin (alone or in combinations with other antibiotics), quinolones, rifampin, aztreonam, sulfonamides, tetracycline, amphotericin, foscarnet, and acyclovir have all been reported to cause ARF (61–70). In each individual case, the value of continuing an antimicrobial agent must be weighed versus the likelihood of that agent causing or contributing to ARF.

## DIRECT AND INDIRECT ASSESSMENT OF RENAL STATUS

Monitoring urine output as a sign of the adequacy of renal perfusion is easy and assumes that patients with diminished renal perfusion excrete a low volume of concentrated urine. The level of nitrogenous wastes in the blood depends on both systemic production and renal clearance. Renal clearance is determined by the delivery of these waste products to the kidney (RBF) and the ability of the kidney to extract them (GFR). The kidney also concentrates the ultrafiltrate; when able to maximally concentrate, a total of 400 to 500 mL of urine is required in order to clear the daily obligatory nitrogenous wastes. Injured kidneys require more urine output to clear the daily obligate solute load. Traditionally, inadequate urinary volume, or oliguria, is defined as urinary output of less than 0.5 mL/kg/hr. Multiple studies, however, have shown no correlations between urine volume and histologic evidence of ATN, GFR, creatinine clearance, or changes from preoperative to postoperative levels of BUN and creatinine in patients with burn injury, trauma, cardiovascular surgery, and shock status. Moreover, measurement of mean and lowest hourly urinary output during aortic vascular surgery has not been predictive of postoperative renal insufficiency (71).

Oliguria may reflect a variety of factors independent of GFR, and a normal hourly urine output does not preclude the absence of renal failure. Among these factors is tubular excretion of solute and water, which is determined by local and systemic levels of renin, aldosterone, and ADH. In addition, patients in the OR are often not hemodynamically stable; decreased blood volume or cardiac output, fluctuating hormone levels (aldosterone, renin, and ADH), and increased catecholamine concentrations, with the effects of general anesthesia, can alter GFR. The data does not support oliguria as a reliable sign of pending renal dysfunction.

### Monitoring Urine Output

A clinically robust intraoperative measure of renal function does not yet exist. The Foley catheter provides an acceptable reflection of intravascular volume in patients with normal renal function, normal serum osmolality (absence of hyperglycemia, alcohol intoxication, and mannitol therapy) and in the absence of other diuretics (e.g., caffeine, lasix).

☞ **Decreased urine output, and rising serum BUN and creatinine are the standard indicators for the development of worsening ARF.** ☞ Creatinine (which is neither secreted nor reabsorbed to any appreciable amount) is a good inverse measure of GFR. However, creatinine elevations occur after the renal insult has occurred, and only reflect the degree of renal insufficiency once a steady state is achieved. Indeed, a doubling of serum creatinine generally represents a 50% decrease in GFR at steady state. However, creatinine may double from 0.8 to 1.6 in a 24-hour period in a patient with essentially zero GFR, because this duration is required for creatinine to accumulate in the blood in essentially anephric patients. Serial determination of creatinine clearance is currently the most sensitive test for predicting the onset of perioperative renal dysfunction; however, the test is not practical for measuring renal function under OR conditions (72).

Urine output measurements recorded every 15 to 60 minutes, are most useful in determining renal perfusion. In the future, the ability to measure intrarenal blood flow distribution may ultimately improve our predictive and diagnostic abilities to assess perioperative ARF. However, methodological constraints limit its use at this time. During acute events, common during surgery (massive exanguination, clamping of major vascular structures), more direct and rapidly responsive measures of arterial perfusion and central venous pressure (CVP) are required. Although these pressures are directly measured, and are excellent indicators of intravascular pressure and volume, they are indirect measures of renal perfusion.

### Indirect Measures of Renal Perfusion: Blood Pressure and Volume Status

#### Invasive Arterial Blood Pressure Monitoring

☞ **An arterial line serves the dual purpose of providing access for repetitive ABG samples, as well as continuous beat-to-beat measurement of arterial BP throughout resuscitation, operative management, and critical care.** ☞

Continuous BP monitoring is useful for surgical procedures where major intravascular volume shifts are likely to cause acute, profound changes in arterial BP. Not only does the absolute systolic, diastolic, and mean arterial pressure have important clinical relevance, but the information contained in the arterial pressure waveform has important hemodynamic information (including rate, rhythm, preload, afterload, and contractility) (73–75).

Any large peripheral artery can be used for catheterization. The risk of radial artery cannulation with a 20 g Teflon catheter is extremely low in adults (76). However, in certain situations (severe vasoconstriction or severe vasodilation), the femoral arterial catheter will more closely reflect the aortic pressure than the radial catheter (77). In addition, certain procedures (e.g., thoracic aortic aneurysm repair) are best managed with pressure measurements obtained above (right radial) and below (either femoral artery) the lesions (78). The complication rate from percutaneous cannulation of the femoral artery is no greater than that of radial artery (79,80).

☞ **Systolic pressure variation (SPV) is a technique for gauging intravascular volume status, which is very useful in renal failure patients.** ☞ Arterial BP has long been known to decrease with positive pressure ventilation. The SPV is a method of quantifying these changes. Perel has shown in both animal experiments and clinical studies that SPV directly correlates with intravascular depletion (81,82). Indeed, when the systolic pressure (delta down component) decreases by more than 10 mmHg in patients ventilated with 10 to 15 cc/kg, these patients are clinically volume under resuscitated (Fig. 5).

#### Systolic Pressure Variation Monitoring Indications

The CVP monitoring is considered a second-tier-monitoring device (recommended if the patient is sick or is undergoing a high risk procedure). The CVP reflects the relationship between the patient's blood volume, venous tone, and right ventricular performance. In patients without significant cardiac disease or pulmonary hypertension, the CVP also provides a useful reflection of right (and left) ventricular preload. Additionally, it provides a port for the administration of cardiovascular drugs, and the insertion of a pulmonary artery (PA) catheter or transvenous pacemaker. For the CRF patient receiving a renal transplant, one of the most important determinants of immediate post transplant renal viability and avoidance of ATN is the adequacy of perfusion to the newly transplanted kidney at the time the vascular clamps are released (83). The CVP (or pulmonary artery pressure (PAP) in patients with left ventricle (LV) dysfunction) should be used to guide therapy in these patients.

**Figure 5** Systolic arterial blood pressure (BP) variation. The systolic arterial pressure variation (SPV) can be used as a measure of ventricular responsiveness to volume. The arterial BP wave form can be divided into a delta-up component and a delta-down component when observed during mechanical ventilation. When the SPV (delta-down component) varies more than 10 mmHg, with a positive pressure breath (tidal volumes 10–15 mL/kg), there is a relative paucity in left ventricular filling and reflects the need for additional intravascular volume administration. The SPV can be used in the operating room or in the surgical intensive care unit to assist in establishing the optimum intravascular volume. Also see Volume 2, Chapter 3. *Source:* From Ref. 81.

☞ **Trauma and critically ill patients with renal insufficiency should have their CVP maintained on the high side to protect against the prerenal state.** ☞

### **Indications for Pulmonary Arterial Catheterization**

The PA catheterization is a second- or third-tier monitor reserved for patients in whom the CVP poorly reflects intravascular volume status (impaired LV function, severe coronary artery disease, known PA hypertension, and mitral or tricuspid valve pathology). In addition, PA catheters are indicated for high-risk procedures (thoracic aorta cross clamping), or when measurement of ventricular performance (SV) or systemic perfusion (cardiac output) is warranted.

Information available from PA catheters includes left-sided filling pressures, measurement of cardiac output, sampling mixed venous blood, calculation of systemic and pulmonary vascular resistances, and PA and wedge pressure waveform analysis. The PA catheter provides estimates of left ventricular (LV) preload [i.e., left ventricular end-diastolic volume (LVEDV)] by measuring left ventricular end-diastolic pressure (LVEDP). This LVEDP/LVEDV relationship is altered by changes in LV compliance (e.g., myocardial ischemia, tissue edema, etc.). Many investigators have demonstrated a poor correlation between pulmonary capillary wedge pressure (PCWP) and LVEDV in acutely ill patients (84). However, a recent study demonstrated reduced mortality in severely injured trauma patients who were monitored with a PA catheter (85). ☞ **In situations where assessment of LVEDV is critical (e.g., hypotension, low cardiac output, and normal- or high-filling pressures by CVP and PACWP), using a transesophageal echocardiography (TEE) provides the more accurate and direct view of LV preload and contractility** (86). ☞

### **Role of Transesophageal Echocardiography**

TEE is an established monitoring and diagnostic tool for the cardiothoracic anesthesiologist. Techniques for insertion, interpretation, and complications have been comprehensively reviewed in Chapter 21. The main benefits in TEE lies in the fact that a picture can truly be worth a thousand words. Direct visualization of both ventricular and atrial chambers provide instantaneous information on preload. Contractility is also directly visualized using the short-axis view (87). Monitoring for ischemia and wall motion abnormalities is excellent with TEE, and automated real-time technologies are emerging (88). Valvular function can be assessed using color-labeled directional flow and Doppler techniques. Pericardial effusions and their effect on atrial and ventricular function are well visualized. Abnormal holes [(atrial septal defect (ASD) and ventricular septal defect (VSD)] can be detected via direct view or administration of agitated saline.

### **Renal Function Testing in ARF**

Evaluating the urine takes time. Therefore, the traumatologist must measure and optimize indirect measures of renal wellbeing (arterial BP, CVPs, and cardiac output) before, or simultaneously with diagnostic studies. Direct visualization and dipstick testing are the first tests that should be done, as both are quick to perform. Next, specific gravity measurement, and then microscopy of the urinary sediment should be employed. Finally, a spot urine test and serum sample of sodium creatinine and BUN should be

done. With these studies, most causes of oliguria will become elucidated.

### **Visual Inspection and Dipstick Evaluation of Urine**

Urine color should be noted and a dip test performed (occult blood, bile, glucose, and protein) to determine if the urine is concentrated. If the urine is dark, it could be concentrated, have bile, or blood. A dipstick positive for occult blood, when there are no red blood cells (RBCs) seen on microscopy is consistent with rhabdomyolysis. This would occur in the setting of a crush injury, compartment syndrome, and severe flame or electrical burns. However, intravascular hemolysis will present in the same manner (rare in noncardiac surgery, common following cardiopulmonary bypass (CPB), especially if hemofiltration is used). When hemolysis occurs in association with blood transfusion, the transfusion must be stopped, and both the patient's blood sample and the partially transfused blood sample should be sent back to the blood bank to determine if there is a cross match, or clerical error. Other rare causes of hemolysis, such as cold agglutinins in a hypothermic patient, should also be considered. If the dipstick is positive for glucose, the patient may not have concentrated urine despite being severely volume-depleted (they would unlikely manifest oliguria in this setting as well).

### **Specific Gravity Evaluation of Urine**

Next, the specific gravity of urine should be assessed. Dilute urine has a specific gravity <1.010, whereas concentrated urine in the setting of hypovolemic oliguria has a specific gravity >1.030.

### **Microscopic Evaluation of Urine Sediment**

In many instances, renal sediment reveals evidence of intrinsic renal dysfunction. Microscopy of the spun urine pellet reveals an expansive array of information. The importance of the presence or absence of RBCs is mentioned earlier. The presence of tubuloepithelial cells with epithelial cell casts is pathognomonic for ATN.

### **Spot Urine and Serum Sodium, Creatinine, and Urea Nitrogen**

A urine sample should be sent to the lab to determine urinary sodium and creatinine [a concomitant blood sample should also be sent to measure serum creatinine and sodium, and to evaluate the fractional excretion of sodium (FENa)—described subsequently]. The previously normal patient with oliguria from renal hypoperfusion should produce a small volume of concentrated urine with a low sodium concentration. Because sodium reabsorption increases and sodium excretion decreases in the setting of hypovolemia (and normal kidneys), the urinary sodium concentration should be less than 20 mEq/L (<10 mEq/L if the patient is seriously prerenal and the kidneys still can maximally concentrate urine).

However, if the patient has a prerenal condition superimposed on existing intrinsic renal dysfunction, or has received a high osmotic load (mannitol, ethanol intoxication), or has received another diuretic (furosemide, caffeine, etc.), the urine may be paradoxically dilute in the setting of severe intravascular depletion.

### **Volume Challenge for Perfusion Pressure Augmentation**

Immediately after documenting oliguria, but before completing the diagnostic work up described earlier, relative

intravascular volume depletion should be presumed and treatment instituted. It is far easier to treat a modest episode of pulmonary edema than it is to treat ARF.

## DIAGNOSTIC FEATURES OF COMMON SYNDROMES

After completing the initial survey, a full history and physical examination should be conducted, and an assessment of the laboratory data should be done. First, any aspect of the patient's history that could indicate a likely etiology of ARF should be evaluated. Examples include recent trauma, mechanism of trauma (clues to vascular, contusion, torsion injuries of the kidney, or crush injury predisposing a patient to rhabdomyolysis), recent procedures (a clue to cholesterol atheremboli from angiography, obstruction for cystoscopy, or intra-abdominal surgery), and constitutional symptoms that might suggest a systemic process or past history of renal disease (which could suggest previous unilateral kidney disease or underlying chronic renal insufficiency). If the patient's history and physical examination does not suggest an etiology, then the results of the initial survey should help determine possible etiologies.

### Prerenal vs. ATN

A bland urinalysis (few cells and minimal or no proteinuria) is consistent with prerenal causes or ATN. However, the way to differentiate between the two etiologies is the assessment of renal concentrating function. Decreased renal perfusion pressure, which is the hallmark of prerenal azotemia, causes a volume retention effect in a normal kidney. The kidneys become sodium avid and the serum ADH rises in response to volume depletion. This results in urine, which has a low sodium concentration (U Sodium < 20 mEq/dL), a low fractional excretion of sodium (FeNa < 1%), an elevated urine osmolarity (Uosm > 450), and an elevated specific gravity (SG > 1.020) (89). In addition, in normal kidneys, the BUN to creatinine ratio will often rise to >20:1 (90). This ratio can be helpful when there are no other reasons for the increased ratio (see Table 4 for a complete list). Although these commonly used indices are often useful in delineating between prerenal and other causes of ARF, they have three distinct limitations. First, if the patient has an underlying renal disease, these parameters may not be accurate. Second, other pathologic processes that cause intra-renal vasoconstriction (e.g., contrast media, vasopressors, and hepatorenal syndrome) will confound these values even if the patient is euvolemic, particularly the low FeNa and low urine sodium concentration. Third, when patients are given diuretics as a clinical challenge to increase urine output, it is difficult to reliably interpret the results of these tests. **The most clinically useful way to diagnose ATN is the evaluation of the urine sediment. The presence of brown granular casts and epithelial cells, singly or in casts, is seen in 80% of**

**Table 4** Causes of Increased Blood Urea Nitrogen:Creatinine Ratio

High protein diet
Gastrointestinal bleeding
Steroid use
Hypercatabolic state
Decreased renal perfusion pressure

patients with ATN (91). However, the absence of casts does not preclude ATN. It is for this reason that patients with ARF should be assumed to have a prerenal state, and pre-emptive correction should be initiated if the patient's clinical condition can tolerate the restoration of renal perfusion pressure (91).  $\alpha$

### Proteinuric Diseases

AIN or a glomerular process should be suspected if the urinalysis shows proteinuria. If the urine protein to urine creatinine ratio [(urine protein) mg/dL divided by (urine creatinine)] mg/dL is greater than 1, a glomerular disease is likely. In most such cases, proteinuria will be found to pre-date the ARF, and to be due to a chronic glomerular disease, such as diabetic nephropathy, a chronic form of glomerulonephritis, or lupus nephritis. This underscores the importance of knowing the baseline urinalysis findings, either the pre-operative result in a surgical patient, or the initial urine obtained from a trauma victim.

New-onset proteinuria with a urine protein-to-creatinine ratio of less than one is typical of AIN; there may also be microscopic hematuria, and pyuria in the absence of urinary infection. AIN is further suggested by the presence of urine eosinophils, white cell casts, and an offending agent known to cause AIN (92). Though AIN is usually associated with a modest amount of proteinuria, NSAID-induced AIN can occasionally cause proteinuria in the nephrotic range (>3 gms protein/d)(93). Unlike AIN from other agents, NSAID-induced AIN does not cause eosinophiluria. Treatment of AIN is supportive and requires withdrawal of the offending agent. Some studies suggest that steroids may be helpful, but this remains controversial (46).

A less common cause of new-onset proteinuria and microscopic hematuria is acute glomerulonephritis. RBC casts in the urine and persistent hypertension further suggest this diagnosis. Visible (macroscopic) hematuria, if it is not due to traumatic Foley catheterization or urinary infection, could suggest an acute glomerulonephritic or vasculitic illness. When these are a strong consideration, urgent consultation from the nephrology service would be warranted, particularly if the patient's serum creatinine is rising rapidly. Additional serologic tests are required for the work-up of glomerulonephritis and renal vasculitis.

### Vascular Causes of Acute Renal Failure

Vascular insults uncommonly cause ARF, but in scenarios where one kidney is previously damaged or when bilateral vascular insults occur, modest proteinuria and significant hematuria are often present. Arterial insults (infarction) often result in flank or back pain. Though nonspecific, active urine sediment, flank or back pain, and an appropriate history (atrial fibrillation, recent aortic manipulation) might suggest a vascular insult (94–96). If the renal infarct is large enough, GFR may be completely compromised and no hematuria will be seen. However, if renal infarction has occurred, the serum lactate dehydrogenase (LDH) should be significantly elevated (97). In one small study, acute renal artery occlusion could be predicted when the urine concentrations of sodium, urea, and creatinine were the same as the serum concentration, along with the FeNa approaching 100% (98). Renal artery occlusion can usually be confirmed by Doppler ultrasound or radionuclide scanning.

Medical therapy with anticoagulation is usually the preferred therapy if diagnosis is made within 24 to 48

hours. If the diagnosis is made promptly, there are many case reports of renal tissue salvage with thrombolytic, interventional, or surgical techniques as far as 35 hours after occlusion (94,96,99).

Atheremboli from cholesterol plaques can cause ARF, and usually has systemic findings. Eosinophilia, eosinophiluria, ARF, livedo reticularis, and evidence of peripheral cyanosis or infarction are all associated with atheroembolic disease (100–102). Risk factors for cholesterol embolization are aortic manipulation (surgical or angiographic) and recent anticoagulation. This process is seen more commonly in patients with large plaque burden, and in some cases can have a subacute course evolving over three to six weeks. Although proteinuria and hematuria are seen with severe cholesterol embolization, the urine can be bland as well, and a high index of suspicion is required to make the diagnosis. Treatment is largely supportive, and cessation of anticoagulation is recommended (103).

Renal vein thrombosis is rare. It is seen almost exclusively in patients with nephrotic syndrome or patients with underlying hypercoagulable state (55,57–59,104). Sporadic cases of bilateral RVT have been reported in patients with underlying nephrotic syndrome and hypercoagulable pathology (105–110). Rarely, RVT is seen as a consequence of trauma and has been reported in pediatric burn patients (56, 111,112). RVT presents usually without any specific symptoms; often, the presenting diagnosis is pulmonary embolization from inferior vena cava thrombosis that has extended from the renal vein (107). Rarely, elevated serum LDH and proteinuria are seen; this is often seen when RVT converts to renal infarction. Investigative studies include Doppler ultrasound, computed tomography (CT), magnetic resonance imaging (MRI), and caval venography. Many nephrologists treat RVT conservatively, because some trials have suggested no long-term benefit using thrombolytics and surgical embolectomy (113–115). However, thrombolytics and surgical thrombectomy have also been applied successfully (107,109,116,117).

### Pigment Induced Causes of ARF

Another cause of ARF that can masquerade as hematuria is pigment-induced ARF. These two disorders are rhabdomyolysis and hemoglobinuria. Both disorders cause ATN via pigment-induced damage of the tubular cells. Both can cause the urine dipstick to be positive for blood; however, microscopic evaluation shows few to no RBCs. When assessing a urinalysis, the actual cell count should be noted. Rhabdomyolysis is caused by muscle necrosis that release myoglobin into the bloodstream, which is then filtered into the tubules, causing ATN. Rhabdomyolysis classically presents with brown-colored urine, pigmented casts in the urine, and an elevated CPK. Rhabdomyolysis can be seen in patients suffering from crush injury, compartment syndrome, operative cases with relative hypovolemia, and in alcoholics who have hypophosphatemia, or myositis (91,118). Many medications can cause high serum CPK levels, including but not limited to: HMG CoA reductase inhibitors (lovastatin), itraconazole, cyclosporine, zidovudine (AZT), amphetamines, and cocaine (119–121). Because rhabdomyolysis can be caused by such a wide variety of mechanisms, and because it is one of the few treatable forms of ARF, serum CPK is included in the initial survey. Although no absolute level of CPK elevation correlates to ARF, most clinicians use the 10,000 u/L as a cut-off. One study showed the cut-off to be 16,000 u/L to be predictive of patients who would develop ARF (122). If the serum CPK

is elevated in a patient, serial measurements should be performed to determine if a rising trend is developing. Initial muscle damage may not reveal an elevated CPK, until volume is restored and the CPK washes out of the muscle tissue. Patients with rhabdomyolysis can sequester enormous amounts of volume in their damaged tissue, and volume resuscitation is the cornerstone of therapy. Once the patient is volume replete, studies in crush patients have shown that maintaining urine flow with mannitol and alkalization of the urine is helpful. Alkalization of the urine is quite difficult and requires significant amounts of sodium bicarbonate. This creates a substantial volume load, and should not be continued if urine flow cannot be established because the patient may become volume overloaded (123). Hemoglobinuria is uncommon and occurs after massive hemolysis. Free hemoglobin is a large molecule and rapidly bound by haptoglobin. In order for hemoglobin to be freely filtered by the glomerulus, the amount of hemolysis must first overwhelm the haptoglobin buffering system. Treatment for hemoglobinuria is therapy targeted at stopping the hemolysis and maintaining urine flow.

### Obstructive Causes of ARF

Obstruction is an uncommon cause of ARF (5–10% of cases), yet because it is reversible and treatable, it should be ruled out in the initial survey (124). In patients who have a clinical history that is highly suggestive of obstruction, an ultrasound that fails to show hydronephrosis should not lead to the abandonment of obstruction as an etiology. If the patient is volume depleted, if the collecting system is encased in fibrosis or malignancy, or if the obstruction is mild, the renal pelvis may not dilate (125). If obstruction is strongly suspected and the renal ultrasound is nondiagnostic, imaging with a repeat ultrasound after volume is given, CT, and/or renal radionuclide scanning are appropriate steps for confirmation (126).

### SPECIFIC RENAL SYNDROMES

There are clinical contexts when uncommon renal syndromes that cause ARF become more likely. Four pathologic processes that can cause ARF in the patients admitted to the ICU are abdominal compartment syndrome (ACS), microangiopathic hemolytic syndromes, hepatorenal syndrome, and the acute development of anuria.

#### Abdominal Compartment Syndrome

Postoperative ICU considerations relevant to renal monitoring and protection include close control of fluid, solute, and acid base status, monitoring for and prevention of bleeding and shock, coagulopathy, and special conditions that can further impair renal reserve (sepsis, MOSE, and additional toxin exposure, such as aminoglycosides, radiocontrast, etc). An additional postoperative complication, which can impair renal function known as “ACS,” has been increasingly recognized in the last decade.

ACS results from increased intra-abdominal pressure (IAP), usually due to bowel and interstitial tissue edema, following laparotomy in patients with shock and massive fluid resuscitation (127). The increased IAP results in impairment of circulation, decreased tissue perfusion, and renal as well as other organ dysfunction (cardiovascular, gut, and pulmonary) (128). The tense abdomen leads to increased

peak airway pressures, hypercarbia, and oliguria. Decreased thoracic venous return, with decreased cardiac output and decreased renal function due to hypoperfusion, are components of the syndrome. Additionally, increased IAP causes decreased tidal volume, increased ventilatory pressures, and increased atelectasis. Increased IAP can also cause venous hypertension and elevate ICP.

Abdominal compartment pressures may be measured by attaching an indwelling Foley catheter to a pressure transducer, leveled to the symphysis pubis (129). Pressures greater than 20 to 25 mmHg require abdominal decompression (130). Normal postoperative abdominal pressure is 0 to 5 mmHg. At pressures greater than 10 mmHg, hepatic arterial blood flow decreases; at 15 to 20 mmHg, oliguria and cardiovascular changes occur; and at pressures between 20 and 40 mmHg, anuria is typical (131).

Patients with abdominal pressures greater than 20 to 25 mmHg require emergency decompressive laparotomy to relieve the pressure and restore renal perfusion. However, extensive delay will lead to renal failure. Furthermore, opening the abdomen results in a rapid decrease in IAP with a resultant reperfusion syndrome that must be anticipated by the anesthesiologist. The reperfusion syndrome following abdominal decompression can lead to life-threatening hypotension, unless proper preparation occurs. Indeed, Morris (132) described asystole, following decompression in 4 of 16 patients who underwent rapid decompression.

Preparation for decompression of ACS involves maneuvers similar to those taken immediately prior to clamp removal during a thoracic aortic aneurysm repair: (i) intravascular volume is increased, (ii) dopamine (or other inotrope and vasopressors) are in line and running, and (iii) acidosis (if severe) is treated with sodium bicarbonate. An increase in minute ventilation is occasionally needed to eliminate CO<sub>2</sub> (neutralize lactate emanating from gut, and increased CO<sub>2</sub> from administered bicarbonate). Calcium chloride is administered to protect against increased potassium (washed out from gut). Calcium is also useful to bolster the transient hypocalcemia, following sodium bicarbonate administration. Morris et al. (132) recommends two liters of normal saline, with 50 g mannitol and 50 mEq sodium bicarbonate per liter prior to abdominal wall release.

Although ACS is thought of as a complication seen in surgical patients, it is becoming recognized as a process that affects many critically ill patients. It is classically described in postoperative trauma patients who have received a massive volume resuscitation, but it also has been reported in patients with decreased abdominal compliance (e.g., burn patients, tight surgical skin closures), pancreatitis, massive ascites, intractable constipation, peritonitis, and retroperitoneal bleeding (133–138). The IAP is usually quite low; however, as IAP increases the abdomen distends to accommodate the increased pressure. As the abdominal wall reaches the limits of its compliance, the IAP increases dramatically. This increased pressure is transmitted to the inferior vena cava and to the renal veins. As these veins are compressed, venous return to the heart diminishes and functional bilateral occlusion of the renal veins ensues. In addition to decreased mesenteric perfusion, renal function rapidly declines and ARF occurs. Various organ systems have different thresholds for dysfunction secondary to increased IAP; the kidneys show signs of oliguria at 15 mmHg and anuria at 30 mmHg (139). If ACS is suspected based on the patient's clinical context, direct IAP monitoring should be done. This can be easily and reliably achieved

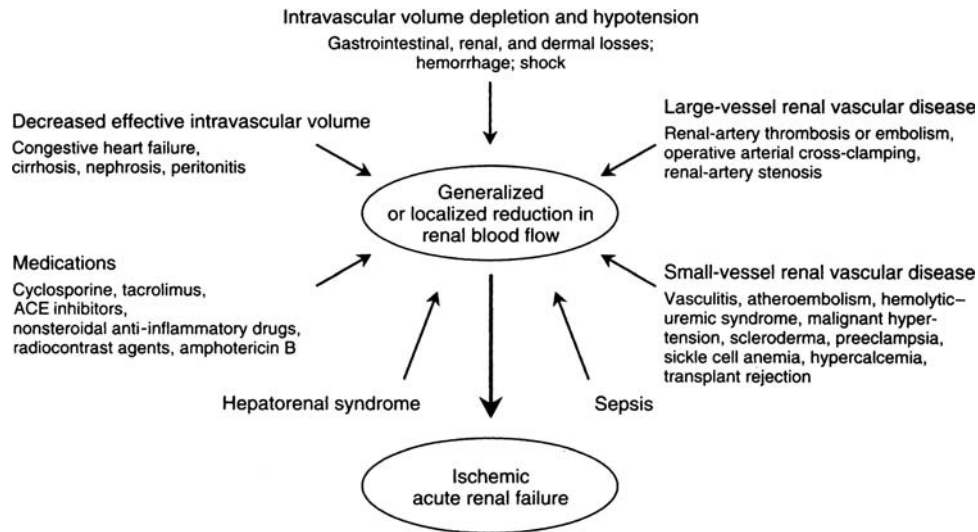

with intravesicular pressure transduction via a Foley catheter (129,140–143). A bladder pressure less than 10 mmHg rules out ACS, and a pressure of greater than 25 mmHg is highly suggestive of ACS (143). If ACS is confirmed by clinical and objective assessment, decompression of the abdomen should commence without delay (141,143).

### Microangiopathic Hemolytic Anemia

MAHA is usually a result of hemolytic-uremic syndrome (HUS) or thrombotic thrombocytopenic purpura (TTP). The HUS presents with ARF and MAHA. In children, this disease is associated with an antecedent diarrheal infection, particularly *Escherichia coli* H7:O157. The diagnosis is confirmed by the presence of anemia, elevated serum LDH, and schistocytes on peripheral smear (144). TTP classically presents as a pentad: fever, ARF, neurologic deficit (stroke, seizure, and delirium), thrombocytopenia, and MAHA. It is important to recognize the possibility of these syndromes because both (TTP in particular) can cause irreversible damage and/or rapid death. Frequently, patients present with a seizure or cerebrovascular accident (CVA) and they are admitted to the ICU for their neurologic presentation. The remainder of their disease becomes evident later in their hospital course. Although most patients will not present with the full pentad, the hallmark of this disease is MAHA as evidenced by evidence of anemia, elevated serum LDH, and schistocytes on peripheral smear (145). This finding in conjunction with thrombocytopenia, ARF, or neurologic findings should raise the suspicion for this diagnosis, and an urgent hematology consultation should be obtained. Treatment of TTP and HUS in adults consists of fresh frozen plasma administration and plasma exchange (144). Platelet infusions should be avoided because they have been associated with worsening of the disease process, resulting in death (146).

### Hepato-renal Syndrome

Hepato-renal syndrome (HRS) is a syndrome in which the kidneys remain histologically normal and are within the spectrum of prerenal azotemia. Patients with severe liver impairment develop a low systemic vascular resistance state, where the incremental increase of renin and angiotensin from hypotension create intrarenal vasoconstriction and profound prerenal azotemia. This disorder is often misdiagnosed in patients with liver disease. Patients with liver disease are also susceptible to other forms of ARF as well, and other etiologies must be ruled out before a diagnosis of HRS is made. The diagnosis of HRS is made by documentation of serum creatinine >1.5 mg/dL, urine sodium <10 mEq/L, absence of other causes of ARF (ATN, nephrotoxic agents, absence of bacterial infection, proteinuria <500 mg/day, and no evidence of obstruction), and no improvement in renal function after withdrawal of diuretic and volume challenge of 1.5 L of normal saline (147). There are two types of HRS, Type I and Type II. Type I is defined by a drop in GFR <20 mL/min, a serum creatinine >2.5 occurring over less than two weeks. These patients are usually oliguric or anuric. Type II HRS is marked by less renal impairment, but those patients have ascites that are diuretic resistant. If the diagnosis of Type I HRS is made, the only definitive treatment is liver transplant. If Type II HRS is present, the role of long-term dialysis, colloid expansion, and porto-systemic shunts is under evaluation (148).

**Figure 6** Summary of conditions that lead to ischemic acute renal failure. A variety of clinical conditions results in a reduction in renal blood flow; however, intravascular volume depletion and hypotension are the predominant culprits. When combined with the wide spectrum of additional toxic insults, renal blood flow can be so severely impaired that acute tubular necrosis results. *Abbreviation:* ACE, angiotensin-converting enzyme. *Source:* From Ref. 27.

### Acute Development of Anuria

The acute development of anuria is rare in clinical practice and has few etiologic agents. If a patient who was previously nonoliguric becomes anuric, four etiologies should be investigated: (i) obstructive uropathy, (ii) massive ATN, (iii) acute cortical necrosis (ACN), and (iv) acute renal artery occlusion. All of these entities have been discussed earlier except ACN. The ACN is a rare result of profound renal ischemia and/or thrombosis. The most common cause worldwide is obstetrical complications, and is also seen as a consequence in patients who develop SIRS, suffer snakebites and HUS (149–153). Diagnosis is usually confirmed by CT or radionuclide scanning. There is no treatment except hemodynamic support. The most common presenting symptom is anuria, and patients who suffer ACN are often dialysis-dependent for life (154).

### EYE TO THE FUTURE

Investigations into the prediction of ARF have yielded early predictive markers that could assist in identifying kidney damage. In a study by McLaren et al. (155), it was found that the protein P53 was directly correlated with the cellular changes seen in ATN. Another study done by Parikh et al. (156) found that elevated levels of the biochemical marker, IL-18 correlated with ATN in mice. Other studies found that IL-18 was also a reliable marker in predicting acute kidney injury (157,158). The benefits of using these markers to test for kidney injury are that they are reliable, inexpensive, and easy to perform. Furthermore, the elevated levels in IL-18 are seen much earlier than elevations in creatinine.

### SUMMARY

Limiting renal impairment begins with identifying patients at increased risk for renal dysfunction (monitoring of renal function is particularly important in these patients), and understanding the physiology of urine formation, the influence of

vasoactive drugs, and intraoperative events on the physiology and pathophysiology of renal function (Fig. 6).

The fundamental principles emphasized include (i) avoidance of hypovolemia or renal hypoperfusion (hypotension or decreased cardiac output) in patients at risk (either due to pre-existing disease or the nature of the operative procedure) and (ii) limitation of toxins that might jeopardize residual renal function (159).

Unfortunately, direct monitors of renal wellbeing are still in the rudimentary stage of development. Accordingly, indirect measures of renal function (CVP and MAP) are relied upon on a minute-to-minute basis, whereas the clinical measurement of urine output is still relied upon when evaluating renal function over longer time intervals.

To date, only one drug (*N*-acetylcystine) has proven to prophylactically improve renal outcome, following a high-risk procedure (radiocontrast administration). Manipulation of autoregulatory vasodilators (nitric oxide and PGE<sub>2</sub>) and vasoconstrictors (endothelin, vasopressin, and AII) may prove helpful in the future. However, at this time, maintenance of adequate intravascular volume, MAP, and cardiac output are the most important renal protective measures an anesthesiologist can provide for high-risk patients.

### KEY POINTS

- ☞ Recent studies indicate that an increased relative risk of death is associated with kidney failure when adjusted for a wide range of covariates (14,15). Accordingly, early and accurate indicators of renal insufficiency or failure are essential to the management of critically ill patients.
- ☞ Intrinsic or intrarenal ARF has many causes, but in trauma and critical care settings, the great majority of cases are due to acute tubular necrosis (ATN) following on from a prerenal hypoperfusion state.
- ☞ The hallmark that underscores experimental models of hemodynamically mediated ARF is a reduction of RBF (injury generally results when RBF is reduced by more than 50%) for at least 40 to 60 minutes.

- 9 Urine output is not always the best measure of renal wellbeing. Rather, indirect measures are at times more reliable during resuscitation of a trauma patient (i.e., mean arterial pressure, preload, and cardiac output).
- 9 Ischemic ATN is typically seen after a prolonged episode of hypotension, particularly when the blood flow to the kidney is interrupted (e.g., aortic cross-clamp) (31–34).
- 9 Most nephrologists would agree that doubling of the serum creatinine and the rising of serum creatinine of 1.0 mg/dL per day over two to three days would constitute a patient in ARF (Table 2).
- 9 Decreased urine output, and rising serum BUN and creatinine are the standard indicators for the development of worsening ARF.
- 9 An arterial line serves the dual purpose of providing access for repetitive ABG samples, as well as continuous beat-to-beat measurement of arterial BP throughout resuscitation, operative management, and critical care.
- 9 SPV is a technique for gauging intravascular volume status, which is very useful in renal failure patients.
- 9 Trauma and critically ill patients with renal insufficiency should have their CVP maintained on the high side to protect against the prerenal state.
- 9 In situations where assessment of LVEDV is critical (e.g., hypotension, low cardiac output, and normal or high filling pressures by CVP and PACWP), using a TEE provides the more accurate and direct view of LV preload and contractility (86).
- 9 The most clinically useful way to diagnose ATN is the evaluation of the urine sediment. The presence of brown granular casts and epithelial cells, singly or in casts, is seen in 80% of patients with ATN (94).

## Renal Protective Agents in Trauma and Critical Care

Ludwig H. Lin and A. Sue Carlisle

Department of Anesthesiology and Critical Care Medicine, UC San Francisco Medical Center, San Francisco, California, U.S.A.

### INTRODUCTION

Acute renal failure (ARF) is a commonly seen complication of critical illness, and carries an additional grave prognosis for its sufferers. It occurs in about 5% of all general hospital patients. By various reports, the frequency of ARF among patients is 1% at the time of admission, 2% to 5% during hospitalization, and as high as 4% to 15% after cardiopulmonary bypass. It is associated with a greater than 50% mortality rate, and increases the relative risk of death by 6.2-fold (1). Even in patients who survive hospitalization and ARF to discharge, duration of stay is prolonged, adding additional costs to their medical care. Between 20% and 60% of patients with ARF would develop end-stage renal disease (ESRD), requiring long-term dialysis, which adds further to health-care costs and significantly affects the quality of life (2).

In order to provide optimal care to the critically ill population, to decrease their mortality and morbidity, and to reduce the already overburdened healthcare budget, the prevention of ARF is of utmost importance to be able to prevent the development of ARF as a comorbidity, or barring that, to be able to treat it. ARF in trauma and critical illness is often reversible, if recognized early and appropriate treatment is promptly instituted. This chapter briefly summarizes the pathophysiology of the common causes of ARF in this population, and then reviews the various prophylactic and/or treatment measures for them.

### PATHOPHYSIOLOGY OF ACUTE RENAL FAILURE IN TRAUMA/CRITICAL CARE

The definition of ARF is imprecise, and various standards exist in the literature. Commonly used definitions include a change in serum creatinine of  $>0.5$  mg/dL ( $44 \mu\text{mol/L}$ ), an increase of more than 50% over the baseline value, a reduction in the calculated creatinine clearance by 50%, or a need for dialysis (see Volume 2, Chapters 40 and 41).

☞ **ARF in the critically ill is often a multifactorial process, but usually involves a combination of hypoperfusion and local hypoxic injury, from inflammatory stress due to toxins or oxygen free radicals.** ☞ The causes of ARF in the surgical intensive care unit (SICU) and/or trauma setting are numerous. However, the list of etiologies is slightly narrower than the differential affecting patients with ARF at the time of admission to the hospital. In addition, as many as a third of patients who develop ARF have some degree of chronic kidney disease as a result of organ damage from pre-existing diabetes, hypertension, or renal vascular atheromatous disease. The renal injury

ranges from an easily treated prerenal azotemia to acute tubular necrosis (ATN) to cortical necrosis.

Many drugs used in the diagnosis or treatment of the critically ill population, such as anti-inflammatory agents, antimicrobials, immunosuppressants, and radiocontrast agents, can induce ARF, and do so by affecting renal blood flow (RBF) and by direct tissue toxicity (Table 1).

### Hypoperfusion

Maintenance of the intravascular volume and preservation of renal perfusion is essential to the well-being of the kidneys. Adequate perfusion ensures two factors for the kidney: that the glomerular filtration rate (GFR) is maintained, which allows for proper homeostasis of electrolytes and fluid balance, and that oxygen delivery is adequate. The partial pressure of oxygen in the renal medulla is actually already quite low at baseline, ranging around 20 torr, compared with 50 torr in the cortex (3). Therefore, any further decrease in its perfusion pressure and oxygen delivery can be devastating. Once hypoxic injury occurs, the resulting necrosis and inflammatory responses are likely to prolong the deleterious effects.

☞ **Endocrine and autocrine functions act reflexively in the renal vasculature to adjust for hypoperfusion.** ☞

The kidney can adapt for brief periods to changing perfusion conditions. The macula densa in the juxtaglomerular apparatus provides a constant feedback to regulate the GFR; it does this by secreting paracrine signals, such as prostaglandins to vasodilate, and adenosine to vasoconstrict the afferent renal arteriole, in response to changing perfusion pressures. Afferent vasodilation increases the perfusion pressure, and thus the GFR; afferent vasoconstriction does the opposite (4). Further endocrine functions follow, such as the activation of the renin-angiotensin II-aldosterone system for blood pressure regulation and increased water and sodium resorption.

### Drugs and Toxic Exposure

Various conditions and therapeutic maneuvers occurring in trauma and critically ill patients can disrupt the baseline regulatory process (Table 2). Rhabdomyolysis, with free myoglobin acting as a scavenger of nitric oxide (NO), promotes afferent and intramedullary vasoconstriction (2,3,5). Rhabdomyolysis may account for nearly 5% of the causes of ARF in critically ill patients. Sepsis and septic shock, while having a direct effect of hypoperfusing the kidneys, probably also exert additional deleterious effects by increasing the amount of inflammatory and prothrombotic signals present, leading to renal microvascular injury, thromboemboli formation, and increased vasoconstriction.

**Table 1** Common Mechanisms of Acute Renal Failure in Trauma and Critical Care

Hypoperfusion	Hypovolemic shock
	Hypotensive shock
	Sepsis
	Thromboemboli
	Afferent renal artery vasoconstriction (from toxins and drugs)
	Rhabdomyolysis
	NSAIDs
	Contrast dye
	ACE-inhibitor agents
	Amphotericin
	Cyclosporine
	FK-506
	Direct renal tubular injury
Aminoglycosides	
Contrast dye	
Amphotericin	
Cyclosporine	
FK-506	
Hypoxia	
Inflammatory processes	

Abbreviations: ACE, angiotensin-converting enzyme; NSAIDs, nonsteroidal anti-inflammatory drugs.

Sepsis syndromes are associated with more than 50% of all cases of ARF in critically ill patients.

Use of nonsteroidal anti-inflammatory drugs (NSAIDs) and cyclooxygenase-2 (COX-2) inhibitors decrease the amount of prostaglandins being produced in the macula densa (4). Prostaglandins are responsible for continued sodium resorption, potassium excretion, and afferent vasodilation. When prostaglandin-mediated afferent arterial vasodilation is disrupted, the decreased arteriolar caliber can lead to decreased tubular perfusion, especially in situations where the patient is also hypovolemic. Amphotericin and contrast dye agents have a similar effect in promoting afferent arteriolar vasoconstriction (6–8). Amphotericin also increases the release of thromboxane A<sub>2</sub> to contribute to hypoperfusion.

Cyclosporine and FK-506 (tacrolimus), both exert a similar afferent renal arteriolar vasoconstrictive effect. The mechanisms are unclear, but part of the phenomenon

**Table 2** Conditions and Agents Disrupting Afferent Arterial Vasodilation and Causing Direct Tubular Injury

Agents disrupting afferent renal artery vasodilation (i.e., cause vasoconstriction)	Agents causing direct renal tubular injury
Rhabdomyolysis	Aminoglycosides
NSAIDs	Contrast dye
Contrast dye	Amphotericin
ACE-inhibitor therapy	Cyclosporine
Amphotericin	FK-506
Cyclosporine	Diuretics
FK-506	

Abbreviations: ACE, angiotensin-converting enzyme; NSAIDs, nonsteroidal anti-inflammatory drugs.

involves the initiation and expression of the renin-angiotensin system. Endothelial activation also appears to be involved, and chronic administration of these agents leads to intimal proliferation of the renal arterioles.

In drug-induced renal toxicity, tubular cell damage occurs as a result of a multipronged injury cascade: direct injury to the tubular cells, disruption of their ion exchange function, as well as increased local concentration of oxygen free radicals (2,7,8). Compounds like peroxynitrite, and products of lipid peroxidation, are noted to be increased in the renal tissue, when aminoglycosides and radiocontrast agents are administered (7–9). They induce direct cellular damage, by damaging the cellular components, and by inactivating enzymes, including mitochondrial respiratory enzymes and membrane pumps, damaging DNA. These agents also deplete the stores of glutathione and endogenous NO to further impair renal perfusion. Amphotericin and aminoglycosides also directly increase the oxygen demand of tubular cells. Cyclosporine and FK-506 both seem to increase the expression of transforming growth factor- $\beta$  (TGF- $\beta$ ), a signal for proliferation of fibroblast and endothelial cells. This results in arteriopathies, as mentioned earlier, and also in tubulointerstitial fibrosis and subsequent renal dysfunction.

The use of diuretics, particularly those affecting the loop of Henle have been promoted to preserve urine output in critically ill patients with ARF. Theoretically, loop diuretics may protect the loop of Henle by reducing its transport-related workload through inhibition of the Na<sup>+</sup>/K<sup>+</sup>/Cl<sup>-</sup> pump. However, clinical trials have not shown a renal protective benefit to loop diuretics. Other effects of diuretics include the reduction of volume overload and control of hyperkalemia and acidosis.

☞ **While diuretics have been used to convert oliguric ARF to nonoliguric ARF, the outcomes have not been improved with their use.** ☞ The Project to Improve Care in Acute Renal Disease (PICARD) study group performed a cohort study between October 1989 and September 1995, and analyzed 552 patients with ARF in intensive care units. Their observation was that diuretic use at the time of consultation (of the nephrology specialist) for the management of ARF was associated with a significant increase in the risk of death or nonrecoverable renal function. While the authors of the study stressed against any inference that diuretics themselves caused harm, they did note that such a lack of support for the use of diuretics to improve morbidity and mortality means that their use should be discouraged (10).

## POTENTIAL PROPHYLACTIC REGIMENS

In order to actively pursue a principle of “renal protection” for trauma and SICU patients, the intensivist must maintain adequate renal perfusion, limit toxic exposure, and consider utilization of renal protective drugs. Furthermore, renal protective strategies should be instituted in high-risk patients, targeting each of the aforementioned mechanisms. Such a multifaceted plan consists of: preservation of perfusion via euvolemia, maintenance of renal arteriolar patency, and decreasing tissue damage from toxins and oxygen free radicals. Various agents have been employed as prophylactic treatment of ARF and are discussed as follows.

### Preservation of Perfusion

#### Fluids

☞ **One of the best renal protective maneuvers is aggressive fluid resuscitation and maintenance of euvolemia.** ☞ In a

recent study of aggressive fluid resuscitation in septic patients, overall survival improved by 30% (30% vs. 46.5% mortality) (11). For the critically ill patient with multisystem organ dysfunction, the importance of preserving organ perfusion cannot be stressed enough (also see Volume 2, Chapters 40 and 41). For the kidney, especially, euvolemia is essential, and will effectively prophylax against many side effects of the toxins mentioned previously. For example, hydration has been demonstrated to prevent the decreased RBF in patients being given NSAIDs and COX-2 inhibitors (4), as well as amphotericin (12) and contrast dye agents (7,8). Goals of volume and fluid replacement for critically ill patients are shown in Table 3 (13).

### Dopamine

Dopamine, mannitol, and diuretics are probably the classic examples of “renal protection.” A combination of these agents is often used in the surgical setting, in patients undergoing high-risk procedures for renal damage, such as abdominal aortic aneurysm repair. In many critical care units a “low-dose” dopamine infusion (1–3 mcg/kg/min) is often used as a renal protective agent (2,5). There is some physiologic basis to support this empirical use, though more recently, its efficacy has been refuted. Dopaminergic receptors exist in the central nervous system as well as the renal circulation, and the DA-1 receptors on the renal vasculature effect vasodilation, and thus theoretically preserve renal perfusion (14). Dopamine has different effects on the various catecholamine receptors at varying concentrations. In the range of 1 to 3 mcg/kg/min, dopamine is primarily an agonist for dopamine<sub>1</sub> (D<sub>1</sub>) receptors, and in higher doses (4–9 mcg/kg/min) can act as  $\beta$ -adrenergic agents to increase cardiac contractility and output, or in extremely high doses (10–20 mcg/kg/min) will exert  $\alpha_1$ -adrenergic effects to increase the systemic vascular resistance via peripheral vasoconstriction. In fact, 25% of dopamine is converted to norepinephrine in the circulation, which probably also partially explains this dose-responsive differential effect (1).

To date, not a single large randomized controlled trial (RCT) has demonstrated a positive outcome (in terms of renal protection, morbidity, or mortality) with the use of renal dose (1–3 mcg/kg/min) dopamine infusion. It is not clear that dopamine infusion has long-term benefits. In both animal and human studies, RBF does increase with low dose dopamine. Urine output increases as well, and probably does so as a result of dopamine’s stimulation of natriuresis, rather than the simple explanation of an increased RBF. There are numerous studies supporting this observation, and low-dose dopamine has been successfully used in conjunction with norepinephrine or epinephrine

**Table 3** Goals of Volume and Fluid Replacement for Critically Ill Patients

Achieve and maintain normovolemia and hemodynamic stability
Optimize oxygen delivery and oxygen consumption
Restore fluid homeostasis in the different fluid compartments
Ensure adequate plasma COP
Improve microcirculatory perfusion
Ensure appropriate inflammatory response and endothelial cell–leukocyte interactions

Abbreviation: COP, colloid osmotic pressure.

Source: Adapted from Ref. 13.

infusions, for example, to provide for “renal vasodilation” during systemic hemodynamic support (15). In a direct comparison to dobutamine, dopamine was associated with better diuresis, kaliuresis, and natriuresis at the same hemodynamic parameters. In dog models, low-dose dopamine therapy seemed to lead to improved urine excretion of sodium, more so in the ischemic injury model of renal failure than the nephrotoxic injury models.

However, none of the small studies demonstrate a long-term benefit and improved survival of patients with ARF following renal dose dopamine administration. Although a few studies were indeed positive, their results could not be duplicated by other investigators (1). The best arguments for the continued use of low-dose dopamine may be that: (i) conversion from oliguric ARF to non-oliguric ARF does improve survival (50–80% vs. 15–20%) (16–18), and perhaps an increase in the GFR; and (ii) as long as low-dose dopamine does no harm to the patient, some clinicians advocate its continued use in selected patients (19).

### Mannitol

While loop diuretics are not helpful, the osmotic diuretic agent mannitol may provide modest benefit by reducing oxidant activity. As discussed earlier, nephrotoxicity from oxygen-free radical damage follows from both ischemic and numerous toxic insults to the renal parenchyma. Mannitol, by forcing diuresis and scavenging oxygen-free radicals, is theoretically beneficial.

There is a small amount of data in the rhabdomyolysis literature to support these claims (20). Mannitol is often used along with fluid repletion, and sodium bicarbonate in the treatment of rhabdomyolysis. With free myoglobin accumulating in the renal tubules, sludging results, and oliguric ARF rapidly develops (21). Myoglobin catalyzes the metabolism of NO, and thus rhabdomyolysis produces a secondary injury through renal arteriolar vasoconstriction and decreased renal perfusion (3).

♣ In rhabdomyolysis, aggressive intravenous fluid hydration, to maintain a urine output greater than 200 mL/hr, is the recommended first priority (21). ♣ Sodium bicarbonate and mannitol are often added to the regimen, with a small study showing some potential benefit (20). While the antioxidant and diuretic activity of mannitol and the alkalization of urine by sodium bicarbonate to prevent urate and myoglobin crystal formation, may indeed be helpful, the conventional thinking is that the intravascular volume expansion, supplied by their administration, probably provides the greatest benefit.

### Fenoldopam

♣ Fenoldopam, a DA-1-specific dopaminergic agonist, actually has documented benefit, in that it improves renal hemodynamics, function, and histology (14). ♣ Fenoldopam exerts renal vasodilation effects, improving both cortical and renal medullary blood flow and decreasing sodium reabsorption in the proximal tubule. Fenoldopam appears to lead to long-term improvement in patients who are receiving amphotericin B or cyclosporine. In a study comparing fenoldopam or placebo in treating patients recovering from thoracoabdominal aortic aneurysm, the survival of patients treated with prophylactic fenoldopam was 93%, compared with 80% for placebo (22). While the number of patients in this study was limited ( $n = 58$ ), the data do suggest that there may be an advantage to fenoldopam that was not

demonstrated with dopamine. Larger studies and trials that seek to duplicate the previous positive results with fenoldopam are needed before any conclusions can be drawn.

### **Atrial Natriuretic Peptide**

Atrial natriuretic peptide (ANP) and its synthetic siblings, urodilatin and anaritide, are all potent renal artery renal vasodilators. ANP is a potent antagonist of renal vasoconstrictor signals (23). In animal models, it reduced the incidence of ARF in both ischemic (24) and toxic (25) models. In a small open label human study; involving 53 patients, it was demonstrated that a 24-hour infusion of ANP resulted in a statistically significant increase in creatinine clearance (26). In the subgroup of patients with nonoliguric ARF, ANP was associated with a significant increase in dialysis-free survival.

Urodilatin may be better than ANP, because it has more potent natriuretic and diuretic abilities, resists rapid breakdown, and does not exhibit tachyphylaxis (27). Some preliminary studies looking at prophylactic use of urodilatin as a renal protective agent, following transplant surgery (cardiac and liver), have been done (28,29), demonstrating favorable results in the small sample sizes used. In these investigations, fewer patients required dialysis, and nonoliguric patients had higher urine flow rates.

An early report found that anaritide treatment did not improve the dialysis-free survival rate in critically ill patients with ATN (30). In fact, it was associated with decreased survival. However, a more recent study showed that anaritide, administered to patients with ischemic ARF sustained as a complication of cardiac surgery, significantly increased renal function and decreased the need for dialysis (31).

### **Vasopressin**

A recent study compared the outcome of fluid resuscitation with vasopressin following liver trauma. Treatment with vasopressin showed improved blood flow, and also prevented further blood loss. It also significantly improved short-term survival, when compared with fluid therapy (32,33). A unique feature of vasopressin, not shared by other vasopressors, is that it causes vasodilation in the renal vasculature. Vasopressin causes vasodilation in key vascular beds, including the pulmonary, cerebral, renal, and coronary circulations—unique features of vasopressin not shared by other vasoconstrictor agents. One mechanism of vasopressin-induced vasodilation is the activation of oxytocin endothelial receptors, which in turn trigger activation of endothelial isoforms of NO synthase (33). Thus vasopressin, at low doses, may have a sparing effect on key vascular beds.

### **Prevention/Reduction of Renal Injury Due to Drugs/Toxins Avoidance of Hyperglycemia**

The strict control of plasma glucose in patients with septic shock has yielded the stunning results of reduced mortality (from the septic shock), as well as decreased incidence of ARF (see Volume 2, Chapter 60) (34,35). Indeed, for the critically ill patient population, the use of aggressive insulin infusion regimens to maintain a glucose level between 80 and 110 mg/dL should now be regarded as a standard element in the prevention of ARF. These beneficial effects of normoglycemia were initially thought to be a secondary effect of the insulin administration, that perhaps the growth-factor-like properties of insulin were responsible.

Interestingly, in a follow-up multivariate analysis, the authors of the initial study demonstrated that the reduction in sepsis mortality was independently associated with the glucose level, whereas the beneficial differences in the incidence of ARF were due to the amount of insulin administered as an independent factor. Therefore, the benefits of insulin administration versus euglycemia need to be clarified in the prophylaxis of renal injury. ⚡ **Tight control of glucose between 80 and 110 mg/dL, via the use of insulin infusions, is useful to prevent renal failure in the septic patient population.** ⚡

### **Daily Dosing of Aminoglycosides**

Altered administration regimens of nephrotoxic drugs have also been found to be helpful. With aminoglycosides, the literature supports utilizing a daily dose, rather than divided doses to deliver the daily total, in order to reduce nephrotoxicity (36). Recent studies have shown that aminoglycoside toxicity is higher when these drugs are administered in the setting of low urine pH, while it is the lowest when administered immediately after a meal, when the urine pH is the highest (6).

### **Radiocontrast Agent Dosing and N-Acetylcysteine Pretreatment Regimens**

Antioxidant agents are being used to treat renal toxicity induced by specific drugs. *N*-acetylcysteine (NAC) is probably the most well known. In the literature, it has been effectively used prophylactically in patients receiving gentamicin or radiocontrast agents (7–9). Using it for contrast dye administration, NAC is given as an oral drug, 600-mg PO BID, for 24 hours, along with ample hydration with intravenous saline (7,8). The NAC dosing is continued for 24 hours after exposure to the radiocontrast agent. In one prospective study (8), the incidence of an increase in creatinine greater than 0.5 mg/dL was 2% in the NAC-treated group compared with 12% in the placebo (half-normal saline) treated group. The absolute creatinine levels achieved were also higher in the placebo group. Numerous studies have also demonstrated the efficacy of hydration protocols, and the use of nonionic isomolar contrast media.

The use of NAC in animal models of gentamicin treatment demonstrate a similar type of prophylactic effect in renal protection (9). On pathology slides, sections demonstrate that animals who received NAC had less tubular necrosis and cast formation. *N*-acetylcysteine treatment also decreases the levels of malondialdehyde and myeloperoxidase, which are involved in lipid peroxidation and oxygen free radicals (9).

The mechanism of action is complicated. *N*-acetylcysteine has direct vasodilatory properties by regenerating endogenous NO at the endothelium. Furthermore, as mentioned in the previous paragraph, it reduces the levels of enzymes responsible for lipid peroxidation and oxygen free radical generation. *N*-acetylcysteine reduces poly (ADP-ribose) synthase expression, meaning that the nuclear enzyme cannot deplete its substrate; nicotinamide adenine dinucleotide (NAD<sup>+</sup>) and nicotinamide adenine dinucleotide phosphate (NADP) are two important coenzymes found in cells. NADH is the reduced form of NAD<sup>+</sup>, and NAD<sup>+</sup> is the oxidized form of NADH. Nicotinamide adenine dinucleotide is converted to NADP with the addition of a phosphate group to the 2' position of the adenosyl nucleotide through an ester linkage. In the setting of hypoperfusion or hypoxia, ATP levels are decreased and

anaerobic metabolism is favored. In the presence of NADH, pyruvate is converted to lactate (anaerobic conditions), whereas in the presence of NAD<sup>+</sup>, pyruvate is converted to acetyl coA (aerobic conditions) to enter Krebs cycle and ATP is produced. Some investigators feel that in the setting of dangerously low ATP levels, increased glycolysis and decreased aerobic metabolism leads to apoptosis and renal tubular necrosis.

Finally, NAC upregulates antioxidant systems, such as superoxide dismutase and glutathione peroxidase, and may enhance oxygen consumption. In summary, NAC is active in all the various mechanisms responsible for renal toxicity: it counteracts vasoconstriction and decreased renal oxygen delivery; it counteracts the direct cellular toxicity of certain drugs; and it decreases the amount of secondary damage by oxygen free radicals (also see Volume 2, Chapter 40, Table 6).

☛ **N-acetylcysteine should be used to prevent drug-induced nephrotoxicity caused by radiocontrast, aminoglycosides, and other susceptible agents.** ☛

The methylxanthines, theophylline, and aminophylline, antagonists of adenosine, have also been considered in treating radiocontrast-induced nephropathy. Adenosine's role in RBF regulation is complex, because it is responsible not only for afferent arteriolar vasoconstriction, but also cortical arteriolar vasodilation (3). Because adenosine is expressed in the juxtaglomerular apparatus and the renal mesangial cells vasoconstrict (37), the thinking is that the methylxanthine compounds can counteract the vasoconstrictive phenomenon, caused by radiocontrast agents. That theory is clinically seen; some trials do suggest a slight benefit to aminophylline/theophylline administration (38–40). However, other studies have not demonstrated the same benefit. Comparing the methylxanthines to NAC, the latter compound demonstrates greater clinical efficacy.

Additional experimental drugs have been mentioned in the recent literature as possible prophylactic agents. These have yet to come into clinical practice. Prostaglandin analogs, such as prostacyclin and alprostadil (prostaglandin E1), have been studied in surgical patients undergoing orthotopic liver transplantation and cardiopulmonary bypass (41,42). Results do not consistently demonstrate benefit, although decreased postoperative creatinine levels and trends toward lesser incidence of dialysis-dependent renal failure were noted in some of the studies. It may be that prostaglandins, with their potent systemic vasodilator effects, have differing effects on renal perfusion, depending on the balance between selective renal arteriolar vasodilation versus systemic hypotension, and a resulting decrease in renal perfusion pressure, so that positive benefits from their administration depend on a detailed administration algorithm. Tirilizad mesylate, a 21-aminosteroid, has been tested for pharmacokinetics and safety in healthy human volunteers (43,44). In rat models, 21-aminosteroids are effective in attenuating the increase in postinjury serum creatinine and improving animal survival (45). They achieve these effects through their role in inhibiting lipid peroxidation, by scavenging lipid radicals and by inhibiting lipid-radical chain reaction, and by inducing NO synthase (46).

### **Amphotericin-B Formulations and Administration Regimens**

In many immunosuppressed patients, severe fungal infections are an often lethal complication, and necessitate the utilization of the most efficacious antifungal agent, amphotericin. Amphotericin is a potent nephrotoxin, decreasing renal function in up to 80% of patients; the risk

appears to be linked to the cumulative dose given (47). The more serious fungal infections requiring amphotericin treatment, such as fungemia, require a higher dose of amphotericin, and thus increase the risk of developing renal insufficiency, and the concomitant presence of other sequelae of critical illness (diuretic use, abnormal serum creatinine at baseline, use of other nephrotoxic drugs) in a patient requiring amphotericin increases the risk as well (48).

To reduce its toxicity, amphotericin can be given as a constant infusion rather than a bolus dose (12); this produces an increased serum creatinine in 33% versus 58% of the patients (49). Sodium infusion, with 1-L 0.9% saline load prior to amphotericin administration, has been used clinically, and a randomized, double-blinded placebo-control study demonstrated efficacy to prevent creatinine rise (50). In addition, various liposomal formulations, which are less nephrotoxic, are now being used. These liposomal amphotericin formulations reduce direct toxicity to the tubular cells, although the mechanism is unclear. The clinical data is scant regarding liposomal amphotericin, but seem to show equivalent efficacy with standard amphotericin, while reducing renal toxicity by 50% (51–56). ☛ **By utilizing different drug formulations and/or different dosing regimens for antimicrobials, like aminoglycosides, amphotericin, and radiocontrast agents, one can decrease their nephrotoxicity.** ☛

## **EYE TO THE FUTURE**

The current research is focused on studying the molecular pathophysiology, to attempt to block the cascades responsible for renal injury. At the same time, the mechanism for inflammatory injury is being elucidated for possible therapeutic intervention. With advances in continuous renal replacement therapy (CRRT) and hemodialysis, further improvements, such as renal tubule assist devices, can help decrease the extent of renal injury. In addition, there is growing interest in blood purification systems to remove circulating mediators in sepsis, which may confer benefit in septic patients.

### **Molecular Pathophysiology**

Lysophosphatidic acid (LPA) binds to a family of G protein-coupled receptors, and has effects on cell proliferation, cell differentiation, survival, and apoptosis suppression. It also functions as an inflammatory mediator. Reperfusion injury of the kidney is correlated with persistently increased levels of LPA (57–59). Three subtypes of LPA receptors exist, and LPA3 receptor antagonism has demonstrated, in the mouse experimental model, to lead to decreased renal ischemia-reperfusion injury (60). The same investigators applied a LPA3 receptor agonist to mouse kidneys, and found an enhanced level of renal injury. These data suggest that an LPA3 receptor antagonist compound could serve as treatment of ischemic ARF.

In addition, studies are examining the clinical utility of antagonists to the A<sub>2A</sub> adenosine receptor. It is one of the four subtypes of adenosine receptors, and appears to function via the G protein-coupled effects on adenylyl cyclase to vasodilate the renal vasculature, and increase RBF and GFR (61). Activation of A<sub>2A</sub> receptors on neutrophils also reduces neutrophil oxidative activity and decreases neutrophil adherence to endothelial cells. The combined effect is that of reduced tissue damage from neutrophil infiltration and the resulting oxidative damage (58,59).

## Immunology

Investigators (62) recently demonstrated that T and B cells were important mediators of renal injury following whole body ischemia. When T-cell-deficient mice were exposed to whole body ischemia conditions, the rise in serum creatinine and tubular injury were significantly decreased. B-cell-deficient mice also had reduced rates of postischemic injury, via a pathway independent of T-cell function (63). Soluble mediators and changes in the expression of adhesion molecules like ICAM-1 are part of the mechanism. Once they are more clearly delineated, these systems may be the targets for future therapy.

## Tissue Engineering

Tissue engineering may be used in the future, for either prophylaxis or treatment of renal injury. A group of investigators (64) treated pigs, inoculated with *Escherichia coli* with CRRT, including a filter with renal proximal tubule cells, forming a "renal tubule assist device" (RTAD), to prophylactically treat for ATN. The results demonstrated decreased plasma levels of IL-6 and gamma interferon, and the treated animals doubled their survival time compared with the sham control group. This result suggests that the idea of utilizing high-volume hemofiltration and other CRRT options may indeed lead to reduced levels of inflammatory cytokines and better survival.

## Other Novel Drugs

One study found fructose-1,6-diphosphate (FDP) to be beneficial in preventing cell edema and protecting renal cells from ischemic damage. This study also suggests that treatment with FDP may, in some cases, be superior to treatment with mannitol (65). Early trials have indicated that recombinant human atrial natriuretic peptides (rhANP) and insulin-like growth factor 1 (IGF-1) may be beneficial in primary prevention of ARF (66,67). Further research is also needed to determine the effects of anti-inflammatory agents in the prophylaxis and treatment of ARF. Specific inducible nitric oxide synthase (iNOS) inhibitors, N-iminoethyl-L-lysine (L-NIL), and  $\alpha$ -melanocyte-stimulating hormone ( $\alpha$ MSH) have exhibited some protective properties against ARF (68,69).

Finally, a study aimed at evaluating the effectiveness of treating kidney trauma with a caffeic acid phenethyl ester (CAPE) found that this treatment provided significant protection against further injury (70).

## SUMMARY

Many cases of ARF in critically ill patients are attributed to nonpreventable causes. Pathological processes, such as septic, hemorrhage, or cardiogenic shock are associated with ARF. In addition, the many diagnostic and therapeutic maneuvers instituted to stabilize and treat critically ill patients also introduce nephrotoxicity via a variety of mechanisms. In most situations of ARF, the etiology is multifactorial, but includes the common final pathways of renal hypoperfusion, oxygen-free radical injury and, in many cases, direct cellular toxicity from a specific nephrotoxic property of the compound administered. In these situations, certain prophylactic and treatment measures can be taken to increase chances of renal recovery. While some are only in preliminary clinical studies and others are pure theories, there are strategies and agents available now with documented clinical efficacy. Their use

should definitely enter into the management plan of a critically ill patient, who has risk factors for developing ARF.

## KEY POINTS

- ✎ ARF in the critically ill is often a multifactorial process, but usually involves a combination of hypoperfusion and local hypoxic injury, from inflammatory stress due to toxins or oxygen-free radicals.
- ✎ Endocrine and autocrine functions act reflexively in the renal vasculature to adjust for hypoperfusion.
- ✎ While, diuretics have been used to convert oliguric ARF to nonoliguric ARF, the outcomes have not been improved with their use.
- ✎ One of the best renal protective maneuvers is aggressive fluid resuscitation and maintenance of euvolemia.
- ✎ In rhabdomyolysis, aggressive intravenous fluid hydration, to maintain a urine output greater than 200 mL/hr, is the recommended first priority (21).
- ✎ Fenoldopam, a DA-1-specific dopaminergic agonist, actually has documented benefit, in that it improves renal hemodynamics, function, and histology (14).
- ✎ Tight control of glucose between 80 and 110 mg/dL, via the use of insulin infusions, is useful to prevent renal failure in the septic patient population.
- ✎ N-acetylcysteine should be used to prevent drug-induced nephrotoxicity caused by radiocontrast, aminoglycosides, and other susceptible agents.
- ✎ By utilizing different drug formulations and/or different dosing regimens for antimicrobials, like aminoglycosides, amphotericin, and radiocontrast agents, one can decrease their nephrotoxicity.

## INTRODUCTION

During the past decades, a number of advances have been made in the field of renal replacement therapy (RRT). In addition, clinicians have gained a better appreciation of the need for early and aggressive management of patients with renal failure in the intensive care unit (ICU) (1). Although a number of treatment modalities exist, there seems to be continued controversy about selection of the most appropriate modality for an individual patient. This chapter briefly reviews the clinical spectrum of renal failure in the ICU, the indications for initiating dialysis, the general principles of dialysis therapy, and unique features, advantages, disadvantages, and utility of various renal replacement modalities.

## DIVERSITY OF CLINICAL RENAL FAILURE IN THE ICU

Appropriate modality selection requires an understanding of the clinical spectrum of renal failure in the ICU. The incidence of acute renal failure (ARF) in the ICU is approximately 10–25% (2,3). Most (70%) of the critically ill patients who develop ARF require dialysis, and most do not survive (50–90% death rate) (2–4). Uncomplicated ARF refers to an acute and transient decline in glomerular filtration rate (GFR) without clinically apparent complications. Dialytic support is often unnecessary in such patients, or may be required for a single indication such as hyperkalemia. In contrast, complicated ARF is characterized by multiple metabolic and volume status perturbations. Often, the patient is oliguric, and the renal failure may be present in association with the multiple organ dysfunction syndrome (MODS). This is the type of renal failure most commonly seen in patients, who suffer from acute trauma or develop postoperative renal failure. The threshold for initiation of dialysis and the choice of dialytic modality will differ depending on associated complications and comorbid conditions.

## INDICATIONS FOR INITIATION OF DIALYSIS

Although there has been an increased appreciation for the need for early and aggressive management of ARF in the

ICU setting, there are no standards for initiation of dialysis and many nephrologists avoid dialysis initiation for as long as possible. Two major factors contribute to the tendency to delay dialysis. First, the dialysis procedure itself has associated risks. Hypotension, dysrhythmias, and complications of vascular access placement are common (5,6). Second, there is a concern that dialysis can delay recovery of renal function (7,8). This contention is supported by animal data in which hypotension resulted in recurrent renal ischemia (9), and human studies that showed a decline in GFR during and after an intermittent hemodialysis session (10,11).

Several factors need to be considered when making the decision to provide RRT. First, it is important to recognize that in the ICU patient, ARF usually does not occur in isolation from other organ system dysfunction. Consequently, providing dialysis can be viewed as a form of renal support for multiorgan dysfunction rather than mere renal replacement (Table 1) (12). For example, in the presence of oliguric renal failure, administration of large volumes of fluid to patients with MODS may lead to impaired oxygenation. In such a setting, early intervention with extracorporeal therapies for management of fluid balance may significantly impact the function of other organs even in the absence of traditional indices of renal failure, such as marked azotemia.

☞ **Indications for dialysis generally fall into one of three broad categories: solute indications such as marked azotemia, volume indications such as fluid overload, or both.** ☞ Often the patient who has suffered acute trauma receives large volumes of blood products, fluids, and nutrition. Such therapy is acutely life-saving, but may result in the manifestation of an indication for dialysis, such as fluid overload or hyperkalemia.

The indication for initiation of dialysis influences outcome. We showed in a randomized controlled trial comparing intermittent therapies with continuous therapies that patients dialyzed for solute control had a better outcome than those dialyzed for volume control (13). Moreover, patients dialyzed for both solute and volume control had the worst outcome. Therefore, it appears that volume overload tends to confer a poorer prognosis. This notion is supported by a number of observational studies. For

**Table 1** Indications and Timing of Dialysis for Acute Renal Failure: Renal Replacement vs. Renal Support

Reason for dialysis	Renal replacement	Renal support
Therapeutic goal	Replace renal function	Support other organs
Timing of intervention	Based on level of biochemical markers	Based on organs involved (e.g., lungs, brain, and so on), and clinical needs
Indications for dialysis	Narrow	Broad
Dialysis dose	Extrapolated from ESRD	Targeted for overall support

*Abbreviation:* ESRD, end-stage renal disease.

*Source:* Adapted from Ref. 108.

example, recent studies have suggested that achieving a negative fluid balance in the first three days of admission for septic shock is a predictor of better survival (14). Moreover, hypervolemia is a common accompaniment to perioperative ARF. Mukau et al. (15) showed that 95% of their patients with postoperative acute renal failure had fluid excesses of more than 10 L at initiation of dialysis.

Consequently, fluid regulation ought to be an important consideration when deciding to initiate dialysis in the ICU patient with ARF. Such renal support provides volume “space,” which permits for the administration of adequate nutritional support without limitations (16). In addition to volume overload, solute disturbances such as hyperkalemia may predispose to life-threatening dysrhythmias, and uncontrolled uremia may lead to a variety of serious complications. Thus, maintaining electrolyte, acid–base, and solute homeostasis is another important factor when considering initiation of dialysis.

## PRINCIPLES OF DIALYSIS

### Overview

Dialysis is a process in which molecules in solution “A” (blood) diffuse across a semipermeable membrane into solution “B” (dialysate) (6). The transfer of solute across the membrane is determined by membrane characteristics and the solute concentration on the two sides of the membrane. Diffusive clearance denotes the movement of small molecular weight solutes from plasma to dialysate under the driving force of an electrochemical gradient. Convective clearance (ultrafiltration, UF) occurs when water is driven across the membrane by either a hydrostatic or an osmotic force. Those solutes that can pass through the membrane pores move along with the water (solute drag).

### Determinants of Diffusive Clearance

Membrane characteristics play a major role in determining the efficacy of diffusive clearance. For example, membranes with larger pores, larger surface area, and a specific geometrical configuration have greater permeability to small and middle molecular weight solutes than membranes with smaller pores and smaller surface area. Most hemodialysis membranes in use today are of the synthetic type and are more permeable than older cellulose-based membranes. Flow rates of blood and dialysate and dialysis time are the principal determinants of diffusive solute clearance. Direction of blood and dialysate flow is also a major determinant of solute diffusion capacity. ⚡ **Currently, all**

**hemodialysis modalities employ a countercurrent mechanism in which the direction of dialysate flow is opposite that of the blood flow.** ⚡ Countercurrent flow serves to maximize the concentration gradient between the blood and dialysate throughout the length of the membrane (6).

### Determinants of Convective Clearance

Because convective clearance is achieved mainly by solute drag during UF, the rate at which UF occurs is the major determinant of convective clearance. Ultrafiltration rate is, in turn, determined by transmembrane pressure, water permeability, pore size, surface area, membrane geometry, and thickness. Moreover, enhanced blood flow rates will increase UF rates because higher blood flow rates prevent the stagnant accumulation of proteins that cannot cross membranes at the surface of UF. As the transmembrane pressure difference increases, more fluid and accompanying solute will be removed. However, the maximum transmembrane pressure that can be applied is limited by the tensile strength of the membrane. The size of solutes that can be “dragged” during convection is determined in large part by the size selectivity of the membrane. In general, convection is more efficient than diffusion at removing middle and large molecular weight solutes (6).

### Vascular Access

In order for blood to be removed from the patient, circulated through the dialyzer, and then returned to the patient, access to the vasculature is required. Although arteriovenous fistulas and grafts are used in chronic dialysis patients, it is more common to use a catheter for vascular access in the acute setting. When arteriovenous acute dialysis was still commonly used, patients would receive one catheter in a major artery and another in a major vein. This type of vascular access has fallen out of favor because of the multitude of complications that arise from the use of chronic indwelling arterial catheters.

Currently, most patients who require acute dialysis receive a dual-lumen venous catheter placed in either the femoral, internal jugular, or subclavian vein. The design of these catheters is such that blood is withdrawn from a proximal opening and returned to a more distal opening. Because of this design, some of the blood returned to the vein will “recirculate” into the withdrawing port and into the hemofilter again, reducing the efficiency of dialysis.

⚡ **Recirculation associated with dual-lumen venous catheters have been shown to be worse in the femoral**

(16%) when compared with the subclavian catheter (4%,  $p = 0.0001$ ) location (17). ⚡

**Anticoagulation**

In order to avoid clotting of blood in the dialysis membrane, circuit tubing, or at the vascular access, patients who receive dialysis will generally require anticoagulation. Although a variety of anticoagulants have been used, including low molecular weight heparin, prostacyclin, and nafomostat, systemic unfractionated heparin anticoagulation, regional citrate anticoagulation, and frequent saline flushing of the system are the most commonly used methods (18).

Heparin anticoagulation is easy to use, but has the disadvantage of necessitating anticoagulation of the entire patient. At our institution we have favored the use of regional citrate anticoagulation (19,20). The use of protocol-driven monitoring and adjustment of anticoagulation has improved the efficiency of both the nursing staff and the physicians. In addition, we have been able to provide dialysis to patients at high risk of bleeding with minimal complications. Citrate anticoagulation works by binding ionized calcium, thereby decreasing its ability to act in the clotting system. Some specific considerations for citrate coagulation include the need for liver function to convert citrate to bicarbonate, and the risk of hypocalcemia (especially in the setting of liver failure).

**DEFINITION OF TERMS**

**Intermittent Therapy**

An intermittent therapy is defined as any extracorporeal dialysis therapy in which the patient is treated for less than 24 hours (Table 2). Included in this category are patients treated with intermittent hemodialysis (IHD), sorbent IHD, intermittent hemodiafiltration (IHDF), intermittent ultrafiltration (IUF), extended daily dialysis (EDD), and sustained low efficiency dialysis (SLED), also termed slow continuous dialysis (SCD) (21).

**Continuous Therapy**

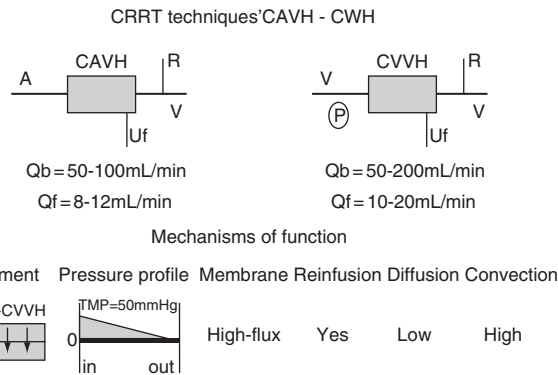

A continuous therapy is defined as any extracorporeal dialysis therapy in which the patient is treated for 24 hours or

**Table 2** Dialysis Modalities for Acute Renal Failure

Intermittent therapies (treatment duration < 24 hours)	Continuous therapies (treatment duration 24 hours per day)
Hemodialysis Single pass Sorbent based	Peritoneal dialysis Ultrafiltration (SCUF) Hemofiltration (CAVH, CVVH)
Hemodiafiltration	Hemodialysis (CAVHD, CVVHD)
Ultrafiltration	Hemodiafiltration (CAVHDF, CVVHDF)
Extended daily dialysis	
Slow continuous dialysis	

*Abbreviations:* SCUF, slow continuous ultrafiltration; CAVH, continuous arteriovenous hemofiltration; CVVH, continuous venovenous hemofiltration; CAVHD, continuous arteriovenous hemodialysis; CVVHD, continuous venovenous hemodialysis; CAVHDF, continuous arteriovenous hemodiafiltration; CVVHDF, continuous venovenous hemodiafiltration.

longer. Included in this category are a number of modalities that will be defined in the following (Table 2).

**Continuous Arteriovenous Hemofiltration**

Continuous arteriovenous hemofiltration (CAVH) is a form of continuous RRT (CRRT) whereby blood is driven by the patient’s blood pressure through a filter containing a highly permeable membrane via an extracorporeal circuit originating from an artery and terminating in a vein (Fig. 1). The ultrafiltrate produced is replaced in part or completely with appropriate replacement solution to achieve blood purification and volume control (22,23).

**Continuous Venovenous Hemofiltration**

Continuous venovenous hemofiltration (CVVH) is a form of CRRT whereby blood is driven through a highly permeable membrane by a peristaltic pump via an extracorporeal circuit originating from a vein and terminating in a vein (Fig. 1). The ultrafiltrate produced is replaced in part or completely with appropriate replacement solution to achieve blood purification and volume control (22,23).

**Slow Continuous Ultrafiltration**

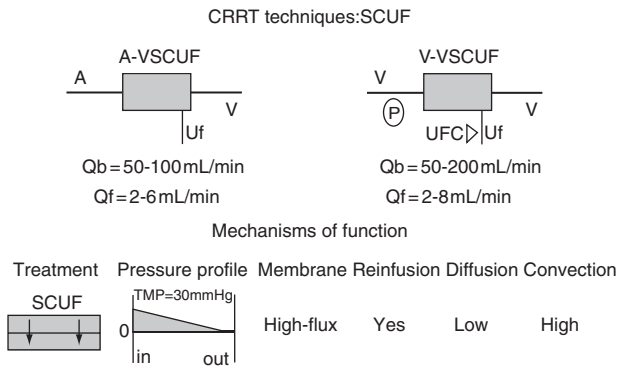

Slow continuous ultrafiltration (SCUF) is a form of CAVH or CVVH not associated with fluid replacement often used in the management of refractory edema with or without renal failure (Fig. 2). The primary aim of SCUF treatment is fluid removal (22,23).

**Continuous Arteriovenous Hemodialysis**

Continuous arteriovenous hemodialysis (CAVHD) is a form of CRRT in which the extracorporeal circuit includes slow countercurrent dialysate flow into the ultrafiltrate–dialysate compartment of the hemofilter (Fig. 3). Blood flow through the blood compartment of the membrane is driven by the patient’s blood pressure through a circuit beginning in an artery and terminating in a vein. Fluid replacement is not routinely administered and solute clearance is mostly diffusive (22,23).

**Continuous Venovenous Hemodialysis**

Continuous venovenous hemodialysis (CVVHD) is a form of CRRT in which the extracorporeal circuit includes slow countercurrent dialysate flow into the ultrafiltrate–dialysate compartment of the hemofilter (Fig. 3). Blood flow through

**Figure 2** Continuous renal replacement techniques: slow continuous ultrafiltration. *Abbreviations:* A, artery; V, vein; Uf, ultrafiltrate; P, peristaltic pump; Q<sub>b</sub>, blood flow; Q<sub>f</sub>, ultrafiltration rate; TMP, transmembrane pressure; UFC, ultrafiltration control system. *Source:* Adapted from Ref. 23.

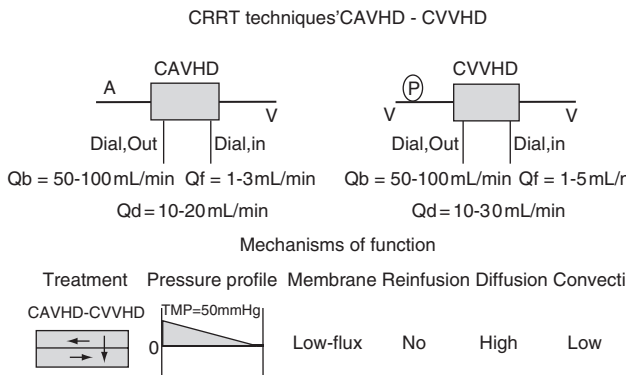

the blood compartment of the membrane is driven by a peristaltic pump through a circuit beginning and terminating in a vein. Fluid replacement is not routinely administered and solute clearance is mostly diffusive (22,23).

**Continuous Arteriovenous Hemodiafiltration**

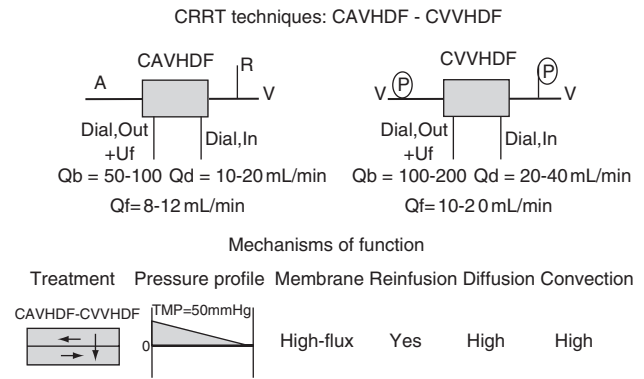

Continuous arteriovenous hemodiafiltration (CAVHDF) is a form of CRRT whereby the CAVH circuit is modified by the addition of slow countercurrent dialysate flow into the ultrafiltrate–dialysate compartment of the hemofilter (Fig. 4). Ultrafiltration volumes are optimized to exceed the desired weight loss to take advantage of convection. Fluid replacement is routinely administered as clinically indicated to replace fluid losses either in part or completely. Solute removal is both diffusive and convective (22,23).

**Continuous Venovenous Hemodiafiltration**

Continuous venovenous hemodiafiltration (CVVHDF) is a form of CRRT whereby the CVVH circuit is modified by the addition of slow countercurrent dialysate flow into the ultrafiltrate–dialysate compartment of the hemofilter (Fig. 4). Ultrafiltration volumes are optimized to exceed the

**Figure 3** Continuous renal replacement techniques: continuous arteriovenous hemodialysis and continuous venovenous hemodialysis. *Abbreviations:* A, artery; V, vein; Uf, ultrafiltrate; P, peristaltic pump; Q<sub>b</sub>, blood flow; Q<sub>f</sub>, ultrafiltration rate; TMP, transmembrane pressure; in, dialyzer inlet; out, dialyzer outlet; Dial., dialysate; Q<sub>d</sub>, dialysate flow rate. *Source:* Adapted from Ref. 23.

**Figure 4** Continuous renal replacement techniques: continuous arteriovenous hemodiafiltration and continuous venovenous hemodiafiltration. *Abbreviations:* A, artery; V, vein; Uf, ultrafiltrate; P, peristaltic pump; Q<sub>b</sub>, blood flow; Q<sub>f</sub>, ultrafiltration rate; TMP, transmembrane pressure; in, dialyzer inlet; out, dialyzer outlet; Dial., dialysate; Q<sub>d</sub>, dialysate flow rate. *Source:* Adapted from Ref. 23.

desired weight loss to take advantage of convection. Fluid replacement is routinely administered as clinically indicated to replace fluid losses either in part or completely. Solute removal is both diffusive and convective (22,23).

**DIALYSIS MODALITIES IN THE SICU**

**Intermittent Therapies**

**Intermittent Hemodialysis**

Intermittent hemodialysis is the procedure that has been widely used over the past four decades in patients with end-stage renal disease (ESRD) and those with ARF (24). The vast majority of IHD is performed using a single pass of dialysate at flow rates greater than that of blood. Several important technological advances have made the procedure safer and more suited for the ARF patient. The availability of variable sodium concentrations in the dialysate, bio-compatible membranes, bicarbonate-based dialysate, and volumetrically controlled UF offer certain advantages that are particularly well suited to the ARF patient (25,26). Nevertheless, most centers use a fairly standard regimen for administration of the therapy.

Because of limitations imposed by the use of dual-lumen catheters for vascular access, only moderate blood flow rates (200–300 mL/min) can be achieved. The standard dialysate flow rate used is 500 mL/min. IHD offers the advantage of providing for rapid correction of electrolyte and acid–base disturbances. A major disadvantage of IHD is the limited time (usually three to four hours) of total therapy per day. As a result, the patient will remain without renal support for the majority of the day during which fluid regulation, acid–base balance, and electrolyte homeostasis are not controlled.

✎ **The most significant disadvantages of IHD in the critically ill patient with ARF are related to hypotension and the possibility of worsening the severity of the renal injury.** ✎ Critically ill patients with hemodynamic instability may not tolerate the higher blood flow rates needed to achieve adequate levels of diffusive clearance in the limited duration (three to four months typically) of the treatment. More importantly, is the demonstration that intradialytic hypotension can contribute to delayed renal recovery

(7,8). Of interest is the demonstration by Schortgen et al. (27) that implementation of strict guidelines for the management and prevention of intradialytic hypotension helped reduce the incidence of such episodes, but did not affect overall mortality.

### **Sorbent System Intermittent Hemodialysis**

Sorbent system IHD is a dialysis system in which dialysate is regenerated by passage through a sorbent cartridge that contains five distinct layers (28,29). The first layer contains activated carbon, the second contains urease, which converts urea to ammonium carbonate, and the third layer contains zirconium phosphate in which cations, such as potassium, calcium, and magnesium are adsorbed and exchanged for hydrogen and sodium ions. The fourth layer of the cartridge contains hydrated zirconium oxide to which phosphate and fluoride are adsorbed and exchanged for acetate. The fifth layer contains activated carbon, which removes creatinine and other waste products. Although this system is used infrequently, it provides the advantage of obviating the need for a source of pure water and providing a highly portable system. In addition, because of the unique characteristics of the regenerating system, sorbent IHD allows for greater flexibility in custom tailoring the dialysate. The biggest disadvantage of the sorbent system is that it is less efficient than single-pass IHD. The slower flow rate of dialysate and the overall adsorptive capacity of the sorbent cartridge impose the main limitations on efficiency of diffusive clearance.

### **Intermittent Hemodiafiltration**

Intermittent hemodiafiltration (IHDF) uses convective clearance for solute removal. The main disadvantage of IHDF is the need for large volumes of sterile replacement fluid. Therefore, the expense associated with IHDF has limited its use in the United States. Proponents of the therapy claim that it offers greater hemodynamic stability and improved middle molecule clearance. Because of these advantages, IHDF has been used extensively in Europe (21,30).

### **Intermittent Ultrafiltration**

Intermittent ultrafiltration utilizes the same device used for IHD, but differs in that the main utility of IUF is fluid removal. Typically, the procedure is used for treatment of pulmonary edema or severe cardiomyopathy with resistant fluid overload. Because the same machine used for IHDF is also used for IUF, some centers use a combination of IUF and IHD in series. Such an approach provides for greater hemodynamic stability and the ability to quickly treat volume overload. A major disadvantage is the loss of time available for diffusive solute clearance.

### **Extended Daily Dialysis**

Extended daily dialysis (EDD) has recently been described by Kumar et al. (31). They treated 25 patients with daily IHD for a duration of six to eight hours during daylight at a blood flow rate of 200 mL/min and a dialysate flow rate of 100–300 mL/min. In comparison with a similar group of patients treated with CVVH, they demonstrated that less total daily heparin was needed and less intensive nursing commitments were required. However, no outcome measures such as survival or renal recovery were assessed. In a similar study using a single-batch dialysis system, Lonnemann et al. described treating 20 patients with ARF for 18 hours at blood flow rates of 70 mL/min and dialysate

flow rates of 70 mL/min. Adequate urea clearance rates were achieved, but there was no control group and no clinical outcome data was reported (32).

### **Slow Continuous Dialysis/Sustained Low Efficiency Dialysis**

The terms SCD and SLED have been used interchangeably within the medical literature; and, this dialytic modality was first reported by Schlaefer et al. in 1999 (33). With this technique, blood flow rates were 100–200 mL/min and dialysate flow rates were also 100–300 mL/min. Patients were treated for 12 hours during the day or evening (33). The procedure was felt to be safe, efficient, and relatively simple to use. More recently, Lornoy et al. (34) showed similar results. Marshal et al. (35) recently reported their experience with SLED in 37 critically ill patients who failed IHD. Adequate urea clearance and volume control were achieved. Mortality in the patients was not different than historical controls with a similar APACHE II score. A major disadvantage experienced in this study was the need for early termination of the procedure in one-third of the treatments because of hypotension or blood clotting. Hypokalemia and hypophosphatemia requiring replacement were also reported (35).

## **Continuous Therapies**

### **Peritoneal Dialysis**

Peritoneal dialysis was the first “continuous” form of dialysis therapy used in the acute setting. In peritoneal dialysis, the patient’s peritoneum acts as the semipermeable dialysis membrane. Dialysate consists of a sterile, lactate-based solution inserted via a peritoneal catheter into the abdominal cavity. Diffusion occurs from the blood perfusing the peritoneum to the fluid in the abdominal cavity across the peritoneum. Once the dialysate becomes saturated (three to four hours), it is removed and fresh dialysate is instilled. Fluid removal is achieved by using an osmotic pressure mechanism in which varying dextrose concentrations in the dialysate provide an osmotic gradient for water flow from the patient’s blood to the peritoneal cavity. The process of dialysate instillation and removal can be automated with a device known as a cycler. The main advantages of peritoneal dialysis are that it is less labor-intensive than hemodialysis, it does not require anticoagulation, and may be better tolerated hemodynamically than IHD. The major disadvantage is that dialysis is relatively inefficient because total solute removal is limited by total peritoneal effluent. In addition, transfer across the peritoneum is highly influenced by both the anatomy of the peritoneum and the underlying hemodynamic status of the patient. Another major disadvantage is that the procedure requires the placement of a peritoneal catheter into the abdominal cavity, which may add to the morbidity of the already compromised ICU patient (36). This later complication is often a major limiting factor in patients who have sustained trauma or have undergone abdominal surgery.

## **Continuous Renal Replacement Therapies**

### **Overview**

Over the last decade, a number of CRRTs have emerged. The definitions of the various therapies were given earlier. All forms of CRRT utilize membranes that are highly permeable to water and low molecular weight solutes. The various forms of CRRT differ in how the vasculature is accessed and the mechanism by which solute clearance is achieved.

The use of continuous arteriovenous modalities has fallen out of favor largely because of the complications associated with indwelling arterial catheters. The various venovenous modalities differ primarily by their mechanisms of solute removal. In SCUF, there is minimal solute removal, but adequate fluid removal. In CVVH, the removal is primarily by convection. In CVVHD, the removal is primarily by diffusion, and in CVVHDF, solute removal is by both diffusive and convective mechanisms.

#### *Operational Characteristics*

CRRT mechanisms have a number of operational characteristics that distinguish them from IHD. The blood flow rate is usually much lower (100–200 mL/min) as is the dialysate flow rate (1–2 L/hr or 17–34 mL/min). Because of the lower dialysate flow rate, the dialysate becomes saturated quickly and is a limiting factor in diffusive clearance capacity. As CUF will result in the loss of significant volumes of plasma water (often 1 L/hr), administration of replacement fluids is necessary. The composition of the replacement solution can be varied depending on the needs of the patient. **Continuous renal replacement therapy is unique in that solute removal is, in effect, dissociated from fluid removal.** Varying the composition of the dialysate or replacement fluid allows for accurate control of solute balance while fluid removal can be manipulated independently by varying the amount of replacement fluid administered. Net fluid removal during a given time period (e.g., each hour) is equal to the ultrafiltrate volume during that time period minus the amount of replacement fluid administered. Another unique feature of CRRT is the fact that the time available for either solute or fluid management is no longer a limiting factor (Table 3) (21,37).

**CRRT provides improved hemodynamic stability, continuous electrolyte control, improved dialysis adequacy, and easier control of volume status.**

#### *Potential Advantages of Continuous Renal Replacement Therapies*

Hypotensive patients may not tolerate the rapid solute shifts associated with the higher blood flow rates required for IHD. Therefore, approximately 10% of all patients with ARF who require dialysis cannot be treated with IHD because of hemodynamic instability (5,10,38–41). Paganini et al. (42) were the first to show that 23 patients who were too unstable to tolerate IHD could be dialyzed with CRRT. Later,

Davenport et al. (39) showed that CRRT was superior to IHD in maintaining hemodynamic stability. Manns et al. (5) and Bellomo et al. (43) showed similar results. However, data from Misset et al. (41) showed no difference between CRRT and IHD with regard to hemodynamic stability. Because of the continuous nature of CRRT, lower blood and dialysate flow rates can be used to achieve blood purification without hemodynamic compromise.

**Rapid alterations in sodium and fluid status have been shown to occur in IHD. Such alterations are implicated as a cause for the cerebral edema that can be observed in IHD.** Moreover, such fluctuations are avoided in CRRT as electrolyte and fluid changes are more gradual (39).

Dialysis dosing will be discussed next in greater detail, but a major advantage of CRRT is the more efficient removal of middle and large molecular weight solutes. Such solutes are removed inefficiently with IHD which utilizes primarily diffusive clearance, but can be cleared more effectively by CRRT modalities that incorporate convective clearance (21,44,45). The efficiency of diffusive small solute removal is less with CRRT, but because of the extended time of treatment and small solute removal with UF overall clearance is similar to IHD.

As fluid balance can be managed on an hour-by-hour basis, CRRT allows for the administration of large volumes of fluids. Of particular importance in this regard is the ability to administer adequate parenteral nutrition to the critically ill patient without concern for exacerbating fluid overload. It is well established that the increased catabolism seen in critically ill patients requires more aggressive nutrition management (46). Several studies have shown that CRRT allows patients with multi-organ failures (MOF) to benefit from adequate nutritional support (16,47,48). A recent study by Tremblay et al. in 12 burn patients showed that patients had gained an excess of 10 kg in weight prior to CRRT initiation, but that the fluid had been removed within a short period of time, allowing for improved nutritional support without compromising overall fluid status (48). In addition, several studies have shown that intermittent procedures often necessitate suboptimal nutrition because of fear of interdialytic volume overload (46) (Table 4).

#### *Potential Disadvantages of Continuous Renal Replacement Therapies*

A number of disadvantages and potential complications also exist for CRRT. Cost, nursing support, anticoagulation, and

**Table 3** Continuous Renal Replacement Therapy (Comparison of Techniques)

	SCUF	CAVH	CVVH	CAVHD	CAVHDF	CVVHD	CVVHDF	PD
Access	A-V	A-V	V-V	A-V	A-V	V-V	V-V	Peritoneal catheter

electrolyte disturbances are some of the main disadvantages or potential complications that may be encountered.

The required nursing support and cost of CRRT may be greater than that needed for intermittent techniques; however, this has not been clearly demonstrated. The requirement for specific nursing training and skills is important, but adequate training can be achieved (49,50). See the section on “Logistical Factors” that follows for a more in-depth discussion of this important topic.

Continuous renal replacement therapies require continuous anticoagulation to avoid clotting of the dialysis filter and tubing. Several choices exist for anticoagulation, but the most widely used anticoagulants are heparin, saline flushes, and citrate. Heparin is easy to use, but the patient is, by necessity, exposed to the anticoagulant for a prolonged period of time. As many patients who suffer from trauma or are in a postoperative state are at increased risk for bleeding, such patient exposure to heparin may be harmful. In our series, we showed that 26% of patients dialyzed with heparin anticoagulation experienced bleeding compared with 0% in citrate anticoagulated treatments (19,20).

Saline flushes were also associated with a low bleeding risk, but filter clotting occurred in 12% of cases and treatments were terminated because of clotting in 28% of cases (19,20). Consequently, we have found the use of regional citrate anticoagulation to be more advantageous in certain patients at high risk for bleeding complications.

Anticoagulation with citrate is achieved by the binding of citrate to ionized calcium, an essential cofactor for coagulation. The citrate is introduced into the circuit as the blood exits the patient and travels through the filter where some of it is removed; most of it enters the patient’s systemic circulation. Postfilter-ionized calcium levels are lowered to 0.25 mmol/L in order to maintain system patency. ⚡ **Systemic citrate is normally metabolized in the liver, liberating three bicarbonate ions for each citrate molecule.** ⚡ Because of the mechanism of action and subsequent metabolism, citrate anticoagulation requires careful attention to acid–base balance and serum calcium levels. The use of citrate also requires the preparation of specialized solutions, which may not be available in all centers (18–20). Although frequent saline flushes have been used in CRRT, the filter life under such circumstances is markedly reduced. Filter life with heparin is also less than that achieved with citrate.

A number of electrolyte abnormalities are seen during CRRT. Although hyperkalemia and hyperphosphatemia are common complications of ARF, both IHD and CRRT are effective at adequately controlling both electrolytes. However, during CRRT hypokalemia and hypophosphatemia occur, commonly owing to the removal of both solutes during UF and diffusion, while replacing removed ultrafiltrate with solutions that do not contain either electrolyte. ⚡ **Phosphate control is achieved faster with CRRT and phosphate reductions are often more profound than those seen with IHD (51).** ⚡ The treatment for either hypokalemia or hyperphosphatemia is to replace the electrolytes with either potassium chloride, potassium phosphate, or sodium phosphate, depending on the need.

⚡ **Hypocalcemia is a major concern in patients receiving CRRT with citrate anticoagulation (52,53).** ⚡ Because citrate complexes ionized calcium, its administration often requires that the patients receive a calcium chloride infusion into a vein outside of the dialysis circuit in order to maintain appropriate systemic calcium levels. Normally, metabolism of citrate liberates the bound calcium, thus limiting overall ionized calcium declines. However, in patients with liver disease and reduced capacity to metabolize citrate, severe hypocalcemia may occur if inadequate calcium chloride replacement is not administered. Conversely, aggressive calcium chloride administration may result in hypercalcemia (52). This is particularly noted when patients with temporary liver dysfunction recover their ability to metabolize citrate liberating large amounts of ionized calcium. In most cases, stopping the calcium infusion and continuation of dialysis are sufficient to control hypercalcemia.

Acidosis is treated by a variety of mechanisms in CRRT. Most dialysate solutions contain either lactate or bicarbonate and thus limit bicarbonate diffusion in acidemic patients. The use of bicarbonate-based replacement solutions allows for delivery of large amounts of bicarbonate without causing volume overload or sodium overload. The exact effect of using bicarbonate replacement on outcomes has not been systematically studied. The use of citrate anticoagulation also delivers bicarbonate to the patient once the citrate is metabolized. Overall, CRRT seems to result in more rapid and normalized correction of electrolyte abnormalities when compared with IHD (52).

## Intraoperative Dialysis

### Overview

The use of dialysis in the operating room has emerged recently as a potentially important therapy for intraoperative management of both solute and volume control. The use of SCUF in cardiothoracic surgery has been in place for many years and has been successful at controlling fluid overload. Recently, the use of intraoperative CRRT in patients with combined liver and renal failure undergoing orthotopic liver transplantation (OLT) has gained acceptance.

### Potential Advantages

⚡ **Tight control of both intravascular volume and plasma solute concentration constitute the major advantages of intraoperative CRRT.** ⚡ Often, patients require infusion of large volumes of blood products, colloids, and crystalloids during lengthy operative procedures in which hemodynamic instability is common, such as in OLT. The use of intraoperative CRRT may prove beneficial in such patients. Previously, we published our experience with the use of intraoperative CRRT in OLT and showed that the typical

patient required approximately 35 units of packed red blood cells and 4–5 L of crystalloid (54). In the setting of renal failure, administration of such large volumes may cause respiratory compromise.

Hyperkalemia secondary to administration of large volume of blood products is better controlled with intraoperative CRRT in oliguric patients. Moreover, recent studies have shown that during OLT there is a predictable pattern of cytokine release that may correlate with hemodynamic instability. Specifically, Miki et al. (55) showed that during the anhepatic phase and up to four hours after reperfusion of the allograft serum levels of interleukin (IL)-1 and IL-6 are increased two to three times the baseline values. Potentially, CRRT may be advantageous if limitation of such rises in cytokine levels can be achieved.

### **Potential Disadvantages**

✎ **The important disadvantages of intraoperative CRRT include the need for anticoagulation of the circuit, and logistics.** ✎ The use of heparin would be contraindicated during surgery, but regional citrate anticoagulation described here may be safer. We reported our experience with the use of regional citrate anticoagulation in 13 patients undergoing OLT (54). The main disadvantage was transient changes in ionized calcium concentrations that were related to either excessive exogenous calcium administration or excessive citrate administration with blood products (54). Protocol-driven adjustments in citrate and calcium administration may be safer for maintaining adequate circuit anticoagulation while avoiding significant serum calcium changes.

The use of CRRT in operations requires the presence of a dialysis machine in what is already a fairly limited space. More important is the need for a well-coordinated multidisciplinary team composed of nephrologists, anesthesiologists, dialysis nurses, operating room nurses, and ICU nurses to ensure that all facets of dialysis, including UF, anticoagulation, vascular access function, and machine troubleshooting are addressed.

## **SELECTION OF DIALYSIS MODALITY**

### **Overview**

In general, the goal of dialysis is to provide adequate renal replacement and/or support while minimizing complications of therapy. Unfortunately, there is no consensus regarding the timing, duration, frequency, and amount of dialysis to be administered for patients with ARF in the ICU. Thus, in current practice, modality choice is dictated by the experience of the provider and the availability of various modalities (56). In a recent survey of nephrologists in the United States, IHD was used most commonly for ARF in the ICU followed by CRRT and peritoneal dialysis (PD) (57). Of those who used IHD most commonly, familiarity with the procedure, efficacy, and ease of use were cited as the main reasons for choosing IHD. Continuous renal replacement therapy techniques were reserved, in large part, for patients with hemodynamic instability or those in need of aggressive nutritional support. The few who preferred PD felt that it offered several unique advantages. Most notably, it provides dialysis with remarkable hemodynamic stability. In addition, PD does not require the use of anticoagulation.

It is clear that the choice of modality must be tailored to the needs of each patient. The factors that influence the selection of dialysis modality can be divided into three main categories: those specific to the patient, those specific to the

modality, and those specific to the practice environment. ✎ **The recognition that CRRT provides the greatest advantages in critically ill patients has fostered an increased trend toward the use of this technique, especially in those with hemodynamic instability, those with traumatic brain injury (TBI), and/or sepsis/systemic inflammatory response syndrome (SIRS).** ✎

### **Patient Factors**

#### **Indications for Renal Replacement Therapy**

The indications for dialysis in the ICU are both diverse and prone to modification over the course of the disease. Consequently, the indication for initiating dialysis will influence the type of modality selected. Certain modalities are more efficient at solute control while others are more efficient at controlling fluid balance. For example, if the main indication for initiation of dialysis is hyperkalemia in a hemodynamically stable patient, then IHD is the modality of choice. Conversely, if volume overload is the main indication for dialysis, particularly in the setting of hemodynamic instability, CRRT may be the preferred modality (10,38,39,41). In many cases, however, the indications are multiple and often include solute and fluid components. In such cases, the time course of the desired response will influence the choice of modality. It is important to recognize that indications and modality selection do influence outcome. In our randomized controlled trial comparing CRRT with IHD, patients dialyzed for solute control had a better outcome than those dialyzed predominantly for volume control (13). Patients dialyzed for both solute and volume control had the worst outcome. The use of protocol-driven hour-by-hour fluid balance management in CRRT affords more sustained and predictable control of volume status. In addition, Bellomo et al. (58) showed that CVVHDF was superior to IHD at controlling azotemia 24 hours after initiation of RRT in ICU patients with ARF (58).

In a recent study of ARF resulting from rhabdomyolysis in victims of the 1999 Marmara earthquake in Turkey, only 15% of patients with ARF died. Dialysis was a predictor of worse outcome with a mortality rate of 17% of those who required dialysis compared with only 9% of those who did not require dialysis. Interestingly, most of the deaths occurred in patients with coexisting thoracic or abdominal trauma and in patients who required an amputation. The level of creatine phosphokinase (CPK) rise did not correlate with mortality (59). A recent report from the experience of the 1999 Taiwan earthquake showed that ARF occurred in 55% of the 90 rhabdomyolysis cases requiring dialysis that were identified. Acute renal failure was associated with a higher mortality (17% vs. 0%), but CPK values were unrelated to mortality. Of the 52 patients with ARF, 32 required dialysis with either IHD or CRRT, but further details are not provided in the report (60).

#### **Presence of Other Organ Failure**

The presence of nonrenal organ failure concomitantly with ARF has a major impact on outcome. Data from the European Dialysis and Transplant Association (EDTA) has shown that patients with isolated ARF experienced a mortality of only 8% (61). Moreover, several investigators have shown that the greater the number of failing organ systems in MODS, the greater the mortality. Lohr et al. (62) described a clinical index to predict survival in patients with ARF undergoing dialysis. These investigators found that the presence of associated organ system failure worsened mortality.

Moreover, the presence of other organ failures in the setting of ARF can influence the choice of modality selection. For example, patients with an abdominal surgery, such as an abdominal aortic aneurysm repair or perforated duodenal ulcer will not be candidates for peritoneal dialysis. Patients with severe hypotension will not be likely to tolerate IHD. Additionally, the impact of anticoagulation is an important consideration. PD and IHD can both be performed without anticoagulation; however, CRRT usually requires some form of anticoagulation (18). The influence of the therapy itself on the function of other compromised organs is another important consideration. For example, IHD, but not CRRT, is often associated with changes in intracranial pressure (ICP) (63,64).

Continuous therapies generally do not compromise hemodynamic stability; however, if not monitored closely volume depletion can ensue from lack of adequate replacement fluid administration. A recent report by Stoves et al. (65) showed that bradykinin release at the start of CRRT was correlated with initiation of hypotension. Interestingly, hypotension was uncommon in patients with sepsis receiving pressor support. Peritoneal dialysis may contribute to worsening hypoalbuminemia in patients with liver disease and may not be the modality of choice in that patient population (36). Moreover, PD is often associated with the enhanced removal of albumin-bound drugs, a problem (or benefit) not associated with hemodialysis (36).

### **Vascular Access**

The ability to obtain appropriate vascular access is one of the most important factors affecting the ability to provide adequate dialysis therapy. The use of arterial vascular access catheters has fallen out of favor because of the many complications encountered with these catheters. A number of complications can limit the ability to use a venous catheter adequately. Clotting or malpositioning of the catheter in the vein can lead to unforeseen reductions in blood flow rate. Currently used peristaltic blood pumps are usually set to withdraw blood from the access at a certain rate. However, in the presence of partial clotting, actual blood flow may be lower than the dialed rate. Such a complication may go unnoticed for many hours. Another important complication is the presence of recirculation in which a portion of “clean” blood returned to the patient from the dialyzer is redrawn by the peristaltic pump before it enters the patients’ overall blood pool (17). Such recirculation will limit the efficacy of dialysis, as the same portion of blood is dialyzed repeatedly.

Infectious and thrombotic complications of dialysis catheters are an additional important consideration. A recent report showed that femoral catheters were associated with increased infectious and thrombotic complications when compared with subclavian catheters (66). In general, subclavian catheters are discouraged in patients with ARF, because stenosis of the subclavian vein may limit the ability to place arm vascular access in the future if the patient survives, but does not recover renal function.

### **Mobility**

In cases where a patient will need to be moved from the bedside for imaging studies, surgery, and so on, it may be difficult to perform CRRT. It is usually not possible to transfer CRRT equipment with the patient because most current CRRT machines are not equipped with a battery-operated module. Disconnecting the patient from CRRT will deprive the patient of important dialysis and UF time, lowering the

efficacy of the treatment. Moreover, because of the need for more intensive nursing monitoring with CRRT, patients who are not in an ICU setting where there is no one-to-one nursing are not candidates for CRRT.

## **Dialysis Modality Factors**

### **Membrane Choice**

There are two factors to consider when choosing the type of membrane used for dialysis: biocompatibility and cytokine removal efficiency. The first issue (membrane biocompatibility) has several ramifications (67–70). Complement activation and neutrophil sequestration are known to occur in IHD with the use of certain membranes. However, because in CRRT the patient’s blood is exposed to the membrane for a prolonged time, the issue of membrane interactions is of paramount importance. Polysulfone and polyacrylonitrile membranes do not seem to activate complement and are often used in CRRT (71). In addition, biocompatible membranes seem to be associated with improved renal recovery (68,69,71–73). However, a recent study comparing cellulose acetate membranes with polysulfone membranes for acute IHD showed no difference in survival or renal recovery (72). A meta-analysis by Subramanian et al. (74) showed that synthetic membranes confer a significant survival advantage over cellulose-based membranes.

The second issue concerning membrane selection is the finding that membranes differ in their capacity to clear certain cytokines, such as TNF $\alpha$ , IL-1 $\beta$ , and IL-6. Conceivably, removal of these cytokines at a critical stage of disease progression may influence outcome. An in vitro model of CAVHD showed that a polyacrylonitrile membrane was two- to threefold more efficient at removing TNF $\alpha$  when compared with a polysulfone or polyamide membrane (75,76). Nevertheless, human studies have shown the ability to remove cytokines in CRRT, but blood levels of cytokines remain unchanged in adults (77–79). This is likely related to the membrane surface area compared with the volume of total body water and solute (which is larger in adults than in children). Although this remains an active area of research, it is not yet a factor that can be consistently used in modality selection at the current time.

### **Dose of Dialysis**

Unfortunately, there are no standard methods for the assessment of dialysis dose in ARF. In ESRD patients, dialysis dose is assessed by using urea kinetic modeling. In such a model, the basic elements measured are the urea levels prior to and after dialysis. Many formulae exist that incorporate weight, UF volume, time, and change in blood urea nitrogen (BUN) for assessment of dialysis dose. A main assumption of these models is that ESRD patients have a relatively constant urea generation rate and are at steady state. Because of this assumption, the method of dialysis dose determination used in ESRD is not directly applicable to patients with ARF. ARF patients tend to have fluctuating body fluid composition and varying urea generation rates. Nevertheless, a number of factors are related to the dialysis dose delivered. For example, in intermittent therapies, higher blood flow rates and longer durations of therapy are associated with an increased dose of dialysis delivered. In some studies, changes in BUN have been used as a surrogate for dose intensity. Clark et al. (44) compared IHD with CRRT using a computer model to determine the number of IHD sessions that would be required to achieve equivalent control of uremia. They found that for a 50-kg male, an average of

4.4 sessions of IHD per week was required to achieve the same uremic control obtained with CRRT. However, in patients with a weight of greater than 90 kg, equivalent uremic control could not be achieved with even daily IHD. Bellomo et al. (58) showed that in similar critically ill patients CRRT was more effective at control of azotemia than IHD.

Although it is difficult to measure dose per se, many have studied the factors that influence dose and their effects on outcomes. In hemofiltration techniques, the amount of ultrafiltrate generated per kilogram of body weight per unit time is associated with dose. Ronco et al. (80) have shown that in patients treated with hemofiltration techniques, a filtration rate of 35 ml/hr/kg was associated with improved 15-day survival. Honore et al. (81) showed that short-term high-volume hemofiltration (35 L in the first four hours) improved survival in patients with septic shock. Schiffel et al. (82) compared, prospectively, daily hemodialysis with every other day treatments. They showed an improvement in survival among patients on daily hemodialysis (15% vs. 22%,  $p < 0.05$ ). Paganini et al. (83,84) showed that approximately 65% of IHD patients received a dialysis dose as measured by urea kinetic modeling that was lower than prescribed. The nonsurvivors in that group of patients had significantly lower actual dose delivered compared with survivors. However, another study by Bouman et al. (85) showed no improvement in 28-day mortality and recovery from renal failure when early initiation of hemofiltration and high ultrafiltrate volumes were used. While the results are provocative, they need to be confirmed in a well-designed large multicenter trial. Such a trial is in progress [The VA/NIH Acute Renal Failure Trial Network Study (ATN)]. The ATN study is a multicenter, randomized controlled trial comparing two dosing strategies for RRT in ARF. In both treatment arms patients move freely between IHD and CRRT and SLED, as determined by their hemodynamic status. In the intensive therapy arm, IHD and SLED are provided on a basis of six times per week with a target  $K_t/V$  of 1.2–1.4 per treatment. Continuous renal replacement therapy is provided with an effluent flow rate of 35 ml/kg/hr. In the less intensive therapy arm, the same modalities of treatment are used; however, IHD and SLED are provided on a basis of three times per week, and CRRT is provided with an effluent flow rate of 20 ml/kg/hr. The primary study endpoint is 60-day all-cause mortality. Target enrollment is 1164 patients.

### **Intermittent vs. Continuous Therapies**

Because of the heterogeneity of ARF patients with respect to illness severity and comorbidities, it is difficult to adequately assess the effect of a particular renal replacement modality on survival. Nevertheless, a number of studies have compared IHD with CRRT in an effort to delineate whether one modality is superior to another with regard to survival. Several retrospective analyses in the early 1990s showed that it was likely that CRRT offered a survival advantage when compared with IHD (43,47,86,87).

In 1986, Mauritz et al. (88) compared IHD with either CAVH or CVVH and found no difference in survival between the groups. In 1992, Bellomo et al. (38,47) compared survival in 84 critically ill patients treated with conventional dialysis with 83 age-matched, APACHE II score-matched, and number of organs failing-matched patients treated with either CAVHDF or CVVHDF. Overall survival was 30% and 41% in the conventional dialysis and CRRT groups, respectively ( $p = \text{NS}$ ).

The same group then compared a prospectively treated group with the same conventional dialysis control group in their initial study. In this second study, patients treated with CVVHDF had better survival if they had two, three, or four organs failing or an APACHE II score of 24–29 (87). However, at the extremes of illness severity survival was not different. This study is difficult to interpret in view of the use of a retrospective control group. In 1993, Kruczynski et al. (89) reported a retrospective analysis of 12 patients treated with CAVH versus 23 patients treated with conventional hemodialysis. Survival was better in the CAVH compared with the conventional dialysis group (25% vs. 82%,  $p < 0.001$ ). However, patients in the conventional dialysis group were significantly older.

In 1991, Kierdorf (90) retrospectively compared 73 patients treated with CVVH with 73 age-matched controls treated with IHD and found a significant survival advantage in the CVVH group. In 1995, van Bommel et al. (91,92) retrospectively compared 34 patients treated with IHD to 60 patients treated with CAVHDF. The CAVHDF had a higher APACHE II score, but survival was not different between the two groups. A recent retrospective analysis by Jacka et al. (93) showed better renal recovery in patients initially treated with CRRT. However, mortality was not affected significantly by RRT mode (93). Thus, the data from retrospective analyses is conflicting, with some studies showing a survival advantage and others showing no advantage for CRRT. A comprehensive review of multiple studies showed that no survival advantage was conferred with the use of continuous therapies (94).

To date there are about six prospective, randomized trials comparing IHD with CRRT. The first study by Kierdorf and Sieberth had a target enrollment of 400 patients (95). An interim analysis of 100 patients showed a survival of 39.6% in the CVVH group and 34.1% in the IHD group. However, five patients in the IHD group were excluded from the analysis as they failed to complete the therapy because of "hemodynamic instability." The final results of this study were not published. In our study, 166 patients with ARF requiring dialysis were randomized to either CRRT ( $n = 84$ ) or IHD ( $n = 82$ ) (13). Patients with a mean arterial pressure (MAP) of less than 70 were excluded. Patients in the two groups were similar except that there were more males in the CRRT group and the APACHE II and III scores were higher in the CRRT group. Intensive care unit (59% vs. 41%,  $p < 0.02$ ) and hospital (65% vs. 47%,  $p < 0.02$ ) mortality was worse in the CRRT group. However, group analysis showed a preponderance of nonrenal conditions associated with a higher mortality in the CRRT group. When logistic regression was applied to adjust for this bias, the odds ratio for death with CRRT was 1.3 (95% CI, 0.6–2.7,  $p = \text{NS}$ ). Subgroup analysis showed that renal recovery was improved in survivors of CRRT when compared with survivors of IHD (92% vs. 59%,  $p = 0.01$ ). One of the main limitations of the study was the exclusion of patients with a MAP of less than 70 mmHg, a group that is likely to benefit the most from CRRT.

One multicenter prospective survey of 28 ICUs in France demonstrated that CRRT was used in 60% of patients dialyzed for ARF. Patients on CRRT had a greater number of organ dysfunction and higher mortality than IHD (79% vs. 59%) (96). More recently, Uehlinger et al. (97) randomized 125 patients over a 30-month period to treatment with either CVVHDF or IHD from a total of 191 patients with ARF in a tertiary-care university hospital ICU and analyzed the impact on in-hospital mortality, recovery from renal

failure, and length of hospitalization. The two groups were comparable at the start of RRT with respect to age ( $62 \pm 15$  vs.  $62 \pm 15$  years, CVVHDF vs. IHD), gender (66% vs. 73% male sex), number of failed organ systems ( $2.4 \pm 1.5$  vs.  $2.5 \pm 1.6$ ), Simplified Acute Physiology Scores ( $57 \pm 17$  vs.  $58 \pm 23$ ), septicemia (43% vs. 51%), shock (59% vs. 58%), or previous surgery (53% vs. 45%). Mortality rates in the hospital (47% vs. 51%, CVVHDF vs. IHD,  $p = 0.72$ ) or in the ICU (34% vs. 38%,  $p = 0.71$ ) were independent of the technique of RRT applied. Hospital length of stay in the survivors was comparable in patients on CVVHDF [median (range) 20 (6–71) days,  $n = 36$ ] and in those on IHD [30 (2–89) days,  $n = 27$ ,  $p = 0.25$ ]. The duration of RRT required was the same in both groups. The authors concluded that there was no evidence for a survival benefit of continuous versus intermittent RRT in ICU patients with ARF (97).

A meta-analysis of continuous versus intermittent therapies looking at all randomized and observational studies and applying strict selection criteria showed several interesting results (98). Overall, CRRT was associated with a lower risk of hospital death (RR 0.48, CI 0.34–0.69,  $p < 0.0005$ ) than IHD when studies in which patients with a similar baseline severity of illness was present. Overall mortality was similar when the two modalities were compared and even after adjustment for a number of factors including quality of the study, underlying condition of the patient, and type of membrane used. The main conclusion of the authors was that “current evidence is insufficient to draw strong conclusions regarding the mode of replacement therapy for ARF.” The authors did note that their analysis did not show that CRRT was worse than IHD even after numerous adjustments (98). Another meta-analysis by Tonelli et al. (99) showed that in comparison with IHD therapy, CRRT does not improve survival or renal recovery in unselected critically ill patients with ARF.

Although there is no definitive evidence that CRRT is superior to IHD, it may be inherently invalid to make such a broad comparison. It might be more appropriate to categorize patients into subgroups. For example, patients with heart failure may have a different outcome with CRRT than patients with sepsis or trauma. Similarly, patients with end-stage liver disease who do not receive a transplant will have a grave outcome irrespective of the modality used (64). Selection of modality based on the anticipated duration of therapy is better judged by the needs of the patients at the time of initiation. In hemodynamically unstable patients in whom fluid control is the main indication, it may be more appropriate to initiate CRRT, whereas in the trauma patient with isolated extremity injuries and rhabdomyolysis-mediated ARF and hyperkalemia and normal blood pressure, an intermittent modality may be preferable.

## Logistic Factors

### Cost

It remains unclear whether CRRT is more expensive than IHD. Some studies have suggested that CRRT may be slightly more expensive (100,101). The higher cost of CRRT can be accounted for in large part by the higher price of the hemofilters that are generally different than those used for IHD. The filters used for IHD are cheaper because they are purchased in bulk for use in the ESRD population. This disparity in cost may be reduced if CRRT is used more frequently and if filter life is extended by adequate anticoagulation. Physician time spent per patient is increased for CRRT;

however, this can be reduced as the physician gains familiarity with the procedure. At our institution, standardized protocols for fluid, electrolyte, and anticoagulation management have markedly reduced the time spent on monitoring and adjusting the CRRT prescription.

## Nursing Expertise and Other Support

Unlike IHD and PD, CRRT requires active participation of the critical care nurse caring for the patient. Consequently, nurses who are unfamiliar with CRRT may have difficulty managing the accurate fluid and electrolyte monitoring that is required to minimize complications (49,50). The availability of simple, easy to understand flow sheets, instructional booklets, and backup support serves to minimize errors related to nursing involvement (49). One of the main advantages of CRRT is the ability to provide the patient with improved nutrition. As a result, involvement of clinical nutrition personnel in the care of the patient becomes essential. Preparation of custom dialysate and replacement fluid, as well as drug dosing adjustment will require the involvement of skilled pharmacists who are familiar with the pharmacokinetics associated with the different dialysis modalities.

☞ Selection of dialysis modality depends on patient, modality, and logistic factors. ☞

## Summary of Modality Selection

A number of factors play a role in the process of deciding which dialysis modality is most appropriate for a particular clinical situation. Consequently, it is important for the intensivist to become familiar with the various modalities available and to gain some understanding of the differences between the modalities and their relative advantages and disadvantages. Table 5 summarizes recommendations regarding the choice of dialysis modality in common clinical circumstances.

## DIALYTIC REMOVAL OF CYTOKINES FOR SEPSIS

☞ The sepsis syndrome is associated with the presence of high levels of circulating and tissue cytokines that result in impairment of vascular permeability, hypotension, and renal failure. ☞ Removal of such cytokines is a potentially attractive therapy for the sepsis syndrome. TNF- $\alpha$  and IL-1 are important mediators of the sepsis response. Early in vitro studies showed that TNF- $\alpha$  was mainly adsorbed to the dialysis membrane and very little was actually filtered (102–104). Hoffman et al. (78) showed that TNF- $\alpha$  levels did not change after hemofiltration in patients with sepsis.

In contrast, Millar et al. (105) and Journois et al. (106) showed that hemofiltration reduced TNF- $\alpha$  levels in pediatric patients undergoing cardiopulmonary bypass surgery. Silvester (103) showed that reductions in TNF- $\alpha$  can be achieved after four hours of hemofiltration if a polyacrylonitrile (PAN) filter was used as opposed to a polysulfone filter. The reports for IL-1 are similarly inconclusive. Lonnenmann et al. (102) showed that IL-1 is adsorbed onto PAN filters, but not filtered. Human studies failed to show a reduction in IL-1 levels, irrespective of the dialyzer type.

More recent studies compared CVVH with CVVHD with a polysulfone dialyzer and blood and dialysate flow rates of 70 mL/min in the treatment of patients with sepsis.

**Table 5** Recommendation for Initial Choice of Dialysis Modality for Acute Renal Failure (ARF)

Indication	Clinical condition	Preferred therapy
Uncomplicated ARF	Antibiotic nephrotoxicity	IHD, PD
Fluid removal	Cardiogenic shock, CP bypass	SCUF, CAVH
Uremia	Complicated ARF in intensive care unit	CVVHDF, CAVHDF, IHD
Increased intracranial pressure	Subarachnoid hemorrhage, hepatorenal syndrome	CVVHD, CAVHD
Shock	Sepsis, ARDS	CVVH, CVVHDF, CAVHDF
Nutrition	Burns	CVVHDF, CAVHDF, CVVH
Poisons	Theophylline, barbiturates	IHD, CVVHDF
Electrolyte abnormalities	Marked hyperkalemia	IHD, CVVHDF
ARF in pregnancy	Uremia in second, third trimester	PD

*Abbreviations:* ARDS, acute respiratory distress syndrome; CAVH, continuous arteriovenous hemofiltration; CAVHDF, continuous arteriovenous hemodiafiltration; CVVH, continuous venovenous hemofiltration; CVVHD, continuous venovenous hemodialysis; CVVHDF, continuous venovenous hemodiafiltration; CAVHD, continuous arteriovenous hemodialysis; PD, peritoneal dialysis; SCUF, slow continuous ultrafiltration.

*Source:* From Ref. 108.

These studies showed that blood from patients treated with CVVH or CVVHD had a reduced capacity to generate TNF- $\alpha$  in a cell culture model. The implication of these studies was that blood treated with CVVH or CVVHD had a reduced capacity to generate proinflammatory cytokines. Interestingly, the effect was more profound in the CVVHD group. Spent dialysate from the CVVHD-treated patients was able to suppress TNF- $\alpha$  production in donor blood by 33%, whereas no suppression was seen from ultrafiltrate obtained from the CVVH patients (107). The use of high-volume CVVH with ultrafiltrate volumes of 8 L/hr was shown to be beneficial in patients with sepsis and renal failure.

When high-volume CVVH was applied to 20 patients with severe septic shock, responders were noted to have received the therapy earlier and had higher UF volumes when compared with nonresponders. In this study, response was defined as an improvement in cardiac index, mixed venous O<sub>2</sub> saturation, pH, and a reduction in pressor dose. Overall, data regarding the utility of conventional CRRT techniques in the treatment of sepsis are lacking and its use for the sole purpose of treatment of sepsis cannot be recommended at this time.

Emerging dialysis techniques, such as high-flux CVVHD and high-volume CVVH may have some application to the treatment of sepsis in the future. Randomized clinical trials to evaluate the efficacy of extracorporeal treatments for sepsis are needed.

## EYE TO THE FUTURE

The determination of the optimal dialysis modality for various clinical presentations of ARF is an area of active investigation. Continuous therapies will likely take the lead role as the dialysis modality of choice for patients with hemodynamic instability, bleeding risk, and possibly the sepsis syndrome. Intermittent therapies will continue to play an important role in patients with isolated ARF, hemodynamic stability, and severe electrolyte abnormalities that require immediate correction. The expansion of dialysis to include treatment of nonrenal conditions is an expanding field. It is conceivable that dialysis may be used more extensively for treatment of the sepsis syndrome, certain intoxications, and heart failure.

## SUMMARY

Acute renal failure in the ICU is a clinically diverse entity. Consequently, the indications for initiation of dialysis therapy are varied. In general, the indications are either solute control, volume control, or both. A variety of dialysis modalities are available to the intensivist and nephrologist; however, there is no consensus as to the optimal modality for any particular group of patients. Nevertheless, a careful understanding of the particular benefits, limitations, and potential complications of each modality coupled with a thorough assessment of individual patient needs formulate the basis for dialysis modality selection. In certain circumstances, the more conventional intermittent therapies are sufficient, whereas in other settings, CRRT techniques are advantageous. The impact of modality selection on outcome remains an area of significant controversy. Future studies in which more uniformity within specific subgroups of patients with ARF is sought may shed light on the optimal modality for a particular patient group. Newer therapies aimed at more optimal and more specific blood purification may prove promising in the management of complex critically ill patients with ARF and other comorbid conditions.

## KEY POINTS

- ☞ Indications for dialysis generally fall into one of three broad categories: solute indications such as marked azotemia, volume indications such as fluid overload, or both.
- ☞ CRRT provides improved hemodynamic stability, continuous electrolyte control, improved dialysis adequacy and easier control of volume status.
- ☞ Recirculation associated with dual-lumen venous catheters have been shown to be worse in femoral (16%) when compared with the subclavian catheters (4%,  $p = 0.0001$ ) location (17).
- ☞ The most significant disadvantages of IHD in the critically ill patient with ARF are related to hypotension and the possibility of worsening the severity of the renal injury.

- 9 Continuous renal replacement therapy is unique in that solute removal is, in effect, dissociated from fluid removal.
- 9 CRRT provides improved hemodynamic stability, continuous electrolyte control, improved dialysis adequacy and easier control of volume status.
- 9 Rapid alterations in sodium and fluid status have been shown to occur in IHD. Such alterations are implicated as a cause for the cerebral edema that can be observed in IHD.
- 9 Systemic citrate is normally metabolized in the liver liberating three bicarbonate ions for each citrate molecule.
- 9 Phosphate control is achieved faster with CRRT and phosphate reductions are often more profound than those seen with IHD (51).
- 9 Hypocalcemia is a major concern in patients receiving CRRT with citrate anticoagulation (52,53).
- 9 Tight control of both intravascular volume and plasma solute concentration constitute the major advantages of intraoperative CRRT.
- 9 The important disadvantages of intraoperative CRRT include the need for anticoagulation of the circuit, and logistics.
- 9 The recognition that CRRT provides the greatest advantages in critically ill patients has fostered an increased trend toward the use of this technique, especially in those with hemodynamic instability, those with TBI, and or sepsis/SIRS.
- 9 Selection of dialysis modality depends on patient, modality, and logistic factors.
- 9 The sepsis syndrome is associated with the presence of high levels of circulating and tissue cytokines that result in impairment of vascular permeability, hypotension, and renal failure.

## Fluid and Electrolyte Disorders

Amy A. McDonald and Charles J. Yowler

Department of Surgery, MetroHealth Medical Center, Case Western Reserve University, Cleveland, Ohio, U.S.A.

### INTRODUCTION

Cellular function is dependent on the proper electrolyte content of the intracellular fluid (ICF) and the extracellular environment. The body has an elaborate mechanism to sustain homeostasis, which includes feedback mechanisms involving the pituitary and renal systems. Significant electrolyte imbalance is rare in a patient with normal renal function and free access to water and nutrients.

However, fluid and electrolyte balance is often disrupted following trauma and during critical illness. The most common initial change is the loss of voluntary intake of food and water, as the patient becomes entirely dependent on the doctor to supply these needs. If the treating physician is unaware of or miscalculates the fluid and electrolyte losses, the resultant imbalance of the internal milieu can further exacerbate the degree of cellular dysfunction. Fluid and electrolyte therapy is, therefore, an essential component of the management of these critically ill patients.

Although significant improvements in the understandings of the clinical effects of various fluid and electrolyte disorders has occurred in the last decade (1,2), the basic physiology and biochemistry have been known for much longer, and the approach to myriad factors, causing fluid and electrolyte disorders, still follows the classification scheme developed by Narins et al. (3) in the late 1970s and early 1980s. The specific injuries resulting from trauma and critical care continue to be elucidated (4).

This chapter begins with a review of the normal distribution of fluid and electrolytes among the different compartments of the body, and then details diagnosis and management of fluid and electrolyte disorders commonly encountered in trauma and critical care. Rather than providing an encyclopedic list of disease states, this review stresses the application of pathophysiologic principles in the classification and diagnosis of fluid and electrolyte disorders, and emphasizes those most commonly encountered in trauma and critical care.

### FLUIDS

#### Distribution of Body Fluids

Total body water (TBW) varies according to lean body mass and age (Fig. 1). Adipose tissue and bone have relatively low water content compared with muscle and solid organ mass. Using indicator dilution methods, TBW approximates 60% of body weight in men, or 42 L in a 70-kg

adult male, and 50% in women (i.e., 35 L). Thin patients may have a 5% to 10% increase in TBW, whereas obese patients have a 10% to 20% decrease on a per-kilogram basis. Age also plays a role with the decrease in lean body mass in the elderly, decreasing TBW by 10–15% of body weight.

The TBW is distributed between the intracellular and extracellular compartments (Fig. 2). Approximately two-thirds of the TBW exists in the intracellular compartment (approximately 28 L in a 70-kg man), and one-third is contained in the extracellular compartment (14 L in 70-kg man). The extracellular fluid (ECF) is further subdivided into the intravascular, interstitial, and transcellular fluid. The intravascular compartment contains the plasma volume, which is approximately 5% of the TBW and 25% of the ECF (i.e., approximately 3.5 L in a 70-kg male). The interstitial compartment is comprised mainly of the acellular tissue matrix surrounding the cells, and equilibrates rapidly with the remainder of the extracellular water. The free phase, which contains water, is freely exchangeable. The free phase, which contains water, is freely exchangeable. The gel phase represents water that is bound as a matrix with hydrophilic components, such as glycosaminoglycans and mucopolysaccharides. The transcellular fluid compartment includes pleural, pericardial, peritoneal, cerebrospinal, synovial, intraocular, and glandular fluids, all of which are poorly exchangeable. It is important to note that TBW, contained in the intracellular, interstitial, and transcellular compartments, is in dynamic equilibrium; hence, a change in one compartment causes compensatory alterations in the others (1–4).

#### Composition of Body Fluids

The chemical compositions of the ECF and the ICF differ in regard to cations, anions, organic acids, and proteins (Table 1). Sodium and potassium are the principle cations within the body. Sodium is mainly relegated to the ECF space, whereas potassium is predominantly contained within the ICF compartment. The sodium content in the average adult is approximately 60 meq/kg; however, about 25% to 30% of this is confined to bone and is not freely exchangeable. Of the exchangeable portion, about 85% is found in the ECF. Potassium, magnesium, and calcium make up the remainder of the cations in the ECF.

☞ **Only a fraction of the total body potassium (about 4 meq/L, or approximately 14 meq in a 70-kg patient) is normally present in the plasma.** ☞ Most of the total body potassium, approximately 150 meq/L, is contained within the 28 L of ICF (approximately 4200 meq in total) and is

**Total Body Water as a Percentage of Total Body Weight**

**Figure 1** Total body water as a percentage of body weight. The number on the bar lists the average percentage of body weight that is accounted for by total body water for various genders and ages of individuals.

freely exchangeable. Smaller amounts of magnesium and sodium are also found in the ICF. The concentration gradient between the ECF and ICF is maintained by an adenosine triphosphate (ATP)-dependent sodium/potassium pump in the cellular membrane.

Chloride is the principal anion in the ECF, with a normal plasma chloride of 103 meq/L (Table 1). The remainder of the anionic content of the ECF consists of bicarbonate, phosphates, anionic proteins, and sulfates.

The primary intracellular anion is phosphate, with a concentration of 116 meq/L. The remainder of the intracellular anionic load is controlled by anionic proteins, with chloride and bicarbonate contributing negligible amounts.

**Concentration of Body Fluids**

Although the ECF and ICF differ in relation to ions and proteins, water is evenly distributed throughout in all compartments, and diffuses freely across the semipermeable

**Distribution of Total Body Water as a Percentage of Total Body Weight**

**Figure 2** Distribution of total body water (TBW) as a percentage of body weight. Two-thirds of the TBW resides in the intracellular space, and one-third is in the extracellular space. Of the extracellular water, 25% is located within the blood vessels as plasma (approximately 3.5 L in a 70-kg patient).

**Table 1** Composition of Body Fluids

Component	Plasma	Interstitial	Intracellular
Na <sup>+</sup>	140	140	12
K <sup>+</sup>	4	4	150
Cl <sup>-</sup>	103	114	3
HCO <sub>3</sub> <sup>-</sup>	24	27	10
Ca <sup>2+</sup>	5	3	0
Mg <sup>2+</sup>	2	1	7
SO <sub>4</sub> <sup>2-</sup>	1	1	0
HPO <sub>4</sub> <sup>2-</sup>	2	2	116
Protein	16	5	40
Organic anions	5	5	0

All values are given in meq/L.

cellular membranes, balancing the osmotic forces. Accordingly, a given bolus of water does little to expand the intravascular compartment. In contrast, sodium-containing fluids expand the ECF, typically expanding the interstitial fluid compartment three times as much as the intravascular compartment, due to the relative volumes of the two compartments.

Osmolality is defined as the number of osmotically active solute particles per kilogram of water, whereas osmolarity is expressed as the number of osmotically active solutes per liter, and the usual units are milliosmoles per liter (mOsm/L). Particles that freely dissociate in water in 1:1 ratio, such as sodium chloride (NaCl), produce 2 Osm. This is in contrast to glucose, which does not freely dissociate, and produces only 1 Osm per molecule. Because water moves freely between the compartments, the tonicity or the relative osmolarity between the ECF and the ICF is maintained between 280 and 290 mOsm/L in normal healthy patients. Isotonic solutions, such as 0.9% NaCl, do not cause the movement of water between ECF and ICF. Urea and alcohol also have little effect of water movement, because they are freely permeable across the cellular membrane; that is, they increase osmolarity without increasing tonicity. However, glucose and mannitol are not freely permeable across the cell membrane, and increase both osmolarity and tonicity.

☞ Plasma osmolarity (Posm) is generally a good estimate of total body osmolarity, because isosmotic conditions are maintained through fluid shifts. ☞ Plasma osmolarity can be roughly calculated by the following:

$$\text{Posm(mOsm/L)} = 2 \times \text{serum[Na}^+] + \text{glucose}/18 + \text{BUN}/2.8$$

The [Na<sup>+</sup>] is usually expressed in meq/L, whereas the glucose and BUN concentrations are provided in mg/dL. Accordingly, these concentrations must be divided by one-tenth of their molecular weights to convert into units mOsm/L.

☞ When the calculated Posm differs by >15 mOsm from the laboratory-measured value, an osmolar gap exists. ☞ In this case, other uncalculated, osmotically active molecules are present. Osmotically active particles that are not normally calculated, but commonly measured in the serum of trauma victims, include ethanol, methanol, mannitol, or polyethylene glycol. Certain disease states

may also lead to an increase in osmolar gap. For example, multiple myeloma proteins or hypertriglyceridemia can both cause this phenomenon. These substances cause an artificial osmolar gap by reducing the plasma water fraction.

Osmolarity is regulated by arginine vasopressin (AVP), also known as antidiuretic hormone (ADH). After being synthesized in the hypothalamus, ADH is stored in the posterior pituitary. The secretion of ADH is stimulated by osmoreceptors, located in the brainstem, and also by baroreceptors, situated in the heart and vasculature. Antidiuretic hormone enhances the water permeability of the collecting ducts in the kidney, resulting in more concentrated urine. When serum osmolarity is  $<280$  mOsm/L, the secretion of ADH is entirely suppressed. When serum osmolarity is  $\geq 280$  mOsm/L, osmoreceptors stimulate the posterior pituitary to release ADH into the bloodstream. The rate of ADH release is normally directly proportional to the serum osmolarity, once it is  $\geq 280$  mOsm/L.

The baroreceptors also stimulate ADH release, in response to reduced intravascular volume or decreased mean arterial pressure (MAP). Although the chief stimulus for ADH synthesis and release is serum osmolarity. The baroreceptor response can stimulate ADH release in the absence of any osmoreceptor-mediated response. Therefore, ADH-regulated renal water reabsorption will continue to occur, despite a serum osmolarity  $<280$  mOsm/L in the presence of hypovolemia and/or hypotension. Other nonosmotic mechanisms that also stimulate ADH release include pain and emotional stress.

Disturbances in plasma tonicity and electrolytes are dependent on the volume and electrolyte composition of the fluid gained or lost. By far the most common disturbance in surgical patients is the loss of isotonic fluids. This may result from blood loss, interstitial fluid loss, or sequestration of fluid due to infection or injury. Restoration of these deficits requires isotonic fluids, such as lactated Ringer's (LR) or 0.9% saline (NS). The loss of hypotonic fluids requires replacement based on the expected concentration of cations and anions in these fluids. "Third space" losses develop when cellular and capillary permeability increase, resulting in loss of fluid from the intravascular compartment. Common clinical conditions associated with "third-space" fluid losses, include burns, poly trauma, and sepsis.

Fluid and solutes are exchanged between the intravascular and interstitial fluid compartments. There is a net unidirectional flow of these substances, including albumin and plasma proteins, from the intravascular space to the interstitium, and then back to the intravascular space via lymphatics, helping to maintain physiologic fluid and solute balance. The flux of water through the interstitium is largely determined by capillary hydrostatic pressure. Hydrostatic pressure is a function of intravascular volume and vascular tone. Opposing the force of hydrostatic pressure is colloid oncotic pressure, the major determinant of which is albumin.

Molecules, such as water, glucose, urea, and electrolytes pass freely through the capillary membrane. Their concentrations in the intravascular and interstitial compartments are essentially equal. The passage of other molecules is dependent upon the relative permeability (or porosity) of the capillary membrane to those substances. Large molecules, such as albumin, fibrinogen, immunoglobulins, and other proteins do not pass readily through the capillary membrane. Accordingly, the concentration of these osmotically active substances is generally higher in plasma than in interstitial fluid and lymph.

The baseline porosity of capillary membranes varies between tissues. For instance, the liver is very porous, whereas, the muscle capillary membranes are generally nonporous. Capillary permeability can also change, in response to the hormonal and autocrine influences of bradykinin and histamine.

The complex movement of fluid across the capillary membrane is described by Starling's equation.

$$Q = K_f[(P_c - P_i) - \sigma(COP_p - COP_i)]$$

where  $Q$  is the net rate of transcapillary fluid movement (mL/min/100 g),  $K_f$  is the capillary filtration coefficient,  $P_c - P_i$  is the hydrostatic pressure gradient,  $\sigma$  is the reflection coefficient, and  $COP_p - COP_i$  is the colloid oncotic pressure gradient.

$K_f$ , or the capillary filtration coefficient, depends on the tissue and surface area. It can also be influenced by atrial natriuretic factor and platelet activating factor. The reflection coefficient,  $\sigma$ , varies from zero to one and represents the ability of capillary membranes to prevent plasma proteins from crossing the membrane. Values closer to zero are highly permeable, whereas values approaching one are highly impermeable. The hydrostatic pressure gradient ( $P_c - P_i$ ) is largely dependent on arteriolar and venous vasomotor tone.

This complex interaction is autoregulated. If there is an increase in hydrostatic pressure with net fluid movement into the interstitium, the protein concentration in the interstitium will decrease. This would cause a higher oncotic pressure in the plasma, further retarding fluid movement into the interstitium. If there is a decrease in plasma colloid oncotic pressure, leading to increased water in the interstitium, more fluid dilutes the interstitial oncotic pressure, reducing oncotic forces.

In the setting of edema, or abnormal accumulation of excess fluid in the interstitium, there is increased permeability of the capillary membrane to plasma proteins. The movement of fluid into the interstitium, however, dilutes the interstitial protein concentration such that further fluid movement is counteracted. Diuresis removes excess interstitial fluid and eventually restores protein distribution to normal.

### Maintenance Therapy

Maintenance therapy provides for the loss of water and electrolytes expended during normal physiologic activities. This consists of sensible and insensible losses. Sensible losses, such as urine and stool can be measured. Insensible losses consist of water vapor lost through the lungs and skin. The rate of insensible loss depends on the water vapor tension of the environment, air movement, rate and volume of respiration, and metabolic rate. Insensible losses increase by 10% for each  $1^\circ\text{C}$  above  $37.2^\circ\text{C}$ . The repletion of water losses, both sensible and insensible, is based on weight (kg).

The electrolyte composition of maintenance fluids is based on weight, and estimated quantity of electrolytes present in fluids lost during normal physiologic conditions. The concentration of electrolytes depends on the source of the fluid. Urine can have varying amounts of sodium, chloride, and potassium. Urinary excretion depends on the overall electrolyte and volume status of the patient, and the balance of hydrogen ion, phosphates, sulfates, and organic acids. Approximately 800 to 1500 mL of water is required to excrete the normal daily solute load. The kidney excretes all sodium in excess of the body's need,

but is less efficient with potassium. Urine sodium concentration can decrease to as low as 1 meq/day. Stool contains a larger amount of potassium, with only small amounts of sodium and chloride. In general, daily sodium requirements are 1–2 meq/kg/day and daily potassium requirements are 0.5–1.0 meq/kg/day. Repletion of calcium, magnesium, and phosphorus is unnecessary in patients with adequate stores of these electrolytes. However, critically ill patients, often require repletion of these on a daily basis. Glucose is typically added to maintenance fluids in order to help maintain tonicity and prevent proteolysis. An appropriate daily maintenance fluid in the 70-kg adult without abnormal sensible or insensible losses is approximately 2 L of D5  $\frac{1}{2}$  NS + 20-meq KCl/L (1–3).

### Replacement Therapy

Acute volume deficits, resulting in hemodynamic instability, are generally replaced via bolus infusion with isotonic fluids (Table 2). Crystalloid and colloid solutions can both be used, but there has been considerable debate regarding which is optimal during resuscitation and maintenance in trauma patients. **Crystalloids should be the initial resuscitation fluid administered in most situations.** Both LR and 0.9% NS are suitable crystalloid resuscitation solutions. Aggressive resuscitation with NS can result in hyperchloremic metabolic acidosis (4). Lactated Ringer's contains a more physiologic array of electrolytes than NS, and is a commonly employed crystalloid solution for blunt and penetrating non-cerebral trauma. However, LR may lead to increased inflammatory activity of leukocytes (see Volume 1, Chapter 11). In addition, NS is preferred by many neurosurgeons for resuscitation from cerebral trauma, because it is slightly more hypertonic than LR and normal plasma.

Hypertonic saline solutions (HTS) are currently being studied for their utility in head-injured (5) and nonhead-injured trauma patients (6), as well as burn patients. The major advantage appears to be the attainment of hemodynamic stability with less volume. Animal models have demonstrated the advantages and disadvantages of HTS in hemorrhagic shock. It seems most useful in controlled hemorrhagic shock (CHS) rather than uncontrolled hemorrhagic shock (UCHS). HTS may increase blood loss in UCHS, due to the effects on blood pressure, vasodilatation, coagulation, and blood rheology. Human studies with HTS, thus far, have shown no statistically significant increase in survival. However, there may be a subpopulation that could benefit, such as those with severe traumatic brain injuries Glasgow Coma Scale (GCS < 8). Hypertonic saline

solutions, in both in-vitro and animal studies of hemorrhagic shock, have an immunomodulatory effect that can attenuate the adverse effects of the systemic inflammatory response and ischemia/reperfusion on the host (7–9). However, it also has been shown, in vitro and in animal studies, to alter platelet and plasma coagulation (10). Its exact role in the resuscitation of the trauma patient has yet to be defined.

There are several colloid solutions available for fluid resuscitation. The most commonly used solutions are albumin and hydroxyethyl starch (HES). The benefit of colloids is theoretically based on their ability to expand the intravascular volume more efficiently. Microvascular permeability of colloids is dependent on the molecular size, shape, and ionic charge of the particles, as well as the porosity of the microvascular membrane. In the presence of injury and shock, microvascular porosity is often increased. Colloid can therefore more easily enter the interstitial space, bringing with it increased oncotic pressure and attendant water. This appears to be more of a problem with albumin (low molecular weight) and polymers of hydroxyethyl starch, with low and medium molecular weights. High-molecular-weight hydroxyethyl starch has, however, been shown to cause a coagulopathy by reducing factor VIII and von Willebrand's factor. The medium- and low-molecular-weight hydroxyethyl starches have less of an effect on coagulation. A newer formulation of hydroxyethyl starch, Hextend<sup>®</sup> (Abbott Laboratories, Chicago, IL, USA) contains a lactate-buffered balanced salt and glucose solution. Clinical studies on this solution have shown less of an effect on coagulation than the NS-based solutions (11). Anaphylactic reactions have also occurred with albumin and HES. According to a study in France of 19,593 patients, the incidence of allergic reactions was 0.099% for albumin and 0.058% for HES (12).

The crystalloid–colloid debate continues (see Volume 1, Chapter 11). Several studies, including meta-analyses, have tried to address this issue (13). A Cochran meta-analysis addressed the crystalloid–colloid question by addressing three categories of patients: (i) surgery or trauma, (ii) burns, and (iii) hypoalbuminemia (14). They demonstrated no survival difference in the surgery/trauma group, but showed an increased mortality following albumin administration for burns and in hypoalbuminemic patients (14). This report changed practice, until a more complete meta-analysis was conducted by Wilkes and Navickis (15). The Wilkes and Navickis evaluation included all of the trials surveyed by the Cochran group, along with several others. They also divided the subgroup analysis into six categories (the original three groups from Cochran, plus a three others: high-risk neonates, ascites, and other indications) (15). The Wilkes and Navickis

**Table 2** Parenteral Fluids

Fluid	Na (meq/L)	K (meq/L)	Ca (meq/L)	Cl (meq/L)	Lactate (meq/L)	Dextrose (g/L)	Osm (mEq/L)	pH
Lactated Ringer's	130	4	2.7	109	28	0	273	6.5
0.9% NaCl	154	0	0	154	0	0	308	6.0
D5 0.45% NaCl	77	0	0	77	0	50	406	4.0
3% NaCl	513	0	0	513	0	0	1027	5.0
25% mannitol	0	0	0	0	0	0	1372	4.5–7.0
5% albumin	145	<2.5	0	0	0	0	330	7.4
25% albumin	130–160	<1	0	0	0	0	269	6.4–7.4
6% hetastarch (Hespan <sup>®</sup> )	154	0	0	154	0	0	310	5.9
Hextend (buffered Hespan)	143	3	5	124	28	0.99	307	5.9

meta-analysis revealed no overall effect of albumin on mortality, but some of the better-conducted studies showed a possible survival benefit from albumin therapy (15).

These disparate results promulgated the American Thoracic Society-Critical Care Group (ATS-CCG) to develop a working group to study the problem, and a consensus statement was published in December 2004 (16). The ATS-CCG working group reviewed the published literature (including all publications between 1996 and 2002) by performing a systematic search of MEDLINE and the Cochran Databases. Their particular focus was on patients in medical, surgical, and cardiovascular intensive care units, and excluded burn injuries and pediatric patients (16). Evidence was graded for a clinically important outcome, according to a standard hierarchical schema (Table 3) (17).

The ATS-CCG Consensus Statement main points are provided in Table 4, and their therapeutic recommendations are summarized in Table 5. In summary, they found no clear advantage of commercially available colloids over crystalloids in the resuscitation of the trauma patient. Crystalloid solutions, due to low cost and absence of significant adverse effects, remain the mainstay of fluid resuscitation in the trauma patient. The role of HTS in trauma and critical care resuscitation is still evolving, as numerous clinical studies are ongoing.

## SODIUM DISORDERS

Sodium is the primary determinant of serum osmolarity, and thus pivotal in body fluid homeostasis (18). If changes in TBW occur without a corresponding alteration in total body sodium content, the serum osmolarity changes. Therefore, the manifestations of hyper- or hyponatremia reflect disturbances in water homeostasis. ⚡ **Hyponatremia almost always represents a hyperosmolar or hypertonic state, whereas hyponatremia can be present in a hypertonic, isotonic, or hypotonic state.** ⚡

### Hyponatremia

#### Causes

Hyponatremia is defined as a serum  $[Na^+] > 145$  meq/L. The most common cause for hyponatremia is inadequate replacement of free water losses. The physiologic response to this loss is the activation of thirst sensation and concentration of urine at the renal tubule (through ADH secretion). Thus, the hospitalized patient who has decreased alertness, and may not be on an oral diet, is vulnerable to the increased free water losses of fever, diarrhea, burns, and/

or diuretic therapy. Both the thirst mechanism and renal concentrating capacity are diminished in elderly patients (see Volume 1, Chapter 37), making them more vulnerable to hyponatremia (19).

The release of ADH is the normal response to the increased osmolarity of hyponatremia. However, brain injury or hypothalamic-pituitary dysfunction, secondary to infection, inflammation, ischemia, or mass lesions, may impair ADH release, resulting in central diabetes insipidus (DI). Drugs, such as ethanol and phenytoin may also inhibit ADH release. Conversely, the ADH receptor at the renal tubule may be impaired, resulting in nephrogenic DI. Acquired nephrogenic DI may be due to obstructive uropathy, a chronic tubulointerstitial disorder, hypovolemia or hypercalcemia. Drugs, such as lithium, demeclocycline, amphotericin B, and foscarnet may also cause nephrogenic DI.

### Symptoms

Clinical manifestations of hyponatremia generally relate to the effect of decreased water content in brain cells. This includes symptoms of restlessness, irritability, confusion, seizures, lethargy, coma, muscle twitching, spasticity, and hyper-reflexia. Intracerebral hemorrhage can result from cell shrinkage and subsequent traction on cerebral vasculature. These symptoms generally do not appear unless the  $Na^+$  is greater than 160 meq/L or serum osmolarity exceeds 320 mOsm/L (20).

⚡ **The work-up for hyponatremia starts with the determination of intravascular volume status, based on history, physical examination, and laboratory data.** ⚡ The initial laboratory tests include urine and Posm and urine sodium. High urine osmolarity in the setting of low urine sodium usually means extrarenal losses of free water. Low urine osmolarity with hyponatremia usually means inappropriate renal losses of free water (Table 6).

### Treatment

Treatment of hyponatremia varies according to the etiology. Hypovolemic hyponatremia requires expeditious replacement of intravascular volume with isotonic fluids (e.g., NS). In this condition, a total body sodium deficiency is present in addition to the free water deficit. Hypotonic fluids, such as 0.45% NS should never be used to rapidly correct significant intravascular volume deficits. Free water deficits need to be replaced slowly to prevent deleterious cellular edema, especially in the brain. Furthermore, chronic hyponatremia should be treated more slowly than acute hyponatremia. In general, after significant intravascular volume deficits have been replaced, the free water deficiency is corrected.

**Table 3** Grades of Evidence for the Quality of Clinical Study Design

Grade	Criteria/description
I	Evidence obtained from at least one properly randomized, controlled trial
II-A	Evidence obtained from well-designed controlled trials without randomization or randomized trials, without blinding
II-B	Evidence obtained from well-designed cohort or case-control analytic studies, preferably from more than one center or research group
II-C	Evidence obtained from multiple time series with or without intervention, uncontrolled cohort studies, and case series
III	Opinions of respected authorities, based on clinical experience; descriptive studies, and case reports; or reports of expert committees
NR	Evidence not rated for clinically nonrelevant outcome

Source: Adapted from Ref. 17.

**Table 4** American Thoracic Society 2004 Consensus Statement on Colloid Use in Critical Care: Summary Points

#	Summary point comments and (level of evidence)
1	Colloids have various nononcotic properties that may influence vascular integrity, inflammation, and pharmacokinetics, although the clinical relevance of these properties has not been elucidated (NR)
2	All colloids affect the coagulation system, with dextran and starch solutions having the most potent antithrombotic effects (II-A)
3	HES may be deposited in the reticuloendothelial tissues for prolonged periods; the clinical significance of this is unknown (II-C)
4	Colloids restore intravascular volume and tissue perfusion more rapidly than crystalloids in all shock states, regardless of vascular permeability (II-A)
5	There is conflicting evidence that HES increases the risk of bleeding after cardiopulmonary bypass surgery (I)
6	Although hydrostatic pressure is more important than COP for accumulation of pulmonary edema, colloid administration reduces tissue edema and may ameliorate pulmonary edema as a consequence of shock resuscitation (II-A)
7	There is no evidence of a benefit of colloids in treating ischemic brain injury (I) or subarachnoid hemorrhage (II-A). Colloids may adversely impact survival in traumatic brain injury (I).
8	Hydroxyethyl starch administration may increase the risk of acute renal failure in patients with sepsis (II-A)
9	Treatment of dialysis-related hypotension with colloids is superior to crystalloids for chronic dialysis patients; presumably, colloids are similarly superior for acutely ill patients (II-A)
10	Colloids are superior to crystalloids in intravascular volume replacement with large-volume paracentesis (II-A) and as adjunctive therapy to antibiotics in treating spontaneous bacterial peritonitis (II-A)
11	Meta-analyses of critical care colloid use are conflicting because of entry trial heterogeneity and varied analytic techniques, and a large prospective trial suggests a neutral influence of colloids on clinical outcomes

Abbreviations: COP, colloid oncotic pressure; HES, hydroxyethyl starch.

Source: Adapted from Ref. 16.

The free water deficit is calculated as follows:

$$\text{Free water deficit} = \frac{(\text{plasma}[\text{Na}^+] - 140)}{140} \times \text{TBW}$$

$$\text{Total body water (TBW)} = \text{body weight (kg)} \times 0.60$$

One-half of the deficit should be replaced over the first 24 hours. The next half should be replaced over the next 48–72 hours. Hypervolemic hypernatremia is rare, but occurs when excess hypertonic or NS is used to replace free water loss. This may occur in the setting of burn injury, and following 3% NS administration for traumatic brain injury (TBI). In the absence of TBI, treatment involves diureses with partial replacement of urine losses using D<sub>5</sub>W, or additional free water via tube feeding. In the setting of TBI, acute treatment should be deferred until brain swelling has decreased, intracranial pressure (ICP) has normalized, and the patient is hemodynamically stable.

Diabetes insipidus classically causes euvolemic or (if allowed to persist untreated) hypovolemic hypernatremia.

☞ **In complete central DI, the urinary osmolality is**

**< 150 mOsm/L, but may be higher in partial DI.** ☞ In the setting of hypernatremia ( $[\text{Na}^+] > 150$  meq/L) and polyuria, a urinary osmolality < 290 mOsm/L is virtually diagnostic of DI, as this constellation of factors is unusual for any other disease process (Table 7). Central DI can be treated with exogenous vasopressin and free water replacement. The usual dose for aqueous vasopressin is 5–10 units every four to six hours. D-des-arginine-vasopressin [desmopressin (ddAVP)] has a longer half-life, and can be used in chronic cases of central DI. The usual dose of ddAVP is 20 μg intranasal every 12–24 hours. Other drugs used in the treatment of central DI are carbamazepine, clofibrate, and chlorpropamide.

Nephrogenic DI is much less common in trauma and surgical critical care. Although most cases of nephrogenic DI are acquired (secondary to various drug use), there is a congenital form. Treatment of nephrogenic DI requires correction of calcium and potassium deficits, discontinuation of offending drugs, low-sodium diet, and thiazide diuretics. Amiloride can be used for lithium-induced DI. The risk of DI resulting from amphotericin B can be

**Table 5** American Thoracic Society 2004 Consensus Statement on Colloid Use in Critical Care: Therapeutic Implications

#	Therapeutic implication(s) and (level of evidence)
1	Crystalloids should be administered first in nonhemorrhagic shock resuscitation (III)
2	Hydroxyethyl starch solutions should be used with caution in cardiopulmonary bypass (meta-analysis) and in patients with sepsis (II-A)
3	Colloids should be avoided or used with caution in patients with traumatic brain injury (I)
4	Fluid restriction is appropriate for patients with hemodynamically stable ALI/ARDS (II-A); the combination of colloids and diuretics may be considered in patients with hypo-oncotic ALI/ARDS (III)
5	Colloids are preferred for treating dialysis-associated hypotension, and in maintaining hemodynamics to achieve dialysis goals (II-A)
6	Hyperoncotic albumin should be administered in conjunction with large-volume paracentesis for diuretic-refractory ascites (II-A)
7	Albumin may be administered in conjunction with antimicrobial therapy to patients with spontaneous bacterial peritonitis (II-A)

Abbreviations: ALI = acute lung injury; ARDS = acute respiratory distress syndrome.

Source: Adapted from Ref. 16.

**Table 6** Causes and Characteristics of Hypotonic (<280 mOsm/L) Hyponatremia

Variable	Extracellular fluid volume status		
	Hypovolemic	Euvolemic	Hypervolemic
Causes	GI losses, excess sweating/poor H <sub>2</sub> O intake (e.g., desert exposure) excess diuretic use, CSW syndrome <sup>a</sup>	SIADH, hypothyroidism, adrenal insufficiency	CHF, cirrhosis, nephrotic syndrome
Urine volume	Decreased	Varies with intake	Usually decreased
Urine osmolarity <sup>b</sup>	>500 mOsm/L	>100 mOsm/L	>100 mOsm/L
Urine [Na <sup>+</sup> ]	<20 meq/L <sup>a</sup>	>40 meq/L	<20 meq/L <sup>c</sup>
Response to 0.9% saline infusion	Clinical and biochemical improvement	No change or worsening hyponatremia	Minimal change in hyponatremia, worsening edema

<sup>a</sup>The urine [Na<sup>+</sup>] would be >40 meq/L in CSW; thus the most important differentiating factor between CSW syndrome and SIADH is that the intravascular volume is decreased with CSW syndrome and normal with SIADH. The urine [Na<sup>+</sup>] would be >20 meq/L with ongoing diuretic use as well.

<sup>b</sup>Urine osmolarity <100 mOsm/L would indicate appropriate antidiuretic hormone and renal response to hyponatremia, and would be expected in the setting of iatrogenic hyponatremia or psychogenic polydipsia (rare in critical care).

<sup>c</sup>The urine [Na<sup>+</sup>] would be >20 meq/L when the hypervolemic condition was renal failure, but in this condition, the serum sodium is less often low.

*Abbreviations:* CHF, congestive heart failure; CSW, cerebral salt wasting syndrome; SIADH, syndrome of inappropriate antidiuretic hormone secretion.

minimized by using the liposomal formulation. (see Volume 2, Chapter 53).

## Hyponatremia

### Causes

The normal serum sodium concentration is 140 meq/L. Hyponatremia is defined as a serum [Na<sup>+</sup>] of less than 135 meq/L.

Hyponatremia is usually associated with a state of hypotonicity. However, it can also occur in the setting of normal tonicity and hypertonicity (when other osmotically active solutes are present in elevated concentrations). Additionally, a clinical entity, known as pseudohyponatremia, can exist in the setting of normal tonicity. Pseudohyponatremia (measured hyponatremia in association with normal tonicity) is usually due to a laboratory measurement error. The most common causes of pseudohyponatremia are hyperproteinemia or hyperlipidemia, and as such, symptoms of hyponatremia do not occur.

Hypertonic hyponatremia occurs whenever there is an increase in nonsodium serum osmoles, most commonly hyperglycemia, but can also exist in the setting of alcohol intoxication or concurrent mannitol use. In this state, excess intravascular solute particles cause a shift of water from the intracellular to extracellular space. This can also result from methanol or ethylene glycol intoxication. In these hypertonic states, total body sodium often remains normal.

Hypotonic hyponatremia, the most common form, can be associated with hypovolemia, euvolemia, or hypervolemia (21,22). In all states, there is excess free water relative to sodium in the extracellular space. Clinical assessment of volume status, urine osmolarity, and urine sodium concentration can aid in assessing the etiology of hyponatremia (Table 7). Renal losses of sodium are suggested by a urine sodium level >20 to 40 meq/L, whereas extrarenal losses are suggested by a urine sodium level <20 meq/L. In the setting of euvolemia, iatrogenic or psychogenic polydipsia is suggested by a

urine osmolarity <100 mOsm/L (this is an unusual etiology in critically ill trauma patients).

The syndrome of inappropriate antidiuretic hormone (SIADH) can occur as a result of cerebral or pulmonary pathology (i.e., trauma, tumor, or infection), as well as various tumors of the pancreas, duodenum, bladder, and prostate. The postoperative and postinjury states often result in transient inappropriate (for serum osmolarity) ADH secretion. It can be further exacerbated by the infusion of hypotonic fluids (23). **✎ The diagnosis of SIADH is suggested by the finding of urine osmolarity >100 mOsm/L and urine sodium >40 meq/L in the setting of hyponatremia (23). ✎**

Hypervolemic hyponatremia occurs in patients with edema and ascites, due to congestive heart failure, nephrotic syndrome, or cirrhosis. A state of total body sodium excess exists; however, TBW is present in excess to an even greater degree. In these states, total effective circulating volume is decreased, thus creating a nonosmotic stimulus for ADH production. Renal hypoperfusion exacerbates the problem with resultant antidiuresis and water retention.

Hypovolemic hyponatremia results from pathologic losses of sodium-rich body fluids (gastrointestinal or biliary losses from tubes, drains, fistulas, vomiting, or diarrhea), which are replaced with inadequate volumes of sodium-deficient fluids. The pediatric patient with severe vomiting from pyloric stenosis or duodenal obstruction may present with hypovolemic hypernatremia, if losses are inadequately replaced with NS, or with hypovolemic hyponatremia, if his losses are replaced with inadequate amounts of dextrose in one-fourth or one-half NS. This emphasizes the fact that Na<sup>+</sup> concentration is generally independent of volume status. Similar conditions can exist in the adult patient with high-volume gastrointestinal or biliary fistulas, depending on the adequacy of fluid and Na<sup>+</sup> replacement.

A unique entity, referred to as cerebral salt wasting (CSW) syndrome, can occur in neurosurgical patients, and presents as a hypovolemic hyponatremia (24). The mechanism for the decreased absorption of sodium in the kidney is thought to be due to the release of a brain natriuretic peptide

**Table 7** Evaluation of Hyponatremia (Plasma  $[\text{Na}^+] > 145$  to  $150$  meq/L)

Variable	Extracellular fluid volume status		
	Hypovolemic	Euvolemic	Hypervolemic
Mechanism	Loss of $\text{H}_2\text{O}$ and $\text{Na}^+$ $\text{H}_2\text{O}$ Loss $>$ $\text{Na}^+$ Loss	Loss of water	Gain of $\text{H}_2\text{O}$ and $\text{Na}^+$ $\text{Na}^+$ gain $>$ $\text{H}_2\text{O}$ gain
Clinical causes	Chronic diuretic use, vomiting, or diarrhea	DI, diuresis, or excessive evaporative loss	Aggressive administration of $\text{NaCl}$ or $\text{NaHCO}_3$
Pretreatment urine volume	Low	High	Usually high
Urine osmolality <sup>a</sup>	Nonrenal $\text{H}_2\text{O}$ losses $> 400$ mOsm/L Renal $\text{H}_2\text{O}$ losses $< 300$ mOsm/L	Nonrenal $\text{H}_2\text{O}$ losses $> 400$ mOsm/L DI <sup>b</sup> and other renal $\text{H}_2\text{O}$ losses $< 290$ mOsm/L	Iatrogenic causes variable mineralocorticoid excess $> 300$ mOsm/L
Urine $[\text{Na}^+]^a$	Nonrenal $\text{H}_2\text{O}$ losses $< 10$ – $15$ meq/L Renal $\text{H}_2\text{O}$ losses $> 20$ meq/L	Nonrenal $\text{H}_2\text{O}$ losses variable DI <sup>b</sup> and other renal $\text{H}_2\text{O}$ losses $< 10$ – $15$ meq/L	Iatrogenic causes variable Mineralocorticoid excess $> 20$ meq/L
Treatment	Replete intravascular volume with normal saline Then, more slowly, replace free $\text{H}_2\text{O}$ deficit	Replace urinary losses with one-half normal saline If DI, treat with vasopressin or ddAVP Slow free $\text{H}_2\text{O}$ replacement later if needed	Loop diuretics Replace urinary losses with one-half normal saline, or add free $\text{H}_2\text{O}$ to tube eedings If renal failure, Rx with dialysis

<sup>a</sup>The values for urine osmolality and urine  $[\text{Na}^+]$  are taken from Ref. 41.

<sup>b</sup>In the case of DI, urine osmolality is usually  $< 150$  mOsm/L and urine  $[\text{Na}^+] < 10$  meq/L.

Abbreviations: ddAVP, desmopressin; DI, diabetes insipidus; Rx, treatment.

(BNP), which acts on the nephron to decrease sodium reabsorption (probably at the proximal tubule) (25). Atrial natriuretic peptide (ANP) and BNP are capable of decreasing autonomic outflow at the level of the brain stem, and thus may have a dual affect, causing hyponatremia (i.e., decreasing neural input to the kidney, and directly inhibiting sodium reabsorption) (26).

In contrast to ANP (secreted mainly by human atria), BNP is secreted by the brain, and also by human ventricles, during times of increased pressure or stretch (27). The increased BNP release, seen in patients with congestive heart failure (CHF), has been used as a measure of left ventricular failure. Recently, a rapid BNP immunoassay (Triage Assay, Biosite Diagnostics, Inc, San Diego, CA, USA) was approved by the Food and Drug Administration for point-of-care testing, returning results within 15 minutes (27). This assay is being used in CHF patients, but has not yet been studied in head injured patients, who may be at risk of CSW syndrome.

✎ **CSW syndrome must be differentiated from SIADH, because their treatments are divergent, and directly effect outcome.** ✎ Heretofore, the distinction was made by noting that euvolemia favored SIADH, and hypovolemia was consistent with CSW syndrome; additionally, the urine osmolality would be  $> 500$  mOsm/L in CSW syndrome (Table 7). The measurement of BNP may soon be useful in differentiating these entities (but this must be prospectively studied first). In the case of CSW syndrome,

both  $\text{Na}^+$  and intravascular volume must be repleted. This can be accomplished by the administration of 3% NS. In CSW syndrome, fluid restriction (the normal treatment for SIADH) would likely be detrimental to neurological recovery.

### Symptoms

✎ **Symptoms secondary to acute hyponatremia typically do not arise until the serum  $[\text{Na}^+]$  is less than 125 meq/L in acute hyponatremic states, or less than 120 meq/L in more chronic conditions.** ✎ The symptoms of hyponatremia are primarily due to the associated hypotonicity, with resultant cellular swelling. The most pronounced effect of cellular swelling is cerebral edema. The resultant symptoms include headache, nausea, vomiting, lethargy, and confusion. If the fall in serum  $\text{Na}^+$  continues, seizures, coma, and respiratory arrest may occur.

Rapid development of hyponatremia may result in irritability and seizures. This most commonly occurs in the setting of unrecognized SIADH with hypotonic fluid replacement.

### Treatment

The hyponatremia treatment plan must address multiple issues, including an estimate of the sodium deficit, and a calculation of the sodium repletion rate that prevents the occurrence of osmotic demyelination, often referred to as

central pontine myelinolysis (CPM) (28). Osmotic demyelination results from rapid transfer of water out of central nervous tissue cells. The injury and symptoms are often delayed for two to six days after the abrupt elevation of serum sodium has occurred. The structural damage and symptoms resulting from CPM are usually irreversible, and can consist of dysarthria, dysphagia, para- or quadraparesis, lethargy, coma, respiratory arrest, and seizures.

The term CPM refers to the earliest descriptions demonstrating demyelination, chiefly in the pons (29,30). However, more recently, it has become recognized that the demyelination occurs along most of the myelinated nerve tracts (31). Because of the rich concentration of myelinated fibers in the pons, lesions do predominate there (65% of cases), but other commonly involved sites include the cerebral periventricular and subcortical white matter, thalami, basal ganglia, internal capsule, and the cerebellar peduncles and white matter (31). All of these commonly demyelinated sites contain interdigitated gray and white matter. This interdigitation may interfere with the diffusion of hypertonic edema fluid into adjacent white matter, making these areas particularly vulnerable to rapid fluid and electrolyte changes.

Conventional computed tomography and magnetic resonance imaging findings lag behind the clinical manifestations of CPM. However, using MR diffusion-weighted imaging, lesions within the central pons have been identified within 24 hours of the onset of patient tetraplegia and before findings are conspicuous with conventional MR imaging sequences (32).

✎ **Experimental studies in animals and observations in humans suggest that the rate of hyponatremia correction in the first 24 hours is the major determinant for the development of osmotic demyelination (28–33).** ✎ It is more common when the plasma sodium concentration is raised by more than 20 meq/L in the first 24 hours, and rare when raised less than 10 to 12 meq/L over

the first day (33). The rate of correction must reflect the presence or absence of symptoms, and the duration of hyponatremia (Table 8). Longstanding hyponatremia should be corrected over a long period (i.e., five to seven days), and should not be corrected faster than 0.25 meq/L per hour, whereas acute hyponatremia can be corrected more aggressively (but should not be corrected faster than 0.5 meq/L per hour, unless symptomatic). Symptomatic patients require more rapid correction, and may require correction rates of 0.5 to 1 meq/L per hour for the first two to three hours or until symptoms resolve. However, the total 24-hour raise in serum sodium should still not be greater than 12 meq/L.

The treatment of hyponatremia further depends upon the volume status and the presence or absence of symptoms (21,22). As described earlier, the treatment of CSW syndrome requires increased intravascular volume and Na<sup>+</sup> (either as 3% NS, or supplemental dietary salt, if tolerating enteral nutrition), whereas water restriction is the primary therapy for asymptomatic SIADH. Symptomatic SIADH requires more aggressive initial therapy, which may include diuresis with the addition of 3% NS. Serum sodium levels need to be obtained every two to four hours to prevent too rapid a rise in serum sodium as detailed earlier. Demeclocycline 600 to 1200 mg/day can also be utilized in SIADH resulting from chronic conditions.

Fluid restriction plus diuresis is necessary in hypervolemic edematous states, such as CHF, renal failure, and cirrhosis. Loop diuretics are the preferred agents, whereas thiazide diuretics should be avoided, as they may exacerbate the hyponatremia. Overly aggressive fluid restriction and diuresis must be avoided, because the resultant decrease in effective circulating volume can exacerbate the stimulus for ADH release and renal conservation of water. The correction of excess free water may take days to weeks, depending upon the rate of mobilization from the extracellular compartment.

**Table 8** Rules for Sodium Correction for Hyponatremia

Rule priority	Sodium correction guidelines	Rationale/comments
1	Correct no more than 12 meq/L in the first 24 hrs of treatment	No patients receiving corrections this slow or slower developed CPM in a recent study
2	Correct no faster than 0.25 meq/L per hour in asymptomatic chronically hyponatremic patients, and complete normalization of sodium in these patients over five to seven days	Chronic hyponatremia results in brain intracellular volume adaption, and redistribution of osmotically active particles from the brain. It takes at least five days to rebuild the stores of the brain's idiogenic osmoles
3	Correct no faster than 0.5 meq/L per hour in asymptomatic acutely hyponatremic patients, and complete normalization of sodium in these patients over 2–3 days	Acute hyponatremia (occurring over 12–24 hr) does not allow time for loss of brain idiogenic osmoles, and patients are theoretically at less risk of demyelination
4	If symptoms are severe (i.e., seizures have occurred), more rapid correction is appropriate (i.e., 0.5–1 meq/L per hour) for the first 2–3 hr or until symptoms abate	Severe symptoms (especially seizures), require prompt treatment to avoid brain injury. These patients should also receive an antiseizure drug (e.g., ativan)
5	Isotonic (0.9%) saline should be utilized for asymptomatic and mildly symptomatic patients. Hypertonic (3%) saline should be reserved for severe symptoms and CSW syndrome	Isotonic (0.9%) saline should raise the serum sodium concentration 1–2 meq/L for each liter infused into a 70-kg patient. Hypertonic (3%) saline, run at a rate of 25–30 mL/hr, will increase the serum sodium 8–10 mEq/L in a 70-kg patient
6	In ECF volume contraction, isotonic (0.9%) saline should be used to expand the ECF volume. Three percent saline is reserved for CSW syndrome, and to supplement other low ECF hyponatremic states	Expanding the ECF volume leads to decreased antidiuretic hormone release, which serves to help correct the serum [Na <sup>+</sup> ]

*Abbreviations:* CPM, central pontine myelinolysis; CSW, cerebral salt wasting; ECF, extracellular fluid.

Hypovolemic hyponatremia requires volume repletion with isotonic saline. The degree to which a liter of any given solution would increase serum sodium can be estimated by the following equation (which can be used in hypernatremic conditions as well):

$$\Delta \text{in serum}[\text{Na}^+] = \frac{\text{infusate}[\text{Na}^+] - \text{initial serum}[\text{Na}^+]}{\text{Total body water} + 1}$$

This formula demonstrates how little the serum  $[\text{Na}^+]$  changes with only 1 L of fluid. To calculate the total number of liters needed to change a hyponatremic condition ( $[\text{Na}^+] = 130 \text{ meq/L}$ ) to a normal serum sodium state ( $[\text{Na}^+] = 140 \text{ meq/L}$ ) by administering NS ( $[\text{Na}^+] = 154 \text{ meq/L}$ ), simply add up the aggregate changes predicted by the earlier equation, in repetitive fashion, until the normal value is being approached.

For a 70-kg patient with  $\text{TBW} = 42 \text{ L}$ , the first-liter NS changes the serum sodium from 130 to 130.56 meq/L, the second liter of NS brings the serum sodium from 130.56 to 131.11 meq/L, and so on. The aggregate number of liters of NS, calculated to bring the serum sodium to normal, divided by 24 provides the hourly infusion rate, if the intention is to make the change in a single day.

Serial measurements of sodium are essential, because the formula has several limitations. The equation does not account for shifts of body water, urinary losses, insensible losses, increases in sodium excretion in the setting of SIADH, or the effects of potassium and other osmotically active solutes.

## POTASSIUM DISORDERS

The average 70-kg adult male contains approximately 60 meq/kg of potassium  $[\text{K}^+]$ . Most of the potassium is intracellular ( $28 \text{ L} \times 150 \text{ meq/L} = 4200 \text{ meq}$ ), with less than 2% extracellular ( $14 \text{ L} \times 4.5 \text{ meq/L} = 63 \text{ mEq}$ ). The intracellular predominance of potassium limits the value of serum potassium in estimating total body potassium stores, except during steady states. ⚡ **Because the extracellular concentration of potassium changes most quickly, it has the greatest effect on cell membrane function, and is particularly important for cardiac and nerve tissues.** ⚡ A sodium-potassium membrane pump ( $\text{Na}^+/\text{K}^+$  ATPase) maintains a gradient of 30:1 to 40:1 of intracellular to extracellular potassium, causing a transmembrane potential of approximately  $-90 \text{ mV}$ , as per the Nernst Equation.

On the whole, potassium balance is dependent on intake and both renal and extrarenal losses. The kidney secretes approximately 90% of ingested potassium, whereas the remainder is excreted in sweat and feces. The net secretion of potassium by the kidney is determined by many factors, including the amount of urine flow, amount of sodium delivery to the distal nephron, plasma potassium concentration, and acid-base status. An increase in urine flow, sodium content, or plasma potassium increases the amount of potassium excreted.

⚡ **The acid-base status of the patient affects potassium through the reciprocal relationship between the hydrogen  $[\text{H}^+]$  and potassium  $[\text{K}^+]$  ions.** ⚡ Acidosis increases intracellular  $\text{H}^+$  and  $\text{K}^+$  flows into the plasma to maintain ionic balance, resulting in serum hyperkalemia. Alkalosis decreases intracellular  $\text{H}^+$  and plasma  $\text{K}^+$  moves

into the cell to maintain ionic balance, resulting in serum hypokalemia. The  $\text{Na}^+/\text{K}^+$  ATPase pump is stimulated by insulin, thyroid hormone, and  $\beta$ -adrenergic catecholamines, resulting in cellular uptake of potassium.

## Hyperkalemia

### Causes

Hyperkalemia is usually defined by a serum  $\text{K}^+ > 5.5 \text{ meq/L}$ . In the critically ill patient, the most common cause of hyperkalemia is renal insufficiency, though an acute rise in extracellular potassium levels can also occur following crush injuries (rhabdomyolysis), or other forms of cellular destruction, and reperfusion injury can also result in hyperkalemia. Other causes include acidemia, hormone abnormalities, and drugs. Drugs can cause hyperkalemia through various mechanisms (Table 9), including transcellular shifts, involving hormonal, renal, or cellular membrane pump effects (34).

The use of succinylcholine, the depolarizing neuromuscular blockade drug, will transiently increase the serum  $\text{K}^+$  concentration by 0.5–1 meq/L in most patients, including those with renal failure. However, patients who have sustained major burns or upper motor neuron trauma (head injuries and spinal cord injuries), as well as those who have been at chronic bed rest, often have an exaggerated release of  $\text{K}^+$ , due to the development of extrajunctional neuromuscular junction (NMJ) receptors (Volume 2, Chapter 6). The degree of  $\text{K}^+$  elaboration may be enough to cause ventricular dysrhythmias, including asystole, which can only be treated by cardiopulmonary resuscitation, the administration of calcium chloride (to stabilize cellular membranes), alkalization (to decrease the plasma  $[\text{K}^+]$ ), by dialysis, if necessary.

### Symptoms

⚡ **The clinical manifestations of hyperkalemia are related to cellular membrane depolarization, the most serious of which involves cardiac muscle.** ⚡ Hyperkalemia shortens

**Table 9** Drug-Induced Hyperkalemia

#### Increased potassium intake

- Potassium supplements
- Herbal and nutritional supplements
- Packed red blood cells
- Penicillin G potassium

#### Transcellular shift

- Beta blockers
- IV amino
- Succinylcholine
- Digoxin intoxication

#### Impaired renal excretion

- Potassium-sparing diuretics (i.e., spironolactone)
- Nonsteroidal anti-inflammatory drugs
- Angiotensin converting enzyme inhibitors
- Angiotensin-II receptor blockers
- Trimethoprim
- Pentamidine acids
- Tacrolimus
- Heparin
- Cyclosporine

the duration of the cardiac action potential, decreases resting membrane potential (which depolarizes the membrane), and suppresses automaticity of cardiac pacemakers. The earliest electrocardiographic (ECG) manifestations are high-peaked T waves, usually first evident in the precordial leads. As the potassium level rises, this progresses to the prolongation of the P-R interval, flattening of the P wave, widening of the QRS complex with the merging of the T wave into a sine-wave configuration, with eventual ventricular fibrillation and cardiac standstill. Peripheral muscle can also be affected by moderate to severe hyperkalemia. Ascending muscular paresis can progress to flaccid quadriplegia and respiratory paralysis.

### Treatment

Treatment depends on the degree of hyperkalemia. Mild hyperkalemia can usually be treated by hydration and the use of loop diuretics, which will increase potassium excretion, or treatment of volume, acid-base, or hormonal disturbances.

The presence of symptoms or ECG abnormalities demands more immediate, aggressive therapy. Immediate treatment with calcium salts will stabilize the cardiac membrane. Using 10 ml of 10% calcium gluconate, given intravenously over 3–5 minutes, provides 4.7 meq of calcium; whereas, 10 ml of 10% calcium chloride given intravenously over 10 minutes, provides 13.6 meq of calcium, but is best administered through a central line because of its damaging effects on small vessels. The effect of calcium salts is temporary, lasting for about 30 minutes. Sodium bicarbonate can also be given to temporarily shift potassium into cells. Insulin and glucose therapy begins immediately, but may require an hour or more to demonstrate a significant effect; likewise, the serum  $[K^+]$  only decreases temporarily via this treatment modality.

Longer lasting therapies that actually decrease total potassium levels from the body include hemodialysis, potassium-exchange resins, and loop diuretics. Onset of action of these therapies on hyperkalemia is slower, and the aforementioned methods should be instituted for immediate relief when necessary. The usual dose of a potassium-exchange resin, such as sodium polystyrene, is 0.5 to 1 g/kg, which is usually dissolved in a sorbitol solution, and can be given orally or rectally.

## Hypokalemia

### Causes

☞ **Hypokalemia, usually defined as a serum  $K^+ < 3.5$  meq/L, is the most common electrolyte disorder in hospitalized patients (35), and is associated with hypomagnesemia, and can result from decreased potassium intake or increased renal or extrarenal potassium losses.** ☞

The most common source for extrarenal losses is the gastrointestinal tract. Drugs can cause hypokalemia through increased renal losses (e.g., diuretics) or transcellular shift (e.g.,  $\beta$ -agonists and methylxanthines). Metabolic alkalosis, associated with excessive abnormal hydrochloric acid losses from vomiting or nasogastric suctioning can also exacerbate hypokalemia. As renal chloride levels decrease, the chloride-linked reabsorption of sodium in the proximal nephron decreases. Increased delivery of sodium to the distal convoluted tubule, in addition to the alkalemia, results in aldosterone-driven sodium reabsorption and potassium (and  $H^+$ ) excretion. This situation drives both the hypokalemia and the alkalosis. The hypokalemic alkalosis

due to excessive gastric HCL losses is termed chloride sensitive, and can be treated with the administration of potassium chloride (no more than 40 meq/hr via a central vein). Non-chloride-sensitive metabolic alkalosis, such as hyperaldosteronism, usually results from increased distal nephron absorption of sodium. Any mineralocorticoid excess can potentially cause hypokalemia through this mechanism. In either case, magnesium is also usually very low, and must be replaced as well.

### Symptoms

The symptoms of hypokalemia can be found in skeletal, smooth, and cardiac muscle, and include muscle weakness and paralysis, absent deep tendon reflexes, paralytic ileus, and cardiac conduction abnormalities. In the average individual with a normal heart, clinical manifestations usually do not occur unless the potassium level is less than 3.0 meq/L.

In patients with underlying heart disease, and especially those on digitalis, even mild hypokalemia can cause cardiac dysrhythmias. The toxic effects of digitalis are potentiated by hypokalemia, secondary to the inhibitory action of digitalis on the  $Na^+/K^+$  ATPase pump. Electrocardiographic manifestations include progressive depression of the S-T segment and a decrease in T-wave amplitude. The U-wave amplitude and Q-T interval increase. A-V conduction prolongation and both ventricular and supraventricular dysrhythmias can result.

### Treatment

☞ **Treatment of hypokalemia requires an understanding that a steady-state serum deficiency of 1 meq/L can translate to a total body deficit of >1000 meq.** ☞ However, no more than 40 meq should be administered per hour to a 70-kg patient (always administer via a central line to avoid peripheral vein sclerosis). Intravenous replacement is required if the patient is unable to take oral supplementation or if ECG changes are present. In general, potassium is replaced as a chloride, which is especially useful in the presence of alkalemia. Replacement via a peripheral vein should occur at a rate no faster than 10 meq per hour, and should rarely ever exceed 20 meq per hour. Cardiac monitoring is required for rates faster than 20 meq per hour.

## CALCIUM DISORDERS

Calcium is a divalent cation. A normal adult contains 1 to 2 kg of calcium, of which the vast majority is deposited in bone (~99%) as hydroxyapatite crystals. Calcium homeostasis depends on bone exchange, renal excretion, and intestinal absorption (36). Calcium influx into the cell occurs through specific voltage-dependent calcium channels, or through receptor-mediated G-protein-linked channels. These G-protein-linked channels are activated through various membrane receptors that respond to endocrine and paracrine substances. Very small amounts of calcium leak passively through the cell membrane. Calcium in the cells functions as a second messenger, and is found in the cytosol and various organelles. Normally, energy is expended to pump calcium out of the cytosol and into the organelles and ECF. However, in the setting of shock with depletion of intracellular energy, calcium accumulates in the cells and has adverse effects, which can lead to widespread organ dysfunction and death.

Calcium exists in three forms in the ECF: ionized calcium, protein-bound calcium, and nonprotein anion calcium complexes. The ionized form functions as the most physiologically active, and comprises about 45% of total serum calcium. About 40% of serum calcium is protein bound. The majority of this calcium is bound to albumin, whereas the remainder is bound to the globulins. The remaining 15% of serum calcium is complexed to nonprotein anions, such as phosphate, citrate, sulfate, bicarbonate, and lactate. Extracellular calcium is tightly regulated, and is determined by a calcium receptor (first described in 1993), several hormones, and calcium itself. The most important hormones in calcium regulation are parathyroid hormone (PTH) and 1,25-dihydroxy vitamin D. Parathyroid hormone secretion is inversely related to serum calcium levels, and regulates calcium through several mechanisms. Within minutes, PTH decreases renal tubular reabsorption of phosphate, and causes an increase in distal tubular Ca reabsorption through a cyclic adenine monophosphate (cAMP)-mediated process. Within hours, PTH causes release of  $\text{Ca}^{+2}$  from the bone through osteoclast activation, serving as the main reservoir for calcium exchange in the body. As hypocalcemia persists, PTH stimulates renal transformation of circulating prohormone 25-hydroxy vitamin D into 1,25-dihydroxy vitamin D, the active form. This hormone facilitates the reabsorption of calcium by the proximal small bowel. 1,25-dihydroxy vitamin D also stimulates bone reabsorption. The hormone calcitonin, secreted by C cells of the thyroid, only moderately affects calcium metabolism.

Normal values of total serum calcium usually range between 8.5 and 10.5 mg/dL. Following trauma and critical care, patients have decreased albumin levels, making the total serum calcium measurement less useful. ⚡ **In the setting of trauma and critical illness, the free ionized (physiologically active) form of calcium is the relevant value that should be measured.** ⚡ The ratio of free calcium to protein-bound calcium is dependent on several factors. For instance, in the setting of low albumin levels, the total serum calcium level will also be low, whereas the ionized or free amount of calcium may remain near normal. There are formulas that exist to correct serum calcium to albumin level; however, in critically ill patients, they are inaccurate. As a general rule in the critically ill patient, therapeutic decisions should be based on the level of ionized calcium alone (rather than total serum calcium).

## Hypercalcemia

Primary hyperparathyroidism is the most common chronic cause of hypercalcemia. Malignancy, caused by bony metastases and/or by a parathyroid hormone-related protein (PTHrP), is the second most common cause. This protein binds to PTH receptors in bone and kidney. Breast, lung, and renal cell carcinoma are the most common solid tumors that can cause hypercalcemia. Multiple myeloma causes hypercalcemia through bony destruction, as a result of inflammatory mediators (IL-1, IL-6, and TNF- $\sigma$ ). In both Hodgkin's and non-Hodgkin's lymphoma, hypercalcemia results from increased conversion of 25-hydroxy-cholecalciferol to calcitriol by tumor cells. Other common causes include granulomatous diseases (i.e., sarcoidosis), drugs (i.e., thiazide diuretics, vitamin A or vitamin D intoxication).

## Symptoms

Symptomatology is often related to the degree and acute nature of the hypercalcemia. Most cases of mild hypercalcemia (levels  $\leq 12$  mg/dL) are asymptomatic, but once calcium levels are above 12 mg/dL, neurologic, gastrointestinal, and renal symptoms usually appear. Neurologic symptoms can begin with mild drowsiness, progressing to weakness, depression, and coma. Gastrointestinal symptoms can involve constipation, nausea, vomiting, anorexia, and peptic ulcer disease. Renal manifestations include nephrocalcinosis, nephrolithiasis, and nephrogenic DI. Serum calcium levels above 13.5 mg/dL generally constitute a medical emergency.

## Treatment

Treatment of hypercalcemia initially involves volume loading with NS and diuresis (usually furosemide). The resulting natriuresis is accompanied by calciuresis. Depending on the degree of hypercalcemia, urine volumes should range from 2 to 3 L/day, up to 6 L/day. The patient must remain euvolemic, as hypovolemia will exacerbate the problem.

The etiology of the hypercalcemia must then be determined. Most cases of severe hypercalcemia are caused by malignancy. Bisphosphonates, which have made mithramycin relatively obsolete, are utilized in the setting of increased osteoclastic activity, such as malignancy. If primary hyperparathyroidism is the underlying etiology, serious consideration should be given to urgent parathyroid surgery after initial patient stabilization. Parathyroidectomy may also be useful in cases of secondary or tertiary hyperparathyroidism. Glucocorticoids have been shown to be helpful in cases of hypercalcemia, secondary to sarcoidosis, hematologic malignancies, and vitamin D intoxication. Hemodialysis, with a low- or no-calcium bath, is also an available treatment modality. Thiazide diuretics and digitalis are contraindicated in the setting of hypercalcemia, as thiazides can decrease calciuria, and digitalis can cause cardiac arrest.

## Hypocalcemia

### Causes

Hypocalcemia is defined as a decrease in the ionized fraction of total serum calcium. ⚡ **Hypocalcemia is a common entity in critically ill patients (37). It is estimated that about 70% to 90% of critically ill patients have decreased total serum calcium levels, and ionized calcium levels are deficient in 15% to 50%.** ⚡ The etiology is often multifactorial.

There appears to be a relationship between sepsis and critical illness, and altered PTH secretion and peripheral action. Inflammatory mediators, such as TNF- $\sigma$ , IL-1, and IL-6 have also been implicated. Chelating substances, such as phosphate, bicarbonate, citrate, and even radiocontrast dye can decrease ionized calcium levels. Hypocalcemia is a particular problem during the anhepatic stage of liver transplant (following massive blood and factor transfusion), and during continuous veno-veno hemodialysis (CVVHD) in patients with severe liver failure in the intensive care unit (ICU). In all these cases the citrate used for chelating calcium (to keep blood products from clotting, and to keep blood on the CVVHD machine from clotting) is not being metabolized by a normal liver, and thus very large quantities of calcium gluconate, and/or calcium chloride are needed to restore the ionized calcium concentration.

Postoperative hypocalcemia can occur following parathyroid, thyroid, or radical neck surgery. This decrease is

exacerbated following surgery for hyperparathyroidism, due to the “hungry bone syndrome,” which causes a rapid accretion of calcium into bone as PTH levels fall to normal or subnormal levels, which may result in profound hypocalcemia.

Conditions of rapid cell destruction, such as rhabdomyolysis or tumor lysis syndrome, which result in hyperphosphatemia, can cause hypocalcemia. This is due to phosphate binding to calcium. Other conditions that are associated with increased organic anions (i.e., citrate toxicity) or free fatty acids (acute pancreatitis) can also decrease serum calcium levels. Renal and hepatic insufficiency can result in hypocalcemia owing to their effects on vitamin D metabolism. Hypomagnesemia interferes with PTH secretion and possibly its peripheral action. Therefore, correction of magnesium deficits is essential in the treatment of hypocalcemia.

### Symptoms

Symptoms of neuromuscular irritability predominate in the setting of hypocalcemia. These symptoms include numbness, paresthesias (typically circumoral and digital), muscle cramps, Chvostek’s and Trousseau’s signs, laryngospasm, tetany, and seizures. Chvostek’s sign is a facial twitch, elicited by tapping the facial nerve just below the zygomatic arch with the mouth open. Trousseau’s sign is induction of wrist and metacarpophalangeal joint flexion, hyperextension of fingers, and flexion of thumb and palm with brachial artery occlusion for three minutes. Hypocalcemia also may cause Q-T prolongation on the ECG, and this can progress to heart block or ventricular fibrillation.

### Treatment

Treatment of hypocalcemia depends upon the acuteness, severity, and etiology. The normal serum ionized calcium concentration is 1.13 to 1.32 mmol/L (4.52–5.28 mg/dL). In severe hypocalcemia (<0.6–0.8 mmol/L), as seen with citrate toxicity from massive blood product administration, and/or hepatic dysfunction in the setting of citrate-anticoagulated CVVHD, aggressive calcium administration is warranted. For this condition, 500 to 1000 mg (elemental calcium equivalent) IV push via a central line, followed by infusion at rates as high as 50 to 100 mg per minute, may be required. In this setting, continuous infusions and frequent (every 15–30 minutes) arterial blood gasses with concomitant ionized calcium values should be obtained to titrate therapy.

Note that in the presence of excess unmetabolized citrate, a safe level of ionized calcium (>1.0 mmol/L or >4mg/dL) will require the total blood calcium to be supranormal. Indeed, in this setting, >17 mg/dL has been recorded with massive transfusion during liver transplantation (36). This concurrence of a low ionized calcium and a high total calcium (“calcium gap”) allows recognition of the citrate accumulation syndrome. If severe, it may prompt a decision to minimize administration of additional citrate-containing products. Otherwise, when the calcium citrate complexes are subsequently metabolized, ionized calcium levels may rise to high levels.

In the less acute setting, symptomatic hypocalcemia and ionized calcium levels of less than 1.0 μmol/L should be treated, but less aggressively. The amount of parenteral calcium given initially in this less acute setting is 100 mg (elemental calcium equivalent) over 5 to 10 minutes. This is followed by an infusion of 0.5 to 2.0 mg/kg/hr.

Magnesium and phosphorus levels, and if clinically indicated, PTH and vitamin D levels, should be determined. Magnesium should be supplemented and phosphorus lowered if indicated. Calcium administration in the setting of hyperphosphatemia can result in metastatic calcium phosphate precipitation. In general, phosphorus levels should be below 6 mg/dL prior to calcium administration. Parenteral calcium is given for acute symptomatic hypocalcemia. Oral supplementation and vitamin D are given for chronic hypocalcemia.

There are different preparations for infusion of elemental calcium. The most commonly used preparations are calcium gluconate and calcium chloride. Calcium gluconate 10% solution contains 93 mg of elemental calcium, whereas calcium chloride 10% solution contains 272 mg. The higher the amount of elemental calcium, the more irritating it is to the veins. Calcium should be infused through a central vein, if possible. There are various oral calcium preparations available. Acute oral therapy generally involves 0.5 to 1.0 g every six hours. Vitamin D<sub>3</sub> or calcitriol can also be given to increase calcium reabsorption from the gut. Of note, there is an increasing body of evidence that cellular calcium overload is detrimental. Therefore, a mild ionized hypocalcemia may be desirable in acute inflammatory states (37).

## MAGNESIUM DISORDERS

Magnesium is the second most abundant intracellular ion. It is an essential cofactor in many enzymatic reactions, including the transfer of phosphate groups (energy metabolism), replication and transcription of DNA and translation of mRNA, membrane stabilization, nerve conduction, ion transport, and calcium channel activity. Total body magnesium content is about 21 to 28 g, most of which is in the skeletal bone mass (>50%). Less than 1% is located in the extracellular space. Normal serum levels range from 1.5 to 2.5 mg/dL. The total body magnesium balance is mainly dependent on gastrointestinal absorption and renal excretion. Bone is an extremely slow exchangeable source of magnesium. Approximately 55% of extracellular magnesium exists in the free ionized form, with the remainder complexed to anions and proteins (38,39).

### Hypermagnesemia

#### Causes

The most common cause of elevated serum magnesium levels is acute or chronic renal insufficiency. This may be exacerbated by the use of magnesium-containing antacids and laxatives in the setting of impaired renal function. Hypermagnesemia may also occur secondary to rhabdomyolysis following burn or crush injuries.

#### Symptoms

Clinical manifestations relate to neuromuscular depression. Synaptic acetylcholine release is inhibited by hypermagnesemia. Loss of deep tendon reflexes occurs at levels of about 8 mg/dL. As levels increase above this, paralysis and coma can occur. Cardiovascular effects consist of hypotension and cardiac conduction disturbances. The P-R interval, in addition to widening of the QRS complex and elevated T waves, can eventually lead to cardiac arrest.

**Treatment**

Treatment involves repleting extracellular volume deficits, correcting acidosis, withholding exogenous magnesium intake, and occasionally hemodialysis. Loop diuretics can also increase magnesium renal excretion. Because hypermagnesemia is generally a rather benign condition (especially in intubated patients), the need for specific therapy is exceedingly rare. However, acute symptomatology in nonintubated patients or hypotensive patients can be temporarily controlled by slow intravenous administration of 5 to 10 meq/L of calcium, which antagonizes the neuromuscular effects of magnesium.

**Hypomagnesemia****Causes**

Poor intake alone is rarely a cause of hypomagnesemia, because of the ability of the kidneys to conserve magnesium. Most states of deficiency result from decreased intake, in addition to increased gastrointestinal losses. Other causes include prolonged intravenous fluid replacement without magnesium replacement, chronic loop diuretic use, and certain drugs, such as cisplatin, aminoglycosides, cyclosporine, amphotericin B, insulin, and mannitol. ⚡ **It is estimated that about >25% of patients on a medical-surgical ward and >75% on the postoperative ICU setting are hypomagnesemic.** ⚡ Serum levels of magnesium correlate poorly with total body stores, which may be reduced despite normal serum levels.

**Symptoms**

Most states of magnesium deficiency are asymptomatic. When symptoms do occur, a severe deficiency usually exists. Neuromuscular symptoms mirror hypocalcemia, with hyperreflexia, tremors, tetany, and positive Chvostek's and Trousseau's sign. Seizures can ensue, as can life-threatening cardiac dysrhythmias. Early ECG changes include prolonged P-R and Q-T intervals and atrial tachydysrhythmias. More life threatening dysrhythmias may result with ventricular tachycardia, including polymorphic ventricular tachycardia (torsades de pointes) and ventricular fibrillation (Volume 2, Chapter 20).

**Treatment**

Acute therapy involves 1 to 2 g of intravenous magnesium sulfate (8–16 meq) over 5 to 10 minutes, followed by an infusion of 0.5 to 1.0 g/hr. Sulfate can bind both calcium and potassium, and therefore, levels of these ions should be measured during therapy. During treatment, clinically significant hypermagnesemia can result. However, the therapeutic window for magnesium is quite large, and the treatment of hypermagnesemia is seldom required (and when needed consists mainly of supportive care). Nonetheless, it is helpful to have calcium gluconate or calcium chloride available for nonintubated patients, who become symptomatic. Magnesium oxide is the preferred agent for oral supplementation.

**PHOSPHORUS DISORDERS**

Phosphorus is primarily contained in the ICF, but is involved in both cellular and extracellular processes. Cellular energy is generated through phosphate bonds (i.e., ATP, creatine phosphate). In addition, phosphate functions as an oxygen

carrier in hemoglobin [as a component of 2,3-diphosphoglycerate (2,3-DPG)], and serves as an integral component of cAMP, cGMP, and inositol polyphosphates. Phosphorus is also involved in the processing and synthesis of DNA, mRNA, and proteins. It is likewise important in acid–base balance, glycolysis, vitamin D metabolism, and in the structure of bone and cell membranes (phospholipids).

Normal total serum phosphorus levels range between about 2.5 and 4.5 mg/dL, though serum levels are not necessarily reflective of total body stores. Fifty-five percent of total serum phosphorus exists in the ionized form. Phosphorus homeostasis is dependent upon intestinal absorption, renal excretion, and bone mineralization/resorption. The kidneys are the primary regulators, and renal phosphorus excretion is increased by PTH, calcitonin, vasopressin, ANP, dopamine, metabolic acidosis, volume expansion, glucose, amino acids, NS, and ketones. Renal phosphorus excretion is decreased by vitamin D, growth hormone, IGF-1, glucocorticoids, thyroid hormone, and metabolic alkalosis. In addition, PTH decreases, and vitamin D increases the intestinal absorption of phosphate.

**Hyperphosphatemia****Causes**

Hyperphosphatemia can result from diminished renal excretory capacity, increased exogenous phosphate or vitamin D load, and transcellular shift. Renal failure is the most common cause of hyperphosphatemia. Initially, in mild-to-moderate renal failure, hyperphosphatemia leads to increased PTH secretion. The increase in PTH leads to decreased renal tubular reabsorption and increased urinary excretion. In severe renal failure (usually glomerular filtration rate <25 mL/min), this mechanism often fails and hyperphosphatemia is almost a universal finding. Cell lysis of any etiology can cause intracellular release of phosphorus to the extracellular space. Acidosis of either a metabolic or respiratory etiology causes the transcellular shift of phosphate with resultant extracellular hyperphosphatemia. Hypoparathyroidism, hyperthyroidism, and acromegaly cause hyperphosphatemia through decreased phosphaturia. Treatment with bisphosphonates can also cause hyperphosphatemia, but this is believed to be secondary to both transcellular shift and decreased renal excretion. Exogenous etiologies of hyperphosphatemia include laxative phosphate salts and phosphate-containing enemas. Patients most susceptible to exogenous hyperphosphatemia are those with intravascular depletion, renal insufficiency, bowel mucosal abnormalities, bowel obstruction, or ileus.

**Symptoms**

The clinical manifestations of hyperphosphatemia are a result of the consequent hypocalcemia and precipitation of calcium phosphate in soft tissues. Hyperphosphatemia causes hypocalcemia by decreasing the renal conversion of vitamin D, decreasing the production of calcitriol, and precipitation. When the calcium–phosphorus product exceeds 70, precipitation in the soft tissues is likely to occur.

**Treatment**

Treatment involves correcting the underlying disorder, elimination of exogenous phosphate sources, increased phosphorus excretion, and treatment of associated hypocalcemia (39). Renal phosphorus excretion is facilitated by NS loading and loop diuretics. Gut absorption is decreased by the use of phosphate binders. Aluminum phos-

phosphate binders should only be used for short periods in patients with renal failure, as aluminum accumulation can be detrimental with long term therapy. Calcium levels need to be monitored closely when calcium carbonate is used, because hypercalcemia can result, and if calcium is given when the phosphorus level is greater than 7 mg/dL, calcium phosphate is likely to precipitate. Hemodialysis is very effective in patients with renal failure. As a temporizing measure, insulin and glucose can cause transcellular shift of phosphorus from the extracellular to the intracellular compartment, but potassium monitoring in this setting is mandatory.

## Hypophosphatemia

### Causes

☞ **Transcellular shift is the most common mechanism of acute hypophosphatemia, though chronic total body hypophosphatemia results from decreased intake and/or increased renal or gastrointestinal losses.** ☞ Clinical situations associated with transcellular shift generally involve conditions that stimulate glycolysis. During glycolysis, phosphorylated glucose compounds are generated and utilized. Refeeding syndromes (in malnourished and chronic alcoholic patients), insulin administration during diabetic ketoacidosis, corticosteroid or catecholamine administration, and CVVHD (with the massive quantities of glucose containing fluids administered) can all cause hypophosphatemia.

Hungry bone syndrome following parathyroidectomy results in massive deposition of phosphorus into bone. Increased urinary losses of phosphorus accompany renal tubular defects, increased PTH, vitamin D deficiency, acidosis, and diuretic use. Up to 30% of patients with malignancy have increased urinary losses of phosphorus. Increased intestinal losses accompany chronic diarrhea, steatorrhea, fistulas, and dietary intake of phosphate binders (i.e., magnesium or aluminum hydroxide). Decreased intestinal vitamin D absorption often accompanies these conditions and exacerbates the problem.

Chronic alcoholic patients are especially susceptible to hypophosphatemia for a multitude of reasons, including dietary deficiency, decreased intestinal absorption (secondary to increase antacid use), vomiting, magnesium deficiency, refeeding syndrome, and renal phosphorus wasting. Diabetic patients are prone to increased renal phosphorus wasting, secondary to accompanying insulin deficiency, glycosuria, ketonuria, and acidosis.

### Symptoms

Clinical manifestations generally do not occur unless the serum phosphorus level is less than 1 mg/dL. As phosphorus is involved in many cellular and extracellular processes, the clinical manifestations can be profound and quite diverse, and can include muscle weakness, respiratory insufficiency, tremors, paresthesias, encephalopathy, ataxia, coma, seizures, anorexia, rhabdomyolysis, hemolysis, thrombocytopenia, immune cell dysfunction, insulin resistance, impaired gluconeogenesis, impaired vasopressor response, and cardiac, renal, and hepatic insufficiency.

### Treatment

Phosphorus repletion is always indicated when the level is less than 1 mg/dL and generally indicated when it is less than 1.5 mg/dL (39). A level of 1.5 mg/dL or above usually does not require supplementation in the absence of other clinical evidence of phosphate depletion. The safest mode

for phosphate repletion is oral, and usual doses are 1 to 3 g/day. Intravenous phosphorus replacement is recommended for levels less than 1 mg/dL. Great care must be taken with intravenous supplementation, as it can precipitate a hypocalcemic crisis, and as such, calcium levels should be followed with appropriate supplementation. Usually the phosphorus is administered as a sodium or potassium salt in NS at 2.5 mg/kg over six hours. Parenteral administration should discontinue when levels are greater than 2 mg/dL.

## EYE TO THE FUTURE

Currently, research appears concentrated in the early detection of electrolyte disorders. Point of care laboratory testing is currently available with resultant reductions in the turnaround time for electrolyte determinations. However, the cost effectiveness of such testing for widespread ICU use remains to be determined.

Indwelling electrodes have been tested that give continuous read-outs of selected serum electrolytes. However, determination of electrolyte replacement requires knowledge of factors other than the serum electrolyte concentration (i.e., volume status, albumin concentration, etc.). The electrodes are also invasive and a potential source of infection.

Additionally, clinical trials are needed to determine the clinical significance of basic science properties specific to the various crystalloid solutions, colloids, and blood products, including their modulation of vascular permeability and systemic inflammation. Outcome-focused clinical trials powered to discern a mortality benefit for various resuscitation fluids in septic shock and/or hemorrhagic shock are needed, along with integrated acid base and systemic electrolyte analyses. Furthermore, well-designed clinical trials are required to evaluate the physiologic effects of colloids and crystalloids, electrolyte and acid-base disturbances with respect to individual organ function (including lung-fluid balance in patients at risk for or with established ALI/ARDS, renal function in patients at risk for renal insufficiency/failure, gut and liver function in patients with pre-existing liver injury or ileus and those at high risk for shock liver, the immune and reticuloendothelial system in patients suffering from sepsis or at risk for sepsis) and the effect on the immune system, and the central nervous system in terms of both short- and long-term outcomes.

Another area of interest is the important problem of CSW syndrome, and the differentiation from SIADH. We believe the rapid determination of BNP (via newly released bedside immunoassay, currently used for CHF) holds promise in more quickly diagnosing CSW syndrome, and beginning important NS and volume repletion therapy (27).

In addition, the problem of CPM, resulting from too rapid a correction of hyponatremia, continues to be a clinically important problem, which may be limited by better understanding of the pathophysiology, and more frequent and earlier measures of serum sodium, so as to protect from the development of the entity in the first place.

## SUMMARY

Fluid and electrolyte disorders are common in the ICU. Their management requires more than the determination of serum chemistries. Proper management of Na<sup>+</sup> disorders requires

the knowledge of volume status and sources of continued fluid and/or  $\text{Na}^+$  losses. Similarly, management of  $\text{K}^+$  disorders requires a determination of the sources of  $\text{K}^+$  loss (diuretics, diarrhea, etc.) or accumulation (renal failure, crush injury). The interpretation of  $\text{Ca}^{2+}$  and  $\text{Mg}^{2+}$  serum concentrations must include the etiology of the disorder and serum albumin concentrations. Phosphorus concentrations are dependent on renal function and calcium homeostasis.

Thus, an approach to fluid and electrolyte disorders that is narrowly based solely on the determinations of serum chemistries will often inadequately correct the abnormality and may, in fact, exacerbate the disorder. Instead, proper treatment requires an in-depth determination of volume status, renal function, serum albumin, and a review of current drug therapy that may be contributing to the disorder. Only then can a plan for the correction of the given disorder be properly formulated.

The initial choice of fluid administration is guided by the goal of optimizing perfusion of tissues; however, there is still limited data that can predict which fluids (colloids or crystalloids) are best in any particular scenario (Volume 1, Chapter 11). There is an increasing amount of information available regarding the physiochemical and biological properties of various colloid and crystalloid fluids available (40). Yet, the goals of providing adequate tissue perfusion (with appropriate levels of intravascular volume), and optimum cellular function (by maintaining normal values of serum chemistries), has not substantially changed in the last decade. The best way to achieve these goals is by frequent measurements of the intravascular volume and plasma solute concentrations, and by both anticipating and monitoring expected perturbations. Frequent monitoring in concert with frequent alterations in the fluid and electrolytes being administered represents the optimum strategy for care. It is more likely that new monitoring modalities will provide a greater impact on trauma and critical care management than the development of new fluid and electrolyte formulations.

## KEY POINTS

- ✂ Only a fraction of the total body potassium, about 4 mEq/dL (approx 67 meq in a 70 kg patient), is in the blood.
- ✂ Plasma osmolarity (Posm) is generally a good estimate of total body osmolarity, because isosmotic conditions are maintained through fluid shifts.
- ✂ When the calculated Posm differs by  $>15$  mOsm from the laboratory-measured value, an osmolar gap exists.
- ✂ Crystalloids should be the initial resuscitation fluid administered in most situations.
- ✂ Hyponatremia almost always represents a hyperosmolar or hypertonic state, whereas hyponatremia can be present in a hypertonic, isotonic, or hypotonic state.
- ✂ The work-up for hyponatremia starts with determination of intravascular volume status, based on history, physical examination, and laboratory data.
- ✂ In complete central DI, the urinary osmolality is  $<150$  mOsm/L, but may be higher in partial DI.
- ✂ The diagnosis of SIADH is suggested by the finding of urine osmolarity  $>100$  mOsm/L and urine sodium  $>40$  meq/L in the setting of hyponatremia.

- ✂ Cerebral salt wasting syndrome must be differentiated from SIADH, because their treatments are divergent, and directly effect outcome.
- ✂ Symptoms secondary to acute hyponatremia typically do not arise until the serum  $[\text{Na}^+]$  is less than 125 mEq/L in acute hyponatremic states, or less than 120 meq/L in more chronic conditions.
- ✂ Experimental studies in animals and observations in humans suggest that the rate of hyponatremia correction in the first 24 hours is the major determinant for the development of osmotic demyelination.
- ✂ Because the extracellular concentration of potassium changes most quickly, it has the greatest effect on cell membrane function, and is particularly important for cardiac and nerve tissues.
- ✂ The acid–base status of the patient affects potassium through the reciprocal relationship between the hydrogen  $[\text{H}^+]$  and potassium  $[\text{K}^+]$  ions.
- ✂ The clinical manifestations of hyperkalemia are related to cellular membrane depolarization, the most serious of which involves cardiac muscle.
- ✂ Hypokalemia, usually defined as a serum  $\text{K}^+ < 3.5$  meq/L, is the most common electrolyte disorder in hospitalized patients (35), and is associated with hypomagnesemia, and can result from decreased potassium intake or increased renal or extrarenal potassium losses.
- ✂ Treatment of hypokalemia requires an understanding that a steady-state serum deficiency of 1 meq/L can translate to a total body deficit of  $>1000$  meq.
- ✂ In the setting of trauma and critical illness, the free ionized (physiologically active) form of calcium is the relevant value that should be measured.
- ✂ Hypocalcemia is a common entity in critically ill patients (37). It is estimated that about 70 to 90% of critically ill patients have decreased total serum calcium levels, and ionized calcium levels are deficient in 15–50%.
- ✂ It is estimated that about  $>25\%$  of patients on a medical-surgical ward and  $>75\%$  on the postoperative ICU setting are hypomagnesemic.
- ✂ Transcellular shift is the most common mechanism of acute hypophosphatemia, though chronic total body hypophosphatemia results from decreased intake and/or increased renal or gastrointestinal losses.

### INTRODUCTION

The invention of the pH probe ushered in a new era of critical care medicine where a definable physiologic endpoint became possible. A series of somewhat contradictory theories regarding acid–base interpretation were developed culminating in the great “Trans-Atlantic Debate” which occurred in the wake of the pH probe’s creation (1). Most of the controversy revolves around the explanation of the metabolic component (i.e., what causes hydrogen ions  $[H^+]$  to increase, decrease, or be buffered). The period during the late 1960s and early 1970s witnessed the evolution of the “classic model” based on the Henderson–Hasselbach relationship and the “standard base excess” (SBE) concept whose roots trace back to standard bicarbonate and buffer base (BB). Both of these models evolved into the establishment of nomograms and formulas for guiding acid–base management.

During the 1980s, Stewart (Canadian born, American physiologist) (2) proposed a new theory of acid–base physiology that challenged the existing paradigm. Stewart’s theory is based on physicochemical principles and direct observation of charge dynamics in various solutions, including plasma. Stewart’s term strong ion difference (SID) utilizes concepts similar to the BB principle developed earlier by Singer and Hastings (3), though they used different nomenclature.

Despite acceptance of the underlying principles involving Stewart’s method, some traditionalists of acid–base balance (ABB) prefer to use the more familiar  $HCO_3^-$  or SBE approach or derived nomograms to evaluate acid–base disorders. All of these approaches, when applied correctly will result in correct ABB determinations for simple disorders. However, the  $HCO_3^-$  and SBE are not dependent variables but rather associated variables that correlate with changes in ABB.

This chapter will explore the Stewart SID paradigm that is increasingly used, along with the more traditional methods of acid–base evaluation. These techniques will be explained so the reader will be able to investigate the common acid–base disturbances that arise de novo or iatrogenically during the care of trauma and critically ill patients.

In a recent review, Schlichtig et al. (4) provide in-depth derivations, explanations, and comparisons of the various techniques for evaluating the metabolic component of ABB reviewed in this chapter, and they also appropriately emphasize that all of these methodologies are internally consistent. Readers interested in reviewing a more traditional (i.e.,  $HCO_3^-$ ) approach to acid–base disturbances and their

analysis are referred to the classic landmark article by Narins and Emmett (5). A shorter, more practical, and clinically based approach utilizing the Narins principles is offered in the review by Haber (6). Other excellent reviews are also recommended for those seeking greater understanding of the traditional acid–base models (7–13).

In addition to the formal derivation of the SID, which some find complicated, the practical graphical approach of ABB presented by Schlichtig et al. (4,14) is also reviewed in this chapter, because its simplicity appeals to graphically minded clinicians. The rules-based approach suggested by Haber (6) is also provided here because it represents the simplest application of the classic approach using the standard concepts put forward by Narins and Emmet (5).

Each phase of trauma care from resuscitation through convalescence can be accompanied by prototypical acid–base derangements. This chapter will help the reader to recognize, characterize, and remedy the common acid–base disorders identified in trauma patients, as well as tertiary acid–base derangements. This chapter will also provide ample examples of clinical conditions where ABB may be perturbed and where application of the SID concept will best explain the acid–base disorder and its treatment.

### ACID–BASE OVERVIEW AND NOMENCLATURE

#### Overview of Acid–Base Balance

By convention, ABB is measured and analyzed from arterial blood samples. However, the data are clinically interpreted to apply to the entire volume of extracellular fluid (ECF). ABB reflects the hydrogen ion concentration in blood and depends upon three independent factors: (i) *respiratory component*, where pulmonary ventilation results in  $CO_2$  elimination and controls the arterial  $P_{CO_2}$  ( $Pa_{CO_2}$ ); (ii) *metabolic component*, primarily affected by tissue metabolism and gastrointestinal output and renal regulation; and (iii) *nonvolatile weak acid buffers*: phosphate and proteins (predominantly albumin and in the case of whole blood, hemoglobin). For the student of ABB, most confusion stems from explanations and interpretations of the metabolic component. ⚡ **The three major presentations of the metabolic component are (i) bicarbonate ion  $[HCO_3^-]$ , (ii) SBE, and (iii) the SID between plasma strong cations and anions.** ⚡

The final result of ABB is the regulation of  $H^+$  ion concentration in blood (normal  $[H^+] = 40$  nM/L). The  $[H^+]$  is normally presented as pH, where pH equals the negative

logarithm (base 10) of  $[H^+]$ . Accordingly, the normal  $[H^+]$  of 40 nM/L corresponds to a pH of 7.40 (Fig. 1). During acidemia,  $[H^+]$  increases and pH decreases  $<7.35$ . During alkalemia,  $[H^+]$  decreases and pH increases  $>7.45$ . The use of logarithmic notation to characterize blood acid–base state is conceptually attractive because the effective range of a buffer generates a characteristic “S” shape when acid or base concentration is plotted against pH, but not when plotted against  $[H^+]$ . The logarithmic scale for  $[H^+]$  is analogous to the Richter scale for earthquake intensity, an integer increase in pH (e.g., 7 to 8) means a 10-fold reduction in  $[H^+]$ . A doubling of  $[H^+]$  (e.g., 40 nM/L to 80 nM/L) decreases the pH by 0.3 (e.g., 7.40 to 7.10).

☞ **ABB is regulated by the respiratory center of the medulla (respiratory component) and by the liver and kidneys (metabolic and weak acid components).** ☞ First, we will examine the effects of changing dissolved  $CO_2$  in blood (changing  $P_{CO_2}$  by changing alveolar ventilation). Second, we will examine metabolic effects on ABB. Third, we will examine the buffer capacity of blood and ECF.

### Respiratory Component ( $P_aCO_2$ )

Dissolved  $CO_2$  is measured as the partial pressure of  $CO_2$  in arterial blood ( $P_{aCO_2}$ ). Alveolar ventilation determines the level of  $P_{aCO_2}$ . Hyperventilation leads to  $CO_2$  elimination, and hypoventilation leads to  $CO_2$  retention. ☞ **The  $P_{aCO_2}$  level is regulated by the medulla, which governs the alveolar ventilation.** ☞

The concentration of dissolved  $CO_2$  is linearly related to  $P_{CO_2}$  by its solubility ( $[dissolved\ CO_2] = P_{CO_2} \cdot Sol_{CO_2}$ , where  $Sol_{CO_2} = 0.0306\text{ mM/mmHg}$ ).  $CO_2$  reacts reversibly with water to generate carbonic acid ( $H_2CO_3$ ), which immediately dissociates into hydrogen and bicarbonate ions:

The hydration of  $CO_2$  is rapid in red blood cells (RBCs) because they contain the enzyme carbonic anhydrase.

**Figure 1** Relationship of pH to hydrogen concentration. Broken line is drawn to emphasize the (approximately) linear relationship between hydrogen ion concentration and pH over the pH range of 7.1 to 7.5.

According to the law of mass action, the dissociation of carbonic acid may be written as

$$K[H_2CO_3] = [H^+][HCO_3^-], \quad (2)$$

where  $K$  is the dissociation constant.

It is almost impossible to measure the concentration of undissociated carbonic acid ( $H_2CO_3$ ) in solution because it rapidly dissociates into dissolved  $CO_2$  and  $H_2O$  as well as  $H^+ + HCO_3^-$ . However, the amount of dissolved  $CO_2$  is easily measured, and the amount of undissociated  $H_2CO_3$  is proportional to the amount of dissolved  $CO_2$ . The rate and depth of breathing is dependent upon the medulla's set pH point and upon its ability to measure pH levels in the blood.

Also, by substituting  $P_{CO_2} \cdot Sol_{CO_2}$  for  $H_2CO_3$  in Equation 2, and by taking the negative logarithm of both sides of Equation 2, and solving for pH, the familiar Henderson–Hasselbalch equation can be derived:

$$\begin{aligned} pH &= pK' + \log\left(\frac{[HCO_3^-]}{(Sol_{CO_2} \cdot P_{CO_2})}\right) \\ &= 6.1 + \log\left(\frac{[HCO_3^-]}{(0.0306 \cdot P_{CO_2})}\right) \end{aligned} \quad (3)$$

The Henderson–Hasselbalch equation assumes that all dissolved  $CO_2$  exists as  $H_2CO_3$ , although only 0.33% is actually hydrated, and the  $pK'$  is 6.1. The true  $pK$  of  $H_2CO_3$  is actually about 3.1.

High  $P_{CO_2}$  [e.g., alveolar hypoventilation during chronic obstructive pulmonary disease (COPD)] will cause respiratory acidosis by driving Equation 1 to the right. In the Henderson–Hasselbalch equation (Equation 3), increased  $P_{CO_2}$  will decrease the log expression and decrease pH.  $P_{CO_2}$  is directly measured in blood gas and pH analyzer machines with a  $CO_2$  electrode.

### Metabolic Component

Changes to the metabolic component result from the addition of strong acids or bases to the acid–base system, where strong acid or base means always ionized, that is, always dissociated from  $H^+$  or  $OH^-$ . ☞ **As opposed to ventilation for elimination of  $CO_2$ , strong acids or bases require either elimination by the kidney (inorganic acids such as HCl or bases such as NaOH, KOH) or gastrointestinal tract, or through metabolism, often in the liver (organic acids such as lactate $^-$ , acetoacetate $^-$ , and  $\beta$ -hydroxybutyrate $^-$ ).** ☞

Hepatic ammoniogenesis (and glutaminogenesis) is important for systemic ABB. Nitrogen metabolism by the liver can result in the formation of urea, glutamine, or  $NH_4^+$ . Normally, the liver releases only a small amount of free  $NH_4^+$ , as most of this nitrogen is incorporated into urea or glutamine. The produced urea or glutamine is subsequently used by the kidney to generate  $NH_4^+$  and to facilitate the excretion of  $Cl^-$ . Thus, the production of glutamine can be seen as having an alkalinizing effect on plasma pH (15).

Examination of Equation 1 reveals that  $[HCO_3^-]$  by itself would be a poor discriminator of the metabolic component. However, Equation 1 does not act in isolation, nor does any acid base system in the body. Furthermore, the ratio of  $P_{CO_2}$  to  $HCO_3^-$  does indeed describe the  $[H^+]$  both in theory (e.g., Equation 3) and in clinical practice.

☞ **The parameter, SBE, has been introduced to measure the purely metabolic component of ABB in the**

**ECF. A negative SBE occurs during metabolic acidosis and a positive SBE is obtained during metabolic alkalosis.** ⚡

The SBE (mM) estimates the amount of strong acid or base that would be needed to correct a metabolic disturbance. Mathematical calculation of the SBE by hand is complicated, but it is automatically computed by most blood gas and pH analyzers from directly measured  $P_{\text{CO}_2}$  and pH.

Once the SBE is determined, the millimoles of  $\text{NaHCO}_3$  required to normalize the pH can be estimated as  $0.3 \cdot \text{Weight (kg)} \cdot \text{SBE}$ , where  $0.3 \cdot \text{Weight (kg)}$  estimates the ECF space in liters. For example, a 70 kg man with a  $\text{SBE} = -8$  would require  $(70 \cdot 0.3 \cdot 8) = 168$  mM of sodium bicarbonate ( $\text{NaHCO}_3$ ) to correct the acidosis. However, in practice the “bicarbonate space” is not as easily defined. The apparent volume of distribution of  $\text{NaHCO}_3$  varies depending on the nature of the acid–base disorder and, as detailed below, is a rather dubious concept to begin with. ⚡ **Clinicians should be aware that the administration of  $\text{NaHCO}_3$  is almost always a temporizing maneuver while simultaneously working to correct the primary disorder causing the metabolic acidosis.** ⚡ Furthermore, full correction is seldom advisable.

### The Weak Acid Buffers

A buffer is a molecule that takes up  $\text{H}^+$  ions when they are in excess and releases  $\text{H}^+$  ions in times of acid deficit, thus preventing marked changes in  $[\text{H}^+]$  and hence pH. Three major buffer systems maintain the pH balance in mammals (the bicarbonate, phosphate, and protein buffer systems). The most powerful buffers are those that have the pK at or near the pH of interest (7.40 for humans) and are present in large concentration.

By this standard, the bicarbonate system is not powerful (the pK is 6.1, and the  $[\text{HCO}_3^-]$  and  $[\text{CO}_2]$  are not present in high concentrations). However, the bicarbonate system is the most important buffer system in the body, because  $[\text{CO}_2]$  and hence  $[\text{HCO}_3^-]$  can be rapidly altered by the respiratory system. Although  $[\text{HCO}_3^-]$  can also be altered directly by the kidneys, the relative impact compared to ventilation renders the renal effect meaningless in buffering against an acute  $\text{H}^+$  ion excess. Instead, the kidneys influence ABB predominantly by regulating the plasma concentration of strong acids and bases and phosphate.

The other buffers in the plasma are weak acids and since their pKs are all close to 6.8, they can be lumped together under the term total weak acids or  $A_{\text{TOT}}$ .  $A_{\text{TOT}}$  includes phosphate, albumin, hemoglobin, etc., but not  $\text{HCO}_3^-$  (this is discussed below). The phosphate buffer system is one such weak acid, but its concentration in the ECF is low, only 1/12 that of the bicarbonate system, and hence its power is relatively limited. The most plentiful buffer system of the body is that provided by the proteins located in the cells and plasma.

Hemoglobin is the principle protein buffer system in whole blood. Proteins are made up of various amino acids, some of which have the ability to dissociate their  $\text{H}^+$  ion. Histadine is the predominant amino acid possessing this property, and the most important amino acid in the blood with regard to pH buffering. The pKa for histadine is around 6.8. Because the proteins are so ubiquitous in the blood, they play the greatest role in buffering, especially *ex vivo* (without the ability of the lungs to ventilate off excess  $\text{CO}_2$ ). For example, when a strong acid is added to blood, the hemoglobin buffer system can reduce the change in pH by 90%, compared to the condition when blood (and

hemoglobin) is absent. In the plasma, albumin is the principal buffer and, like hemoglobin, the histadine moieties on its surface supply most of its buffer capacity.

The fact that hemoglobin is contained within circulating RBCs provides another important element impacting the interaction between the bicarbonate system and the protein buffer systems in the transport of  $\text{CO}_2$  from its tissue sites of cellular production to the lungs for excretion. Briefly,  $\text{CO}_2$  diffuses out of metabolizing tissues into the capillary venous flow where it penetrates the RBC membrane. Inside the RBC, the enzyme carbonic anhydrase catalyzes the hydration of  $\text{CO}_2$  into  $\text{H}_2\text{CO}_3$ , which immediately ionizes into  $\text{H}^+$  and  $\text{HCO}_3^-$  (as per Equation 1). The histadine moiety of hemoglobin absorbs the  $\text{H}^+$ , whereas the  $\text{HCO}_3^-$  exits the RBC in exchange for entering chloride (so called “chloride shift”). The reverse occurs in the capillary bed of the lungs where the lower  $P_{\text{CO}_2}$  in alveolar air enables the diffusion of  $\text{CO}_2$  from the hypercapnic mixed venous blood, of the pulmonary artery capillaries, into the alveolus.

The SBE represents the metabolic component by assuming that the mean buffer strength of the human ECF equals that of blood with 5 g/dL hemoglobin. Despite individual variation of hemoglobin, the effective buffer system changes little.

### Four Primary Acid–Base Conditions

Four primary acid–base derangements are classically described: metabolic acidosis, metabolic alkalosis, respiratory acidosis, and respiratory alkalosis. The preceding overview helps one understand these four basic conditions prior to identifying and repairing complex disorders such as tertiary acid–base disorders. The clinical history is exceedingly helpful in determining the cause and each of the four primary acid–base conditions can be acute or chronic (Table 1).

#### Metabolic Acidosis

⚡ **Metabolic acidosis exists when there is more metabolic acid present than can be balanced by the available BB.** ⚡ This is analogous to having inadequate positive charge in the serum or a reduced SID (as with  $\text{Cl}^-$  loading). When metabolic acidosis is the only process, the  $\text{HCO}_3^-$  is lower than normal. The respiratory compensation for metabolic acidosis is  $\text{CO}_2$  elimination. The observed pH is lower than expected for the observed  $P_{\text{CO}_2}$  (for every 10 torr change in  $P_{\text{CO}_2}$  there is a reciprocal and inverse change of 0.08 pH units).

#### Metabolic Alkalosis

This state stems from having an excess of base relative to the available acid. It is analogous to having too much serum positive charge (increased SID) leading to proton consumption (as in  $\text{Cl}^-$  loss or  $\text{Na}^+$  loading). This concept is critical to understanding how sodium bicarbonate ( $\text{NaHCO}_3$ ) raises pH. According to Stewart (2),  $\text{HCO}_3^-$  is a dependent variable and does not set pH. Rather, the pH is set by the three independent variables of  $P_{\text{CO}_2}$ ,  $A_{\text{TOT}}$ , and the SID. Thus,  $\text{NaHCO}_3$  raises pH by increasing the serum sodium concentration since it delivers  $\text{Na}^+$  without another negatively charged strong ion; since  $\text{HCO}_3^-$  is not a strong ion, it does not influence the SID or the pH. Therefore, with  $\text{NaHCO}_3$  administration, the serum becomes more positive and proton consumption is the expected mechanism to restore electrical homeostasis. At the same time, each liberated  $\text{HCO}_3^-$  ion combines with an  $\text{H}^+$  ion and as per Equation 1 is converted

**Table 1** Medical Conditions, Historical and Physical Findings Suggesting Particular Acid–Base Disturbances

Acute	Chronic
<b>Respiratory acidosis</b> ( $\text{PaCO}_2 \geq 45$ )	<b>Compensation:</b> $\uparrow \text{HCO}_3^-$
Respiratory arrest	COPD (increased baseline $[\text{HCO}_3^-]$ )
Opioid or sedative drug overdose	Increased $V_D/V_T$ (can be acute also)
Under ventilation	
Exacerbation of asthma	
<b>Respiratory alkalosis</b> ( $\text{PaCO}_2 \leq 35$ )	<b>Compensation:</b> $\downarrow \text{HCO}_3^-$
Pain, fear, anxiety, hypoxia	Cerebrovascular accident
Fever, pneumonia	Recovery from head injury
Congestive heart failure	Jaundice, cirrhosis
Salicylate overdose (and metacidosis)	Pregnancy (until post partum)
Sepsis	Hyperthyroidism
<b>Metabolic acidosis</b> ( $\text{SBE} \leq -4$ )	<b>Compensation:</b> $\downarrow \text{PaCO}_2$
Shock (hemorrhagic, septic, cardiogenic)	Chronic renal failure
Seizures (lactate)	Renal tubular acidosis
Ketosis, toxins	
Diarrhea, acetazolamide	
Sulfamylon (burn patient)	
Acute renal failure	
Malignant hyperthermia	
Iatrogenic (e.g., NSS resuscitation)	
<b>Metabolic alkalosis</b> ( $\text{SBE} \geq 4$ )	<b>Compensation:</b> $\uparrow \text{PaCO}_2$
Chloride responsive: $\downarrow$ 'd $[\text{K}^+]$ , $\downarrow$ 'd $[\text{Cl}^-]$	Chloride unresponsive (usually increased intravascular volume)
Contraction alkalosis (may need $\text{Mg}^{2+}$ also)	
Vomiting	Chronic diuretic use (Lasix)
NG aspirate	Hyper aldosteroneism
Past excessive diuretic use	Cushing's syndrome
Posthypercapnea	Exogenous steroid use
	Licorice (inhibits cortisol degradation)
	Bartter syndrome (hyper rennin)
	Citrate (postmassive blood products)

to  $\text{H}_2\text{CO}_3$  and then to  $\text{CO}_2$  (eliminated in the lungs) and water. The clinical outcome is the development of metabolic alkalosis.

### Respiratory Acidosis

Respiratory acidosis is identified as a  $\text{PaCO}_2 > 42$  torr. This state generally emerges during clinical decompensation of a trauma patient from respiratory failure due to increased work of breathing [e.g., due to pulmonary contusion, bronchospasm, acute respiratory distress syndrome (ARDS)] or due to decreased ability to do the work (e.g., flail chest), decreased drive to breath (e.g., opioid

intoxication), or decreased neuromuscular function (e.g. spinal cord injury). Respiratory acidosis also occurs as an expected condition when using permissive hypercapnia to manage acute lung injury (ALI)/ARDS (16).

In patients with an intact  $\text{CO}_2$  response mechanism,  $\text{CO}_2$  retention triggers an increase in the respiratory rate, which serves to normalize the  $\text{PaCO}_2$ . In cases where excessive  $\text{CO}_2$  is being produced (e.g., fever or other causes of hypermetabolism), respiratory rate must increase significantly to normalize the  $\text{PaCO}_2$ . This is also the case in situations where the alveolar dead space is increased (e.g., pulmonary embolus). Thus, fever, hypermetabolism, and increased alveolar deadspace situations are counterproductive when attempting to liberate a patient from mechanical ventilation.

The renal compensation for respiratory acidosis is slower as it requires altering the SID (i.e.,  $\text{HCO}_3^-$  reabsorption). One should note that the deliberate induction of a metabolic alkalosis (increasing the SID) during weaning of a COPD patient (who retains  $\text{CO}_2$ ) can occasionally facilitate liberation from mechanical ventilation because the metabolic alkalosis helps normalize the pH change caused by respiratory acidosis and decreases the  $V_E$  required to normalize  $\text{CO}_2$ , thereby reducing the work of breathing.

### Respiratory Alkalosis

Respiratory alkalosis is present when a primary process causes the  $\text{PaCO}_2$  to be  $< 38$  mmHg. It is commonly associated with hypercatecholamine states (e.g., pain, fear, and anxiety). In the case of metabolic acidosis, compensatory hyperventilation will decrease the  $\text{PaCO}_2$  and decrease water dissociation via the law of mass action on Equation 1. A secondary respiratory alkalosis is also associated with sepsis for the same reason (compensation for metabolic acidosis). The clinician identifies this compensation as hyperventilation in the nonintubated patient or as increased minute ventilation ( $V_E$ ) in the spontaneously breathing mechanically ventilated patient.

☞ **Tachypnea and respiratory alkalosis commonly occur in compensation for a primary metabolic acidosis in the early post-trauma time frame, typically due to hypoperfusion or iatrogenic hyperchloremia.** ☞ This finding may be one of the first signs to herald metabolic acidosis of numerous etiologies [e.g., diabetic ketoacidosis (DKA), alcoholic ketoacidosis, lactic acidosis, hyperchloremic acidosis, and various poisons]. Tachypnea is prominent in severe shock; however, when there is insufficient energy and/or cerebral blood flow to fuel the respiratory compensation or when there is a superimposed primary respiratory acidosis (e.g. opioid intoxication, spinal cord injury lung injury), respiratory compensation can fail and acidosis will worsen.

☞ **Metabolic alkalosis is more commonly seen in the postresuscitation phase of trauma patients, commonly during induced diuresis with a loop diuretic (induced by the net effect of  $\text{Cl}^-$  loss in the urine).** ☞ One should note that in elderly patients on daily doses of loop diuretics, metabolic alkalosis may be a pre-existing state prior to the traumatic injury. In this scenario, development of an acute metabolic acidosis will often initially be occult due to the elevated baseline SID and  $[\text{HCO}_3^-]$ . Accordingly, the initial compensatory respiratory alkalosis will be blunted compared to what would normally be expected based, for example, on the patient's lactate concentration.

## CLINICAL MODELS OF ACID–BASE BALANCE

### The Classical or Henderson–Hasselbalch Model

The classical model of ABB based on the Henderson–Hasselbalch equation has been the most widely accepted (especially in North America) and is well incorporated into medical education and practice. It holds that the pH and thus the proton concentration ( $H^+$ ) is related to a balance between protons and the bicarbonate ion in relation to the BB that is in plasma and the red cell mass (17). Directly related to the Henderson–Hasselbalch equation are the “Six Bostonian Rules” of acute versus chronic primary acid–base disorders (Table 2), as well as the well-known acid–base nomogram (Fig. 2). The so-called Bostonian Rules characterize the expected human metabolic or respiratory compensation for primary acid–base disorders. In the case of metabolic acidosis or alkalosis, the respiratory compensation occurs quickly, thus there is only one compensation formula needed for each entity. In the case of respiratory disorders, the renal compensation takes longer, thus there is an expected acute response, and a chronic response, associated with each primary disorder.

### The Standard Base Excess and Graphical Approaches to Acid–Base Analysis

ABB can be depicted using a graphical relationship (Fig. 2) charting two of three interdependent variables: (i)

**Table 2** Expected Human Metabolic or Respiratory Compensation to Acid–Base Disorders

#### Expected metabolic compensation for a change in $PaCO_2$

(assume starting  $[HCO_3^-] = 24$  mEq/dL)

Acute respiratory acidosis or alkalosis  $0.1 \cdot \Delta PaCO_2$  (e.g.,

$PaCO_2 = 60$  mmHg  $\Rightarrow HCO_3^- = 26$ )

Chronic respiratory acidosis or alkalosis  $0.4 \cdot \Delta PaCO_2$  (e.g.,

$PaCO_2 = 60$  mmHg  $\Rightarrow HCO_3^- = 32$ )

For every 10 mmHg increase in  $PaCO_2$ , the pH will decrease 0.08 pH units (e.g., when  $PaCO_2$  increases from 40 to 70 mmHg, the pH will decrease from 7.40 to 7.16) (Providing no other concomitant disorders are occurring, i.e., this is a primary disorder)

#### Expected respiratory compensation for a change in SBE

(assume starting  $PaCO_2 = 40$  mmHg)

Metabolic alkalosis  $\Delta PaCO_2 = 0.6 \cdot \Delta SBE$  (e.g., +5 SBE  $\Rightarrow$

$PaCO_2 = 43$  mmHg)

Metabolic acidosis  $\Delta PaCO_2 = 1.0 \cdot SBE$  (e.g., –5 SBE  $\Rightarrow$

$PaCO_2 = 35$  mmHg)

For a pure metabolic acidosis, Winter’s formula predicts the respiratory compensation:

$PCO_2 = 1.5 \cdot HCO_3^- + 8 (\pm 2)$  (e.g.,  $HCO_3^- = 19 \Rightarrow PaCO_2 = 35$ –37 mmHg)

Alternatively

$PCO_2 = 40 + SBE (\pm 2)$

*Note:* Also note that some references will list greater metabolic compensation for a respiratory acidosis than for a respiratory alkalosis. The table provides just one number to simplify memorization, and the ranges provided are adequate for clinical decision-making. Also note that this table provides some acute metabolic compensation for an acute respiratory process. This is because whenever  $CO_2$  is added to the system both  $HCO_3^-$  and  $H^+$  are increased (Equation 1). However, the pH decreases because the proportion of  $PaCO_2$  to  $HCO_3^-$  is increased (Equation 3). Although this is a departure from other standard reference tables, it is more accurate.

*Abbreviations:* “ $\Delta$ ” denotes change in variable; SBE, standard base excess;  $PaCO_2$ , arterial blood  $PaCO_2$ .

*Source:* From Ref. 14.

**Figure 2** Detailed clinical map of the average or typical human compensations for acid–base imbalances. Arrows show direction of compensatory changes from uncompensated acid–base imbalances. Linear pH isopleths permit location of a patient data set on the diagram when only a pH and  $PaCO_2$  are known. Solid lines have these slopes. Primary respiratory:  $PaCO_2$  affects SBE: Acute = AR (SBE = 0) and chronic = CR ( $\Delta SBE = 0.4 \Delta PaCO_2$ ). Primary metabolic: SBE affects  $PaCO_2$ : acidosis (lower line) = M ( $\Delta PaCO_2 = 1.0 \Delta SBE$ ) and alkalosis (upper line) = M ( $\Delta PaCO_2 = 0.6 \Delta SBE$ ). *Abbreviations:* M, metabolic acidosis or alkalosis; AR, acute respiratory acidosis or alkalosis; CR, chronic respiratory acidosis or alkalosis; SBE, standard base excess;  $PaCO_2$ , arterial  $PCO_2$ . *Source:* From Ref. 60.

respiratory  $PaCO_2$  (mmHg, x-axis) and (ii) metabolic SBE (mM, y-axis). When using the graphical method,  $P_{CO_2}$  is plotted against calculated SBE, and pH isopleths are plotted on the same graph. A change in ventilation (respiratory component) moves the intersection of  $P_{CO_2}$  and SBE horizontally rightward (respiratory acidosis) or leftward (respiratory alkalosis). A metabolic change moves the point upward (alkalosis) or downward (acidosis).

During acute respiratory acid–base disturbances, SBE equals zero because there has not been time for metabolic compensation to occur; this is reflected graphically by acute respiratory changes occurring along the SBE = 0 line of Figure 2. Chronic respiratory aberrations lie vertically between no metabolic compensation (SBE = 0) and complete compensation (pH = 7.40). The kidney eventually increases or decreases SBE (by altering SID) but rarely to the point of complete compensation. Metabolic disturbance lie horizontally between zero to complete respiratory compensation. Respiratory compensation for simple, primary metabolic disorders is generally immediate. Table 2 summarizes the mathematical relationships governing the amount of respiratory or metabolic compensation in response to a disturbance to the other variable.

One of the pitfalls of the graphical approach occurs when chronic (compensated) respiratory acidosis is superimposed with an acute metabolic acidosis. Chronic hypoventilation results in decreased pH due to increased  $P_{CO_2}$ . The metabolic compensation increases SBE to partially correct pH. Then, a superimposition of a metabolic acidosis could normalize SBE. However, the continued increase in  $P_{CO_2}$  and decrease in pH would suggest only acute respiratory acidosis, masking the serious presence of the acute, and clinically relevant, metabolic (e.g., lactic) acidosis. In this situation, clinical presentation may help make the

diagnosis. Also, examination of the anion gap (AG) or strong ion gap (SIG) (both defined below) would detect the presence of unmeasured anion (in this example, lactate<sup>-</sup>).

Another pitfall of the SBE approach to patient management involves the following common clinical example: A 70 kg patient, with normal kidneys and tissue perfusion, undergoes a 12-hour bladder resection and urinary diversion procedure, involving a 3000 mL estimated blood loss. The losses are replaced with six units of packed RBCs, and 12 L of 0.9% saline. Blood pressure and heart rate are stable throughout the case, urine output is 150 cc per hour. The arterial blood gas and electrolytes at the end of the case are: pH = 7.36, PaCO<sub>2</sub> = 31 mmHg, [HCO<sub>3</sub><sup>-</sup>] = 15 mmol/L, [Na<sup>+</sup>] = 140 mmol/L, and [Cl<sup>-</sup>] = 115 mmol/L. Using the SBE, a significant base deficit (of -8 to -10) would be obtained and could trigger additional needless fluid resuscitation or bicarbonate administration. Review of the electrolytes reveals a normal AG = 10 mmol/L, thus eliminating lactate and underperfusion as the etiology of the acidosis. This scenario represents a case of iatrogenic hyperchloremic metabolic acidosis, which will resolve by itself (if the kidneys are provided time to excrete the elevated Cl<sup>-</sup> and reabsorb HCO<sub>3</sub><sup>-</sup>).

Another limitation to the SBE approach is that SBE is slightly unstable as P<sub>CO<sub>2</sub></sub> changes (Fig. 3). Furthermore, the SBE equation assumes a normal A<sub>TOT</sub>. When albumin or phosphate is decreased, a common scenario in the critically ill and injured, SBE will result in even more instability (Fig. 3). Although recent attempts to correct the SBE for changes in A<sub>TOT</sub> have resulted in a formula that agrees much more closely with experimental data in humans, this formula has not yet been widely applied.

$$\begin{aligned} \text{Corrected SBE} &= (\text{HCO}_3^- - 24.4) + [(8.3 \times \text{albumin} \times 0.15) \\ &+ [0.29 \times \text{phosphate} \times 0.32]] \times (\text{pH} - 7.4) \end{aligned} \quad (4)$$

Albumin is expressed in g/dL and phosphate in mg/dL.

### Importance of the Anion Gap in Acid-Base Analysis

The AG concept is based upon electroneutrality of total anions and cations in solution (5). The importance of the AG in clinical medicine is underscored by the two examples

**Figure 3** Carbon dioxide titration curves. Computer simulation of in vivo CO<sub>2</sub> titration curves for human plasma using the traditional Van Slyke equation and various levels of A<sub>TOT</sub> (total weak acids) from normal (17.2) to 25% of normal. Also shown is the titration curve using the A<sub>TOT</sub> corrected standard base excess.

provided above and will be developed further in this section. The addition of 1 mmol of acid to blood results in approximately 1 mmol of bicarbonate consumption and replacement of the lost bicarbonate with approximately 1 mmol of anion. The character of the substituted anion influences the pattern of normally measured serum electrolytes and has important diagnostic and therapeutic value. The AG is the difference between the concentration of cation (sodium and potassium) and anion (chloride and bicarbonate) concentrations in plasma:

$$\begin{aligned} [\text{AG}] &= ([\text{Na}^+] + [\text{K}^+] - ([\text{Cl}^-] + [\text{HCO}_3^-])) \\ &= 14 \pm 2 \text{ mEq/L} \end{aligned} \quad (5)$$

Because the changes in serum potassium concentration compatible with life are relatively small, some authors omit the potassium from AG calculation, resulting in an expected AG of 10 ± 2 mEq/L. The “normal” AG occurs because of the normally unmeasured anions [mostly due to albumin, PO<sub>4</sub><sup>2-</sup>, SO<sub>4</sub><sup>2-</sup>, and some normal organic acids (Fig. 4)].

♣ The normal AG is up to 14 ± 2 (if [K<sup>+</sup>] is included) and 10 ± 2 (when [K<sup>+</sup>] omitted), and assumes a normal albumin concentration and a P<sub>CO<sub>2</sub></sub> of 40 torr (15,18). ♣ Recall that the AG represents the negative charge that is contributed by anions that are not measured in the usual chemistry panel, but are necessarily present to balance the existing positive charge in the plasma. The remainder of this discussion assumes the [K<sup>+</sup>] is included in the calculation of the AG.

The expected or normal range for AG must be corrected when A<sub>TOT</sub> is abnormal. There are several ways to calculate this correction (15). A reasonable approximation is to assume that the expected AG should equal [alb] × 2.5 (where [alb] is expressed in g/dL). A more precise method

**Figure 4** Circulating cations always counterbalance circulating anions, thereby maintaining electroneutrality (left). In routine electrolyte assays, however, only a portion of circulating anions is measured, and an apparent cation-anion disparity exists (right). This difference, in mEq/L, is termed the anion gap.

incorporates the affect of phosphate levels, as shown in Equation 6.

$$\text{Expected AG} = 2[\text{alb}(\text{g/dL})] + 0.5[\text{PO}_4^{2-}(\text{mg/dL})] \pm 2 \quad (6)$$

Failure to use the correct expected AG when  $A_{\text{TOT}}$  is reduced will result in the failure to identify an AG acidemia when it is present (unless it is very large). For example, an AG of 12 mEq/L in a patient with a serum albumin concentration of 2 g/dL and  $\text{PO}_4^{2-}$  of 2 mg/dL and metabolic acidosis by arterial blood gas (ABG) analysis might be initially attributed to a nongap cause. However, the expected normal range for the AG in this patient with low levels of albumin and  $\text{PO}_4^{2-}$  is  $2(2) + 0.5(2) = 5 \pm 2$  and thus a measured AG of 12 indicates that 5 to 9 mEq of unmeasured anion exists. Accordingly, the clinician needs to employ the AG differential diagnosis (Table 3).

Not only will the baseline AG will be lower than normal in hypoalbuminemia states, it will also be low in the setting of excess positively charged “para-proteins” (e.g., Waldenström’s macroglobinemia). An increase in a patient’s AG from baseline reflects anions contributed by an acid other than HCl (since  $\text{Cl}^-$  ion is measured and will thus not raise the AG). An increase in the AG helps detect the presence of significant unmeasured anions, such as lactate<sup>-</sup>,  $\alpha$ -ketoglutarate,  $\beta$ -hydroxybutyrate<sup>-</sup>, and those associated with other organic acidosis syndromes listed in Table 3. ⚡ **The use of the AG in acid–base analysis is critical in order to detect most of the acute disturbances requiring immediate therapy (Table 3).** ⚡

Metabolic acidosis is generally separated into two categories: (i) non-AG (hyperchloremic), meaning that the AG is normal, and (ii) AG metabolic acidosis, where the AG is greater than normal. Following a rigorous rules-based approach to acid–base analysis (including determination of the AG) will diminish the chance of misdiagnosing a metabolic acidosis. Some have dismissed the utility of the AG in acid–base analysis because it is often insensitive in the critically ill and injured (19). Adjusting the expected or “normal” range of the AG for the patient’s albumin and phosphate concentrations as described above (Equation 6) will avoid this insensitivity.

Hyperchloremic metabolic acidosis most commonly results from the excess administration of  $\text{Cl}^-$  ions (e.g., NaCl). However, hyperchloremia may be due to renal tubular acidosis (RTA) in which ion handling by the kidney is impaired or as result of ion loss (as can occur with profound diarrhea). Table 4 lists the common causes of hyperchloremic metabolic acidosis.

### The Stewart Model

The Stewart model of ABB is compatible with other models which all hold that electrical balance is related to ionic balance and therefore, proton concentration. However, the Stewart approach emphasizes the importance of independent versus dependent variables and that only three independent variables control pH ( $P_{\text{CO}_2}$ ,  $A_{\text{TOT}}$ , and SID). All three of these factors affect the mechanism for proton generation via water dissociation. Understanding how water dissociation is controlled is essential to comprehending pH control in the Stewart model.

There are three independent control mechanisms for water dissociation. The first is the reaction that occurs when  $\text{CO}_2$  combines with  $\text{H}_2\text{O}$  to generate carbonic acid which then dissociates into bicarbonate and a proton (Equation 1).

The second is the sum of the weak acid buffers ( $A_{\text{TOT}}$ ) which may exist in a form associated with a proton (AH) or in the dissociated state ( $A^-$ ). In healthy humans, the charge of  $A_{\text{TOT}}$  is approximately 16–20 mEq/L and is principally derived from the histidine residues on albumin (~78%), phosphate (~20%), and other proteins (~2%). The negatively charged portion of  $A_{\text{TOT}}$  ( $A^-$ ) together with the negative charge of bicarbonate is counterbalanced by a positive charge from excess of strong cations in plasma, the SID.

Strong ions are those that are completely (or nearly completely) dissociated from their partners at physiologic pH. The principal strong ions are  $\text{Na}^+$ ,  $\text{K}^+$ ,  $\text{Ca}^{2+}$ ,  $\text{Mg}^{2+}$ ,  $\text{Cl}^-$ , and lactate. Unlike the others, lactate is only partially dissociated, although at pH 7.4 only 1 in 3000 ions is not dissociated; thus, for all intents and purposes, lactate can be considered a strong ion. ⚡ **The SID is the difference between the strong cations and strong anions (Equation 7) and in health has an approximate value of 40 to 42 mEq/L.** ⚡

$$\text{SID} = (\text{Na}^+ + \text{K}^+ + \text{Ca}^{2+} + \text{Mg}^{2+}) - (\text{Cl}^- + \text{lactate}) \quad (7)$$

There is a parallel similarity between SID and the AG, which are offset by approximately 25 mEq/L, which is the sum of the  $[\text{HCO}_3^-]$  plus the difference between the normally circulating strong ions and cations that are not included in the normal AG calculation (i.e.,  $\text{Ca}^{2+}$ ,  $\text{Mg}^{2+}$ , lactate, urate).

Only three variables,  $P_{\text{CO}_2}$ ,  $A_{\text{TOT}}$ , and SID set the proton concentration in plasma, as these three are the only independent control mechanisms; all other entities that have been traditionally thought important in pH regulation are actually dependent variables (e.g.,  $[\text{HCO}_3^-]$ ). The SID’s positive charge is counterbalanced by the charge carried by the BB ( $\text{HCO}_3^-$  plus  $A^-$ ). It is the relative balance of the total plasma charge that determines water dissociation.

For example, in patients with hypoalbuminemia, the decreased quantity of negative charges results in a net excess of plasma positive charge compared to the SID. A chemical response to this imbalance is proton consumption, which decreases the plasma positive charge and generates a metabolic alkalosis. Similarly, a patient with a normal albumin, but acute  $\text{Cl}^-$  loss (e.g., gastric outlet obstruction, excessive vomiting, or NG suction without proton generation blockade) would have a net excess of plasma positive charge due to the loss of an anion that cannot be regenerated ( $\text{Cl}^-$ ). Once again, the acute chemical response is to reduce the plasma positive charge by proton consumption.

More germane to trauma patients is the addition of excess  $\text{Cl}^-$  in the form of large amounts of 0.9% NS, and to a lesser extent, even large amounts of LR during resuscitation (20). Each of these intravenous fluids (IVFs) are hyperchloremic with regard to plasma normal saline solution (NS): 154 mEq  $\text{Cl}^-$ /L; lactated Ringer’s solution (LR): 110 mEq  $\text{Cl}^-$ /L; plasma: 100 mEq  $\text{Cl}^-$ /L. Large volume resuscitation (i.e., 5–10 L or more) will raise the  $\text{Cl}^-$  out of proportion to plasma  $\text{Na}^+$  creating an excess of negative charge (Example 1). The effect is to generate protons to counterbalance the excess negative charge, leading to the well-identified hyperchloremic metabolic acidosis (21).

Of course, one must recognize that acidosis is not an invariable response to hyperchloremia secondary to crystalloid resuscitation. There are accompanying reductions in the weak acids (albumin, phosphate) and in many cases strong acids such as lactate are reduced, first through

**Table 3** Elevated Anion Gap Metabolic Acidosis

Acidosis type	Offending acid	Clinical setting	Associated findings	Treatment
Lactic	Lactic	Shock, sepsis, hypoxia, seizure, drugs, liver failure, etc.	↓ Cardiac function ↓ BP ↑ LFTs (if liver failure)	O <sub>2</sub> , ↑ volume, ↑ $\dot{D}O_2$ to tissues, remove toxins, liver transplant (if liver failure does not recover)
DKA	Acetoacetate, b-hydroxybuterate	Diabetes, stress (including sepsis)	↑ Glucose, falsely elevated creatinine	↑ volume repletion, insulin titrated [glucose], electrolyte repletion (especially, Mg <sup>2+</sup> , K <sup>+</sup> )
AKA	Acetoacetate, b-hydroxybuterate	Chronic excessive alcohol intake	Glucose may be normal or low, PO <sub>4</sub> <sup>2-</sup> , K <sup>+</sup>	↑ volume repletion, PO <sub>4</sub> <sup>2-</sup> , K <sup>+</sup> , Mg <sup>2+</sup> repletion
Uremic	Phosphoric, sulfuric, mixed organic	End stage renal failure, worse with: catabolism, SO <sub>4</sub> <sup>2-</sup> diet, infrequent dialysis	↑ BUN and creatinine ↑ Osm., 'd SO <sub>4</sub> <sup>2-</sup> ↑ PO <sub>4</sub> <sup>2-</sup> (mixed gap, non-gap)	Dialysis, improve nutrition (catabolism increases acid load), minimize sulfur containing amino acids in diet, oral supplementation of HCO <sub>3</sub> <sup>-</sup>
Methanol	Formic	Toxic ingestion of methyl alcohol	↑ Osmolality, ↑ Amylase, retinal (papillary) edema	Ethanol (ETOH competes with alcohol dehydrogenase—the enzyme that converts methanol to the toxic formic acid). Hemodialysis if severe
Ethylene glycol	Glycolic	Toxic ingestion of ethylene glycol (active ingredient in antifreeze)	↑ Osmolality, calcium oxalate crystalluria, cerebral edema, direct injury to kidneys, lungs, liver, heart, muscles, retinas	Ethanol or Fomepizole (ETOH competes with alcohol dehydrogenase—the enzyme that converts ethylene glycol to glycoaldehyde (precursor to the toxic glycolic acid). Fomepizole directly inhibits the enzyme.
Propylene glycol	Lactic, pyruvate	Prolonged etomidate infusion. Propylene glycol is an alcohol vehicle used for some hydrophobic drugs	↑ Osmolality, protamine like effects, intravascular hemolysis, perception deafness, skin irritation, renal insufficiency	Stop etomidate infusion. ↑ volume, supportive care Renal function improves with etomidate cessation. Other drugs (phenytoin, diazepam, pentobarbital) using propylene glycol as a vehicle, can cause propylene glycol toxicity (unusual when normal doses used)
Aspirin	Salicylate	Toxic ingestion of aspirin (children most prone)	Rapid deep respiration, confusion, coma, vomiting, sweating, dehydration	O <sub>2</sub> , ↑ volume, K <sup>+</sup> , Cl <sup>-</sup> , Mg <sup>2+</sup> repletion alkalization of the urine, hemodialysis if severe
Iron	Lactic, mixed organic and inorganic (hydration of Fe <sup>3+</sup> )	Toxic ingestion of FeSO <sub>4</sub> (children most prone)	Vomiting (blood from gastric erosions), shock, coma, liver failure, renal failure	O <sub>2</sub> , ↑ volume, desferrioxamine (chelation therapy), whole bowel irrigation (GoLyte <sup>®</sup> ), supportive care
Paraldehyde	Mixed organic	Sedative hypnotic—no longer used in USA	Coma, paraldehyde odor	O <sub>2</sub> , ↑ volume, supportive care

Abbreviations: AKA, alcoholic (starvation) ketoacidosis; DKA, diabetic ketoacidosis; LFT, liver function test; ↑, increased; ↓, decreased.

simple dilution and second by restoring tissue perfusion. These reductions lead to the commonly identified hypoalbuminemia and hypophosphatemia that characterize the significantly resuscitated trauma patient. However, these compensatory reductions in negative charge are generally

insufficient to offset the increased negative charge from the added Cl<sup>-</sup> (particularly in the case of NS), thus resulting in a clinically relevant increase in proton concentration which creates a state of hyperchloremic metabolic acidemia.

**Table 4** Common Causes of Normal (i.e., Non-) Anion Gap Metabolic Acidosis

Fistulae (pancreatic)
Uretero-enteric fistulae
Saline (0.9 or 3% NaCl administration or saline-based TPN)
Endocrine (hyperparathyroidism)
Diarrhea
Carbonic anhydrase inhibitors (e.g., Diamox <sup>®</sup> , Sulfamylon <sup>®</sup> )
Arginine, lysine, chloride (total parenteral nutrition with excess)
Renal tubular acidosis
Spirinolactone

Note: The mnemonic F-Used Cars are sometimes used to remember this list.  
Abbreviation: TPN, total parenteral nutrition.

The transparency and simplicity of the Stewart model is appealing to many students and researchers of ABB. For clinicians, understanding how an acid–base derangement is created allows one to select a repair strategy, as well as to understand how that repair strategy works. More importantly, understanding these principles allows one to select appropriate plasma volume expanders to minimize the impact on ABB as a consequence of resuscitation (i.e., avoid hyperchloremic metabolic acidosis).

Another application of the Stewart model is the SIG. The SIG is the difference or “gap” between the SID calculated from Equation 7 and BB calculated from  $\text{HCO}_3^-$  and  $A_{\text{TOT}}$ . The SIG is similar to, but distinct from the AG (22). The BB is a term used by Singer and Hastings, and is equal to the sum of the weak acids (chiefly albumin,  $\text{PO}_4^{2-}$ ,  $\text{SO}_4^{2-}$ ) or  $A_{\text{TOT}}$ , and  $[\text{HCO}_3^-]$

$$[\text{SIG}] = [\text{SID}] - [\text{BB}] \quad (8)$$

The SIG identifies unmeasured ions that are not accounted for by any other method (Fig. 5) (22). The SIG is normally near zero (<4 mEq/L in healthy humans). When abnormal, it is usually positive (indicating excess unmeasured anions) but may be negative (indicating excess unmeasured cations). Several clinical conditions have been associated with the genesis of unmeasured ions including liver failure, trauma, resuscitation, and shock (15,23).

The entire source of these unmeasured ions is incompletely understood. Strong ions (e.g., D-lactate, ketones, sulphate) appear to be responsible for at least half. The residual portion may be related to intracellular or transmembrane proteins that are released during apoptosis-triggered cell death or other types of cell destruction. What is increasingly clear is that unmeasured ions are useful markers of deranged physiology. Accordingly, the utility of the SIG as a predictive tool with regard to mortality in trauma patients has been explored for those with major vascular injury, and a high correlation with the risk of death has been shown (24). Indeed, SIG is a more powerful predictor of outcome in this population than lactate or injury severity score.

### Reconciling Different Acid–Base Models

Given the wide range of seemingly contradictory inferences that can be drawn from the three models of ABB presented in this chapter, it is easy to see why “opposing camps” have been formed, each advocating one approach over the others, often with a zeal that could only be described as religious. To the casual observer, this may seem inevitable but in fact all three models are fully compatible and no model is

**Figure 5** Charge balance in blood plasma. “Other cations” include  $\text{Ca}^{2+}$  and  $\text{Mg}^{2+}$ . The strong ion difference (SID) is always positive (in plasma) and  $\text{SID} - \text{SIDe}$  (effective) must equal zero. Any difference between SID apparent ( $\text{SIDa}$ ) and  $\text{SIDe}$  is the strong ion gap and must represent unmeasured anions.

perfect. Although we believe that Stewart’s quantitative physical chemical model yields predictions that are more consistent with experimental data, we do not deny that the more traditional approaches are valid and may have value in certain situations. Moreover, all three models have important common elements and apparent differences are fairly easy to resolve. The classical model uses the Henderson–Hasselbalch equation as a guide and then uses a set of “rules” to analyze ABB. The SBE model builds on the classical model by conceptualizing nonvolatile ABB as changes in BB. Finally, the Stewart model takes this one step forward by using the term SID in place of BB and by no longer assuming that weak acids are either normal or constant as the other models do. Thus, a change in SID is equal to a change in BB which is equal to SBE.  $A^-$  (the charged portion of  $A_{\text{TOT}}$ ) is equal to the AG. In this way, the Stewart model is merely a more complete model of ABB.

## A PARADIGM FOR EVALUATING AN ACID–BASE DISORDER

### Clinical Setting

☞ An initial step in the evaluation of an acid–base disorder is to assess the clinical circumstance of the patient and to develop an initial differential diagnosis based upon the likely acid–base disorders associated with the clinical picture. ☞ The injury history is essential in making this determination (i.e., large volume blood loss, hypothermia, toxic ingestion, etc.). The assessment is then tempered by physical examination evidence.

### Physical Exam

☞ Cool extremity temperature has been validated as an indicator of hypoperfusion (excluding exposure to hypothermic environments and peripheral vascular disease with arterial insufficiency). ☞

The physical examination usually provides important indicators of a patient’s underlying condition and acid–base status. A patient with hemorrhagic shock is expected to

demonstrate signs and symptoms of impaired perfusion, including cool extremities, confusion, tachycardia, narrowed pulse pressure, and ultimately hypotension. Low or unreadable pulse oximetry is a common finding as well (25). These patients evidence lactic acidosis and an elevated AG.

The acid–base analysis becomes more complex when the trauma patient also suffers from chronic renal failure, as a pre-existing elevated AG acidosis (elevated  $[\text{SO}_4^{2-}]$ ) and a non-AG acidosis (renal tubular defects) will be present. Conversely, pre-existing chloride loss from excessive vomiting will create a metabolic alkalosis, where normalization will hinge on  $\text{Cl}^-$  replacement. Chloride replacement may be best achieved using KCl, but 0.9% NS may be more appropriate, especially when fluid resuscitation is also required.

Also, as discussed above, the AG may appear normal with conditions that create albumin loss (nephrotic syndrome, cirrhosis with hypoproteinemia, massive crystalloid resuscitation, chronic disease) necessitating that a corrected range for expected or normal AG be used.

In the intensive care unit (ICU), physical examination has long been used, and recently validated as a sensitive and specific means to detect hypoperfusion (26). The value of combining the presence of a cool peripheral extremity examination with a decreased  $[\text{HCO}_3^-]$  level was that this combination strongly predicted an increased arterial lactate concentration and a low cardiac index. In contrast, warm extremity examination and a normal or increased  $[\text{HCO}_3^-]$  was strongly predictive of a normal lactate level and a normal or elevated cardiac index. Two confounders were also identified: (i) hyperlactatemia from hypermetabolism in a patient with warm extremities and a normal or elevated cardiac index and (ii) distributive or “warm” shock where the extremities are warm and accompanied by an increased cardiac index but low bicarbonate and high arterial lactate concentrations. This method has not been validated in patients with peripheral vascular occlusive disease, an important consideration in geriatric trauma patients.

### Biochemical Evaluation

The next step in the evaluation is to assess the serum chemistries and the arterial blood gases. The first step is to determine whether the  $\text{P}_{\text{CO}_2}$  is normal or abnormal. There is a reciprocal relationship between  $\text{P}_{\text{CO}_2}$  and pH such that for each 10 torr  $\Delta\text{P}_{\text{CO}_2}$  there is an inverse  $\Delta 0.08$  pH. Thus, one can determine whether the  $\Delta\text{pH}$  is entirely attributable to the  $\Delta\text{P}_{\text{CO}_2}$ . When the pH is not explained by the  $\text{P}_{\text{CO}_2}$ , one must explore further.

Next, the SBE must be determined. The SBE is an excellent indicator of the presence or absence of nonvolatile acidosis prior to resuscitation. Assuming a constant  $\text{A}_{\text{TOT}}$ , the SBE defines the amount that the SID must be changed in order to restore the pH to 7.40 assuming a  $\text{P}_{\text{CO}_2}$  of 40 (15). ⚡ **The value of the SBE (in isolation) as an indicator of lactic acidosis is corrupted following resuscitation because the electrolyte composition of the IVF will significantly impact pH and therefore, the SBE.** ⚡ Using an initial SBE, one then assesses whether there is an acidosis (a base deficit more negative than  $-4$ ). Alternatively, one can examine the serum  $[\text{HCO}_3^-]$ ; if less than 22 in a patient with a low pH, then a metabolic acidosis is present (though other processes can also be occurring). However, unlike SBE or SID, the change in  $[\text{HCO}_3^-]$  does not quantify the amount of acidosis only that it is present.

If a metabolic acidosis is present, the next step is to calculate the AG to determine whether there is an “AG” or “non-AG” metabolic acidosis. ⚡ **The differential diagnosis**

**for an AG acidosis can be remembered using the mnemonic “MUD PILES” and include methanol, uremia, dehydration, paraldehyde, INH, lactate, ethylene glycol, and salicylates. However, the differential diagnosis also includes other conditions including ketoacidosis, sepsis, and liver failure, making the mnemonic somewhat incomplete (Table 3).** ⚡

The differential diagnosis of non-AG acidosis is even more broad (Table 4). Metabolic alkaloses may be grouped into two classifications based upon their chloride responsiveness (Table 1).

Recall that the normal range for the AG should be corrected (Equation 6) when the protein concentration is less than normal. If the measured gap exceeds this value, then a positive AG acidosis is present.

Next, one must assess for the presence of any of the known causes of an increased AG. Most clinical laboratories can also provide an arterial lactate value using the ABG machine. If this is elevated, then one must ask whether the increase in the AG is due to the lactate (a 1:1 relationship exists). If it is not, then other unmeasured ions are also present. Rarely, even the corrected AG can miss small quantities (usually less than 5 mEq/L) of unmeasured anions. The SIG, though more cumbersome to calculate, can provide a more accurate quantification of missing anions.

The standard biochemical means of detecting acid–base disorders regardless of time frame requires a serum chemistry panel and an arterial blood gas sample. New monitoring systems will allow the clinician to obtain serum chemistries and ABG analysis every two to five minutes using an indwelling catheter attached to an automated sampling system and point-of-care testing device. New instrumentation allows this kind of device to be similar in size to an alphanumeric pager. These two tests will cover the basic disorders of metabolic acidemia or alkalemia and respiratory acidemia or alkalemia. A brief discussion of the basic derangements was provided above.

There remains significant controversy regarding the pH that is deemed dangerous. Previous data suggested that at a  $\text{pH} < 7.25$ , catecholamine efficiency was reduced and that a return to normal pH range was indicated (27). This notion has been challenged by more recent data (28). Nonetheless, the recent data fail to supplant the observation that mean arterial pressure commonly increases with  $\text{NaHCO}_3$  administration to the hypotensive and pressor dependent patient. The reader should recognize that this observed manipulation of mean arterial pressure has not been demonstrated to confer a survival advantage. Yet, in the authors’ experiences, failure to respond to the administered  $\text{NaHCO}_3$  often portends impending death.

### Differential Diagnosis

#### Graphical Evaluation

The graphical methodology of Grogono et al. (Fig. 2) has been explained above. This method works well for visual thinkers, especially when the acid–base disorder is simple. However, for complex acid–base disorders, the rules-based approach using  $\text{HCO}_3^-$ , or SBE along with a calculation of AG, and/or employing the SID method of Stewart are recommended.

#### Rules-Based Approach Using $\text{HCO}_3^-$ vs. SBE Along with AG

⚡ **Although algorithms and nomograms are useful (if present at the bedside), the most important factor in evaluating acid–base perturbations is to understand how they occur in the human body and to take a systematic approach in diagnosis.** ⚡ The technique of Haber (6)

involves a simple, easy to remember, rules-based approach incorporating the concepts developed by Narin and Emmitt and represents a practical clinical approach.

**Step 1** Look at the pH, determine if acidemia (pH < 7.38) or alkalemia (pH > 7.42) is present. This step is based upon the principle that the human body does not fully compensate, and never overcompensates, for any primary acid–base disturbance.

**Step 2** Determine the AG (Equations 5 and 6)

If the AG is increased, refer to Table 3 for sources.

If the AG normal, but the patient has a metabolic acidosis (negative SBE), the patient has a non-gap metabolic acidosis (refer to Table 4 for sources).

If the AG is significantly increased (>5 mEq/L above expected), a primary metabolic acidosis is present regardless of the pH, base excess, or  $\text{HCO}_3^-$ . This is because the body does not generate a large AG to compensate for a primary disorder (6).

**Step 3** Calculate the excess AG (the calculated AG from Step 2 minus the normal expected AG (from Equation 6) is added to the value of the measured  $[\text{HCO}_3^-]$ ).

If the excess AG is significantly greater than the normal serum  $[\text{HCO}_3^-]$  of 24 mmol/L (i.e., >30 mmol/L), there is an additional underlying metabolic alkalosis.

If the excess AG is significantly lower than the normal serum  $[\text{HCO}_3^-]$  (i.e., <20 mmol/L), there is an additional underlying nongap metabolic acidosis.

This third step is based upon the physical chemical principle that 1 mmol of unmeasured acid will titrate 1 mmol of  $\text{HCO}_3^-$  (6). Using this technique, mixed acid–base disorders can be identified. However, it must be emphasized that neither nomograms, nor graphs, nor a series of rules can be used in isolation. The history and physical exam should suggest a differential diagnosis, and the acid–base analysis (as provided above) should corroborate the clinical suspicion. Table 1 provides a list of historical and physical findings, which suggests a classic acid–base disturbance. In addition, Tables 3 and 4 provides clinical information that is useful in diagnosing AG and non-AG metabolic acidosis conditions.

### Stewart Approach

Although some clinicians, using programmable calculators, calculate SID and  $A_{\text{TOT}}$  at the bedside, a simpler approach is as follows. First, one can evaluate  $\text{PCO}_2$  as described above. Next, one can assess the approximate change in SID, if any, by examining the SBE. This method is superior to calculating the apparent SID (Equation 6) because the SIG may be increased or  $A_{\text{TOT}}$  may be decreased, both of which will alter the interpretation of SID. If SBE is increased either the SID has increased or  $A_{\text{TOT}}$  has decreased or both have occurred. If the SBE is decreased, the answer is usually that the SID has decreased since an increase in  $A_{\text{TOT}}$  is unusual.

Next, one can estimate the SIG by comparing the measured AG to the normal expected value from Equation 6. In health, SIG is near zero and the measured AG will equal the normal value. The differential diagnosis for an increased SIG is shown in Table 3, whereas a metabolic acidosis (decreased SID) without an increased SIG is shown in Table 4. The primary value of the Stewart model

is that it is completely quantitative; thus, even a triple acid–base disorder can easily be broken down.

### Clinical Example Using Stewart Approach

A 75-year-old female was struck by a bus and was run over. She was hypotensive in the field and her trachea was intubated. She underwent evaluation in the Trauma Resuscitation Suite, where a positive focused assessment by sonography in trauma (FAST) examination revealed free abdominal fluid and she was taken to the operating room (OR). A ruptured right hemidiaphragm, multiple rib fractures, as well as a devascularized right lobe of the liver were identified. She underwent large volume resuscitation after controlling hemorrhage with a Pringle maneuver and a partial hepatic resection, diaphragm repair, and the placement of a tube thoracostomy. She received 8 L of LR, 8 U packed red blood cells (PRBC), 6 U fresh frozen plasma (FFP), 750 cc Cell saver, and 2 L of 0.9% NS; her abdomen was packed and a temporary abdominal wall closure was placed. She returned to the surgical intensive care unit (SICU) about 1.5 hours after arrival in the hospital.

Her extremities were cool and slightly clammy. An active convective external warming device was placed to manage hypothermia (core temperature = 94.6 F), and additional warmed fluid resuscitation was undertaken. Her ABG was as follows: 7.18/34/518 ( $\text{FIO}_2 = 1.0$ ). The SBE = -15 and thus the SID is markedly decreased and there is a metabolic acidosis.

The electrolytes and derived values are as follows:

$\text{Na}^+$ 138	$\text{Cl}^-$ 115	BUN 9	$\text{iCa}^{2+}$ 1.0	$\text{Mg}^{2+}$ 1.3	$\text{PO}_4^{2-}$ 1.0	Alb 2.3
$\text{K}^+$ 3.8	$\text{HCO}_3^-$ 12	Cr 0.5	Gluc 88	Lactate 2.9		

According to Equation 5, the above electrolyte values show a calculated AG = 14, whereas Equation 6 predicts that the adjusted normal range for this patient (with low albumin and  $\text{PO}_4^{2-}$ ) is  $5.1 \pm 2$ . The lactate is 2.9 and thus, the SIG is approximately 6 mEq/L ( $14 - 5.1 - 2.9$ ) and there is an increased SIG acidosis. Therefore, another mechanism besides lactic acid (LA) is responsible for the acidosis. However, this patient appears to have a hyperchloremic metabolic acidosis as well, since the SBE is -15, the SIG is only 6, and lactate is only 2.9 (i.e., 6.1 mEq are from a non-SIG, non-LA source).

Finally, there is a respiratory disorder as well. Expected  $\text{PCO}_2$  should equal  $40 + \text{SBE} (-15) = 25$ , yet the  $\text{PCO}_2$  is 34 indicating a respiratory acidosis as well. In summary, this patient has at least three sources for the metabolic acidosis and a concomitant respiratory acidosis. The Stewart SID methodology facilitated identification of these various disturbances.

A calculator capable of performing this sort of analysis is downloadable from the internet at the Acid–Base Forum (30). Inputting the data from above allows one to derive the following values: SID SIG, AG, expected  $\text{PCO}_2$ , and SBE. One can readily determine that there are unmeasured anions and that the patient has a tertiary acid–base disorder: a respiratory acidosis, a metabolic acidosis (LA and SIG), and a hyperchloremic metabolic acidosis. This knowledge is imperative insofar as it prompts a change in therapy. Failure to discern and understand this information would lead to a standard response to the presence of a metabolic acidosis, such as providing additional IVF and  $\text{Cl}^-$ . This hypothetical patient does need additional resuscitation, but not additional  $\text{Cl}^-$  as it would accelerate the metabolic acidosis by further reducing the SID. It is not possible to

change the presence of unmeasured anions, thus compensation for them must be initiated by using a low  $\text{Cl}^-$  resuscitation fluid. Therefore, a colloid for resuscitation could be used to limit  $\text{Cl}^-$  loading—a departure from the standard high  $\text{Cl}^-$  crystalloid resuscitation paradigm.

Trauma patients frequently have pre-existing or concurrent illness. The patient in the preceding example may have hyperchloremia secondary to NS resuscitation or she may have had an underlying RTA. The respiratory acidosis may be due to chest wall and/or lung injury or sedation, or it may be due to respiratory muscle failure in the setting of profound hypophosphatemia. The increased SIG is an ominous prognostic finding. In one series, trauma patients had nearly 100% mortality when their initial SIG was greater than 7 mEq/L. This may be due to acute phase stress response protein release by injured cells. However, poisoning including methanol and ethylene glycol (alcoholics) and toluene (glue sniffing) is also occasionally seen in this population.

## ACID–BASE STATUS AS A MEASURE OF RESUSCITATION

### Effect of Acidosis on Urine Output

☞ Urine output can be quite deceptive as a measure of resuscitation success and as a guide to ABB. ☞ However, acid–base disorders may influence urine output. It has been demonstrated that infusion of large volumes of highly hyperchloremic solutions (0.9% NS) will decrease glomerular filtration rate, renal blood flow, and the rate of urine flow compared to a less hyperchloremic solution (lactated Ringer's solution) (31). Moreover, acidotic disorders such as DKA may artificially elevate the urine output due to osmotic diuresis. The  $K_m$  for renal glucose transport is breached at about 180 mg% in the healthy adult. Therefore, glucose containing solutions should not be used for resuscitation so as to not overwhelm renal transport mechanisms and initiate an osmotic diuresis.

### End-Tidal $\text{CO}_2$ Measurements

The use of monitoring devices to track the success of resuscitation is common. Recent data have validated the ability to detect a pulse oximetry signal as a valid tracking measure of progress in resuscitation (25). The pulse oximeter signal amplitude has also been studied as an indicator of the adequacy of resuscitation. In addition, routine application of end-tidal  $\text{CO}_2$  ( $P_{\text{ET}}\text{CO}_2$ ) analysis may aid in evaluating cardiac performance. Abnormalities of  $P_{\text{ET}}\text{CO}_2$  tracings, not recorded values, have correlated well with the failure or success of cardiopulmonary cerebral resuscitation (CPR) and trauma resuscitation (32), although this device seems best suited to identifying instances of abnormal perfusion (i.e., low cardiac output), rather than when it is inadequately high (i.e., high cardiac index, but persistent lactic acidemia).

### Sublingual $\text{CO}_2$

A relatively new device, the sublingual  $\text{CO}_2$  oximeter ( $\text{SLCO}_2$ ) shows promise in the early detection of poor perfusion ( $\text{SLCO}_2 > 70$ ) (33). However, the value may return to normal more rapidly than the establishment of a truly adequate cardiac profile. The near infrared spectrometer (NIS) has also been successfully utilized to track the adequacy of resuscitation using a thigh muscle monitoring site as an indicator of limb perfusion (34). In this study, the NIS method was more sensitive than  $\text{SvO}_2$  and the gastric-mucosal  $\text{CO}_2$  gap obtained via gastric tonometry

(Chapter 10). This device shows promise, but needs additional investigation prior to recommending it as a first-line source of information. The role of the pulmonary artery (PA) catheter in the acute setting remains controversial. At least one study in trauma patients observed reductions in morbidity with routine use, but failed to demonstrate a survival advantage (35).

## Invasive Monitoring Tools

However, central venous pressure (CVP) monitoring in combination with ABG and vital sign-derived indices have shown strong correlations with determining fluid requirements for critically ill patients with sepsis in the Emergency Department; unsurprisingly, morbidity and mortality reductions were observed for the better and earlier resuscitated group (36). This observation underscores the need for timely identification of hypoperfusion and rapid reversal of inadequate oxygen delivery and consumption. A host of sophisticated monitoring devices using the combination of a CVP line and an arterial catheter are available (i.e., PICCO, Metracor, etc.). Despite the attractiveness of an easily inserted monitoring system, its efficacy in reducing mortality in the trauma setting remains undetermined.

## ACID–BASE DISORDERS IN TRAUMA PATIENTS

### Lactic Acidosis and Hypoperfusion

Acid–base disorders in trauma patients may be conveniently divided into several phases including prehospital, resuscitation suite, OR, ICU, and then general ward/convalescence (37). Generally, the first three time frames are quite similar and may be considered together. Recall that, based on changes in cytokine levels, trauma resuscitation may be divided into a flow and ebb phase or an early and late phase. When one evaluates the phase of care with regard to mortality, there is an early phase (<72 hours post-trauma) and a late phase (more than seven days post-trauma) that correspond to defined mortality time-points on the continuum of trauma care. One must recognize that the majority of late-phase deaths are related to multi-system organ failure (MSOF) and occur in the ICU. The impact of iatrogenic acid–base disturbances is important during both phases, but may not be as appreciated during the early resuscitative phase as during the late time frame.

☞ The early phases of the postinjury period are often dominated by lactic acidosis. ☞ Lactate has been identified as an important marker for mortality since the early work of Abramson at Kings County Hospital where he identified reduced survivorship in patients admitted to a trauma center who failed to clear their lactate in less than 24 hours (38). These findings helped establish a paradigm of initial hypoperfusion reflected by lactic acidosis that could be corrected by volume resuscitation and hemorrhage control. The correlation is that by so doing, survivorship would improve. This paradigm was recently buttressed by Claridge et al. (39) and Blow et al. (40) as they noted that survivorship and morbidity were related to failed lactate clearance whether overt or occult. Consequently, the rather surgical notion of massive volume resuscitation as a salubrious maneuver was born and then deeply entrenched in surgical dogma. The side effects of massive volume resuscitation outside of pulmonary edema, abdominal hypertension, and subcutaneous edema have only been examined at cursory levels. Furthermore, although lactic acidosis may indicate hypoperfusion, it is neither sensitive nor specific. Integrating the information

from clinical examination and hemodynamic monitoring with ABB will greatly enhance both sensitivity and specificity.

### Hyperchloremic Acidosis Following Saline Resuscitation

☞ **A negative side effect of massive volume resuscitation is hyperchloremic metabolic acidosis, which principally occurs during the perioperative and ICU phase of trauma therapy (21).** ☞ This finding has long been recognized in the anesthesia literature as an expected consequence of massive volume resuscitation. However, only in the past decade have surgical manuscripts addressed this problem. In Example 1 (discussed earlier), we demonstrated that the addition of 10 L of 0.9% NSS could significantly increase  $[\text{Cl}^-]$  and induce acidosis in a healthy individual. If this acidosis was initiated in a patient with pre-existing lactic acidemia from hypoperfusion related to hypovolemic shock, then the resultant pH may be dangerously low particularly if lactic acidosis does not resolve quickly with resuscitation.

### Relationship Between Acidosis and Acute Lung Injury

☞ **Recent work has demonstrated a strong relationship between large volume resuscitation and the development of ALI (41).** ☞ Patients who developed ALI received larger volumes and evidenced a lower pH than their counterparts who did not develop ALI. One must question whether the low pH was due to the addition of greater amounts of  $\text{Cl}^-$  in the group who received larger volumes of crystalloid resuscitation and whether the ALI was related to the increased minute ventilation ( $\dot{V}_E$ ) needed to blow off the excess  $\text{CO}_2$  and buffer the acidosis. Unfortunately, the study by Eberhard et al. was not reported in sufficient detail to answer these questions. Instead, the study assessed the ability of different kinds of fluids to trigger a white cell immune activation response and found crystalloids to be potent triggers indeed (41). Data from isolated cells in culture suggest that acidosis itself may result in inflammatory effects.

### Acidosis and Coagulopathy

The clotting cascade is comprised of serine proteases whose activity is pH dependent. It has been widely established that acidosis is a common consequence of acute injury (locally and systemically). It is also known that severe acidosis impairs the efficiency of the clotting cascade. Thromboelastography (TEG) is a sensitive means of assessing the interaction of all parts of the clotting cascade as they work in concert (42). In a large trial of general surgery patients undergoing large volume blood loss surgery (>500 cc), the presence of hyperchloremic acidosis correlated with the development of coagulopathy. Ex vivo data evaluating the impact of high chloride solutions on the TEG profile also indicates clotting dysfunction when the serine proteases are in a  $\text{Cl}^-$  rich and acidic environment (43). Gross measures such as prothrombin time (PT) and aPTT are also deranged by raising the  $\text{Cl}^-$  concentrations in ex vivo specimens by 16 to 20 mEq/L above baseline with 0.9% NSS or 3% NSS (44).

### The Lethal Triad and Damage Control Surgery

The triad of acidosis, hypothermia, and coagulopathy (the so-called “lethal triad”) has been well reviewed by Spahn and Rossaint (45). Acidosis-related coagulopathy is further exacerbated by the presence of hypothermia (Volume 1, Chapter 40). Much like enzyme activity is related to pH, it is also intimately related to temperature. In fact, a core temperature of 33°C is equivalent to a clinically relevant,

functional factor deficiency despite normal factor levels (46). ☞ **The presence of hypothermia (in combination with metabolic markers of acidemia) has been identified as a trigger to pursue damage control (DC) surgery instead of a definitive procedure (47).** ☞

Ideally, a DC procedure (Volume 1, Chapter 21) should be decided upon at the initiation of surgery, rather than identified as an appropriate strategy at the end. The goals of DC surgery are to arrest hemorrhage, control gastrointestinal (GI) contamination, and deliver a viable patient to the ICU for ongoing resuscitation and metabolic restoration. The DC surgery time frame limits the time in the OR with an open major body cavity and reduces heat loss. DC surgery also potentially reduces the extent of coagulopathy by limiting the blood loss that could accrue from ongoing blood loss while attempting to achieve complete surgical repair in partly resuscitated patients.

### Acidosis in the Elderly

The geriatric patient population presents unique challenges that can compound the impact of lactic acidemia on outcome (Volume 1, Chapter 37). This patient population is likely to present with multiple comorbidities including coronary artery disease, hypertension, chronic renal impairment, hepatic failure, and peripheral vascular disease (48). Each of these entities may impair the patient’s ability to tolerate hypoperfusion and repair trauma or resuscitation-related acidosis. These sequelae are identified as persistent acidosis and a failure of lactate clearance. Recent data have shown survivorship of elderly patients is directly related to their injury complex as well as the number of comorbidities at the time of injury (48).

The term elderly as utilized by the American College of Surgeons Committee on Trauma (ACS-COT) is in part derived from the data of Rutherford et al. (49) where a lethal dose ( $\text{LD}_{50}$ ) for base deficit was influenced by the presence of absence of TBI. Patients younger than 55 years old developed the same mortality curve as those older than 55 years if the younger patients also had brain trauma. The reason for this observation is unclear, but may be related to the elaboration of apoptotic triggers following the induction of secondary brain damage. Furthermore, in a large database analysis of US trauma centers, the ACS-COT identified that the mortality rate for men acutely rose at the age of 55 (50). Thus, despite a general trend in the literature to define elderly as  $\geq 60$  to 65 (Volume 1, Chapter 37), there may be a re-evaluation and reduction in the elderly age designation to 55.

### Lactate Clearance and Mortality

Interestingly, not all patients who fail to clear their lactate levels in 24 hours die. It remains unclear from the current literature whether this represents persistent lactic acidemia, or the more subtle entity, hyperlactatemia. It has been well documented that plasma epinephrine levels may remain elevated (up to 4000 pcg/mL; normal <200 pcg/mL) for several weeks after injury (51). This is especially true in chronically stressed patients who are under-resuscitated and/or inadequate analgesia. The effect of the elevated epinephrine levels is to increase metabolic rate and induce a catabolic state. The increased flux through the Krebs cycle increases the total lactate production, but does so in proportion to pyruvate. Thus, the lactate/pyruvate ratio remains constant. Arterial lactate, when measured in this circumstance, will be greater than normal.

An additional confounder to lactate interpretation is that lactate may be released from the lungs of patients with ALI or ARDS (52). This lactate release does not represent systemic hypoperfusion and does not need to be treated as such. In fact, treating such a patient with additional volume loading may worsen the lung injury and aggravate the lactate output. This diagnosis is suggested by identifying an elevated lactate level in a patient who appears to be well resuscitated, but who has a lung injury. Drawing an arterial lactate and comparing it to a lactate level from mixed venous blood obtained from a pulmonary artery catheter (PAC) will establish the diagnosis. The lactate from the PAC will be higher than that from the peripheral artery. In a patient with an increasing arterial lactate level, a positive gradient across the lung indicates pulmonary lactate release.

### Multiple Organ Dysfunction Syndrome and Acidosis

The late phase of trauma care is dominated by acid–base derangements related to organ failure as well as to iatrogenic acid–base disturbances. The ultimate pH is determined by the proportion of acidosis or alkalosis that is generated by the individual organ failure in relation to the prevailing electrolyte content and protein content of the patient’s blood plasma. Acidemia from renal or hepatic failure is commonly mixed with alkalemia from the use of loop diuretics. Dilutional hyponatremia coupled with hyperchloremia leads to a narrow SID and a metabolic acidemia. It is not uncommon to identify complex acid–base disorders during the late phase of trauma care for these reasons. Identifying these disorders has important implications for IVF administration, total parenteral nutrition (TPN) composition, as well as enteral formulation selection, as the electrolyte composition of a patient’s plasma is variable while the protein composition is not (acutely). Thus, the patient’s ABB is directly related to both intrinsic disease and clinician intervention.

### FLUID ADMINISTRATION AND ACID–BASE BALANCE

Volume 1, Chapter 11 reviews the relative merits of crystalloids versus colloids and their meta-analyses, whereas this chapter focuses only on the relative effect of different plasma volume expanders on lactate clearance,  $\text{Cl}^-$  loading, and induced acidemia.

Earlier, we reviewed the effect of loading a patient with 10 L of 0.9% NSS with regard to the SID and pH. **☞ The degree to which hyperchloremic metabolic acidosis occurs following significant resuscitation is related to the total fluid volume and the SID of the fluid in relation to the patient’s SID and any electrolyte losses.** **☞** Solutions that are rich in  $\text{Cl}^-$  (relative to plasma) will predictably produce hyperchloremia. However, metabolic acidosis occurs as function of the SID of the solution and volume infused. Since no crystalloid contains albumin,  $A_{\text{TOT}}$  will always decrease as a result of crystalloid resuscitation and will always have a mildly alkalizing effect. A stronger effect on ABB comes from the change in SID. A solution with a SID of 0 (e.g., NS) will reduce the plasma SID and this has a stronger acidifying effect relative to the alkalizing effect of reducing  $A_{\text{TOT}}$ . Compared to 0.9% NS ( $\text{Cl}^-$  154, SID 0), LR has a more physiologic  $\text{Cl}^-$  concentration 110 and a higher SID (20). Of note, the SID of LR is equal to its lactate concentration (28 mEq/L) provided that the lactate is metabolized. Lactate will be metabolized quickly

in most situations, but if lactate is not metabolized the SID of LR is 0, just like NS.

Since one may utilize colloids suspended in low  $\text{Cl}^-$  vehicles, and colloids achieve a 3:1 superiority over crystalloids with regard to retained intravascular volume, resuscitation with colloid in a low  $\text{Cl}^-$ , higher SID solution would markedly reduce the total  $\text{Cl}^-$  load. This strategy would be expected to improve ABB relative to a high  $\text{Cl}^-$ , low SID strategy.

### Evidence Supporting Lactated Ringer’s Solution

The above hypotheses are validated by data derived from large volume blood loss surgery. In two studies, one conducted in the United States and one in the U.K., patients resuscitated with  $\text{Cl}^-$  rich, low SID fluids were found to have metabolic acidosis when they were resuscitated with NS-based IVF or NS-based colloid solution relative to LR or an LR-like vehicle for colloid delivery (53,54). Moreover, gastric tonometry derived gut perfusion was improved in the low  $\text{Cl}^-$  group, as was lactate clearance. Importantly, one of the studies identified the tripartite association of hyperchloremic acidemia, NS-based resuscitation, and impaired clotting identified by TEG.

**☞ Hyperchloremia is known to independently diminish measures of renal function, including glomerular filtration rate (GFR), urine flow, and creatinine clearance (30,55). It has been identified to be the factor most important for induced acidosis not associated with lactate in the OR.**

**☞** Moreover, volume loading of healthy volunteers with either 0.9% NS or LR (50 cc/kg bw) at equivalent rates leads to a longer time to urine generation and abdominal pain in the NS group, as well as central nervous system (CNS) changes (55). It is suggestive that the abdominal pain may be related to intestinal perfusion since the above studies in the elderly identified markedly improved gastric tonometry values in the group resuscitated with a lower  $\text{Cl}^-$  regimen.

### An Empiric Approach to Minimize $\text{Cl}^-$

Alterations of daily practice paradigms would appear to be in order. On the basis of the above data, it is appropriate to avoid large volume  $\text{Cl}^-$  loading of trauma patients to avoid compounding an existing lactic acidosis with one stemming from hyperchloremia. For those patients who have already undergone significant fluid resuscitation and have an extant hyperchloremic metabolic acidosis, reducing  $\text{Cl}^-$  and increasing the SID in their maintenance fluid is a reasonable approach. The authors employ solutions containing 25 to 150 mEq/L  $\text{NaHCO}_3$ , even as maintenance fluid in select patients. Since  $\text{HCO}_3^-$  is converted to  $\text{CO}_2$  and removed almost instantly by ventilation, it has no real role in determining pH; thus this solution is a  $\text{Na}^+$  delivery vehicle with the intent being to increase the plasma SID. This induces proton consumption and reverses the hyperchloremic metabolic acidosis. Ongoing restoration of the effective circulating (a.k.a. “stressed”) volume can be accomplished by colloid in a balanced salt solution (BSS) solution to minimize the total amount of  $\text{Cl}^-$  that is delivered during resuscitation. However, no prospective studies have yet shown benefit to this practice.

### Effect of Fluids and Acid–Base Balance on Coagulation

The clotting cascade is dependent on a series of serine proteases (Chapters 58 and 59). Recall that enzymes demonstrate a pH-dependent activity profile and, as such, evidence diminished activity when their microenvironment shifts outside of the pH optimum. This concerns many topics of this chapters

regarding independent control mechanisms of pH to bear upon the problem of trauma-related coagulopathy. It is reasonable to hypothesize that the induction of hyperchloremia and the accompanying acidosis may induce coagulopathy. Coagulopathy is most commonly assessed by gross measures such as PT and aPTT, associated elements such as platelets and fibrinogen, but most sensitively by TEG. The TEG assesses all of the elements involved in coagulation and displays these data by means of a strain gauge coupled to a computer deflection trace. Delayed clotting is most clearly obvious as an increased time to clot formation, as well as decreased maximal amplitude of the trace.

Recent data address these hypotheses. In an *ex vivo* whole blood model, the deliberate induction of hyperchloremia with either 0.9% saline or 3% saline predictably decreased pH (30). Using 3% saline allowed the  $\text{Cl}^-$  to be changed without altering the concentration of the clotting cascade proteins. As a control, Hetastarch (HES) in 0.9% NS or HES in a balanced salt solution were added to separate tubes; no significant pH abnormalities were identified. This observation stems from the much smaller  $\text{Cl}^-$  load that was delivered to the system in the HES groups. Importantly, the crystalloid groups consistently demonstrated a prolonged PT and aPTT at  $\text{Cl}^-$  increases  $>20$  mEq/L. Since neither HES group demonstrated coagulopathy, this observation cannot be related to the presence of  $\text{Ca}^{2+}$  in the HES in BSS group since there is no  $\text{Ca}^{2+}$  in the HES in 0.9% NS arm. A limitation of this study is the lack of TEG analysis.

TEG data have been provided for serial dilutions of blood with LR, HES in 0.9% NS, and HES in a balanced salt solution. It is clearly demonstrated that progressive dilution of blood with a chloride-rich solution results in multiple TEG abnormalities (43). Further data stem from an FDA phase III trial in which HES in BSS was found free of coagulation abnormalities up to 5000 cc in a 24-hour period, whereas HES in NS was clearly associated with TEG abnormalities (54). This further implicates  $\text{Cl}^-$  as an important arbiter of coagulopathy, as the main difference between the two regimens was the  $\text{Cl}^-$  content. Nonetheless, the potential role of  $\text{Ca}^{2+}$  must be evaluated. Since none of the patients in either group was receiving a massive transfusion, the role of induced hypocalcemia is unlikely in explaining the abnormal TEG profile.

## TOXIN-INDUCED ACID–BASE DERANGEMENTS

Acute intoxications with agents other than alcohol derive their acid–base imbalance from their effect in their native state, or more commonly, as they are degraded by hepatic metabolism and exert deleterious effects upon the liver or the kidney (Volume 1, Chapters 30 and 31). The most common finding is metabolic acidosis, stemming from one of a variety of causes including (but not limited to) direct acid loading, tissue destruction, induction of lactate, induction of hypoperfusion from cardiovascular failure, poisoning of mitochondrial metabolism, decreased level of consciousness with hypoventilation and subsequent hypoxemia (respiratory and metabolic acidosis), and the induction of hepatic and renal failure.

Therapy consists of supportive measures including the standard care directed by Advanced Trauma Life Support (ATLS). However, certain intoxicants are removed by dialysis or charcoal hemoperfusion, whereas others are remedied by antitoxins (i.e., marine toxin envenomation) or antivennins (i.e., snake or spider bites) (Volume 1, Chapter 32).

## EYE TO THE FUTURE

There is surprisingly much to discover about acid–base physiology, despite this topic having been the subject of intense scrutiny over the past several decades since the development of the practical hospital-based blood gas analyzing machine. The exact identity of the unmeasured ions remains obscure. Intense investigative efforts have explored whether the unmeasured ions are lectins, serum proteins, lysed cells, or denatured circulating proteins.

The most likely answer appears to be that the etiology of increases in SIG is multifactorial, and different acids are present in different patients. Similarly, the unmeasured ions have demonstrated remarkable correlation with poor outcome in some sepsis studies, while not in others. However, in trauma patients, the presence of an  $\text{SIG} \geq 7$  prior to fluid therapy strongly correlated with 72-hour mortality regardless of mechanism of injury (24,56). In an animal model of endotoxemia, where it was predicted that the gut and liver would be primary sources of unmeasured ions, the liver was either neutral or took up ions (baseline) and then released anions during early endotoxemia. In contrast, at baseline, the gut was neutral to anions, but then consumed anions as endotoxemia progressed. The lung and kidney were neutral to anions, neither generating nor consuming in this model (57). The author has embarked upon a search into the natural history of unmeasured ions, as well as the development of a prognostic model for those admitted to the critical care area.

Alterations of plasma volume expansion with agents that are constructed to minimize acid–base derangements may represent a major advance in altering the course of trauma patients during the acute resuscitation phase, especially in the areas of ALLI, coagulation abnormalities, and immune activation. Moreover, programs using colloid resuscitation that are aimed at reducing the need for blood product administration are being jointly developed with the U.S. military. One such program, STORM ACT (Strategies to Reduce Military and Civilian Transfusion), is supported in part by the International Trauma Anesthesia and Critical Care Society (ITACCS), as well as a variety of other academic organizations and trauma societies. A number of forward thinking articles have been published speculating how trauma resuscitation will progress over the next decade (58). However, only multi-institutional trials that are sufficiently powered to enable outcome analysis will serve to accurately guide advances in resuscitation and ABB.

## SUMMARY

Three widely used approaches to acid–base physiology have been reviewed in this chapter. Each utilizes specific variables to assess changes in ABB. Complete parity can be brought to all three acid–base approaches. Conversion between the descriptive approaches using  $\text{HCO}_3^-$  or SBE and AG and the quantitative approach using SID and SIG are fairly straightforward and have been recently reviewed elsewhere (59).

The authors favor the use of the Stewart model because it explains the mechanisms that underpin each acid–base abnormality, in terms of independent and dependent control mechanisms, and thus best guides therapeutic intervention. Understanding the concepts of SID and SIG allows one to rationally select appropriate resuscitation

fluids to achieve effective resuscitation while minimally impacting pH. These concepts have also been applied to common acid–base problems that occur during trauma resuscitation and subsequent care to illustrate the improved control of metabolic derangements possible for insults resulting as a consequence of injury, as well as those that stem from the therapy for those conditions.

## KEY POINTS

- ✂ The three major presentations of the metabolic component are (i) bicarbonate ion ( $\text{HCO}_3^-$ ), (ii) SBE, and (iii) the SID between plasma strong cations and anions.
- ✂ ABB is regulated by the respiratory center of the medulla (respiratory component) and by the liver and kidneys (metabolic and weak acid components).
- ✂ The  $\text{PaCO}_2$  level is regulated by the medulla, which governs the alveolar ventilation.
- ✂ As opposed to ventilation for elimination of  $\text{CO}_2$ , strong acids or bases require either elimination by the kidney (inorganic acids such as HCl or bases such as NaOH, KOH) or gastrointestinal tract or through metabolism, often in the liver (organic acids such as lactate<sup>-</sup>, acetoacetate<sup>-</sup>, and  $\beta$ -hydroxybutyrate<sup>-</sup>).
- ✂ The parameter, SBE, has been introduced to measure the purely metabolic component of ABB in the ECF. A negative SBE occurs during metabolic acidosis and a positive SBE is obtained during metabolic alkalosis.
- ✂ Clinicians should be aware that the administration of  $\text{NaHCO}_3$  is almost always a temporizing maneuver, while simultaneously working to correct the primary disorder causing the metabolic acidosis.
- ✂ Metabolic acidosis exists when there is more metabolic acid present than can be balanced by the available BB.
- ✂ Tachypnea and respiratory alkalosis commonly occur in compensation for a primary metabolic acidosis in the early post-trauma time frame due to hypoperfusion or iatrogenic hyperchloremia.
- ✂ Metabolic alkalosis is more commonly seen in the post-resuscitation phase of trauma patients, commonly during induced diuresis with a loop diuretic (induced by the net effect of  $\text{Cl}^-$  loss in the urine).
- ✂ The normal AG is up to  $14 \pm 2$  (if  $[\text{K}^+]$  is included) and  $10 \pm 2$  (when  $[\text{K}^+]$  omitted), and assumes a normal albumin concentration and a  $\text{PCO}_2$  of 40 torr (15,18).
- ✂ The use of the AG in acid–base analysis is critical in order to detect most of the acute disturbances requiring immediate therapy.
- ✂ The SID is the difference between the strong cations and strong anions (Equation 7) and in health has an approximate value of 40 to 42 mEq/L.
- ✂ An initial step in the evaluation of an acid–base disorder is to assess the clinical circumstance of the patient and to develop an initial differential diagnosis based upon the likely acid–base disorders associated with the clinical picture.
- ✂ Cool extremity temperature has been validated as an indicator of hypoperfusion (excluding exposure to hypothermic environments and peripheral vascular disease with arterial insufficiency).
- ✂ The value of the SBE (in isolation) as an indicator of lactic acidosis is corrupted following resuscitation because the electrolyte composition of the IVF will significantly impact pH and therefore, the SBE.

- ✂ The differential diagnosis for an AG acidosis can be remembered using the mnemonic “MUD PILES” and include methanol, uremia, dehydration, paraldehyde, INH, lactate, ethylene glycol, and salicylates. However, the differential diagnosis also includes other conditions including ketoacidosis, sepsis, and liver failure, making the mnemonic somewhat incomplete (Table 3).
- ✂ Although algorithms and nomograms are useful (if present at the bedside), the most important factor in evaluating acid–base perturbations is to understand how they occur in the human body and to take a systematic approach in diagnosis.
- ✂ Urine output can be quite deceptive as a measure of resuscitation success and as a guide to ABB.
- ✂ The early phases of the postinjury period are often dominated by lactic acidosis.
- ✂ A negative side effect of massive volume resuscitation is hyperchloremic metabolic acidosis, which principally occurs during the perioperative and ICU phase of trauma therapy (21).
- ✂ Recent work has demonstrated a strong relationship between large volume resuscitation and the development of ALI (40).
- ✂ The presence of hypothermia (in combination with metabolic markers of acidemia) has been identified as a trigger to pursue DC surgery instead of a definitive procedure (46).
- ✂ The degree to which hyperchloremic metabolic acidosis occurs following significant resuscitation is related to the total fluid volume and the SID of the fluid in relation to the patient’s SID and any electrolyte losses.
- ✂ Hyperchloremia is known to independently diminish measures of renal function including GFR, urine flow, and creatinine clearance (30,54). It has been identified to be the factor most important for induced acidosis not associated with lactate in the OR.

### **INTRODUCTION**

*Humanity has but three great enemies; fever, famine and war; of these, by far the greatest, by far the most terrible, is fever.*

—Sir William Osler

The ability to elevate body temperature in a controlled manner in response to injury or infection is highly conserved throughout both vertebrate and invertebrate species. Even the single-celled paramecium is capable of a regulated increase in its core temperature (a febrile response) (1). It seems unlikely that such an energy-expensive response would be so near universally present in the animal kingdom if it were not beneficial. Fever has been both deliberately induced and aggressively suppressed, and considered both a good and a bad prognostic sign. Accordingly, core temperature is one of the vital signs routinely monitored in trauma and critically ill patients.

Numerous causes of fever exist; these are generally classified into noninfectious and infectious etiologies. The two can also coexist in trauma and critically ill postsurgical patients. Differentiating the causes of fever and determining the proper treatments can be quite vexing in this patient population. Elevations in temperature often provoke elaborate and expensive diagnostic evaluations, fever control therapies, and empiric antibiotic administration.

Although the importance of treating fever varies with the clinical situation, the main virtue in quickly evaluating a new fever is that it frequently reflects an inflammatory state owing to an infectious or noninfectious etiology, which may or may not be life threatening.

This chapter reviews the clinical significance, diagnosis, and treatment of fever in trauma and critically ill surgical patients. The historical accounts of fever and its interpretation over time is initially surveyed and the basic physiology of thermoregulation is reviewed. Because fever occurs so commonly in the first couple of days following noninfectious tissue injury and inflammatory conditions associated with trauma, these are discussed first. The infectious causes of fever rarely occur less than three to five days following trauma or surgery. However, after five to seven days infections are the most common causes of fever. These are discussed roughly in the order of their frequency and/or

urgency for treatment. Some disease processes are more fully discussed in other dedicated chapters, and the reader is referred there as appropriate.

### **BRIEF HISTORY OF FEVER**

Elevations in body temperature were probably one of the first symptoms of disease recognized by early man (2). The Edwin Smith papyrus (circa 2500 BC) records symptoms complicating a wound to the shoulder that likely represented infectious-related fever. References to a “hot disease” were described in Assyria (circa 670 BC) and first century BC China. Pictographs representing this term were typically based on fire or a brazier (3). The same term was often used for wound infections, inflammation, or fever from systemic illness, depending on whether the condition was localized or generalized.

The scientific understanding of fever began with the development of the thermometer, which provided physicians with the ability to quantify body temperature (4). Philo of Byzantium and Hero of Alexandria in the second or first century BC are credited with the first written descriptions of devices that reflected the expansion or contraction of air that occurs with changes in temperature using devices called thermoscopes (5). Sanctorius (1561–1636), a colleague of Galileo, was the first to apply quantitative determinations to the thermoscope and actually make a crude thermometer (6). The term thermometer first appeared in the literature in Leurechon’s “Récréation Mathématique” (1624) (6), as a device to test the intensity of fever.

But it was Sanctorius, a man with a passion to quantify all aspects of human physiology, who recognized that the human body has a normal temperature and that variations in temperature could be an aid in diagnosis. Two centuries later, Carl Rheinhold August Wunderlich (1815–1877) quantified temperature in a large patient population. His 1868 *opus magnus*, *Das Verhalten der Eigenwärme in Krankheiten* (The Course of Temperature in Diseases), evaluated the results of over a million temperature measurements in 25,000 patients in a Leipzig clinic (7). He described the diurnal variation in body temperature and that “normal temperature” varied among individuals with 98.6°F (37°C)

being the average “normal body temperature.” He also established 100.4°F (38°C) as the upper limit of this normal range and by doing so offered the first quantitative definition of fever.

Efforts to suppress fever were also employed by antiquarian physicians; indeed, cooling measures utilized to treat the fever of Alexander the Great in 323 BC, using water baths, are well documented (8). Cooling cloths or cool baths were also used to provide symptomatic relief from the headache, myalgias, and arthralgias associated with fever. Pharmacologic treatment of fever was also known to the ancients. Hippocrates wrote of a bitter powder derived from the bark of the willow tree, as did texts from Egypt, Samaria, and Assyria. This substance was first made available commercially in 1899, with the introduction of the minimally toxic agent “aspirin.”

Conversely, fever has also been induced in an effort to treat disease, a practice which can also be traced back to the era of Hippocrates. Fever was popularly applied to the treatment of syphilis as early as 1659. Following the extensive studies of Julius Wagner-Jauregg in the 1880s, fever therapy for syphilis (alone or in combination with drugs) became widely accepted. Indeed, this approach was so well received that Wagner-Jauregg received the Nobel Prize for this work in 1927 (9). Fever therapy has also been employed to treat multiple sclerosis, tuberculosis, and rheumatic fever, among other conditions. Interestingly, induced malaria was the standard means of creating a fever, but hot baths, hot air, heat cabinets, and heat lamps were also employed. The development of effective drug therapy along with the complications of fever therapy led to the abandonment of this form of treatment.

## DEFINITION OF FEVER

☞ **Fever is perhaps best defined as: “an elevation in core body temperature  $>1^{\circ}\text{C}$  above the patient’s thermoregulatory set point (TRSP).”** ☞ However, clinicians seldom know what a patient’s TRSP is prior to trauma or critical illness. Therefore, most traumatologists will define fever according to a set temperature criterion (e.g., 38.5°C). ☞ **In a joint statement of the Society of Critical Care Medicine (SCCM) (10) and the Infectious Disease Society of America (IDSA) (11), fever is defined as a temperature greater than or equal to 38.3°C ( $\geq 101^{\circ}\text{F}$ ).** ☞

Wunderlich was the first to emphasize that fever was a sign of illness, and not a disease in itself. His definition of fever is still in use today, both by the medical profession and the general public. In the 1870s, Liebermeister suggested that fever was not a result of the host’s inability to regulate temperature, but rather that a higher TRSP was set (12). Today, most investigators working in the field of temperature regulation agree with the Liebermeister concept (13,14).

## THERMODYNAMICS AND THERMOREGULATION

### Thermodynamics

Biological organisms are energy converters and as such are subject to the same fundamental laws of thermodynamics as are inanimate objects. Energy derived from foodstuffs is converted to high-energy bonds such as ATP for storage. These high-energy storage molecules then supply energy for cellular transport, movement, synthesis, and so on. These intracellular chemical reactions are not perfectly

efficient. Most such reactions dissipate 50–75% of the available energy as heat. For temperature to be maintained at a constant level, heat loss must equal heat production. Humans are capable of manipulating both variables in this relationship to maintain a stable core temperature.

When heat production needs to be increased quickly and significantly, as required following exposure to a cold environment, shivering is the primary method for rapid increases in heat production. Under hypothalamic control, skeletal muscle rhythmically and rapidly contracts, generating large amounts of heat. Heat production can be supported or even stimulated by catecholamines, thyroxine, glucocorticoids, or insulin. A second chemical mechanism of generating additional heat, so-called nonshivering thermogenesis, exists but is most significant in the first year of life (13–15). Nonshivering thermogenesis occurs primarily in brown fat, a specialized tissue that largely disappears in humans after infancy.

The body loses heat to its environment via one of four mechanisms: conduction, convection, radiation, and evaporation as described in Volume 1, Chapter 40 and Chapter 11 in this Volume (15). The rate of heat loss is subject to manipulation by both physiologic and behavioral means. For example, in a cold environment, cutaneous vessels constrict, skin temperature is reduced, and less heat is lost via radiation, conduction, and convection (Volume 1, Chapter 40).

Clinicians frequently speak of body temperature as though it was a single number but there is no unique temperature that represents the body as a whole. The core or central compartment consists of the brain, heart, and the other viscera. The temperature of this core is best measured by a thermistor on a pulmonary artery catheter, nasopharyngeal, or esophageal probes. The tympanic membrane also reflects core temperature. Oral, rectal, bladder, axillary, and skin temperatures correlate with the core, but may be offset, and often lag behind core temperature changes (also see Volume 2, Chapter 11).

Body temperature is a reflection of the thermal energy stored in the body. The heat content of any object is determined by its mass, temperature, and specific heat. The specific heat of biologic tissues varies depending on the tissue in question, but the average specific heat for mammalian tissue is 0.83 kcal/kg (15). The higher the specific heat of a material, the more energy must be added to raise its temperature.

### Thermoregulation

Body temperature, like many physiologic systems, is regulated by a negative feedback control system. Hammel et al. (16) first proposed a model involving the hypothalamus to explain this feedback to the control system. Essential to this model is the concept of a reference TRSP. Feedback signals from several core and peripheral receptors are continuously compared with the TRSP. However, the TRSP can be altered by physiologic conditions such as sleep, the administration of sedatives or analgesics, as well as pathologic conditions such as inflammation from both infectious, and noninfectious causes.

If this thermostat in the anterior hypothalamus is heated, heat loss mechanisms (e.g., peripheral vasodilation) are invoked. Conversely, if this area of the hypothalamus is cooled, heat production is stimulated (13,14). Temperature control involves a hierarchy of regional inputs from various central and peripheral thermoreceptors (refer Volume 1, Chapter 40) (13–15). Although certain neural lesions lead to varying degrees of dysfunction in

thermoregulation, they seldom completely abolish thermoregulation in the absence of total brain and brainstem death. Skin temperature primarily influences the gain of the system. For example, when the skin is relatively cold, a small decrement in hypothalamic temperature produces a larger response than if the skin were warm.

The effectiveness of this system is demonstrated by the observation that man's core body temperature rarely varies more than  $\pm 1^\circ\text{C}$ , despite large changes in environmental temperatures. This tight control is expensive in terms of energy demands (17). The high-energy expenditure is beneficial to the mammalian internal milieu by helping to maintain enzyme reaction rates and substrate needs relatively constant, providing a degree of biochemical stability.

The mechanism by which localized or even generalized infection or inflammation leads to an elevation in body temperature has been the source of much investigation. The current understanding of this process involves a release of soluble mediators, referred to as pyrogens, from cells involved in the inflammatory process (18,19). These pyrogens travel to the central nervous system (CNS), either crossing or interacting with the blood-brain barrier (BBB) and altering the hypothalamic thermostat so that the TRSP is raised. When the TRSP is raised, both autonomic and volitional heat conservation mechanisms are invoked. These responses include shivering, vasoconstriction of the skin, and behavioral changes such as seeking a warmer environment or more cover. This reset thermostat explains why patients may feel subjectively cold despite having elevated core temperatures.

Pyrogens can be classified into two groups: exogenous and endogenous. The exogenous pyrogens arise from bacteria, viruses, or foreign bodies causing fever (and inflammation), while the endogenous pyrogens arise from the host's own cells. The most extensively studied exogenous pyrogens are endotoxins derived from the cell wall of Gram-negative bacteria. However, Gram-positive bacteria, viruses, and even antigen-antibody complexes also have the capability to induce fever.

Most if not all exogenous sources of fever also act via the production of endogenous pyrogens by the host's immune cells (14,15). Such endogenous pyrogens include interleukin-1 (IL-1), tumor necrosis factor- $\alpha$  (TNF- $\alpha$ ), and IL-6. It has been widely believed that these pyrogens cause the synthesis or release of other mediators (prostaglandin E) at a circumventricular area such as the *organum vasculosum laminae terminalis* (OVLT) (15), which is located near the preoptic region of the hypothalamus and has a more permeable BBB than other regions. Endogenous pyrogens differ in several significant ways from endotoxin and other exogenous pyrogens. The endogenous pyrogens are small proteins produced by various leukocyte populations, predominantly polymorphonuclear leukocytes (PMNs) and macrophages as components of the inflammatory response.

It has long been known that neuronal changes combine to raise the hypothalamic TRSP, inducing a febrile response (16). Prostaglandin E<sub>2</sub> (PGE<sub>2</sub>) and the cyclooxygenase<sub>2</sub> (COX<sub>2</sub>) pathways are known to be centrally involved in fever. Prostaglandin E<sub>2</sub> binds to thermoregulatory neurons in the hypothalamus; mice lacking the COX<sub>2</sub> enzyme do not mount fever following exposure to exogenous pyrogens (20). However, additional influences beyond prostaglandins are involved in the febrile response. Neuronal responses to PGE<sub>2</sub> may be activated by pyrogens, and some pyrogens may directly inhibit warm-sensitive and stimulate cold-sensitive neurons in the preoptic area of the hypothalamus (21).

## BENEFITS AND ADVERSE CONSEQUENCES OF FEVER

### Beneficial Role of Fever in Host Defense

No convincing study in humans has yet established that fever is either beneficial or detrimental to patients. Such studies are difficult to perform as temperature is essentially never the only variable involved in illness, or its treatment. For example, administration of an anti-inflammatory, antipyretic drug such as ibuprofen reduces fever but also reduces inflammatory and other components of the acute phase response (APR). The use of external cooling reduces fever but imposes additional stresses on the host, including increased muscular activity such as shivering, which can confound experimental observations.

Investigators of elevated temperature on host defense have examined individual components of the immune response in vitro and have utilized animal models with a standardized infection. However, neither approach provides perfect experimental conditions; accordingly, contradictory results have occurred.

PMNs have been shown to accelerate chemotaxis at  $42^\circ\text{C}$  compared with  $37^\circ\text{C}$  (22). Phagocytosis and killing of pathogens by PMNs from human blood is enhanced at  $40^\circ\text{C}$  compared with that found at  $37^\circ\text{C}$  (22). Yet, at higher temperatures PMN chemotaxis is reduced (23). However, others have not confirmed these results (24). Although less well studied, mononuclear phagocytes (25) and complement (26) probably behave in a similar manner.

T-cell proliferation in response to mitogens is known to increase when cultured at  $39^\circ\text{C}$  compared with  $37^\circ\text{C}$  (27). In other studies, this enhancement occurred at  $38.5^\circ\text{C}$ , but not at  $40^\circ\text{C}$ . There appears to be an augmentation of the lymphocyte response with moderate temperature increases above normal, but these are blunted or eliminated when the temperature is increased still further. Antibody production is also enhanced, and the timing of the temperature increase relative to antigen exposure appears to be critical (28).

The release and activity of most cytokines and pyrogens is also temperature sensitive. In some cell lines, TNF- $\alpha$  protein synthesis is stimulated at increased temperature, but the associated m-RNA is less stable leading to an augmented, but less persistent TNF- $\alpha$  effect (26).

In summary, the body's immunoinflammatory responses become more robust with a modest increase in core temperature ( $1.5\text{--}2.0^\circ\text{C}$ ), indicating that modest fever during infection is likely beneficial, but that higher fevers are less helpful to the host. Because higher fevers are associated with more severe infection and inflammatory states, uncertainty is added to the question of whether fever benefits the host or not.

Fever is just one component of the APR (29). The most familiar components of this response include: increased metabolic rate, protein catabolism, leuko- and thrombocytosis, alterations in protein and hormone synthesis, and release as well as changes in various minerals such as zinc and copper. These changes appear to result from resets of other "homeostats" by cytokines such as IL-1, IL-6, and TNF- $\alpha$  in a manner similar to resetting of the hypothalamic thermostat to produce fever (29,30).

### Adverse Consequences of Fever

Despite the apparent benefits of fever, it is often accompanied with malaise, lethargy, anorexia, somnolence, and subjective discomfort including headache, arthralgia, and myalgia. Changes in the TRSP often lead to severe chills, shivering, and profuse sweating (13). The subjective

findings, while not life threatening, can produce significant discomfort for the conscious patient. Furthermore, when fever becomes very high seizures can occur, and/or somnolence can progress to stupor and coma, both conditions requiring airway management.

The febrile response is associated with an increase in metabolic rate (oxygen consumption, nutritional need, or heat production) of 7–8% per degree centigrade increase in core temperature. In addition, fever is usually associated with an increase in the pulse of eight beats per minute for each degree centigrade of temperature increase (Liebermeister's rule). Such increased oxygen needs (and myocardial work) may be difficult for a patient with limited cardiopulmonary reserve to meet. The associated increase in CO<sub>2</sub> production requires an increase in minute ventilation. Fever is also directly associated with increases in intracranial pressure (ICP) at the same time that CNS oxygen demands are increased. Temperatures greater than 41°C have the ability to produce direct damage to sensitive tissues, particularly in the CNS.

## INITIAL FEVER EVALUATION

The differential diagnosis of fever should take into account the many conditions that can alter a critically ill patient's body temperature and include environmental factors (large volumes of fluids, dialysis, hot lights, heating, or cooling devices) as well as clinical factors that may point to the etiology. Fever is generally divided into infectious and noninfectious causes (31).

☞ **Fever is frequently seen in the initial 48 hours after trauma, burns or surgery; however, such fevers are usually noninfectious in origin.** ☞ Blood cultures, chest X-rays, and urine studies are usually not necessary in this circumstance unless the physician has a particular reason for concern. A careful examination of the patient is warranted with particular attention to traumatic and surgical wounds, the chest examination, as well as any indwelling devices such as central lines. Particular attention should be devoted to the patient's history including events prior to admission as well as anything that might suggest increased bacterial numbers or virulence (e.g., barnyard injuries, open fractures, witnessed aspiration, or immunosuppression).

Routine cultures are not necessary but removal of the dressing and frequent careful inspection of all wounds is mandatory. ☞ **Although infection is unlikely in the first 48 hours following injury, Group A streptococcal infections and Clostridial myonecrosis represent uncommon, but important, exceptions which can present within this time period.** ☞

The longer the patient has been in the intensive care unit (ICU), the greater the probability that the fever is secondary to infection, and the more aggressively the diagnosis of infection should be pursued. Evaluation of the source of fever following trauma and critical care includes ruling out of the etiologies shown in Tables 1 and 2. In addition, the greatest focus needs to be on eliminating particularly virulent infections and the noninfectious etiologies with greatest mortality.

Examination of the patient includes scrutiny of the entire body surface, along with every orifice, every tube (or other foreign body passing through the skin), and

**Table 1** Noninfectious Causes of Fevers

Cause	Example and comments
Tissue injury	Trauma, burns, postsurgical
Cerebral hemorrhage	Tissue trauma, inflammatory mediators
Reabsorption of hematoma	DVT, PE <sup>a</sup> , procedure-related (e.g., groin), spontaneous (e.g., retroperitoneal, rectus)
ARDS	Fibroproliferative phase of disease
Alcohol or other drug withdrawal	Increased adrenergic state, leads to hypermetabolism
Fat embolus PE <sup>a</sup>	Release of pyrogens in the pulmonary circulation beyond normal hematoma reabsorption-related factors
Drug related (nonallergic)	MH, NMS, nonallergic drug toxicity serotonin syndrome, atropine, cocaine, methamphetamines
Allergic	Antiseizure drugs (DPH)
Pancreatitis	Inflammatory SIRS
Adrenal insufficiency	Hemorrhage, chronic use of corticosteroids, metastatic malignancy
Thyroid storm	Excessive metabolic heat thyrotoxicosis
Transfusion-related	WBC membrane-related, and release of cellular constituents
Other causes	Post MI, autoimmune, malignancy

<sup>a</sup>PE can cause fever through a number of mechanisms. Some are similar to those occurring with the reabsorption of any hematoma. Other mechanisms include the elaboration of inflammatory mediators into the pulmonary circulation.

*Abbreviations:* DVT, deep venous thrombosis; PE, pulmonary embolus; ARDS, acute respiratory distress syndrome; MH, malignant hyperthermia; NMS, neuroleptic malignant syndrome; DPH, Diphenylhydantoin (phenytoin); SIRS, systemic inflammatory response syndrome; MI, myocardial infarction.

**Table 2** Most Frequent Sites of Infection in Trauma Patients Admitted to the Surgical Intensive Care Unit (SICU)

Site of infection	Comments
Lower respiratory	Ventilator-associated pneumonia is most common cause of fever in SICU
Urinary tract	Although a common site of infection, urinary tract infections rarely cause SICU fever
Surgical wound	Rarely a cause of early (<72 hours postoperation) fever. However, these are responsible for approximately 25% of the nosocomial infections occurring in trauma and postsurgical patients <sup>a</sup>
Line sepsis	Approximately 70% of bloodstream infections are associated with invasive lines
Blood stream	All sources of invasive infection can cause bacteremia. Endocarditis is rarely the initial cause of infection or fever in trauma and surgical critical care
Intra-abdominal	3–15% of surgical injuries to the gastrointestinal tract can become infected (Volume 2, Chapter 50)

<sup>a</sup>Adapted from Ref. 119.

every wound on the body. The extremities can be quickly eliminated as a source of fever, if they are free of cellulitis, lymphagitis, lymphadenitis, or swelling (associated with DVT). Next the head can be evaluated for sinusitis (as described in the following), parotiditis (ruled out if parotid glands are normal), intracranial causes [ruled out if neurological status, head computed tomography (CT), and cerebrospinal fluid (CSF) studies are all normal]. The neck should be evaluated for swelling, including lymph nodes, and any internal or external jugular lines examined for signs of infection.

If all of these are negative, attention can then be directed solely on the torso. A complete examination of lungs, heart, abdomen, and pelvis is essential. The skin should be surveyed for rash, lesions, or decubitus ulcers. A rectal exam can rule out perirectal abscess, and the genitalia should be examined for various forms of infection. The chest should also be evaluated with chest radiography, chest CT, or bronchoscopy, as appropriate (32,33). A chest CT may be useful to evaluate pneumonia, empyema (34), and noninfectious causes of fever, and infiltrates such as pulmonary contusion, hemothorax, pulmonary embolus, and so on. The abdomen, pelvis, and retro-peritoneum can be evaluated by CT scan as well (see Volume 2, Chapter 50). Generally, at least one week should have elapsed since operation or the last abdominal CT scan for useful information to be provided using this imaging modality (35).

With these physical and imaging studies, most localized causes of infection will be suggested (36–38). Gram stain supplements this and helps suggest empiric antibiotic therapy (if indicated); culture data later confirms diagnosis and allows for narrowing of antibiotic coverage. When these evaluations are negative, and/or the patient has any other features (e.g., rash, muscle rigidity, and the like), then noninfectious etiologies may be identified. The most common of these will be reviewed in the next section.

## NONINFECTIOUS CAUSES OF FEVER

Noninfectious fever is common following trauma, burns, and surgical procedures. The list shown in Table 1 is far from complete, but includes some of the more frequently encountered possibilities as well as those that require specific and urgent treatment. Noninfectious causes of fever rarely lead to temperatures greater than 38.9°C (102°F). ⚡ **If the temperature exceeds 38.9°C, the patient**

**should be considered to have an infectious etiology until negative cultures demonstrate otherwise.** ⚡ Exceptions to this generalization include drug fevers, transfusion reactions, malignant hyperthermia (MH), neuroleptic malignant syndrome (NMS), and heatstroke (36).

### Tissue Injury

Trauma, burns, and surgery all cause tissue destruction; the more severe, the greater the associated injury. Along with the tissue trauma, inflammatory mediators are released into the circulation, some of which are pyrogens. In addition, macrophages and other cells that clear cellular debris also release cytokines.

### Cerebral Hemorrhage—Hematoma

Cerebral hematomas release brain tissue thromboplastin and other toxins into the circulation, lending to an increased risk of disseminated intravascular coagulation (DIC), inflammation, and fever. When blood is released into the subarachnoid space, fever occurs, probably because of the release of pyrogens that enter the hypothalamus.

### Noncerebral Hematoma

Hematomas located anywhere in the body, including deep venous thrombosis (DVT), pulmonary embolus (PE), and those occurring in tissue (because of trauma, procedure-related, or spontaneous), all release inflammatory mediators, cytokines, and pyrogens.

### Drug-Related (Nonallergic)

#### Malignant Hyperthermia

The syndrome of MH typically occurs soon following induction of anesthesia with volatile anesthetics or succinylcholine (39,40). Extremely rapid temperature increases are the hallmark of MH; it can also have an insidious and delayed onset (41). Malignant hyperthermia is characterized by elevated core temperature, muscle rigidity, tachycardia, and excess CO<sub>2</sub> production. Hyperthermia, hyperkalemia, and lactic acidosis are common. Hypoglycemia is often present as well. Malignant hyperthermia is a genetic disease of skeletal muscle with variable patterns of inheritance (42–44). The pathophysiology involves the uncontrolled increase in intracellular calcium in skeletal muscle resulting in intense and sustained muscle contraction, with resulting increase in heat production and temperature. The molecular basis of MH is more fully discussed in Volume 1, Chapter 40.

Treatment consists of discontinuation of the causative agent if still in use, immediate administration of 100% O<sub>2</sub>, and dantrolene sodium. In addition, aggressive volume replacement and control of acidosis and hyperkalemia are key elements of care, along with the institution of core temperature cooling measures. External cooling should be instituted immediately with ice packs, cooling blankets, iced saline lavage, and so on, and continuous core temperature monitoring is critical.

### Neuroleptic Malignant Syndrome

The NMS is a relatively rare but potentially lethal drug-related complication that includes fever and muscle rigidity, and frequently is associated with the use of neuroleptic drugs (e.g., haloperidol) (45–47). In addition, creatine phosphokinase (CPK) values may be elevated secondary to rhabdomyolysis. The muscle rigidity is of the “lead pipe” variety. The resulting chest wall involvement may result in tachypnea and hypoventilation, even requiring mechanical ventilatory support. Extrapyramidal symptoms such as dyskinesia and dysarthria may also be seen. Leukocytosis is a common finding.

A wide variety of drugs are associated with NMS including phenothiazines and butyrophenones (48). Alcoholic patients, sicker patients, and those with underlying infection or organic neuromuscular diseases appear to be at increased risk of developing NMS. The pathophysiology of NMS is not clearly established, but it is related to a functional dopamine<sub>2</sub> (D<sub>2</sub>) deficiency resulting from either the use of a drug with anti-D<sub>2</sub> side effects (e.g., haloperidol), or from the abrupt discontinuation of a D<sub>2</sub> agonist (e.g., Sinemet) in patients with Parkinson’s disease (45–49).

Successful management of NMS requires prompt recognition, immediate withdrawal of D<sub>2</sub> antagonists, and if appropriate the reintroduction of D<sub>2</sub> agonist. Supportive care also requires hydration, support of respiration, treatment of acidosis, and reduction of fever. Although not proven to enhance survival, specific therapy appears to significantly shorten the course of NMS in comparison with supportive care alone (47). The D<sub>2</sub> agonist bromocriptine mesylate (Parlodel®) has also been shown to reduce rigidity and temperature. Hypotension is the usual limiting side effect of this therapy. Dantrolene sodium, the drug of choice for malignant hyperthermia (discussed earlier), decreases the calcium available for muscle contraction and leads to improvement in the rigidity, which in turn leads to less heat production and a decrease in the temperature. Clinical improvement in patients treated with either of these two agents begins within hours in contrast to days required with supportive care alone. Other D<sub>2</sub> agonists such as amantadine and carbidopa have also been used successfully (45–49). Rechallenge with neuroleptic drugs after NMS may or may not result in recurrence of the syndrome (45). If the use of such drugs is necessary, re-exposure can usually be accomplished safely with either less potent drugs or lower initial doses in the closely monitored patient.

### Nonallergic Drug Toxicity

Nonallergic drug toxicity is common when patients are administered high levels of drugs with CNS effects, or side effects. Common drugs in this category are the anticholinergics (atropine, scopolamine), drugs of abuse (e.g., cocaine, methamphetamines, and the like), as well as elevated doses of drugs prescribed for depression particularly

selective serotonin reuptake inhibitors (SSRIs) with monoamine oxidase inhibitors (MAOIs) or MAOIs along with tricyclic antidepressants (TCAs).

Serotonin syndrome (SS) is a recently recognized source of temperature elevation that occurs most frequently as a result of combination therapy with psychotropic medications that increase brain serotonin activity (50,51). ⚡ **The SS is usually associated with combinations of SSRIs with MAOIs, or MAOIs with TCAs (50,51).** ⚡ Illicit drugs such as MDMA (ecstasy) have also been associated with the syndrome. Patients with SS usually respond to discontinuation of the offending agent and general supportive care. However, antiserotonin therapy with cyproheptadine or methysergide and/or propranolol may be indicated in severe cases (50–52).

### Allergy-Related Fevers

Numerous drugs used in trauma and critically ill patients can cause fever. There is no absolute physical finding or laboratory test to confirm the diagnosis of drug fever. Drug fevers are often high, spiking fevers with associated chills (53). Leukocytosis and eosinophilia may be present but are not consistent; maculopapular rash may be present as well. Drug fevers can only be diagnosed after excluding likely infectious causes and stopping the drug in question, hence drug fever is often referred to as a “diagnosis of exclusion.”

⚡ **After stopping a drug responsible for fever, 48–72 hours are usually required for the temperature to fully normalize.**

⚡ The β-lactam antibiotics and diphenylhydantoin are probably the two most frequent causes of drug-induced fevers in the surgical intensive care unit (SICU), but other common causes include other antibiotics, dobutamine (54), and antidysrhythmics (53). Many other medications have been implicated in drug fevers and include those that may be easily overlooked, such as pain medications, sedatives, and sulfa-containing stool softeners (Table 3).

Alcohol and drug use and abuse are common in the trauma patient population. Patients and families should be questioned carefully for any history of alcohol or drug use but often this use is minimized or denied. Patients who develop disorientation, tremor, hyperarousal, or hallucinations one to three days or more after admission should be evaluated for withdrawal and managed appropriately. Findings that may suggest withdrawal include fever, tachycardia, hypertension, agitation, and delirium.

### Pancreatitis

⚡ **Pancreatitis is one of the classic inflammatory conditions that can cause significant noninfectious fever, with signs similar to sepsis.** ⚡ Fortunately, the majority of patients with pancreatitis have minimal organ dysfunction and recovery is uneventful. However, approximately 20% of patients may go on to develop systemic inflammatory response syndrome (SIRS), leading to a fulminant course with pancreatic necrosis and multiorgan failure. The SIRS state is partly caused by activation of the inflammatory cascade mediated by cytokines, immunocytes, and the complement system (Volume 2, Chapters 47 and 63) (55). Many of the cytokines associated with disease progression are also known to be major causes of SIRS, evoking a febrile response (e.g., IL-1, IL-6, and TNF) (14,15).

Because the development of infected pancreatic necrosis significantly increases the mortality in patients with acute pancreatitis, much attention has been given to the prevention and early identification of patients at risk

**Table 3** Drugs Commonly Implicated in the Development of Fever

Common	Less common	Rare
Antidysrhythmics	Allopurinol	Antacids
Amphotericin B	Azothioprine	Antihistamines
Barbiturates	H <sub>2</sub> blockers	Insulin
Methyldopa	Hydralazine	Corticosteroids
Penicillins	Iodides	Aminoglycosides
Cephalosporins	Isoniazid	Macrolides
Phenytoin	Rifampin	Tetracyclines
Diuretics	Carbapenems	Clindamycin
Sleep medications	Vancomycin	Vitamin preparations
Sulfonamides (including sulfa-containing laxatives)	Nifedipine	
	Nonsteroidal anti-inflammatory drugs	

Source: Adapted from Refs. 120 and 121.

of developing Gram-negative pancreatitis sepsis. The major source of Gram-negative bacteria is the gut, hence empiric antibiotic therapy targeted at these organisms is often employed (56).

### Adrenal Insufficiency

☞ Patients who have a vasodilated picture suggestive of sepsis but in whom sepsis is unlikely may have adrenal insufficiency. Serum cortisol determination, a cosyntropin stimulation test or even empiric corticosteroid administration may be indicated. ☞ Fever associated

with adrenal insufficiency in the trauma ICU patient is most often secondary to chronic use of corticosteroids with resulting adrenal suppression. Primary adrenal failure can occur as a result of adrenal hemorrhage associated with sepsis, coagulopathy, or other conditions (57). This diagnosis should be considered in any patient with sudden hemodynamic collapse. A history of previous corticosteroid use, anticoagulants, metastatic malignancy, or other medical conditions may help to suggest the diagnosis but cannot exclude it.

Suggestive laboratory abnormalities include hyponatremia, hyperkalemia, hypoglycemia, and prerenal azotemia. Eosinophilia can be present. Patients with adrenal insufficiency can develop hyperdynamic shock (58), manifested by elevated cardiac index ( $\geq 4$  L/min/m<sup>2</sup>), tachycardia, hypotension and low systemic vascular resistance, and a high pulmonary capillary wedge pressure. A random serum cortisol  $<10$   $\mu\text{g/dL}$  is sufficient to confirm the diagnosis while a level of 10–15  $\mu\text{g/dL}$  is suggestive (59).

These standard diagnostic criteria are not sufficient to exclude adrenal insufficiency in the ICU population. The “normal” cortisol level in critically ill patients has not been well established. Furthermore, relative adrenal insufficiency may play a role in the critically ill. In this condition, cortisol levels are elevated above the normal range, but metabolic needs may require an even higher cortisol level. The cosyntropin (ACTH) stimulation test can help with the recognition of these patients (60). Because untreated adrenal insufficiency is almost 100% fatal in critically ill patients in shock, it is appropriate to initiate therapeutic steroid replacement without waiting for the results of the cortisol assay or the cosyntropin stimulation test.

### Thyrotoxicosis

Thyroid storm results from excessive metabolic heat production (61,62). It is most often characterized by fever, and tachycardia in the presence of an enlarged thyroid gland. Tachydysrhythmias, particularly atrial fibrillation, are common. Treatment includes large doses of glucocorticoids combined with propylthiouracil and iodine (62). Propranolol antagonizes the peripheral effects of thyrotoxicosis. The combined  $\beta_1$ - and  $\beta_2$ -blockade is preferable to the more selective  $\beta_1$  antagonism seen with esmolol or metoprolol. The metabolic effects of thyroid hormone are in part mediated by the  $\beta_2$  receptors. Supportive measures should include surface cooling, acetaminophen, and volume replacement.

### Transfusion-Related Fevers

Transfusion-related fever is caused by cellular constituents contained in blood products, and can occur with packed red blood cells, fresh frozen plasma, platelets, or cryoprecipitate (63). ☞ Most febrile reactions following transfusions are related to white blood cells (WBC), as leukocyte-depleted blood products have a low rate of this complication (64). ☞ However, WBC cell wall components and various antigen-antibody complexes can also have an immunological involvement, possibly involving circulating immune cells.

### Other Noninfectious Causes

Numerous other noninfectious causes of fever exist, including postmyocardial infarction syndromes (65), autoimmune disorders (66), and various forms of malignancy (67).

## IMPORTANT INFECTIONS IN TRAUMA AND CRITICAL CARE

Although a host of noninfectious conditions can cause fever in the ICU (Table 1), infections represent the most common cause, particularly after the first 48–72 hours. More than 50% of trauma patients admitted to the ICU develop an infection. In general, fevers caused by infection will have clinical findings indicating the source (if a thorough exam is employed). To an extent, higher temperatures are most often because of infection. Miller et al. (31) found that temperatures greater than or equal to 102°F predicted infection with a sensitivity of 72% and a specificity of 83%. However, when the temperature is  $>41^\circ\text{C}$ , MH, NMS, heat

stroke, and other drug-related causes should also be considered (Volume 1, Chapter 40).

The infections reviewed in this chapter constitute the most troublesome, either in terms of their prevalence (e.g., nosocomial pneumonia, line sepsis, and abdominal abscesses), rapidity of progression (e.g., necrotizing fasciitis, meningococemia), or uniqueness to the trauma population (e.g., orthopedic fracture prophylaxis and postsplenectomy prophylaxis). These infections are reviewed in terms of the organisms involved, their virulence factors, and the appropriate antibiotics for each condition (Volume 2, Chapter 53).

Blood cultures should be performed on patients with new fever unless there is strong reason to doubt an infectious cause, such as is an early post-trauma or postoperative patient without evidence of wound infection. The SCCM/IDSA guidelines suggest no more than three blood samples (in most cases two are sufficient) for culture during the initial 24 hours of fever (10,11). A second pair of cultures should be obtained in the second 24 hours if the fever persists. Additional cultures are usually needed only if the suspicion of bacteremia or fungemia is strong. A common source of bacteremia is central venous lines. The highest risk is with noncuffed temporary hemodialysis catheters and the lowest risk is for small peripheral catheters. However, catheters placed in field are at high risk for infection, and should be replaced within 24 hours of admission. Femoral lines are also associated with increased risk of DVT, and should be considered for replacement on a daily basis. Multiple other sites of possible infection exist (Table 4). Rational diagnostic approaches have been described (10,11,36–38), and will not be reviewed further here.

Atelectasis has been widely credited as a cause of fever but proof for this remains elusive (68). Experimental atelectasis usually does not produce fever although levels of some pyogenic cytokines are elevated (69). **Most investigators now recognize that atelectasis does not cause fever in the absence of infection.** However, patients with alveolar collapse are more prone to developing subsequent infections, owing to the interruption of normal cleansing of secretions, as microinfections (which would normally be cleared) become established as a result of stagnant clearance. Therefore, while the pathophysiologic connection between atelectasis and fever is not fully understood, patients with atelectasis demonstrated by diminished breath sounds or typical chest X-ray findings should receive aggressive pulmonary toilet and re-expansion of alveolar volume to decrease the risk of subsequent infection.

### Nosocomial and Ventilator-Associated Pneumonia

**The most common infectious cause of fever in critically ill patients is ventilator-associated pneumonia (VAP).** Members from the American Thoracic Society (ATS) and the IDSA have recently published a consensus document

**Table 4** Less Frequent Sites of Infection in Intensive Care Unit Trauma Patients

containing recommendations for the management of hospital-acquired pneumonia (HAP) and VAP in adults (70). Nosocomial HAP is divided into two categories, early-onset HAP, which occurs within the first five days of hospitalization, and late-onset HAP, which occurs after the fifth hospital day. As a generality, the organisms that cause pneumonia that develops within the first few days of hospitalization are essentially the same organisms that are associated with community-acquired pneumonia (CAP): pneumococci, *Hemophilus influenzae*, so-called atypical pathogens such as *Chlamydia pneumoniae*, *Mycoplasma* spp., and *Legionella* spp., along with viral pathogens. When patients develop late-onset nosocomial pneumonia, multiresistant bacterial pathogens are much more likely to be the microbiologic cause of pneumonia. Common pathogens include methicillin-resistant *Staphylococcus aureus* (MRSA), *Pseudomonas aeruginosa*, *Acinetobacter* spp., Gram-negative enteric flora such as *Klebsiella* spp. or *Enterobacter* spp., which may contain the genetic capability to express extended spectrum beta-lactamases (ESBLs).

Oral anaerobes are only rarely involved as pathogens in late-onset HAP. The change in species distribution results from changes in bacterial colonization of the buccal mucosa that occurs in all patients within 48–72 hours, after hospitalization for an acute illness. The appearance of novel binding sites on mucosal cells, specific for enteric Gram-negative organisms and pseudomonal species, allows these organisms to completely replace the normal flora, resulting in the virtual disappearance of viridans streptococci and obligate anaerobes from the mouth. Aerobic Gram-negative rods are the most common class of organisms causing nosocomial aspiration pneumonia. Ventilator-associated pneumonia is a subset of nosocomial pneumonia but is extremely important because of the associated high morbidity and mortality.

Proper treatment for early-onset HAP comprises use of the same antibiotics recommended in modern guidelines for CAP, including a third-generation cephalosporin in combination with either a macrolide, a quinolone, or doxycycline (71). Methicillin-sensitive *Staphylococcus aureus* (MSSA), especially secondary to a viral respiratory illness like influenza can also present as an early-onset pneumonia and can be treated with semisynthetic antistaphylococcal penicillin or cephalosporin (71).

As late-onset HAP and especially VAP are more likely to result from multidrug-resistant organisms, the antibiotic recommendations for empiric treatment differ from those of early-onset HAP (70). Treatment for Gram-negative rods should always include the possibility of pseudomonal infections. Initially, treatment with two drugs in different drug classes is indicated because of the possibility of resistance to at least one of the agents. In general, the recommended strategy is to combine a beta-lactam agent with either an antipseudomonal fluoroquinolone (e.g., ciprofloxacin or levofloxacin), or with an aminoglycoside.

Third-generation cephalosporins such as ceftazidime or cefepime are good beta-lactam choices; aztreonam should be selected in patients with severe penicillin allergies. Alternative treatment strategies include the use of carbapenems or beta-lactam/beta-lactamase inhibitors (e.g., piperacillin/tazobactam). Among the carbapenems, imipenem and meropenem are first choices, as ertapenem lacks significant effective antipseudomonal activity. Of the available beta-lactam/beta-lactamase inhibitors, piperacillin/tazobactam is the most effective antipseudomonal drug combination. As anaerobic organisms are of only minor significance in late-onset HAP and VAP (unless associated with postextubation

aspiration), empiric anaerobic treatment is only required if aspiration is the source of pneumonia.

Alternatively, a beta-lactam drug can be used with either a fluoroquinolone or an aminoglycoside for the first several days. Owing to the increased prevalence of multiply-resistant Gram-negative organisms, the rationale for dual therapy is to use at least one drug that is active against the infecting bacteria. Ciprofloxacin and levofloxacin have been widely preferred over aminoglycosides for this purpose because they are easier to dose (drug level monitoring not required), and because they have almost no nephrotoxicity. However, as the level of fluoroquinolone resistance among *P. aeruginosa* has risen, in some places to over 30% of isolates, they are becoming less effective as first-line therapy. Aminoglycosides are an alternative despite toxicity and a relatively poor distribution into lung tissues compared with other tissues.

The need for dual antibiotic coverage in nosocomial pneumonia is much debated. Available studies suggest that outcomes are similar with either dual antibiotic therapy or monotherapy as long as the causative microorganism is sensitive to the single drug used. Therefore, in those situations where two drugs are used initially, one can be discontinued when the final culture with sensitivities are known. When these drugs are used for pneumonia, the doses are generally higher than when used for other diseases.

As pneumonia caused by *S. aureus* and especially by MRSA is an important concern in an ICU, initial empiric coverage should include linezolid or vancomycin. Although recent data suggest that survival is improved with the use of linezolid instead of vancomycin in MRSA pneumonia, inadequately low doses of vancomycin were used as the comparator drug in some of the studies. Vancomycin is a large molecule, and its distribution into the lung parenchyma is low. As a result, the current guidelines recommend that trough levels of vancomycin should be between 15 and 20 mg/L rather than the usual 5–10 mg/L. The increase in dosage will require monitoring and carries the risk of increased nephrotoxicity.

Of important note, daptomycin probably results in the greatest killing of MRSA in all cavities of the body except for the lungs, where the surfactant has been found to inactivate it. Accordingly, daptomycin is contraindicated in pneumonia.

Patients who receive early and appropriate therapy have better survival than those who receive inappropriate antibiotics. This emphasizes the need to obtain cultures early, preferably before starting therapy, and with a technique such as bronchoalveolar lavage or protected brush specimen. Duration of therapy should be for a period of seven to ten days (also refer Volume 2, Chapters 48 and 53) (72).

### Aspiration Pneumonia

Aspiration and subsequent aspiration pneumonia are common in patients who have experienced multiple trauma (73). Aspiration can occur in the field, especially during a period of decreased level of consciousness, or during emergent intubation, either in the field or on arrival to the trauma unit, or following extubation in debilitated patients. In some cases, the aspirated material contains stomach contents, including previously eaten food remnants. In addition, it may contain hydrochloric acid and digestive proteolytic enzymes which can both cause an inflammatory chemical pneumonitis. In addition to gastric contents, the patient can aspirate the bacterial flora residing

in the buccal cavity. The organisms that cause disease are predominately microaerophilic streptococci and oral anaerobes; most of these bacteria live in the gingival crevice. As a result, therapy should be directed against this set of organisms. Antianaerobic therapy may not be necessary in edentulous patients. As they lack a gingival crevice, they have a much diminished anaerobic microbial burden in the mouth.

Penicillin had been the mainstay of treatment for aspiration pneumonia, and can be effective as a single therapy, but clindamycin has resulted in slightly better outcomes and fewer relapses (73). Ceftriaxone also has antianaerobic activity and provides a more than adequate coverage as a single agent. Combination therapy with ceftriaxone and clindamycin, though common, has not been demonstrated to be more effective than either drug alone. Quinolones with antianaerobic activity, such as moxifloxacin, are also effective. Metronidazole is also effective against oral anaerobes; as it has no activity against aerobic Gram-negative or Gram-positive bacteria, it must be combined with another agent (e.g., ceftazolin or ceftriaxone) that is active against those organisms.

### Invasive Line Sepsis

Infections associated with peripheral intravenous catheters can cause cellulitis, thrombophlebitis and, if untreated, severe infections. When extremity infections are becoming severe, lymphangitis and lymphadenitis are typically present, and should be specifically assessed for. If these signs of advancing local infections are present, systemic manifestations (fever and leukocytosis) are common, and generally represent strong corroborative evidence for the source of infection. As discussed earlier, the extremities should be closely examined in the fever work-up. If a source is found, the offending catheter should be removed and antibiotics started.

Central venous catheters are a considerable source of morbidity and mortality in ICU patients (Volume 2, Chapter 49). **Seventy percent of nosocomial blood stream infections occur in patients with central venous catheters.** As these catheters pierce the skin to enter the vasculature, the skin break itself is the usual portal of entry for microorganisms. However, there is not always a good correlation between cultures of the skin site and cultures from the catheter tip. Studies have demonstrated that the catheter hub lumen is also a common source of contamination (74,75).

The predominant organisms associated with vascular catheter infections are skin flora. Indeed, coagulase-negative staphylococci and *S. aureus* comprise 90% of all isolates from both peripheral and central line infections. The coagulase-negative staphylococci secrete biofilms that allow the bacteria to survive in sites that are protected from host defenses and antibiotics; biofilms containing other species have also been described. Gram-negative rods such as *Escherichia coli* and other Enterobacteriaceae are the third most common group of infecting microbes. *Candida* spp., which was uncommon in previous decades, has become the fourth most common organism in line-related infections, and is becoming an increasing problem in critically ill patients.

Infections can also be caused by contamination of the infusate and any intravenous fluid can potentially become contaminated. The most notable of these are infections with lipid-dependent yeasts like *Malassezia furfur* and *Candida parapsilosis*, which are associated with contaminated lipid emulsions in total parenteral nutrition (TPN).

Determining whether a central venous catheter is infected is not always straightforward. Data exists to support the use of semiquantitative cultures of the catheter tips (76), the differential time to culture positivity in blood samples drawn from the central lines and from peripheral sites (77), and the use of quantitative blood cultures (78). A recent meta-analysis suggests that quantitative cultures, comparing colony forming units per milliliter of blood in central line and peripheral blood samples, have the best sensitivity and specificity (78).

As Gram-positive cocci are the largest group of infecting microbes, empiric treatment should target staphylococci. The vast majority of coagulase-negative staphylococci are methicillin-resistant (MRSAs), and because of the increasing prevalence of MRSA, vancomycin should be used as initial empiric therapy. Daptomycin, linezolid, and quinupristin/dalfopristin and, perhaps, tigecycline are alternative initial empiric choices. If the organisms are methicillin-sensitive, first-generation cephalosporins or antistaphylococcal penicillins are therapy of choice.

When Gram-negative line-associated bacteremia is a possibility, or is associated with greatly increased mortality (e.g., a neutropenic patient), therapy should include an anti-pseudomonal beta-lactam/beta-lactamase inhibitor, carbapenem, or cephalosporin, possibly in combination with an aminoglycoside. If a patient remains febrile for several days after initiating broad antibacterial treatment, the practitioner should consider the possibility of line-associated candidemia.

Removal of infected central venous catheters is generally mandatory, especially with *S. aureus*, Gram-negative bacilli, and *Candida* spp. Successful short-term salvage of lines is possible with coagulase-negative staphylococci, but recurrences of bacteremia are nearly universal, making this an unattractive option.

## Wound Infection

♣ **Surgical wound infections should be considered in all critically ill trauma patients, and postoperative surgical patients with fever, especially when beginning >48–72 hours following surgery or trauma.** ♣ Although wound infections rarely develop prior to this period, dressing should be taken down and wounds examined to rule out necrotizing soft tissue infections (discussed next). Infected surgical wounds manifest all the cardinal signs of inflammation, *rubor, color, dolor, tumor*, and *functio laesa* (redness, heat, pain, swelling, and loss of function), as were known since the times of Hippocrates and Galen. In addition, infected wounds will usually be associated with a discharge of infected fluid or pus. Occasionally, no discharge is present when the infection is deep, and the skin site still closed. Whenever wound infection is diagnosed, the wound should be opened to express the purulent material and the patient should go to the OR for complete incision and drainage. Appropriate antibiotics are also administered.

## Necrotizing Soft Tissue Infections

In contrast to a simple cellulitis which only involves the cutaneous layers of the skin, necrotizing soft tissue infections rapidly spread, often along the deep fascia with secondary necrosis of the fascia, subcutaneous tissues, and occasionally muscles (79). The presence of gas-forming organisms classically results in subcutaneous air in the tissues that may be palpated on physical examination or seen radiographically, on plain films or by CT scan (though these signs are often absent). Because the infection spreads along the deep fascial

planes and the overlying skin is less involved, the extent of the infection is often underappreciated with regards to its severity and lethality. Thus, a high index of suspicion is necessary to make the diagnosis and promptly initiate therapy.

The bacteria associated with necrotizing fasciitis produce toxins including cytolytins and sphingomyelinases, which destroy tissue and allow rapid progression along tissue planes. The fascial necrosis is followed by thrombosis of the arterioles that bridge the space between the skin and the fascial layer, causing loss of blood flow and oxygen to the skin, resulting in death of the overlying skin. Necrotizing soft tissue infections are fully discussed in Volume 1, Chapter 29 (extremity trauma) only the salient points are provided here. Soft tissue infections are often associated with a paucity of inflammatory cells, which presumably are killed by the bacterial hemolysins. The inability to deliver antibiotics to the involved areas of muscle fascia and the overlying skin make cure with antimicrobials alone futile, and surgical resection (usually wide and extensive) is the only effective therapy.

Necrotizing soft tissue infections can occur following trauma (especially involving puncture wounds, and following IV drug abuse), but can also occur following surgery contaminated with organisms that flourish in the relatively anaerobic environment of the surgical wound, or deep fascial planes. It is more common in situations involving unrecognized foreign bodies, delayed presentation to medical care, and in patients with immunosuppressive conditions (e.g., diabetes, alcoholism, peripheral vascular disease, HIV, neutropenia, renal failure, and so on).

Classically, necrotizing soft tissue infections are associated with anaerobic organisms, specifically *Clostridia* spp. and particularly *Clostridium perfringens*, the organism most commonly associated with gas gangrene, especially from battlefield wounds. *Streptococcus* spp. are the second most common group of organisms isolated from wounds (79). *Staphylococcus aureus* or facultative aerobic Gram-negative rods like *E. coli* are rarely isolated as the single etiologies of necrotizing fasciitis, but are often found in combination with other organisms and may be facultative in some mixed infections (79,80).

Mixed synergistic necrotizing fasciitis can involve a combination of bacteria, including anaerobic pathogens such as *Bacteroides*, *Clostridium*, *Peptostreptococcus* as well as enteric Gram-negative rods like *E. coli*, *Proteus*, *Serratia*, *Enterobacter*, and *Klebsiella*. *Pseudomonas* is also occasionally seen. Mixed infections usually arise from the traumatic implantation of foreign material (e.g., oral flora in a drug addict's needle) or in proximity to the bowel.

Swabbing of deep wounds, as apposed to superficial wounds, followed by immediate Gram stain can provide a presumptive microbiologic diagnosis, which can be used to guide empiric therapy, but operative debridement is the most important factor.

The selection of empiric antimicrobials will also depend on anatomic location, mechanism of infection, and Gram stain results. High-dose penicillin in combination with clindamycin is appropriate (unless *Bacteroides fragilis* is presumed or documented). Aggressive fluid repletion and immediate wide surgical debridement is mandatory to save the life of an individual with established necrotizing fasciitis caused by clostridial spp. and by beta-hemolytic streptococci.

Infections with *S. aureus* alone are an unusual cause of necrotizing fasciitis although there are a few case reports describing this (80,81). When *S. aureus* is the etiologic organism,

treatment with vancomycin or an antistaphylococcal penicillin or cephalosporin is indicated. Because of the high prevalence of MRSA (in many hospitals it is above 50%), vancomycin should be part of the initial antibiotic treatment. In cases of mixed synergistic infection, appropriate coverage for facultative aerobic Gram-negative rods and obligate anaerobes will include a carbapenem, a beta-lactam/beta-lactamase inhibitor, or a third- or fourth-generation cephalosporin in combination with metronidazole.

As many of the manifestations of necrotizing soft tissue infection are toxin-mediated, clindamycin should be used in conjunction with other antibiotics because, as a protein synthesis inhibitor, it shuts down further production of toxins; it is also active in situations of high bacterial density (i.e., in wounds) where beta-lactams and vancomycin may not be—a phenomenon known as the “Eagle Effect” (82). As an adjunctive measure, hyperbaric oxygen (Volume 2, Chapter 73) has been shown to be effective in delaying or stopping progression of the affected areas in necrotizing fasciitis (83), but operative debridement should occur first.

Interestingly, a high proportion of community-acquired MRSA (CA-MRSA) strains (nearly 100%) express a unique hemolysin, the Panton-Valentine leukocidin (PVL), which contributes to virulence by causing lysis of WBCs, specifically PMNs, thereby crippling the immune response. Typically, only about 2% of *S. aureus* express this toxin. In addition, PVL also affects cells other than WBCs and causes separation of tissue layers, contributing to the spread of the infection in the host. Vancomycin is the antimicrobial of choice against these infections, but newer antibiotics such as daptomycin, linezolid, and tigecycline are also effective. Rifampin, in combination with vancomycin, can provide synergistic antibacterial action.

### Orthopedic Fracture Infections and Prophylaxis

Open orthopedic fractures constitute a surgical emergency, and are prone to infections. Accordingly, these patients should receive antibiotic prophylaxis. The most common system used to classify orthopedic fractures and the associated risk of infection are those that have been modified from that of Gustilo and Anderson (83).

This system divides fractures into three grades and further subdivides grade 3 fractures, the most severe fracture, into three subtypes. All grades can become infected, but the prevalence of infection is higher with more severe injury.

Grade 1 fractures are usually simple transverse or oblique fractures that result from low-energy injuries with skin wounds less than 1 cm in length. Grade 2 fractures result from an injury with more energy absorption and cause some degree of comminution and moderate crushing component along with a skin wound that is larger than 1 cm. Grade 3 injuries are usually the result of significant mechanical injury, such as gunshot wound, motor vehicle injuries, especially motorcycle injuries, and other traumatic injuries. These injuries usually have extensive soft tissue damage, severe comminution, and large areas of denuded skin. These wounds are likely to be contaminated with external debris, like soil, from the site of the accident. Grade 3A injuries generally do not require extensive reconstructive surgery to provide skin coverage to the injured site. Grade 3B injuries, on the other hand, have more extensive soft tissue and periosteal injury and require major reconstructive plastic surgery to provide a flap for cutaneous coverage.

Grade 3C fractures are associated with vascular compromise and may necessitate vascular reconstruction.

The key therapeutic principles in treating actual or potentially infected fractures are extensive and include: adequate debridement of all infected and necrotic tissue, removal of foreign bodies, copious irrigation of the wound, management of dead space and coverage of exposed bone with appropriate flaps, and minimizing the time to operation (84). Prophylactic antibiotics are adjunctive in the sense that they decrease the incidence of wound infection and osteomyelitis, but do not entirely prevent all infections.

A large meta-analysis and Cochrane review demonstrated that single-dose antibiotic prophylaxis significantly decreased superficial and deep wound infections by about 60% (85). Prolonged treatment did not yield a better outcome than single-dose prophylaxis. In a similar meta-analysis, the data also supports the efficacy of prophylactic antibiotics in preventing infections in patients with open fractures (86). Most infections are caused by skin flora, primarily by coagulase-negative staphylococci and *S. aureus*, but aerobic Gram-negative rods and soil anaerobes are increasingly frequent with more traumatic, open fractures.

In general, first-generation cephalosporins, antistaphylococcal penicillins, and vancomycin are effective prophylactic antibiotics for closed fractures and grades 1 and 2 fractures. For grade 3 fractures, aminoglycosides and clindamycin are useful additions (Volume 2, Chapter 53). **Despite antibiotic prophylaxis, patients with open fractures and fever should have their wounds examined for infections, and if present, incision and drainage should be performed.**

### Abdominal Infections: Following Trauma/Surgery with Colonic Contamination

Abscesses following abdominal trauma result from injuries to the bowel and spillage of intestinal contents into the peritoneal cavity. In blunt trauma, the organisms that cause disease derive from the normal commensal flora. In penetrating trauma (e.g., gunshot wounds or shrapnel), additional organisms can be directly implanted at the time of injury. In addition, when a projectile travels through soiled clothing before it penetrates the victim, it carries the environmental flora living on the clothing that enters the wound.

The most common classes of organisms causing abdominal infections in previously healthy trauma victims are enterococci, Gram-negative enteric organisms, and intestinal anaerobes. The types of organisms that predominate in a particular patient also depend on which portion of the intestine is injured. A stomach injury can cause gross contamination following a large meal, or may release essentially sterile contents if injured between meals after prior contents have been bathed in hydrochloric acid and proteolytic enzymes. *Candida albicans* is usually a component of the mouth; it is present normally in the esophagus and often survives in the stomach because it is moderately acid-tolerant. If the patient is taking medications that decrease the gastric pH, that is, antacids, H<sub>2</sub>-blockers, or proton pump inhibitors, oral flora, particularly oral anaerobes, and streptococci may colonize the stomach.

The small intestine is normally colonized with facultative anaerobic Enterobacteriaceae, like *E. coli*, and enterococcal spp. In biliary trauma, the same organisms will most likely be involved; the presence of anaerobes is unusual. As one progresses distally along the bowel, one finds an increasing proportion of anaerobic bacteria, such

as *Bacteroides*, *Prevotella*, and *Peptostreptococci*. In the colon, greater than 99.99% of the bacteria are anaerobic.

The Surgical Infection Society and the IDSA have recently published guidelines for treating intra-abdominal infections (87,88). In general, regimens that treat enterococcal spp. have no better outcomes than those that do not. This is because of the relative avirulence of the enterococci, especially in nonimmunocompromised individuals. Similarly, although *Pseudomonas* can be an intestinal colonizer, especially in children, it is not necessary to use antibiotics effective against *Pseudomonas* in an empiric fashion for intra-abdominal infections. In the past, studies showed that second-generation anaerobic cephalosporins, like cefoxitin, were as effective as monotherapy. However, there has been a steady increase in the number of *B. fragilis* group organisms that are resistant to these agents. Accordingly, cefoxitin should no longer be used alone for empiric treatment of intra-abdominal infections. Adding metronidazole to both second- and third-generation cephalosporins is now necessary to provide adequate treatment for *B. fragilis*. The newer fluoroquinolones (e.g., moxifloxacin and gatifloxacin) possess intrinsic activity against intestinal anaerobes; however, the prevalence of fluoroquinolone-resistant *Bacteroides* has increased to >50% in some countries. Accordingly, abdominal infection treatment with fluoroquinolones should occur only in combination with metronidazole (88). Metronidazole remains the backbone of treatment regimens for intra-abdominal sepsis. Additionally, monotherapy with either carbapenems or beta-lactams/beta-lactamase inhibitors is an attractive alternative strategy because of simplicity. Of note, none of these therapies adequately treats MRSA, but MRSA is not generally a cause of intra-abdominal infection in previously healthy individuals. If the patient is at high risk for MRSA, for example, in an SICU after a surgical procedure, then vancomycin or other drugs effective against MRSA should be used. If the presence of vancomycin resistant enterococcus, vancomycin intermediate sensitivity, *Staphylococcus aureus*, or vancomycin resistant *Staphylococcus aureus* complicates an abdominal infection, then linezolid, daptomycin, tigecycline, or dalbopristin/quinupristin should be used.

Isolation of fungi from intraoperative peritoneal cultures is increasingly common (89), especially in patients with renal failure who are being treated with chronic ambulatory peritoneal dialysis (CAPD). *Candida* spp. cause the vast majority of fungal peritoneal infections as it is a normal constituent of the gastrointestinal (GI) flora, but other fungi such as *Aspergillus* spp. and zygomycetes (e.g., mucor) have also been reported in association with CAPD catheter infections. Most of the candidal isolates are fluconazole-susceptible *C. albicans*, but the use of fluconazole as prophylaxis is changing the epidemiology of candidal infections so that fluconazole-resistant *Candida* spp. are causing a greater proportion of invasive candidiasis. For patients who have not received prophylactic azoles, fluconazole is an effective empiric treatment in most cases. If the patient has received prophylaxis, then voriconazole, an echinocandin (caspofungin, micafungin, anidulafungin) or amphotericin should be used. Antibiotic treatment is an adjunct to and not a replacement for proper surgical drainage of abscess collections.

### Sinusitis

Sinusitis can occur in critically ill trauma patients with tubes or packing in their noses, or those who have sustained nasal trauma prior to admission (90). The paranasal sinuses are

four paired structures with drainage ostia in the nose. The sinuses are lined with ciliated pseudostratified columnar epithelium. The cilia of the sinus mucosa propel secretions, bacteria, and foreign material toward their ostia in the nose. When the ostia becomes obstructed because of foreign bodies (tubes/packing) or swelling (direct trauma), the bacteria are not cleared and begin to proliferate, causing a clinical sinusitis infection (90).

Common bacteria involved in nosocomial sinusitis are quite different from those of community-acquired (91). In most reports, the etiology is usually polymicrobial with about one-third being Gram-positive and two-thirds Gram-negative organisms. *Staphylococcus aureus* is by far the predominant Gram-positive organism and *Pseudomonas* spp. are the leading Gram-negative organisms. While highly resistant organisms, such as MRSA, VRE, and *Acinetobacter* spp. have not been reported in this disease; with their increasingly important roles in nosocomial infections these organisms must be considered when selecting antibiotics for treatment.

Diagnosis includes, fever, purulent nasal discharge, tenderness to percussion over the sinus (often notable in sedated or obtunded critically ill patients). Further clinical features, diagnostic work-up (including use of nasal endoscopy and imaging studies), and treatment recommendations are provided in Volume 2, Chapter 51 (90,91).

### Urosepsis

Urinary tract infections (UTI) are the most common nosocomial infection in the United States (causing about a third of the infections in hospitals and nursing homes) (92). However, UTI is an infrequent cause of fever or sepsis following trauma and critical care. Almost all UTIs occurring in critical care are associated with instrumentation of the bladder.

In the normal, uncatheterized bladder, several mechanisms allow for clearing uropathogens from the urinary tract. These include: Tamm-Horsfall protein, glycosaminoglycans, and an intact bladder mucosa. Micturition alone will remove 99.9% of all microbes that enter the bladder. A catheter overcomes these protective mechanisms by providing a direct conduit to the bladder from outside; the presence of a foreign object can also irritate and disrupt the uroepithelial mucosa. Once a catheter is in place, microbes can enter the bladder either extra- or intraluminally. Estimates are that about one-quarter of urinary tract colonization is intraluminal with the remaining occurring extraluminally (i.e., between the urethral epithelium and the catheter). Some uropathogens, such as *E. coli* K1, have specialized fimbriae that allow attachment to uroepithelial cells. Additionally, the presence of a glycocalyx or biofilm along the catheter surface can allow colonization and persistence of bacteria in the presence of both host immune effectors and antibiotics (93).

Risk factors for catheter-associated bacteriuria or funguria include: (i) the length of catheterization, (ii) absence of a urinometer or drip chamber, (iii) colonization of the drainage bag, (iv) diabetes, (v) abnormal renal function, and (vi) breaks in proper catheter care (92). If bacteria or yeast are in the urine cultures of an afebrile patient, the first step in management is to change the catheter and repeat the urinalysis and culture.

Dysuria, suprapubic pain and tenderness, back pain and costovertebral angle tenderness may be clinical clues to a diagnosis in a cognitively aware patient. However, assessment of these signs and symptoms in an SICU setting is difficult in sedated patients and in those with

altered mental status. Fever is the most common sign. On occasion, physical exam is useful when one finds an enlarged epididymis on the testis or a soft, mushy prostate, but diagnosis usually is dependent on the results of urinalysis and urine culture.

The majority of microbes that colonize the urinary tract are the host's resident flora, usually deriving from the GI tract. These are predominantly facultative anaerobic enteric Gram-negative rods, *Pseudomonads*, *Enterococci*, and *Candida* spp. Truly anaerobic colonic bacteria rarely cause UTIs in the absence of a direct connection from the urinary tract to the GI tract, as in the case of an enterovesicular fistula. The most common organisms are Gram-negative rods (94–96).

Aminoglycosides are an attractive first choice because they are excreted renally and are concentrated in the urine; bactericidal levels of drug can be present for days after even a single dose. Third-generation cephalosporins and quinolones are second-line options. Carbapenems can be used for multidrug-resistant organisms. Vancomycin spp. are generally sensitive to ampicillin and vancomycin and should be used first. Approximately 30% of a linezolid dose is excreted into the urine unchanged and can be used to treat vancomycin-resistant organisms. Daptomycin, active against VRE is 80% renally excreted and is an alternative choice. *Candida* spp. also can cause UTIs and are an increasingly common problem. Fluconazole is the only antifungal drug that achieves significant levels in the urine and is, therefore, the drug of choice to treat candiduria. The echinocandins and voriconazole do achieve measurable amounts in the kidney parenchyma, but only about 3% of either drug is excreted into the urine itself. Changing the catheter is the first step in managing candiduria and may, by itself, be therapeutic. Alternatively, amphotericin B bladder washes can also be effective (97).

### Postsplenectomy Sepsis and Prophylaxis

Asplenic patients are at higher risk for bacteremia and fulminant septic shock, known as overwhelming postsplenectomy sepsis (OPSS) (98). Asplenic patients include not only postsplenectomy patients but also those individuals who are functionally asplenic, such as those with sickle-cell anemia (owing to repetitive infarct-mediated autosplenectomy), infiltrative disorders with splenomegaly (e.g., myelodysplasias), or deficiencies in the terminal components of the complement (99). The microorganisms that cause these syndromes are usually those with polysaccharide capsules that resist phagocytosis by PMNs and macrophages unless they are bound by anticapsular antibody or complement (i.e., opsonized). The most common organisms include *Streptococcus pneumoniae*, *Haemophilus influenzae*, and *Neisseria meningitidis*. Of these, the pneumococcus is the most common organism causing OPSS, having a case-fatality rate as high as 60%. Vaccines exist against all of these species, and their use is recommended (as described in Volume 2, Chapter 52 (100)).

Many hyposplenic individuals will also have received prophylactic antibiotics, usually penicillin, either orally or sometimes in monthly injections. In many cases, they will have prescriptions for another class of antibiotics, like fluoroquinolones. ⚡ **Postsplenectomy patients should be instructed to keep antiencapsulated bacteria antibiotics readily available, to take them at the onset of an acute, febrile illness, and to also seek medical evaluation at that time.** ⚡ When these patients are sick enough to be admitted to the SICU, therapy should be directed against the most likely organisms; third-generation cephalosporins or

quinolones are drugs of choice. Postsplenectomized trauma patients should also be given a card and med-alert bracelet declaring their condition.

### Meningococcemia

The term meningococcemia is used here to describe the fulminant septic disease complicated by hemorrhage, purpura, and thrombosis-associated tissue infarcts (often involving distal extremity) (101).

The typical patient presents with fever, generalized weakness and malaise, headache, skin rashes, and the abrupt onset of hypotension and sepsis requiring admission in the SICU or burn unit. A number of authors have described a prominent rubella-like maculopapular rash, which is initially painless, nonpruritic, and temporary. Most commonly, the initial rash consists of 1–2-mm petechial lesions that are usually seen on the trunk and lower extremities, but may occur in places like the palpebral conjunctiva or the buccal mucosa. Often the rash is prominent under belts or on areas that are subject to pressure. Gradually, the petechiae enlarge and coalesce to form larger ecchymotic lesions. The petechial bleeding is a result of thrombocytopenia. The rapid evolution from petechiae to large ecchymotic lesions is known as purpura fulminans. ⚡ **The pathophysiology of fulminant meningococcemia results from sepsis, vascular collapse, shock, disseminated intravascular coagulation (DIC), and tissue infarcts (101).** ⚡

Some manifestations of purpura fulminans result from damage to the vascular endothelium and protein C levels are decreased, participating in the debilitating microvascular infarcts of digits and extremities. Accordingly, some have hypothesized that the use of activated protein C (APC) might improve the outcome (102). Although, the number of patients studied in prospective randomized controlled trials (RCTs) with APC is low, the available series suggest that APC does provide benefit. If APC is employed, it should be administered early and judiciously because of the increased risk of bleeding associated with its use (103; refer to Volume 2, Chapters 47 and 63).

### Meningitis

There are a myriad of causes of infective meningitis. Organisms of all classes, including viruses, typical bacteria, mycobacteria, spirochetes, Rickettsial spp., fungi and sometimes parasites, including protozoa and helminths, have all been described as causes of meningitis (104). Meningitis can also follow trauma by direct implantation of foreign matter and can occur as a complication of therapeutic and diagnostic intracranial devices (e.g., ventriculostomy).

Correct management of meningitis requires establishing an etiologic diagnosis. The use of CT scan or magnetic resonance imaging may show diffuse meningeal enhancement, but this is not specific for any particular organism (104).

The key procedure for establishing a diagnosis of meningitis is sampling of the CSF. Examination of the CSF should include assays for glucose, total protein, differential cell counts, and Gram stain and routine culture (104). If appropriate, there are stains for fungi (e.g., India ink for *Cryptococcus neoformans*) and mycobacteria. Latex agglutination assays are routinely available to detect the capsular polysaccharides of *Cryptococcus*, *Haemophilus* type B., the *Meningococcus*, and the pneumococcus in CSF. Advances in molecular biology-based techniques, such as polymerase chain reaction are now available for the diagnosis

of enterovirus, cytomegalovirus (CMV), Epstein-Barr virus (EBV), herpes simplex viruses (HSV), and others.

The *Pneumococcus*, the *Meningococcus*, enteroviruses, and herpes simplex virus are the most common causes of meningitis in immunologically normal hosts (104). Selected hosts have an increased predisposition to infections with other organisms, such as *Cryptococcus neoformans* in AIDS patients, and other immunocompromised patients and *Listeria monocytogenes* in pregnancy (104). In trauma patients with CNS shunts or ICP monitoring devices, the most common organisms are *Staphylococci* (implicated in ~80% of shunt infections). Gram-negative aerobic bacilli comprise the great bulk of the remainder of the causes. True anaerobes comprise only a small percentage of the remainder of organisms; if they are present, especially in patients with ventriculo-peritoneal shunts, it is strongly suggestive of intestinal perforation at the abdominal end of the shunt with ascending infection.

Empiric therapy should be directed against the most likely causative organism. Identification of a specific pathogen allows de-escalation to a specifically targeted regimen. The ability of an individual antibiotic to cross the BBB is a primary determinant for the outcome (104).

Most antibiotics do not cross the BBB in the absence of inflammation. With inflammation, the levels of drugs like penicillin and ceftriaxone increase markedly, but higher doses are still a requirement to exceed the minimum inhibitory concentrations of most pathogens. For acute bacterial meningitis, ceftriaxone at a dose of 2 g IV every 12 hours provides adequate therapy for the *H. influenzae*, the *Meningococcus*, and penicillin-sensitive pneumococci. In hospitals with a high prevalence of penicillin-resistant *S. pneumoniae*, most authorities recommend the addition of vancomycin to the regimen. Corticosteroids are useful therapeutic adjuncts in cases of meningitis caused by *S. pneumoniae*, *H. influenzae*, and *Mycobacterium tuberculosis* (105–107).

For patients with infected intracranial devices, targeted therapy based on initial Gram stain is the best. As most organisms are nosocomially acquired and drug-resistant, vancomycin is the initial drug of choice. However, vancomycin does not penetrate BBB well. As drug levels may be subtherapeutic even in the presence of inflammation, intrathecal administration of vancomycin may be the preferred route.

If the organisms are methicillin-sensitive, it is wise to switch to antistaphylococcal penicillin; rifampin may be a useful synergistic agent in the presence of prosthetic material. Aminoglycosides, colistin, and amphotericin can also be administered intrathecally.

For Gram-negative bacteria, ceftazidime and meropenem achieve therapeutic levels of drug in the CSF. Shunt removal is usually necessary for cure of the infection. The most efficacious strategy seems to be externalization of the shunt, treatment with antibiotics, and replacement of the shunt after an adequate duration of therapy. Duration of antibiotic administration depends on the infecting organisms; *S. aureus* may need 10 days of therapy before replacement of the shunt. Gram-negative organisms may require 14–21 days of therapy (104).

## TREATMENT OF FEVER

☞ In the absence of traumatic brain injury (TBI) or other CNS injury, temperature elevation between 37°C and 39.5°C may be beneficial. ☞ Side effects of fever including tachycardia and increased ICP will benefit from lowering

body temperature. In the conscious patient, fever is usually associated with malaise, headache, myalgias, and/or arthralgias. In such patients, symptomatic relief may be obtained by reducing the fever.

The most extensively studied and utilized method of reducing temperature is to reset the thermostat downward and let the body correct the temperature. This approach employs drugs classified as antipyretics, such as aspirin and ibuprofen. Other options to lower temperature require either reducing heat production or increasing the rate of heat loss. Heat production can be lowered somewhat by reducing or eliminating skeletal muscle activity, reducing pain, and anxiety, and so on. Increasing heat loss can be accomplished by sponging with cool liquid, cold baths, cooling blankets, fans, or ice packs. Each of these techniques has pros and cons.

## Antipyretic Drug Therapy

Antipyretic agents can be classified into three types: the largest class includes aspirin, ibuprofen, and other nonsteroidal anti-inflammatory drugs (NSAIDs); while corticosteroids and acetaminophen are each in a class by themselves (108). The NSAIDs are inhibitors of both central and peripheral COX. Acetaminophen decreases the production of prostaglandins in the brain but does not inhibit COX at peripheral sites. Corticosteroids are thought to interfere with fever by blocking transcription of IL-1 and by inhibiting phospholipase A<sub>2</sub> (108). Without a doubt, the high fevers seen in heat stroke, MH, and NMS ( $\geq 42^{\circ}\text{C}$ ) are inherently damaging to tissues, but these temperatures are unresponsive to antipyretics. Regulated fevers such as seen with inflammatory processes rarely exceed 41°C (109). However, specific subgroups benefit from antipyretic therapy, including those with CNS pathology and critically ill patients with cardiopulmonary dysfunction (limiting oxygen delivery).

Both animal and human studies of brain injury indicate that fever is common and associated with a worse prognosis (110). However, the use of antipyretic drugs to lower temperature has not been shown to reduce brain injury and is not always effective (111,112). Regarding the safety of NSAIDs in TBI patients, hypotension with reduced CPP, along with nephrotoxicity and oliguria, have been reported (113). Acetaminophen is comparable with NSAIDs in its ability to reduce temperature in TBI patients. Although corticosteroids have been studied in TBI (and found to be efficacious), there are little or no data on their use specifically as an antipyretic. Clinical studies demonstrate a positive correlation between ICP and brain temperature (114). Simultaneous measurement of core and brain temperature demonstrated that in some patients core temperature significantly underestimated brain temperature, suggesting that if antipyretic therapy is to be utilized in patients with brain injury it may be more effective if based on brain temperature (114). ☞ **The administration of antipyretics to ICU patients in an effort to reduce fever is common practice, but data proving a benefit to this practice is lacking.** ☞ Very few studies have addressed the use of antipyretics such as acetaminophen in the ICU patients. The data available suggests only a limited efficacy for antipyretics in critically ill patients (115). The risks of GI bleeding, acute renal failure, platelet dysfunction, and the like should be considered when reducing fever to decrease metabolic demand, or ICP.

## External Cooling Techniques

External cooling reduces body temperature by increasing heat loss but does not change the TRSP. Therefore, the

hypothalamus sends out feedback stimulation to return core temperature to the TRSP via means such as shivering and vasoconstriction. The net effect can more than offset the gains made by lowering temperature. Accordingly, when external cooling techniques are employed, sedatives and analgesics (which decrease the TRSP) should be used.

Although several single institution trials of hypothermia have shown it to be advantageous in brain-injured patients (116), a larger, prospective, randomized multicenter trial failed to demonstrate such a benefit to hypothermia (117). This negative trial has not eliminated the use of hypothermia to treat brain injury. **Antipyretics are usually the initial treatment for a febrile ICU patient because they are convenient and well tolerated by patients, but external cooling has generally been more successful at lowering core temperature (115).**

External cooling is widely employed for all patient types in critical care units, sometimes by nursing personnel without physician participation in the decision. External cooling in the absence of sedation and/or neuromuscular blockade often results in shivering and increased peripheral vasoconstriction, making it ineffective at lowering temperature. But, if adequate sedation analgesia and/or muscle relaxants are employed, metabolic demands, cardiac output, and heart rate can all be reduced (118). Frequent monitoring of core temperature is required during external cooling to achieve appropriate temperature goals.

## EYE TO THE FUTURE

A number of fundamental questions regarding fever remain unanswered. Of greatest importance to the clinician is whether fever should be treated or not. A major difficulty in answering this question is the difficulty in maintaining close control of the temperature. Failure to eliminate the fever or overly aggressive efforts and hypothermia complicate the interpretation of the results. This is exemplified by studies in TBI patients in whom fever is known to be detrimental, and hypothermia is associated with its own set of complications. Future studies will need to ensure that cooling is initiated early enough, and continues long enough with greater CNS effect (i.e., case of cooling helmet) and use of sedatives and analgesics to drop temperature.

## SUMMARY

Elevation in body temperature has been recognized as a significant diagnostic and therapeutic finding since the beginning of recorded medical history. The obvious diagnostic value of fever in the ICU patient is often complicated by the numerous confounding problems leading to expensive and sometimes excessive testing and the risks of inappropriate antibiotic therapy.

Both fever and infections are common complications in critically ill trauma patients. In this group, temperatures greater than 102°F have a high probability of being the result of an infection, and should be assumed infectious until proven otherwise. A short list of noninfectious causes of fever must also be ruled out in the setting of high fevers (MH, NMS, SS, and the like).

Despite a long history of experimental study, we still cannot say with certainty how we should respond therapeutically to the febrile patient. Only in cases of extreme temperature elevation, such as MH, NMS, or heat stroke, or in patients with acute TBI, or other brain injury, or limited cardiopulmonary reserve should temperature elevations be routinely treated. The optimal method of treating such temperature elevations remains uncertain.

## KEY POINTS

- ☞ Fever is perhaps best defined as: “an elevation in core body temperature  $>1^{\circ}\text{C}$  above the patient’s thermoregulatory set point (TRSP).”
- ☞ In a joint statement of the Society of Critical Care Medicine (SCCM) (10) and the Infectious Disease Society of America (IDSA) (11), fever is defined as a temperature greater than or equal to  $38.3^{\circ}\text{C}$  ( $\geq 101^{\circ}\text{F}$ ).
- ☞ Fever is frequently seen in the initial 48 hours after trauma, burns or surgery; however, such fevers are usually noninfectious in origin.
- ☞ Although infection is unlikely in the first 48 hours following injury, Group A streptococcal infections and Clostridial myonecrosis represent uncommon but important exceptions which can present within this time period.
- ☞ If the temperature exceeds  $38.9^{\circ}\text{C}$ , the patient should be considered to have an infectious etiology until negative cultures demonstrate otherwise.
- ☞ The SS is usually associated with combinations of SSRIs with MAOIs, or MAOIs with TCAs (50,51).
- ☞ After stopping a drug responsible for fever, 48–72 hours are usually required for the temperature to fully normalize.
- ☞ Pancreatitis is one of the classic inflammatory conditions that can cause significant noninfectious fever, with signs similar to sepsis.
- ☞ Patients who have a vasodilated picture, suggestive of sepsis, but in whom sepsis is unlikely, may have adrenal insufficiency. Serum cortisol determination, a cosyntropin stimulation test or even empiric corticosteroid administration may be indicated.
- ☞ Most febrile reactions following transfusions are related to white blood cells (WBC), as leukocyte-depleted blood products have a low rate of this complication (64).
- ☞ Most investigators now recognize that atelectasis does not cause fever in the absence of infection.
- ☞ The most common infectious cause of fever in critically ill patients is ventilator-associated pneumonia (VAP).
- ☞ Seventy percent of nosocomial blood stream infections occur in patients with central venous catheters.
- ☞ Surgical wound infections should be considered in all critically ill trauma patients, and postoperative surgical patients with fever, especially when beginning  $>48$ –72 hours following surgery or trauma.
- ☞ Despite antibiotic prophylaxis, patients with open fractures and fever should have their wounds examined for infections, and if present, incision and drainage should be performed.
- ☞ Postsplenectomy patients should be instructed to keep antien capsulated bacteria antibiotics readily available, to take them at the onset of an acute, febrile illness, and to also seek medical evaluation at that time.
- ☞ The pathophysiology of fulminant meningococemia results from sepsis, vascular collapse, shock, disseminated intravascular coagulation (DIC), and tissue infarcts (101).

- ✂ In the absence of TBI or other CNS injury, temperature elevation between 37°C and 39.5°C may be beneficial.
- ✂ The administration of antipyretics to ICU patients in an effort to reduce fever is common practice but data proving a benefit to this practice is lacking.
- ✂ Antipyretics are usually the initial treatment for a febrile ICU patient because they are convenient and well tolerated by patients, but external cooling has generally been more successful at lowering core temperature (115).

### INTRODUCTION

The development of antibiotics in the second half of the twentieth century led to dramatic reductions in the mortality rates of many infectious diseases. However, the mortality rate of a subset of acute infections associated with shock and organ dysfunction remains high at about 30% to 60% despite modern antibiotics and critical care (1). Septic shock is a relatively common problem; there are about 750,000 cases of severe sepsis due to bacterial or fungal infections each year in the United States (1). The incidence of septic shock is increasing. From 1979 to 1987 the percentage of infectious disease diagnoses that included sepsis increased from approximately 10% to 25% (1). This increase may be due to the increased use of cytotoxic and immunosuppressive drugs, aging of the patient population, the increased use of invasive medical devices, and an increase in antibiotic resistant organisms.

This chapter will review the definition and pathophysiology of sepsis and its molecular mechanisms, as well as the clinical signs and symptoms, laboratory characteristics, inciting infections and therapeutic options. This summary will also include a discussion on the recent successful activated protein C trial for sepsis, as well as a review of several of the trials that failed to improve outcome. Finally, we will present a brief glimpse at promising therapies still on the clinical horizon in the "Eye to the Future" section.

### DEFINITION OF SEPSIS AND RELATED SYNDROMES

In the past, the diagnosis of sepsis required the presence of a positive blood culture in the setting of fever, leukocytosis, and a hemodynamic profile consistent with hypotension or shock. However, disagreements over the essential diagnostic features, variations in sepsis research entry criteria, and the recognition that the systemic response to infection is what differentiates sepsis from mere bacteremia, led to much confusion and debate about diagnostic criteria. In an effort to bring order to this subject, Roger Bone and others organized a consensus conference in 1991 involving the American College of Chest Physicians (ACCP) and the Society of Critical Care Medicine (SCCM) to propose new definitions for sepsis and the related syndromes (Table 1).

The attendees concluded that sepsis is the systemic inflammatory response to documented infection, but also acknowledged, and emphasized, that this response may be observed in a number of other clinical conditions not involving infection (see also Volume 2, Chapter 63). According to the 1991 ACCP/SCCM criteria, sepsis is a subset of the systemic inflammatory response syndrome (SIRS). Similarly, severe sepsis is a subset of sepsis, and septic shock a subset of severe sepsis (Table 1). An individual patient may meet all of these definitions as time progresses. The 1991 ACCP/SCCM criteria have also been widely used to describe SIRS resulting from trauma, surgery, burns, pancreatitis, etc., in the absence of infectious diseases. Because the definition of SIRS is very broad, its clinical utility has been challenged (2,3). In 2001, another consensus conference was convened to review the 1991 ACCP/SCCM definitions and address methods to improve their diagnostic accuracy (4). The group of experts from the SCCM, European Society of Intensive Care Medicine (ESICM), ACCP, American Thoracic Society (ATS) and the Surgical Infection Society (SIS) concluded that there was insufficient data to change the 1991 ACCP/SCCM definitions (4). However, they did recommend expanding the list of signs and symptoms used as diagnostic criteria for sepsis because (i) the clinical presentation is variable and (ii) they resolved that accurate bedside diagnosis was of a higher priority than clear and simple entry criteria for clinical trials (4). The newly expanded diagnostic criteria for sepsis are shown in Table 2.

The 2001 SCCM/ESICM/ACCP/ATS/SIS consensus conference also concluded that the use of biomarkers for diagnosing sepsis may soon be available, but their use is currently premature. Despite this proclamation, they specifically included the biomarkers procalcitonin (PCT) and C-reactive protein (CRP) in their discussions, in their expanded diagnostic criteria for sepsis (Table 2), and in their first iteration of the new staging system for sepsis called PIRO (Table 3) (4). The PIRO system stratifies patients by their "P" predisposing conditions, the nature and extent of the insult (in the case of sepsis "I" infection), the nature and magnitude of the "R" host response and the degree of "O" organ dysfunction.

The PIRO staging system aims to stratify patients by both their baseline risk of an adverse outcome, and their potential to respond to therapy (4). The PIRO system is a work in progress. The inaugural version ranks the patient's predisposition, insult infection, response, and degree of organ dysfunction in terms of currently available factors,

**Table 1** 1991 ACCP/SCCM Definitions and Criteria for SIRS/ Sepsis and Related Syndromes

SIRS/sepsis category	Criteria/comments
SIRS	A widespread inflammatory response to a variety of severe clinical insults (infectious or noninfectious) Recognized by the presence of two or more of the following: Temperature >38°C or <36°C Heart rate >90 beats/min Respiratory rate >20 breaths/min or PaCO <sub>2</sub> <32 mmHg WBC >12,000 cells/μL, <4000 cells/μL, or with >10% immature (band) forms
Sepsis <sup>a</sup>	The systemic response to infection If patient has sepsis, they will then have the clinical signs of SIRS with concrete evidence of infection
Severe sepsis	Associated with organ dysfunction hypoperfusion, or hypotension Clinical manifestations of hypoperfusion may include lactic acidosis, oliguria, or an acute alteration in mental status
Septic shock	Sepsis with hypotension, despite adequate fluid resuscitation, combined with perfusion abnormalities that may include, but are not limited to, lactic acidosis, oliguria, or an acute alteration in mental status
Hypotension	Patients who require inotropic or vasopressor support, despite adequate fluid resuscitation, are in septic shock Defined as a systolic BP of <90 mmHg or a reduction of >40 mmHg from baseline in the absence of other causes for the fall in blood pressure
Multiple organ failure	The presence of an altered organ function in acutely ill patient such that homeostasis cannot be maintained without intervention

<sup>a</sup>Note the criteria for sepsis was expanded in 2001 (Table 2).

Abbreviations: BP, blood pressure; SIRS, systematic inflammatory response syndrome; WBC, white blood cell.

Source: From Ref. 2.

as well as considerations and criteria that are not yet available, but are on the horizon (Table 3).

SIRS and sepsis are usually thought of as an over-exuberant inflammatory response, which is then followed by an anti-inflammatory response. Therefore, many of the attempts to treat sepsis have been directed at blunting the inflammatory response. More recently, some authors have stressed the anti-inflammatory and apoptotic elements of SIRS and sepsis, and suggested that these aspects of sepsis may be suitable targets for therapy (2,3). **SIRS and sepsis are such global responses that focusing on one or a few aspects of the response necessarily oversimplifies the true pathophysiology of the disease.** Nevertheless, targeted therapy can influence the outcome of SIRS and sepsis (see below). SIRS and sepsis affect many organs.

**Table 2** 2001 SCCM/ESICM/ACCP/ATS/SIS Diagnostic Criteria for Sepsis<sup>c</sup>

Diagnostic criteria	Clinically acceptable definitions, and diagnostic ranges
Infection <sup>a</sup>	Documented or suspected, and some of the following <sup>b</sup>
General variables	Fever (core temperature >38.3°C) Hypothermia (core temperature <36°C) Heart rate >90/min or >2 SD above the normal value for age Tachypnea Altered mental status Significant edema or positive fluid balance (>20 mL/kg over 24 hr) Hyperglycemia (plasma glucose >120 mg/dL or 7.7 mmol/L) in the absence of diabetes
Inflammatory variables	Leukocytosis (WBC count >12,000/μL) Leukopenia (WBC count <4000/μL) Normal WBC count with >10% immature forms Plasma C-reactive protein >2 SD above the normal value Plasma procalcitonin >2 SD above the normal value
Hemodynamic variables	Arterial hypotension <sup>b</sup> (SBP <90 mmHg, MAP <70 mmHg, or an SBP decrease >40 mmHg in adults or <2 SD above normal for age) Svo <sub>2</sub> >70% <sup>b</sup> Cardiac index > 3.5 L/min/M <sup>2</sup> <sup>b,c</sup>
Organ dysfunction variables	Arterial hypoxemia (PaO <sub>2</sub> /F <sub>I</sub> O <sub>2</sub> <300) Acute oliguria (urine output <0.5 mL/kg/hr) Creatinine increase >0.5 mg/dL Coagulation abnormalities (INR >1.5 or aPTT >60 sec) Ileus (absent bowel sounds) Thrombocytopenia (plasma count <100,000/μL) Hyperbilirubinemia (plasma total bilirubin >4 mg/dL or 70 mmol/L)
Tissue perfusion variables	Hyperlactatemia (>3 mmol/L) Decreased capillary refill or mottling

<sup>a</sup>Infection defined as a pathologic process induced by a microorganism.

<sup>b</sup>Svo<sub>2</sub>sat >70% is normal in children (normally, 75–80%).

<sup>c</sup>CI 3.5–5.5 is normal in children; therefore, NEITHER should be used as signs of sepsis in newborns or children.

Note: Diagnostic criteria for sepsis in the pediatric population are signs and symptoms of inflammation plus infection with hyper- or hypothermia (rectal temperature >38.5°C or <35°C), tachycardia (may be absent in hypothermic patients), and at least one of the following indications of altered organ function: altered mental status, hypoxemia, increased serum lactate level, or bounding pulses.

Abbreviations: aPTT, activated partial thromboplastin time; INR, international normalized ratio; MAP, mean arterial blood pressure; SBP, systolic blood pressure; Svo<sub>2</sub>, mixed venous oxygen saturation; WBC, white blood cell; SD, standard deviation.

Source: From Ref. 4.

**Table 3** The PIRO System for Staging Sepsis

Domain	Present	Future	Rationale
Predisposition	Premorbid illness with reduced probability of short term survival. Cultural or religious beliefs, age, sex.	Genetic polymorphisms in components of inflammatory response (e.g., TLR, TNF, IL-1, CD14); enhanced understanding of specific interactions between pathogens and host diseases.	In the present, premorbid factors impact on the potential attributable morbidity and mortality of an acute insult; deleterious consequences of insult heavily dependent on genetic predisposition (future).
Insult infection	Culture and sensitivity of infecting pathogens; detection of disease amenable to source control.	Assay of microbial products (LPS, mannan, bacterial DNA); gene transcript profiles.	Specific therapies directed against inciting insult require demonstration and characterization of that insult.
Response	SIRS, other signs of sepsis, shock, CRP.	Nonspecific markers of activated inflammation (e.g., PCT or IL-6) or impaired host responsiveness (e.g., HLA-DR); specific detection of target of therapy (e.g., protein C, TNF, PAF).	Both mortality risk and potential to respond to therapy vary with nonspecific measures of disease severity (e.g., shock); specific mediator-targeted therapy is predicated on presence and activity of mediator.
Organ dysfunction	Organ dysfunction as number of failing organs or composite score (e.g., MODS, SOFA, LODS, PEMOD, PELOD).	Dynamic measures of cellular response to insult—apoptosis, cytopathic hypoxia, cell stress.	Response to pre-emptive therapy (e.g., targeting microorganism or early mediator) not possible if damage already present; therapies targeting the injurious cellular process require that it be present.

*Abbreviations:* CRP, C-reactive protein; HLA-DR, human leukocyte antigen-DR; IL, interleukin; LODS, logistic organ dysfunction system; LPS, lipopolysaccharide; MODS, multiple organ dysfunction syndrome; PAF, platelet-activating factor; PCT, procalcitonin; PELOD, pediatric logistic organ dysfunction; PEMOD, pediatric multiple organ dysfunction; SIRS, systemic inflammatory response syndrome; SOFA, sepsis-related organ failure assessment; TLR, toll-like receptor; TNF, tumor necrosis factor.

*Source:* From Ref. 4.

Table 4 lists some of the more prominent organs involved in sepsis and their role in mediating SIRS. The inflammatory nature of SIRS (without regard to etiology) is the subject matter of Volume 2, Chapter 63, whereas this chapter focuses mainly on the infectious disease etiology of sepsis.

## PATHOGENESIS OF SEPSIS

A major early insight into the molecular mechanisms of sepsis occurred following the recognition that the bacterial cell wall constituents reproduced many of the signs and symptoms of sepsis. Abraham Braude demonstrated that infusion of blood contaminated with cold-growing bacteria, (i.e., unable to grow in vivo) caused sepsis just as effectively as spontaneous bacteremia with organisms that grow at body temperature. He reasoned that bacterial products had to be responsible for sepsis. He focused on bacterial lipopolysaccharide (LPS) because of the epidemiologic association between septic shock and Gram-negative bacteremia that was seen in the 1960s. We now realize that Gram-positive, Gram-negative bacteria and fungi are all associated with septic shock.

✎ **The constituents of microbial organisms that elicit inflammatory responses are collectively known as Pathogen Associated Molecular Patterns (PAMPs) (5).** ✎ Pathogens have molecular structures that are not shared by mammals, but are shared by related pathogens, and are relatively invariant (i.e., do not evolve rapidly). These structures are known as PAMPs. Examples of PAMPs include

flagellin of bacterial flagella, LPS of Gram-negative bacteria, and peptidoglycan of Gram-positive bacteria.

We have recently come to appreciate that the PAMPs are recognized by mammalian Pattern Recognition Receptors (PRRs) that signal the responding cells that PAMPs are present in the environment (6–8). PRRs are found on many cell types, including monocytes, macrophages, dendritic cells, polymorphonuclear phagocytes (PMNs), endothelial cells and some types of epithelial cells. One increasingly understood family of PRRs are the Toll-Like Receptors (TLRs). These evolutionary conserved receptors are homologues of the *Drosophila* Toll gene, and thus named after them. TLRs identify the nature of the pathogen and turn on an effector response appropriate for dealing with it. Mammals have 11 known TLRs, each of which specializes in a subset of PAMPs (often with the aid of accessory molecules). Binding of the pathogen molecule (PAMP) to the TLR initiates a signaling pathway leading to the activation of nuclear factor- $\kappa$ B (NF- $\kappa$ B). NF- $\kappa$ B turns on genes needed for cell proliferation, adhesion, and angiogenesis. NF- $\kappa$ B also turns on various cytokine genes. A new TLR (TLR-11) is expressed in liver, bladder, and kidney and may have a role in protecting against uropathogenic bacteria. Table 5 lists the currently known TLRs and associated PAMPs.

Lipopolysaccharide, also known as endotoxin, is a major constituent of the cell wall of Gram-negative bacteria. It is a glycolipid that usually has a large sugar component on the extracellular face of the cell membrane linked to a glycolipid region that provides osmotic stability to the

**Table 4** Organ Systems Involved in Sepsis and Their Role in Mediating the Inflammatory Response

Organ system	Mediations involved in SIRS and sepsis
Hypothalamic-pituitary adrenal corticoid axis	ACTH → Cortisol
CNS	Fever, obtundation
Peripheral sympathetic and parasympathetic nervous system	Epinephrine Norepinephrine Acetylcholine
Endothelial cells	Early Tissue factor ICAM, VCAM TNF, IL-1, IL-6, NO Late Apoptosis, IL-10, TNF receptors
Monocytes/ macrophages	Early TNF, IL-1, IL-6 Tissue factor MHC class II Late IL-4, IL-10 IL-13 Apoptosis
Liver	Acute phase proteins C-reactive protein IL-6, LPS-binding protein many others
Lung	Acute lung injury ARDS
Kidney	Acute tubular necrosis

**Abbreviations:** ACTH, adrenocorticotrophic hormone; ARDS, acute respiratory distress syndrome; CNS, central nervous system; ICAM, intracellular adhesion molecule; IL, interleukin; LPS, lipopolysaccharide; MHC, major histocompatibility complex; NO, nitric oxide; SIRS, systematic inflammatory response syndrome; TNF, tumor necrosis factor; VCAM, vascular cellular adhesion molecule.

**Table 5** Pathogen-Associated Microbial Patterns and Their Specialized Toll-Like Receptor

TLR #	PAMP	Comments
TLR-1	Lipoproteins	Also bound by TLR-1 and TLR-6
TLR-2	Peptidoglycan, lipoproteins, lipoteichoic acid glucan (fungal)	Peptidoglycan is a cell wall constituent of gram-positive bacteria (e.g., Staph and Strep). Lipoteichoic acid is a constituent of the cell wall. Glucan is a fungal constituent. Another receptor binding glucan is dectin
TLR-3	Double-stranded RNA (dsRNA)	dsRNA genomes belong to such viruses as the Colorado tick fever virus
TLR-4	LPS also known as endotoxin	LPS is located in the outer membrane of gram-negative bacteria (e.g., <i>E. coli</i> , <i>Salmonella</i> ) Other receptors also binding to LPS include MD-2, CD-14, LPS-binding protein
TLR-5	Flagellin	Flagellin is a constituent of the flagella found on many motile bacteria (e.g., <i>Listeria</i> )
TLR-6	Lipoproteins	Also bound by TLR-1 and TLR-2
TLR-7	Single-stranded RNA (ssRNA)	ssRNA genomes belong to such viruses as influenza, measles, and mumps
TLR-8	Single-stranded RNA (ssRNA)	(see above)
TLR-9	Unmethylated CpG of the DNA	CpG islands in mammals are located around "promoters" of genes, and tend to have methyl groups attached.
TLR-10	Unknown	Similar in structure to TLR-1 and TLR-6
TLR-11	Unknown	Found in liver, bladder, and kidney, may have a role against uropathogenic bacteria (i.e., <i>E. coli</i> )

**Abbreviations:** CpG, cytosine phosphodiester guanine (a specific dinucleotide motif of DNA); LPS, lipopolysaccharide; PAMP, pathogen associated microbial patterns; TLR, toll-like receptor.

organism. The glycolipid region, known as lipid A, is responsible for the toxicity of LPS. Infusion of LPS into human volunteers elicits many of the signs and symptoms of septic shock (9). Peptidoglycan is a complex sugar consisting of N-acetylglucosamine and N-acetylmuramic acid units cross linked by pentapeptides. Peptidoglycan is found both in gram-negative and gram-positive bacteria. Lipoteichoic acid is limited to gram-positive bacteria, whereas lipoproteins and flagella are found in both gram-positive and Gram-negative bacteria.

Some of the interactions between PAMPs and PRRs are complex. Optimal recognition of LPS requires a plasma protein that binds LPS (known as LPS binding protein or LBP) (10). LBP catalytically transfers the LPS to a second protein known as CD14 (11). This protein exists both on the surface of macrophages and PMN and circulates in the plasma. Membrane CD14 is part of the macrophage receptor LPS receptor; soluble CD14 is part of the endothelial cell LPS receptor. CD14 binds LPS very well and is needed for a robust LPS response, but it cannot signal the cell that LPS is present, because it lacks a transmembrane region. CD14 associates with PRRs known as Toll-Like Receptor 4 (TLR-4) and an associated protein MD-2 (12,13). TLR-4 is responsible for signaling the interior of the cell that LPS is present in the environment by forming clusters of protein that activate intracellular kinases. Some of the other PAMPs react with more than one type of TLR, so that combinations of PRRs can signal the presence of a specific PAMP (14). Once the TLR has signaled that PAMPs are present within the environment, a complex series of intracellular signaling events is triggered (15). The end result of these signals is the transcriptional activation of many genes. Studies in human dendritic cells demonstrated that roughly 10% of the genes measured had significant changes in transcription levels after exposure to whole *E. coli* bacteria (16). Some of the specific genes that are affected by PAMP interaction with PRR will be discussed.

## The Mammalian Response to Pathogen-Associated Microbial Patterns: The Cells

☛ A wide variety of mammalian cells respond to PAMPs. These include PMNs, blood monocytes, tissue macrophages and dendritic cells. ☛ All these cells express CD14 and TLRs and are major participants in the inflammatory response to PAMPs and microbial infection. The endothelial cell is also responsive to PAMPs. Though it lacks CD14, it responds to LPS via soluble CD14 and TLR-4; the endothelial cell also expresses the other TLRs important for responses to PAMPs (15,17). Epithelial cells, such as respiratory epithelial cells, bladder epithelial cells and many other types of epithelial cells susceptible to infectious organisms, are also responsive to various microbial derived products. Vascular smooth muscle cells, cardiac myocytes and a wide of other cell types also respond to PAMPs.

## Mammalian Response to Pathogen-Associated Microbial Patterns: Genes and Protein Induction

As mentioned above, the transcriptional response to PAMPs is very dramatic. To briefly summarize the response of macrophages, there is a decrease in the transcription of genes associated with phagocytosis and genes coding for PRR (16). Conversely, there is a transient, but dramatic, increase in cytokines (e.g.,  $TNF-\alpha$ ,  $IL-1\alpha$  and  $\beta$ ,  $IL-6$ ,  $IFN-\gamma$ ), chemokines (e.g.,  $IL-8$ ) and receptors for these proteins. Tissue factor expression is also up-regulated. In addition, there is an up-regulation of genes coding for antigen presentation molecules, and genes for enzymes that make reactive oxygen intermediates and reactive nitrogen intermediates. As time progresses, expression of the anti-inflammatory cytokine  $IL-10$  develops, as does expression of genes involved in programmed cell death or apoptosis (16).

The response of endothelial cells is similar with early increases in expression of cytokines and chemokines and increased expression of the surface adhesion molecules. Two of the most well described adhesion molecules are the intercellular adhesion molecule (ICAM) and the vascular cell adhesion molecule (VCAM). In the case of ICAM and VCAM, these adhesion molecules bind to integrins located upon the cell surface of circulating leukocyte (Fig. 1). The binding of these receptors allows the leukocyte to undergo other modifications involved in the immune response to infection.

Other adhesion molecules include tissue factor, and inducible nitric oxide synthase (iNOS) (18–20). Many of the activated genes express proteins that act to stimulate cells further. For example,  $TNF-\alpha$  stimulates macrophages and endothelial cells to produce more  $TNF-\alpha$ ,  $IL-1\alpha$ ,  $IL-6$ , and to activate expression of genes leading to apoptosis, or programmed cell death. The response to microbial infection changes with time: early on, there is a prominent inflammatory response, but as time progresses the response changes to an anti-inflammatory one, with  $IL-10$  production and apoptosis of many cell types becoming predominant (discussed further in Volume 2, Chapter 63).

The induction of inducible iNOS probably plays a major role in the early “warm shock” state sometimes seen. This is low systemic vascular resistance (SVR) in the face of hypotension; often good perfusion of the skin is seen when the central organs are not being adequately perfused. Nitric Oxide (NO) made by iNOS diffuses from the endothelial cell into the adjacent vascular smooth muscle cell and triggers muscle relaxation.

Induction of tissue factor on the surface of endothelial cells and macrophages triggers the coagulation pathway. The expression of tissue factor activates Factor VII to VIIa, which

**Figure 1** Binding of leukocyte and its integrins to the endothelial cell by way of immunoglobulin adhesion molecules during the process of neutrophil migration. During inflammation adhesion molecules promote leukocyte emigration from capillaries through a series of steps involving various adhesion molecules. Rolling of the leukocyte upon the endothelial occurs after binding L-, P-, and E-selectins (not shown). The leukocyte is stopped by binding to ICAM-1 and VCAM-1 (as shown). Shape change and aggregation occurs after binding with LFA-1 receptors (shown in figure). Migration through the endothelial cell wall occurs after binding of ICAM-1, and VCAM-1, as well as others not shown. *Abbreviations:* ICAM-1, intercellular adhesion molecule; LFA, lymphocyte functional antigen-1; Mac-1, macrophage antigen-1, CD11b/CD18; VCAM-1, vascular cell adhesion molecule; VLA-4, very late antigen 4 or CD49d/CD29. *Source:* From Ref. 46.

stimulates the coagulation cascade leading to the formation of fibrin clots. This is the major mechanism by which sepsis triggers disseminated intravascular coagulation (DIC).

Bacterial surfaces, LPS, peptidoglycan and immune complexes activate the complement cascade. This leads to activation of C5 to C5a, which is an anaphylotoxin. This protein elicits PMN chemotaxis, release of granular enzymes from phagocytic cells, vasodilatation, and increased vascular permeability (21).

## DIAGNOSIS OF SEPSIS

### The Clinical Presentation

All physicians have been trained to recognize sepsis. It is a problem that does not respect medical or surgical boundaries. However, definitions tend to be fairly broad. The current and most widely used definitions are shown in Table 1. SIRS has a very broad definition that includes most people with significant infections. In addition, people with pancreatitis, severe trauma or thermal burns can present with SIRS (see Volume 2, Chapter 63). Only a subset of patients with SIRS has sepsis. Conversely, not all patients who are septic have SIRS. Patients who are elderly, those who are chronically ill, and those on corticosteroids or other immunosuppressive drugs tend not to generate as robust of an inflammatory response as young, healthy individuals.

There are a few clinical clues to sepsis that deserve mention. Patients frequently present with an intense feeling of anxiety. Altered mental status is also a condition that should trigger suspicions of sepsis as well as central nervous system disease. Tachypnea is another very early sign of sepsis; tachypnea with a low  $PaCO_2$  and a normal pH suggests that lactic acidosis is occurring. All patients with SIRS should

have a complete and careful physical examination in search of signs of infection and possible sources. The “classic” presentation of septic shock is as “warm shock,” where the patient is hypotensive with warm and well perfused skin and extremities. This state is due to a high cardiac output and low SVR. Later in the course of sepsis, or in patients who can’t increase their cardiac output, the hypotension may become associated with peripheral vasoconstriction, and petechial lesions suggest DIC (e.g., meningococemia). A complete physical may suggest a source of infection that will help focus efforts to collect appropriate cultures and or drain an abscess. Frequent sources of infection in critically ill trauma patients include the lungs (pneumonia), invasive lines, the abdomen (if injured or operated upon—especially if known fecal contamination occurred), and the urinary tract, among others (Table 6). Areas that are often forgotten include the paranasal sinuses (Volume 2, Chapter 51), the throat, the joints, the sacrum (decubitus ulcers), and rectum (peri-rectal abscess).

## The Laboratory Examination

### Standard Laboratory Tests

Patients with SIRS typically have an elevated WBC count with a shift toward immature band forms. However, in some cases the WBC count falls rather than rises (Table 2). The platelet count is variable; low counts suggest DIC (Volume 2, Chapter 58) while high platelet counts are associated with the inflammatory response (Volume 2, Chapter 63). The erythrocyte sedimentation rate (ESR) has long been used as a nonspecific indication of infection or inflammation. Both the ESR and CRP are acute phase proteins, and tend to be elevated, just like those that play a role in the pathogenesis of

sepsis, such as LPS binding protein. Recent studies have tested the ability of other markers to predict the development of septic shock in patients with SIRS. The proteins IL-6, IL-8, and procalcitonin have been investigated as markers of sepsis. One group has shown that an elevated procalcitonin level is a good predictor of sepsis and septic shock (22). These tests are not widely available, and others have suggested that clinical parameters are perfectly adequate predictors (23). The current understanding of CRP and procalcitonin in sepsis and SIRS is more fully developed in Volume 2, Chapter 63.

Currently, there is no clinically useful test for LPS in the blood. Potential reasons for this include the high degree that LPS is bound to serum lipoproteins and a short circulating half-life. Furthermore, since Gram-positive bacteria can cause septic shock, a useful test for LPS could miss as many as 50% of the cases, making LPS a less useful universal test for sepsis, even if available.

In severe sepsis there is a tendency for lactic acid to accumulate so the patient presents with an anion gap metabolic acidosis. Often the patient will have a compensatory tachypnea, lowering the PaCO<sub>2</sub> and almost normalizing the pH. If organ damage develops the laboratory signs of that damaged organ are seen.

✎ **The timely and appropriate collection of cultures is a mainstay of diagnostic management of sepsis.** ✎ The results of cultures are not available immediately, but if cultures are not collected before antibiotics are administered, it is impossible to clinically distinguish patients with bacteremia from those with SIRS due to noninfectious causes. All patients with a diagnosis of SIRS should have blood and urine cultured. If there is a pulmonary infiltrate, sputum Gram stain and cultures should also be obtained.

**Table 6** Sources of Infection in Trauma and Critical Care

Source	Diagnostic criteria <sup>a</sup>	Comments/clinical examples
Lungs (pneumonia) (see Volume 2, Chapter 48)	Pulmonary infiltrate, sputum gram stain and culture identifying specific organism	Aspiration may occur at scene or during resuscitation ALI, ARDS from TRALI, fat emboli, pulmonary contusion, Later >3–5 days, nosocomial organisms (e.g., <i>Pseudomonas</i> , <i>Enterobacter</i> )
Invasive lines (Line sepsis) (see Volume 2, Chapter 49)	Differential blood cultures (catheter and peripheral site), pus and erythema around skin entry site (unless immunosuppressed)	Catheters should be removed whenever infection suspected (do not change over wire).
Abdomen (peritonitis) (see Volume 2, Chapter 50)	Obvious acute abdominal source. Not tolerating tube feeding	Rare unless prior ABD trauma, or prior ABD operation (risk ↑ with spilled visceral contents.) or in cirrhotic patients.
Urinary tract infection (UTI) (see Volume 2, Chapter 46)	Dysuria, frequency, urgency, bacteriuria	Bacterial colonization is common in catheterized patients. Significant UTI more common in immunosuppressed, or those with stone, tumor, clots, or obstruction.
Soft tissue (Abscess → necrotizing fasciitis Volume 1, Chapter 29)	Tenderness, swelling erythema over site, becomes fluctuant with abscess, subcutaneous emphysema and disruption of fascial plane with necrotizing fasciitis	Many sources of skin disruption following trauma and critical care; ↑ risk in diabetes, and immunosuppressed.
Sinus tract (sinusitis) (see Volume 2, Chapter 51)	Headache, purulent nasal discharge, pain over involved sinus(s)	Presence of tubes in nares prolonged supine position all ↑ risk.
Acalculous cholecystitis (see Volume 2, Chapters 35 and 50)	Tenderness over G.B. bed (“Murphy’s Sign”), G.B. wall thickening and sludge on ultrasound	Prolonged GI tract disuse. ↑ risk (i.e., npo +/- TPN).

<sup>a</sup>Fever and leukocytosis are common diagnostic finds for each of these sources.

Abbreviations: ALI, acute lung injury; ARDS, acute respiratory distress syndrome; TRALI, transfusion associated lung injury; ABD, abdomen; GB, gall bladder; npo, non per os (nothing per oral route); TPN, total parenteral nutrition; ↑, increased.

### Microbiology

☞ **In the setting of trauma, most patients with SIRS do not have an infectious source.** ☞ Overall, only about 30% to 40% of trauma patients with SIRS turn out to have an infection (24). In these patients, there is roughly a 50% incidence of infections due to Gram positive bacteria and 50% incidence of infections due to Gram negative bacteria (1,24–26). A breakdown of the most common organisms found in bacteremic sepsis in one typical study is shown in Table 7 (24). The most prevalent organisms are *E. coli* and *Staphylococcus aureus* or coagulase negative, depending on the study). In some ICU settings, yeasts account for 10% of the cases of septicemia, with the majority of these being *Candida albicans* (26). Meningococemia and streptococemia, classic causes of sepsis, are rare compared to these organisms. The primary sources of bloodstream infections are typically the pulmonary tree (40%), the abdomen (32%), urinary system (8%), soft tissue (5%), and intravenous catheters (4%) (24). Patients do not have to be bacteremic to develop sepsis.

Fungemia is a growing cause of sepsis in the ICU setting. This is almost always due to *Candida* species, usually *C. albicans*. Candidemia is most often a nosocomial infection in a patient receiving broad spectrum antibiotics, which affects the normal gastrointestinal flora and allows overgrowth of the yeast. As colonization spreads from the GI tract to the airway, the skin, and the urinary tract, the probability of candidemia increases. Blood cultures for yeast often take several days to be recognized as positive.

The most common parasitic cause of septic shock is malaria. *Plasmodium falciparum* is a very common cause of sepsis in the endemic area and should be considered in travelers to the tropics. The other species of *Plasmodium* are usually not associated with shock.

Viruses are uncommon causes of sepsis except in young children.

### TREATMENT

#### Antibiotic Therapy for Sepsis

One of the first tasks in managing patients with trauma and SIRS is to assess the patient and decide whether they have SIRS or sepsis. Most patients with trauma and SIRS on

**Table 7** Blood Culture Isolates from Patients with Bacteremic Sepsis

	No.	Percentage
<i>Gram positive (n = 473)</i>		
<i>Staphylococcus aureus</i>	180	20
Coagulase-negative Staph.	90	10
Pneumococcus	74	8
Enterococci	46	5
$\beta$ -hemolytic streptococci	34	4

admission to the hospital do not have sepsis (24). Those with a fever, an elevated WBC count with a left shift or signs and symptoms of a localized infection are more likely to have sepsis. Elevated plasma levels of procalcitonin have also been found by one group to be associated with sepsis in patients with trauma (22). The development of SIRS in the hospital raises the level of suspicion that an infection has developed, either as a result of the trauma or a nosocomial infection.

☞ **There is no evidence that antibiotic therapy improves the outcome of SIRS in the absence of sepsis.**

☞ A great deal of money is spent on prophylactic antibiotics in patients with SIRS and these antibiotics have an adverse effect on the antibiotic resistance profile of organisms found in the ICU.

☞ **The distinction between SIRS and sepsis is critical because it triggers the decision tree for the administration of antibiotic therapy.**

☞ Patients with presumed sepsis should all receive antibiotics, while those with SIRS alone should not. The choice of antibiotics depends upon the presumed or known microbiologic source of sepsis (Table 6), the antibiotic sensitivity profile of bacteria in the hospital, allergies affecting that patient, and the antibiotic choices offered by the hospital formulary. For example, in patients with sepsis and evidence of a urinary tract infection, coverage should be focused on Gram-negative rods and/or Enterococci. If there is no clear source of infection, antibiotic coverage should include both Gram-positive and Gram-negative bacteria. The incidence of Methicillin-resistant *Staphylococcus aureus* (MRSA) varies greatly from area to area. In most urban centers, however, the incidence of MRSA is high enough (>15%) to warrant the initial use of vancomycin (until isolates demonstrate sensitivities). Similarly, the antibiotic sensitivity pattern of Gram-negative bacteria is highly variable. In general, a third-generation cephalosporin or an anti-pseudomonal penicillin with a beta-lactamase inhibitor (with or without a quinolone) are reasonable choices for Gram-negative organisms. The low incidence of obligate anaerobes in the bloodstream (Table 7) is probably due to the source of sepsis; in patients with an abdominal source of sepsis obligate anaerobes should be covered as well.

Regarding fungal sepsis, fluconazole is adequate therapy for candida colonization and prophylaxis. However, candida species other than *albicans* are not reliably sensitive to fluconazole. Sepsis due to filamentous fungi is very uncommon, and only occurs in the immunocompromised. Invasive fungal infections require treatment with amphotericin-B, an echinocandin (e.g., caspofungin), or voriconazole (see Volume 2, Chapter 53).

Clinicians should develop reasonable antibiotic treatment strategies to achieve microbial coverage for commonly encountered pathogens and use those antibiotics in the majority of situations. That allows the physician to become familiar with the antibiotic dosages and side effects. One should avoid using unfamiliar or novel antibiotics unless there is a clear rationale for their use. Just as importantly, the results of cultures should be used to modify decisions. If the patient has bacteremic sepsis without a clear source, the antibiotic use can be tailored to treat the organism causing the bacteremia. Volume 2, Chapter 53 provides a review of antibiotic selection for various causes of sepsis. If the patient has no positive cultures and the SIRS are improving, antibiotics can be stopped.

☞ **A major source of sepsis in the ICU is IV catheters.** ☞ Care should be taken to insert all catheters

aseptically, and catheter care should be a part of the daily routine. If the patient develops sepsis in the hospital, blood cultures should be drawn through the central venous and arterial catheters as well as from a peripheral vein. If a decision is made to change an IV catheter a new puncture site should be used to insert the new catheter; changing a catheter over a wire does not decrease the chance of catheter-related bacteremia. Prevention of ventilator-associated pneumonia and urinary tract infections associated with Foley catheters is also important.

### Early Goal-Directed Therapy of Fluids and Vasopressors

A recent study has emphasized the usefulness of early, aggressive and structured therapy with crystalloid and vasopressive agents (27). The study randomized patients to "early goal-directed" therapy versus standard therapy. In those who were treated with the goal-directed therapy, a central venous catheter capable of sensing mixed venous O<sub>2</sub> (ScvO<sub>2</sub>) and an intra-arterial catheter were inserted in the Emergency Ward. The patients were given fluids, vasopressors, or vasodilators to maintain the central venous pressure between 8 and 12 mmHg, the mean arterial pressure between 65 and 90 mmHg, and urine output >0.5 ml/kg/hr and the ScvO<sub>2</sub> >70%. Once these parameters were achieved, SaO<sub>2</sub> >93%, hematocrit >30%, and the cardiac index was maximized by blood transfusion and use of dobutamine in increments of 2.5 µg/kg/min (adjusted every 30 min) to maintain the central venous oxygen saturation at 70% or higher with a maximal dose of 20 µg/kg/min. If these parameters could not be achieved, the patients were sedated and mechanical ventilation was started to decrease oxygen consumption. This therapy was done in the Emergency Ward. After six hours of therapy, the two groups of patients were treated identically. The mortality rate was monitored for 60 days. The group treated with early goal-directed therapy had a dramatically lower in-hospital mortality (30.5%) compared to the standard therapy group (46.5%). The 28- and 60-day mortality rates were also better in the early goal-directed therapy group. This was a relatively small study (263 patients total), but this approach makes a great deal of common sense, should be easy to implement, and is inexpensive.

### Glucose Management

☞ An important recent discovery impacting outcome in sepsis is the importance of tight glucose control in the surgical ICU population (28). ☞ Patients who were treated with an insulin drip to maintain their blood sugar between 80 and 110 mg/dl had a significantly better survival than patients whose blood sugar was allowed to rise to 180 mg/dl before insulin therapy was stated. The incidence of sepsis was also lower in the tight glucose control group (see Volume 2, Chapter 60).

### Corticosteroids

The role of corticosteroids has been studied intermittently for 40 years. It is clear that high dose steroids are not helpful in sepsis. More recently, the finding that some patients had "relative" adrenal insufficiency revived the notion that low dose corticosteroids might be helpful in sepsis. The concept of "relative" adrenal insufficiency is somewhat fuzzy. Patients with SIRS or sepsis tend to have elevated baseline cortisols, which may explain their poor

response to adrenocorticotrophic hormone (ACTH). One small clinical trial has suggested that patients with a blunted response to ACTH (75% of the total) had a lower mortality rate than controls if they were treated with 50 mg hydrocortisone IV every six hour and 50 mg of fludrocortisone orally every day for seven days (29). All patients were enrolled within eight hours of admission to the ICU. There was no difference in the mortality rates in those patients without relative adrenal insufficiency but there was a difference in mortality rate in the whole patient population. This paper supports the use of low dose corticoid therapy. However, it is a single, relatively small study. There is no clear consensus definition of a blunted response to ACTH. The incidence of blunted responses in this study seems extraordinarily high. For all these reasons, the routine use of steroids cannot be recommended. In patients who are on chronic steroids, or those who have adrenal insufficiency, stress dose steroids should be administered.

### Adjunctive Therapies for Sepsis

#### Activated Protein C- PROWESS Trial

☞ Activated protein C is the first useful adjunctive therapy for sepsis documented in a large, international randomized clinical trial (PROWESS: Protein C Worldwide Efficacy Trial in Severe Sepsis) (30). ☞ The rationale for this therapy was that activated protein C (APC) inhibits the clotting cascade at several points and has anti-inflammatory properties (31). The levels of APC are depressed in patients with meningococcal sepsis, and those patients are not able to activate exogenous protein C (32). In the PROWESS trial, patients had to be enrolled within 24 hour of onset of SIRS. Patients with <30,000 platelets, or on therapeutic doses of anticoagulant, those with recent surgery, head trauma, GI bleeding, chronic renal failure, cirrhosis, bone marrow transplants, or HIV infection were excluded. APC was given as a 96 hour continuous infusion. The study showed that 25% of the patients treated with APC died by 28 days after treatment compared to 31% in the control group (P = 0.005). The levels of D-dimer and IL-6 were significantly lower in the APC group than in the control patients. APC therapy improved the outcome in patients with both Gram-positive and Gram-negative sepsis. Those patients older than 50 and with more than one dysfunctional organ had maximum benefit. The incidence of serious bleeding was higher in the APC group than in the control group (3.5% vs. 2%), but did not quite reach statistical significance (P = 0.06).

The PROWESS trial indicates that APC is a useful adjunctive therapy for the treatment of septic shock. There is disagreement among experts about how widely APC should be used. The Food and Drug Administration (FDA) has approved APC for the therapy of septic shock in patients with an Acute Physiological and Chronic Health Evaluation (APACHE II) score >25. There are many issues left unresolved. The drug is expensive, costing \$6000/patient, so it should not be given to patients with SIRS without strong evidence of an infection. Furthermore, many of the exclusion criteria are common clinical situations. If a patient has DIC and platelets of <30,000, should they be excluded? What about patients with chronic renal failure on dialysis, or those who have been treated with a bone marrow transplant? These questions remain unanswered.

It is interesting that another inhibitor of the coagulation pathway, anti-thrombin III, is not an effective therapy for sepsis (33). There is no clear reason why APC is effective and anti-thrombin III is not.

### **Failed Attempts of Adjunctive Therapy**

There have been many other randomized trials of adjunctive therapies for sepsis over the past 30 years and almost all of them have failed to demonstrate any benefit. There are several excellent reviews of these trials (21,34–39). Problems that all of these trials face include heterogeneity of the patient population, uncertainty of the optimal timing of the administration of the potential therapy, uncertainty of the optimal dose of the potential therapy and the use of “all cause mortality” as an endpoint. These trials are also now facing the reduction in mortality rate of sepsis to 30%. Given the severity of some cases of sepsis, it is not clear how much lower the mortality rate can be expected to fall, even with effective adjunctive therapy. The decreasing mortality rate for sepsis increases the number of patients that must be enrolled in a given clinical trial, and therefore, increases the expense and time involved. It is no wonder that the “nearly 40-year history of clinical trials of anti-inflammatory strategies for the treatment of sepsis has been referred to as a ‘graveyard’ for pharmaceutical companies . . .” (21).

Marshall has suggested a rational approach to deciding what compounds should be tested in clinical sepsis trials and how those trials should be done (34). These include testing in a panel of animal models of sepsis, including endotoxemia and sepsis, to ensure that the intervention actually has some promise in preclinical studies. He also suggests that physiologic testing be done for patients with sepsis before an efficacy trial is considered. He also proposes that morbidity, as well as mortality, be considered as an endpoint. We will not extensively review the unsuccessful treatments here, but will briefly touch on a few of the most prominent trials.

### **Anti-endotoxin Therapy with Antibody**

The first trial of anti-endotoxin strategy was done using polyclonal antiserum to a whole bacterial vaccine, using an *E. coli* strain that lacked most of its polysaccharide (40). Patients with Gram-negative sepsis were the population treated, and there was a statistically significant decrease in the mortality rate in those given immune serum compared to those given preimmune serum. This led to the creation of a monoclonal antibody to the lipid A region of LPS, known as HA-1A. HA-1A was tested in two trials. In the first, patients with Gram-negative sepsis were thought to benefit from antibody therapy (41). In a second clinical trial there was no benefit seen (42). Since only 50% of the patients with septic shock have Gram-negative infections, it is perhaps not surprising that this therapy was not effective in the total population. However, subsequent *in vitro* experiments suggested that the monoclonal antibody bound to LPS poorly and did not neutralize its biological activity (43). There are naturally occurring LPS binding proteins. One of these is called bactericidal/permeability-increasing protein (BPI). This is a protein naturally found in the granules of neutrophils. A recombinant fragment of BPI was found to have some activity in meningococcal sepsis, using morbidity as an endpoint (44). The study was underpowered to detect differences in mortality, primarily because so many patients died or became moribund before the study drug could be administered. This study does validate the concept that anti-LPS therapy might work in a disease where endotoxin is the primary PAMP, such as meningococcal disease.

### **Anti-tumor Necrosis Factor Therapy**

The most extensively studied adjunctive treatment for sepsis has been anti-TNF therapy, with either monoclonal antibodies or soluble TNF receptors. The 10 studies investigating anti-TNF therapies have been recently reviewed by Marshall (34). Though some small studies show a trend toward benefit, larger studies show no effect. In one study using a tumor necrosis factor:Fc receptor fusion protein, higher doses of the protein appeared to be associated with increased mortality (45).

### **Nitric Oxide Synthase Inhibitors**

Since Nitric Oxide is a potent vasodilator, there was initially a great hope that inhibition of its formation would be an effective therapy for septic shock. Unfortunately, several different types of NO synthase inhibitors have been tested and found to improve blood pressure and decrease the need for vasopressors but not improve the mortality in sepsis (34).

## **EYE TO THE FUTURE**

Bacterial resistance to antibiotics is an increasing problem in medicine. Improved understanding of the receptors allowing bacterial adherence and virulence are yielding multiple promising areas to focus treatment of sepsis. Indeed, we may soon have techniques for manipulating surface adhesion molecules to either promote leukocyte migration or inhibit bacterial adherence in the first place (46). In addition, the recent success of the PROWESS trial and progress made in understanding the molecular basis of septic and inflammatory mediators has fostered a renewed enthusiasm in the pharmaceutical industry to investigate therapies for sepsis. The interest of physicians in this problem remains high because of the large number of patients who die every year. We will briefly discuss a few promising ideas that are on the clinical horizon, but have not yet been tested in clinical trials.

### **Extracorporeal Blood Purification**

The idea of purifying blood of inflammatory mediators and/or PAMPs by hemofiltration or hemadsorption is an intuitively appealing one. There are a variety of techniques that could be used. Some of these are used in septic patients with renal failure, and they seem to be safe. However, there are no clinical trials to formally assess safety or efficacy (47).

### **High Mobility Group B1 Protein**

High mobility group B1 (HMGB1) protein was initially identified as a nuclear binding protein. It also binds to the macrophage and endothelial cell receptor for advanced glycation end products and activates those cells to produce inflammatory cytokines (36,48). In mouse models of endotoxemia and peritonitis, antibody to HMGB1 protein improved survival (48,49). HMGB1 protein levels are high in patients with sepsis, and in one very small sample, appeared to be correlated with mortality. There are no intervention studies (or clinical trials) in nonhuman primates.

### **Complement C5a and C5a Receptor**

The mannose on bacterial surfaces activates complement through the classical pathway via the mannose binding

protein, and LPS activates the alternative complement pathway. Both pathways generate the C5 peptide fragment C5a, which is a chemoattractant and a pro-inflammatory peptide. Antibody to C5a improved survival in a rat model of peritonitis (50). There are no studies in humans or non-human primates. An obvious hurdle is that C5a at the site of infection is beneficial only for a brief window of time (when sepsis syndrome is overwhelming but bacterial burden is low).

### Apoptosis

The idea that apoptosis of immune cells, antigen presenting cells, and epithelial cells is a critical part of sepsis has become recognized over the past several years (3,51,52). One intriguing finding is that activated protein C activates anti-apoptotic genes in endothelial cells, which may partially explain its activity in sepsis (31). Specific caspase inhibitors have been shown to improve survival in a mouse model of peritonitis (53). This protection appeared to be dependent upon lymphocytes, though lymphocyte-deficient mice were much more susceptible to peritonitis compared to controls.

Two recent studies in septic rodents demonstrated significant survival benefit by inhibiting apoptosis (54,55). The first utilized the knowledge that the protease inhibitor (PI) class of antiretroviral agents is known to prevent apoptosis *in vitro*, and was evaluated in a mouse cecal perforation and ligation (CPL) sepsis model in regards to lymphocyte apoptosis and consequent cytokine production (54). The investigators used a PI mixture consisting of 125 mg/kg nelfinavir (Agouron Pharmaceuticals, La Jolla, CA, U.S.A.) and 13 mg/kg ritonavir (Abbott Pharmaceuticals, Abbott Park, IL, U.S.A.) in 2% ethanol in distilled water or vehicle control (2% ethanol). Mice pretreated with PIs demonstrated improved survival (67%;  $P < 0.0005$ ) compared with controls (17%) and a significant ( $P < 0.05$ ) reduction in lymphocyte apoptosis. Even mice receiving therapy beginning four hours after perforation demonstrated improved survival (50%;  $P < 0.05$ ) compared with controls.

PI therapy is also associated with an increase in the Th1 cytokine TNF- $\alpha$  ( $P < 0.05$ ) early in sepsis and a reduction in the Th2 cytokines IL-6 and IL-10 ( $P < 0.05$ ) late in sepsis; despite no intrinsic antibacterial effects, PI also reduced quantitative bacterial blood cultures. The beneficial effects of PI appear to be specific to lymphocyte apoptosis, as lymphocyte-deficient Rag1<sup>-/-</sup> mice did not experience benefit from treatment with PI. Thus, inhibition of lymphocyte apoptosis by PI is a candidate approach for the clinical treatment of sepsis (54).

The second study demonstrated that the serine threonine kinase Akt over expressed in lymphocytes prevents sepsis-induced apoptosis, causes a Th1 cytokine propensity, and improves survival (55). Findings from this study strengthen the concept that a major defect in sepsis is impairment of the adaptive immune system, and further bolsters the concept that strategies to prevent lymphocyte apoptosis represent an important new avenue of sepsis therapy. Once again, there are no studies of this promising approach in nonhuman primates or human beings.

### SUMMARY

Sepsis continues to be an important problem responsible for the majority of deaths in the ICU. As we enter a new

millennium, the mortality rate is at 30% in the most aggressively and carefully managed patients. It is likely that further progress in this syndrome will be incremental, rather than dramatic. The most important keys to the management of patients with sepsis are careful attention to their fluid and pressor management and judicious use of appropriate antibiotics. Adjunctive therapy with activated protein C should be strongly considered in patients who meet the admission criteria and should be thoughtfully contemplated in some patients who would have been excluded. As in all phases of medicine, prevention is superior to therapy, so preventing nosocomial infections should also be a focus of the ICU practice.

### KEY POINTS

- ✎ SIRS and sepsis are such global responses that focusing on one or a few aspects of the response necessarily oversimplifies the true pathophysiology of the disease.
- ✎ The constituents of microbial organisms that elicit inflammatory responses are collectively known as PAMPs.
- ✎ A wide variety of mammalian cells respond to PAMPs. These include PMNs, blood monocytes, tissue macrophages and dendritic cells.
- ✎ The timely and appropriate collection of cultures is a mainstay of diagnostic management of sepsis.
- ✎ In the setting of trauma, most patients with SIRS do not have an infectious source.
- ✎ There is no evidence that antibiotic therapy improves the outcome of SIRS in the absence of sepsis.
- ✎ The distinction between SIRS and sepsis is critical because it triggers the decision tree for the administration of antibiotic therapy.
- ✎ A major source of sepsis in the ICU is I.V. catheters.
- ✎ An important recent discovery impacting outcome in sepsis is the importance of tight glucose control in the surgical ICU population.
- ✎ Activated protein C is the first useful adjunctive therapy for sepsis documented in a large, international randomized clinical trial (PROWESS: Protein C Worldwide Efficacy Trial in Severe Sepsis).

### INTRODUCTION

Hospital-acquired or nosocomial pneumonia is the second most common nosocomial infection in the United States and is associated with substantial morbidity and mortality (1). Conservative analyses estimate the cost related to increased length of hospital stay and resource utilization to over \$1.5 billion annually (2).

Most hospitalized patients who develop pneumonia have one or more risk factors, including the age of 65 years or more, immuno-suppression, altered-sensorium, significant pre-existing cardiac or pulmonary disease, or have undergone major thoraco-abdominal surgical procedures (3).

Ventilator-associated pneumonia (VAP) is defined as nosocomial pneumonia (NP) in patients who have received mechanical ventilation for a time period of more than 48 hr and did not demonstrate any prior signs or symptoms of pneumonia (4). Although individuals receiving mechanical ventilation do not comprise the largest subgroup among all patients that develop NP, they are at the highest individual risk for this infection. Mechanical ventilation increases the risk for NP in a time dependent fashion by a factor of 6–21 (5).

Recent data from the Centers for Disease Control (CDC) National Nosocomial Infection Surveillance (NNIS) group documents that trauma patients have one of the highest VAP rates (16.2/1000 ventilator days, Table 1) amongst critically ill patients (6).

Therapy of VAP can be difficult due to the involvement of resistant organisms and overall reduced state of health of the host. This contributes to the significant morbidity and high mortality rates. Prevention of VAP through an organized multimodality approach is one of the most important goals in patients receiving mechanical ventilation.

### PATHOPHYSIOLOGY OF VENTILATOR-ASSOCIATED PNEUMONIA

The pathophysiology of VAP is complex and includes host-related, equipment-related, and microbial factors that promote colonization of the tracheobronchial tree, impaired clearance of micro-organisms, and alteration of the local immune response, ultimately leading to pulmonary infection (Fig. 1).

### Ventilator Equipment and Health Care Worker Cross Contamination

Ventilator equipment and health care worker cross contamination have long been implicated in the pathogenesis of VAP via means of aerosolization and inhalation of micro-organisms. The relative risk of contamination contributed by each component in the chain of infection is reviewed in Table 2. Although there are numerous possible equipment related sources of infection, healthcare worker cross contamination is generally a far more important contributor.

Because of the use of filters, the internal machinery of mechanical ventilators is not considered an important source of bacterial contamination of the inhaled gas. Routine sterilization or high-grade disinfection is currently not recommended (7–9). The current generation of filters is capable of protecting the internal pathways from colonization. However, these filters require periodic replacement. Furthermore, if patients are ventilated without the filters in place, high-grade disinfection of the internal machinery is required.

Studies have shown, however, that the external breathing circuit may become colonized with bacteria within 8 to 24 hours of use (9). In an attempt to decrease the rate of VAP the impact of scheduled circuit changes at frequencies ranging from daily to weekly have been studied. No consistent benefit could be demonstrated with these changes and there is some evidence that changes more often than every 48 hours may actually increase the incidence of VAP (10–12). At the same time no data exists that delineates the maximum safe duration of use for the circuit tubing. Given the significant materials and labor costs, routine circuit changes are currently not recommended and when used should not be done more frequently than every 48 hours (13–17).

One of the mechanisms believed important in contaminating the patient's tracheo-bronchial tree is related to accidental spillage of contaminated condensate in the tubing by improper handling. Spillage of condensate should be avoided. No studies have shown consistent benefits of condensate traps versus periodic drainage of the condensate (18,19).

Most hospitals in the US currently use bubble-through or wick humidifiers, which does not produce significant amounts of aerosols. Although inspiratory-phase tubing condensate formation may be increased, there is no data to convincingly show an increase in the rate of VAP. The water in these devices is usually heated to temperatures that reduce bacterial growth; however, it is currently

**Table 1** Ventilator-Associated Pneumonia in the Intensive Care Setting<sup>a</sup>

Type of ICU	Number of ICU's	Ventilator days <sup>b</sup>	Mean VAP rate <sup>c</sup>	Median VAP rate <sup>d</sup>

recommended to use sterile or distilled water when operating these devices to avoid contamination with more temperature resistant species that may be found in tap water (20–24). High-grade disinfection between uses in different patients is recommended (21–25). Condensate formation may be reduced by using heat-moisture exchangers (HME) or hygroscopic condenser humidifiers (HCH, “artificial nose”). Some of these devices are equipped with bacterial filters. The advantage of using such filters is not known, and all of these devices can increase the anatomic dead space and resistance of breathing. Respiratory secretions may lead to partial or complete obstruction and frequent device surveillance is required (26–32). Another relatively new attempt of decreasing inspiratory-phase condensate formation is made through use of heated circuit tubing. To date no studies adequately assess its effect on VAP.

Small volume in-line and hand-held nebulizers for the application of medications can produce bacterial aerosols if they or their circuit access site becomes contaminated through improper handling. It is currently recommended to use sterile fluids for nebulization, disinfect and air dry

the devices between uses, maintain strict aseptic technique when accessing the circuit, and avoid multi-dose vials whenever possible. Under these circumstances these devices are not considered a significant source of aerosol contamination (33–34). It is currently recommended to avoid large volume nebulizers (greater than 500 cc in volume) whenever possible. When used, all equipment should be sterilized or high-grade disinfected between uses or at least every 24 hours (35–38).

✎ **Health care worker (HCW) cross contamination has been shown to play an important role in the pathogenesis of VAP.** ✎ The pathogens that cause NP are ubiquitous in the hospital environment, especially in critical care areas. Transmission occurs via the hands of HCW, improper access to the circuit or patient's tracheo-bronchial tree, as well as improper care of respiratory equipment (3). It is of utmost importance to maintain an aseptic technique when accessing the circuit for the administration of medications, tracheal suctioning, or other manipulations. Washing hands before and after contact and wearing of gloves must be strictly enforced, and spillage of circuit condensate into the patient's tracheo-bronchial tree should be avoided (39–41).

With regard to tracheobronchial suctioning, no studies clearly support the preferential use of multi-use closed system catheters over open systems [single-use catheters, as long as sterile technique (catheter, gloves)] is maintained when using open systems (42–45).

**Figure 1** Pathophysiology of ventilator-associated pneumonia.

### Endotracheal Tube and Tracheal Colonization

✎ **Endotracheal tube (ETT) bio-film formation and tracheal colonization have been acknowledged as potentially significant factors leading to (chronic) tracheo-bronchitis and subsequent lower airspace infection.** ✎ Certain organisms, particularly *Haemophilus influenzae* and Streptococci (group I pathogens, early VAP) as well as *Staphylococcus* spp., *Pseudomonas* spp. and other enteric gram negative bacteria (group II pathogens, delayed VAP) seem to have a greater propensity to colonize the ETT bio-film.

**Table 2** Ventilator Equipment and Health Care Worker Cross-Contamination as a Source of Ventilator-Associated Pneumonia

Cross-contamination mechanism	Relative importance as a contamination-source—comments
Internal machinery of mechanical ventilation	Not a significant source as long as filters are in place.
External breathing circuit	Source of bacterial colonization after 24 hr of use. But not a significant source as long as condensate is frequently emptied (see below) and only one patient is assigned to be ventilated on each breathing circuit.
Spillage of condensate	Large quantities of condensate and exhaled secretions can mix in external tubing. If spilled into patient's trachea, this can represent a large inoculum. Condensate must be emptied frequently.
Humidifiers	Humidifiers can become contaminated. However, with proper disinfection between patients, the use of sterile or distilled water, and frequent emptying of condensate (see above), contamination is minimized.
In-line hand-held nebulizers	In-line nebulizers have been a source of contamination. However, when sterile fluids and strict aseptic techniques are used, these are not a significant source of contamination.
Tracheal-bronchial suctioning	If MDIs are used one MDI is issued per patient.
Healthcare worker cross-contamination	As long as sterile technique is maintained, not a source of contamination. This is the dominant source of patient cross contamination! Infectious secretions can be accessed by the health care worker from all of the above sources, and carried secretions from one patient to the next. Strict hand washing and the use of gloves are mandatory when touching these items, and any others that may be contaminated.

Abbreviation: MDI, metered dose inhalers.

Colonization of the tracheo-bronchial tree was found to precede the development of VAP in the majority of patients (46). In one study, over 70% of patients that developed VAP had identical bacterial isolates recovered from cultures of the ETT bio-film and tracheo-bronchial suctioning. This correlation was not found in patients that did not develop VAP (47). Similar to the ventilator circuit, colonization of the ETT polyvinyl chloride (PVC) material begins within hours after intubation. In this process the bacteria change from a suspension-type to a sessile-type growth mode with formation of a protective glycocalyx layer. Layering of bacteria and polymorphonuclear neutrophils suggests a progressive accretion of respiratory secretions. The sessile bacteria demonstrate greater resistance [higher minimal inhibitory concentration (MIC)] against commonly used antibiotics (48). Local disinfectants (chlorhexidine, hexetidine) demonstrate greater bactericidal activity than standard antibiotic agents against these sessile bacterial concretions (49). Infection of the lower airspaces is believed to result from a progressive descending spread rather than aerosolization of bio-film material. Distal spread is aided by trans-ETT airway manipulations (suctioning) and impaired muco-ciliary clearance of the proximal airways (50). Early colonization (<24 hours) was found to be a significant risk factor (odds ratio 4.1) for VAP in trauma patients (51). Head trauma patients were found to have more than 60% colonization within 24 hours, which may partially explain the higher VAP rates in these patients (52). Late colonization with group II pathogens in some studies has been linked to the prior use of systemic antibiotics; the use of these agents predicted the development of late-onset VAP with an odds ratio of 9.2 (53). Currently, only preliminary data on the use of alternative ETT materials (i.e., silver-coating) is available; although these materials seem to reduce bacterial growth in vitro, their in vivo effect on the incidence of VAP is not clear (54). All of these devices are associated with significant cost and have not yet found widespread utilization in routine clinical practice (54).

### Tracheostomies

The early use of tracheostomies has been proposed as an alternative to ETT to reduce the incidence of VAP. In certain patient populations (neurosurgical patients with Glasgow Coma Scale (GCS) less than nine, multiple-trauma patients, burn patients with inhalations injury) a 20–40% reduction of the mean duration of mechanical ventilation was shown by some authors through the use of early (day 3–10 of mechanical ventilation) tracheostomy (55–58). However, no consistent differences in the incidence of VAP or mortality rates however been demonstrated. Furthermore, in a large prospective study on a mixed ICU cohort, the presence of a tracheostomy carried a significantly increased risk for the development of VAP (odds ratio 6.7) (59).

With a tracheostomy in place the air stream bypasses the physiologic filter and immune surveillance organs of the upper airways. Similar rates of airway colonization and impairment of muco-ciliary clearance as those found with ETTs have been demonstrated (60). In addition, tracheostomies, like ETTs, have low-pressure cuffs and do not prevent (micro-) aspiration of pooled oropharyngeal secretions (61–63). These findings may in part explain the offset of results that could be expected from a reduction in duration of mechanical ventilation. The technique of placement (open surgical vs. percutaneous) does not alter outcomes and both can be associated with significant complications (64). To date no universal recommendations can be made as to when and in what patient population to consider for early tracheostomy (65).

### Oropharyngeal/Gastrointestinal Colonization and (Micro-) Aspiration

Oropharyngeal and gastrointestinal colonization and (micro-) aspiration have long been implicated in the pathogenesis of VAP. The most commonly found organisms in patients with

VAP are believed to be endogenously acquired, and are part of the enteric flora. In radioisotope tracer studies, healthy non-intubated adults were found to aspirate gastric contents 45% of the time (66). The aspiration rate is believed higher in intubated patients, particularly in the presence of oral or nasogastric tubes, with evidence of gastrointestinal dysmotility (i.e., after abdominal procedures), and in those patients with swallowing abnormalities (i.e., prolonged intubation, and depressed consciousness) (67–73).

✦ **Increased colonization of the esophagus and stomach with a bacterial shift towards pathogenic enteric gram-negative species and candida has been demonstrated in critically ill patients.** ✦

### **Gastric pH Elevation vs. Sucralfate for Ulcer Prophylaxis**

Gastric pH elevation (above four) facilitated by antacid, H<sub>2</sub>-blockade, or proton pump-inhibition has been used as ulcer prophylaxis or therapy. However, pH elevation regimens and continuous gastric tube feeding with duodenal-gastric reflux has been shown to lead to gastric bacterial overgrowth (74–76).

A few small clinical trials assessing VAP risk, using sucralfate as an alternative regimen for peptic ulcer prophylaxis, demonstrated lower gastric bacterial counts and a trend towards lower VAP rates with sucralfate use (77–79). Meta-analyses did not show a strong correlation and one study suggested that there might not be a difference in early onset (<4 days) VAP but a significant reduction in late-onset VAP (5% w. sucralfate vs. 16% w. antacids and 21% w. H<sub>2</sub>-blockers) (80–82).

✦ **It is currently recommended to use agents that do not raise the gastric pH in patients with low to moderate risk of upper GI bleeding. Drugs that lower pH are recommended for patients at high risk of upper gastrointestinal bleeding.** ✦

Indeed, it has been well-documented that patients with respiratory failure requiring mechanical ventilation for more than 48 hours have a 15.6-fold increased risk of developing a gastrointestinal bleed, compared with other ICU patients (total study cohort = 2252), and therefore appropriate stress ulcer prophylaxis is of paramount importance (79). In the largest prospective randomized (sucralfate vs. ranitidine) study done to date (n = 1200 patients requiring mechanical ventilation), sucralfate was associated with a higher risk of stress-ulcer-related bleeding (3.8 vs. 1.7%, p = 0.02) and no difference in pneumonia rates was identified (p = 0.19) (83).

### **Selective Decontamination of the Digestive Tract**

Selective decontamination of the digestive tract (SDD) has been suggested for two decades as alternative strategy to address gastro-enteric bacterial colonization and risk reduction for VAP (84–86). Optimal SDD regimens are aimed at reducing colonization with aerobic gram-negative bacilli and *Candida* spp. without altering the (protective) anaerobic flora. Various regimens have used combinations of nonabsorbable antibiotics (i.e., aminoglycosides, polymyxin) or quinolones with Amphotericin B or nystatin, applied (as paste or solution) to the oropharynx or enterally via oral or nasogastric tube, as well as combinations with prophylactic systemic agents (i.e., 2nd or 3rd generation cephalosporins, trimethoprim) (87–92). Two early, prospective, randomized, double-blind trials using bronchoalveolar lavage (BAL) or protected specimen brushing (PSB) for the diagnosis of VAP failed to demonstrate any

significant benefit from SDD in terms of duration of mechanical ventilation, incidence of VAP, or mortality (93,84). However, most studies, including several recent meta-analyses, have shown an overall decrease in nosocomial infections (particularly after abdominal procedures) using SDD. The overall impact of SDD on VAP has been difficult to fully assess because of differences in study designs and populations, as well as non-stringent criteria for the diagnosis of VAP and, for the most part, short follow-up periods (95–97). Formal cost-benefit analyses have not yet been performed, and the development of antibiotic resistance continues to be a theoretical concern. Because of the unknown cost-benefit equation, and the concern for resistant organisms, the recent evidence based guidelines on VAP developed by the Canadian Critical Society did not recommend SDD (98).

### **Enteral Feeding**

Enteral feeding (Volume 2, Chapter 32) has been demonstrated to be beneficial in terms of overall infection rates, organ dysfunction, nutritional status, and outcome in critically ill patients (99–103). However, the presence of oral or nasoenteric tubes and increases of gastric pH caused by continuous gastric feeding have been implemented in the development of VAP. It is currently recommended to routinely verify the position of these tubes in all patients prior to starting feeds; the patient's enteric motility should be assessed routinely by clinical examination and documentation of gastric residuals. Although gastric feeds should be withheld upon evidence of significant gastric pooling (despite motility agents), no data demonstrates a universal benefit of post-pyloric tubes. Similarly, no clear benefit has been demonstrated through use of small-bore tubes. Further distal tubes (i.e., jejunal) and tubes with the combined ability to feed distally and decompress the gastric reservoir (i.e., gastro-jejunoscopy) that bypass the oropharyngeal-esophageal route may be beneficial but have not been studied adequately. All transesophageal feeding tubes should be removed as soon as clinically feasible (69,100). Acidification of gastric feeds has been demonstrated to reduce bacterial colonization of the stomach (104), but no significant difference in the incidence of VAP was demonstrated in a prospective randomized multicenter trial (105). Likewise, no data to date convincingly demonstrates a difference in VAP with the use of bolus versus continuous enteral feeds (106,107). Randomized trials show that the semi-recumbent position (elevating the head of bed  $\geq 30^\circ$ ) compared with the supine position is associated with less gastroesophageal aspiration and pneumonia in patients receiving mechanical ventilation (102,107,108).

### **Oropharyngeal Colonization, Pooling of Secretions, and Micro-Aspiration**

More recently the concept of oropharyngeal colonization, pooling of secretions, and micro-aspiration in the pathogenesis of VAP has drawn some attention. Studies have shown that the currently used high-volume low-pressure ETT cuffs do not prevent leakage of secretions into the trachea. Although the pathogens most commonly responsible for VAP are found only infrequently and in low numbers in the pharynx of healthy individuals, a bacterial shift and colonization similar to that of the stomach occurs in the critically ill (109,110). The likelihood of (early) colonization substantially increases with depressed consciousness, immunosuppression, shock, renal failure, malnutrition, and placement

of oral or nasogastric tubes (111). Bacterial (adherence) factors and alteration of the patient's mucosal defense (surface proteins and polysaccharides, IgA, pH, etc.) improve bacterial adherence and growth (112–115).

✎ **Recent studies have demonstrated significant reductions in VAP (37–69%) and mortality (40–45%) in critically ill surgical and cardiac surgery patients by improving oral hygiene through frequent suctioning of pooled secretions and the use of the topical disinfectant chlorhexidine (116–118).** ✎

### **Specialized Hi-Lo Evac Endotracheal Tubes Assist with Continuous Aspiration of Sub-glottic Secretions**

In mechanically ventilated patients, subglottic secretions pool above the ETT cuff, where they can contaminate the lower respiratory tract and cause pneumonia (119). Recently, a specialized ETT with an additional lumen that terminates in the sub-glottic space above the ETT cuff has been developed to allow for continuous aspiration of sub-glottic secretions (CASS) (120). The Malencrodt Hi-Lo Evac ETT utilizes the CASS principle, and compared to a standard ETT has been shown to reduce the incidence of VAP by up to 75% (120).

However, these tubes are associated with increased material costs, some problems still exist with occlusion of the suction port by respiratory secretions, and benefits for patients that are intubated for less than 72 hours may be questionable (121,122).

### **Pulmonary De-recruitment**

✎ **Pulmonary de-recruitment (atelectasis, alveolar collapse) begins early and is progressive in supine patients receiving mechanical ventilation.** ✎ The weight of the abdominal contents is transmitted preferentially through elevation and dysfunction of the posterior diaphragm to the posterior inferior lung aspects. At the same time the weight of the mediastinum is transmitted posteriorly. This leads to a shift in the ventilation-perfusion (V/Q) zones and relative under-ventilation and vascular congestion of the posterior lung aspects. Thoracic and abdominal procedures significantly interfere with chest and abdominal wall compliance and function and aggravate this problem. The use of higher FiO<sub>2</sub> with associated nitrogen washout as well as loss of surfactant associated with more severe respiratory failure augments the alveolar collapse. Atelectatic areas of the lung are at higher risk for bacterial infection due to increased build up of stagnant secretions. Conventional mode ventilation (low inspiratory to expiratory [I:E] time ratio) and use of positive end-expiratory pressure (PEEP) do not reliably prevent progression of this process. Several strategies have been employed to address this problem but none have been studied rigorously.

Inverse I:E ventilation, higher levels of PEEP, and alternative modes like Airway Pressure Release Ventilation (APRV) may offer strategies for the prevention of progressive de-recruitment in individual patients with adult respiratory distress syndrome (ARDS).

Kinetic Beds [continuous lateral rotational therapy (CLRT)] has been shown to be beneficial (123–128). Turn continuously and slowly between 40–60° off the neutral position to either side along the long axis. Some beds incorporate vibration elements to simulate the effects of chest physiotherapy. The few studies on this subject have yielded variable results and suffered from small patient

numbers and flawed design (no randomization, no clear definitions of pneumonia, no adjustment for confounding factors); these beds carry a significant cost, impose added difficulties in routine patient care, and currently cannot be recommended for routine use (123–128).

Prone positioning therapy has recently evolved as an alternative means to counteract posterior lung de-recruitment and attempt to reverse V/Q mismatching. Patients are positioned on special bed frames that can rotate 180° along the longitudinal axis and are designed to allow access to the face in the prone position (i.e., Stryker frame) or turned and positioned in conventional hospital beds. Several studies have shown improved PaO<sub>2</sub>/FiO<sub>2</sub> ratios, decreased barotrauma and reversal of diffuse posterior atelectasis, faster weaning from mechanical ventilation, and improved outcomes in patients with severe respiratory failure (129,130). However, no studies to date have specifically looked at the impact of this mode of therapy on the incidence of VAP.

### **Duration of Mechanical Ventilation**

✎ **Duration of mechanical ventilation itself may be the single most important risk factor for the development of pneumonia.** ✎ The risk for VAP increases in a time dependent fashion (5). Daily cumulative hazard rates are quoted between 1.3% and 3.3% and the overall risk approached 100% after 30 days of ventilation (131). The time dependent risk increase of VAP does not follow a linear pattern. There is an early steep rise in the incidence of VAP during the first 5–10 days (early VAP) and a second phase of more gradual risk increase at two to three weeks of mechanical ventilation (late VAP). Several studies have now shown clear benefits in terms of VAP reduction (40–60%) and outcome improvement (reduced mortality by more than 40%), employing strategies designed to decrease the duration of mechanical ventilation (132).

The best results may be achieved by combining several preventative strategies that address different aspects of the pathophysiology of VAP. Standardized weaning protocols based on physiologic parameters (Volume 2, Chapter 28) help decrease the duration of ventilation particularly in patients with mild to moderate reversible respiratory failure (133). Intensive chest physiotherapy, patient positioning, and ventilator recruitment maneuvers decrease the progression of atelectasis. Improved oropharyngeal hygiene through suctioning, topical chlorhexidine, semirecumbency, and possibly CASS decrease the impact of upper gastrointestinal (GI) colonization and micro-aspiration. Appropriate nutritional support (avoidance of large gastric volumes, enteral feeding access, motility agents) helps to avoid the complications associated with malnutrition and aspiration. Strict compliance with contamination precautions and aseptic techniques when handling airway-related equipment will decrease tracheo-bronchial inoculation. Prevention of VAP is the foremost goal in any patient receiving mechanical ventilation and requires implementation of institutional multi-specialty programs (118,119,131–134).

## **DIAGNOSIS OF VENTILATOR-ASSOCIATED PNEUMONIA**

### **Clinical Diagnosis**

Consensus regarding the diagnosis of ventilator-associated pneumonia has been difficult to reach in the past. ✎ **The clinical diagnosis of VAP is based on the appearance of new infiltrates on plain chest radiographs, new or altered**

appearance of respiratory secretions, and general signs of infection (i.e., leukocytosis and fever).  $\alpha^6$

### **Radiographic Evaluation of Lung Parenchyma**

Critics of this purely clinical diagnosis concept point out several problems: Plain film chest radiographs are not sensitive and are often inaccurate for the assessment of pulmonary infiltrates (Volume 1, Chapter 16). In the ICU setting the chest radiographs are most often done as portable anterior-posterior films with the patient in a supine position [Figs. 2(top) and 3(top)]. The anterior and posterior costo-diaphragmatic as well as the retro-cardiac and lingular lung areas are difficult to assess. Critically ill patients receiving mechanical ventilation may develop significant regional lung collapse (atelectasis) that can mimic infiltrates on plain chest films. This de-recruitment may be so extensive that patients require increased ventilatory support, develop (low grade) elevated temperatures, and in the past have been labeled with the diagnosis ARDS (Volume 2, Chapter 24) (135–140). Computed Tomography (CT) of the chest better delineates the distribution of parenchymal changes but cannot reliably differentiate between collapse and infiltration (Fig. 3) (141,142).

### **Changed Respiratory Secretions**

As outlined before, essentially all mechanically ventilated patients develop bacterial tracheo-bronchial colonization and altered muco-ciliary clearance with subsequent changes in respiratory secretions (increased amount, purulent appearance, numerous PMNs). Although not well studied in ventilated patients, changes in the character and color of sputum correlates with the degree of bacterial proliferation in the airways. In a recent study in bronchitic patients, “purulent” sputum was much more likely to have pathogenic bacterial growth than “mucoïd.” Additionally, a darkening of the sputum color (from yellowish to brownish) was associated with an increased yield of gram-negative organisms (143). Although tracheo-bronchitis does not necessarily represent pneumonia, the majority of critically ill patients with purulent sputum and tracheo-bronchitis should receive appropriate antibiotic therapy (see Volume 2, Chapter 53).

### **Fever and Leukocytosis**

Fever and leukocytosis are common in critically ill patients and may represent a systemic inflammatory response syndrome (SIRS) due to the underlying illness or trauma (Volume 2, Chapter 46). Other potential sources of infection, particularly of the blood stream (i.e., intravenous catheter related), urinary tract, wounds, and intra-abdominal infections are common in this patient population and must be sought diligently.

### **Transtracheal Aspiration of Sputum and Blood Cultures**

In the past, transtracheal aspiration specimen of sputum and blood cultures have been the gold standard to solidify the diagnosis of NP and VAP (Table 3). The use of blood cultures is problematic for several reasons: The majority of patients who develop VAP (at least initially) do not have a concomitant bacteremia; and at the same time the false negative rate of “routine” blood cultures (most often obtained after a temperature spike to  $\geq 38.5^{\circ}\text{C}$ ) is significant (144). The use of qualitative

**Figure 2** Pulmonary infiltrates representing retained secretions and atelectasis. This series of images depicts a patient a few days after significant blunt torso and extremity trauma. The patient required increasing ventilator support and was (low grade) febrile. The supine anterior-posterior projection plain film chest radiograph (top) shows bilateral opacifications in both upper and lower lung fields, consistent with pneumonia or ARDS. The computed tomography (CT) image of the patient’s chest (middle) shows predominant posterior consolidation consistent with pneumonia of dependent atelectasis. A repeat CT of the same patient after 48 hours of intermittent prone position therapy and intensive chest physiotherapy demonstrates near complete resolution of the above changes. The patient did not require antibiotic therapy. *Abbreviation:* ARDS, adult respiratory distress syndrome.

**Figure 3** Pulmonary infiltrates representing pneumonia. This series of images depicts a patient after motor vehicle crash with significant blunt injury to the head and extremities. The supine anterior-posterior projection plain film chest radiograph (*top*) shows right middle and left lower lobe consolidation. The patient was febrile, and demonstrated leukocytosis and increased sputum production. Aggressive chest physiotherapy did not significantly change the patient's clinical picture. A computer tomographic image of the patient's chest (*bottom*) demonstrates the consolidation and air-bronchograms consistent with pneumonia.

sputum cultures obtained via standard trans-endotracheal tube suctioning techniques is likewise flawed. It is impossible to reliably guide the suction catheter (blindly) to the area in question [segment with infiltrate on chest x-ray (CXR)]; the so-obtained specimen may become contaminated with colonized tracheobronchial secretions. Although, in the presence of late VAP, there may be a  $\geq 70\%$  correlation between the pathogens recovered in tracheo-bronchial secretions and those responsible for pneumonia (145), this correlation is less reliable in early VAP and the true presence of VAP is difficult to establish. Several studies have noted variable sensitivities (44–86%) and specificities (95–52%) with accuracies between 61% and 82% for quantitative endotracheal aspirate cultures (cut-off levels between  $10^3$  and  $10^7$  cells/ml) when compared to histopathologic findings at autopsy (146–150).

In a study of 255 patients, the statistical agreement of classical CDC NNIS diagnosis, Johanson Criteria and MD

Probable diagnostic criteria was analyzed (151). Agreement was poor ( $\kappa < 0.3$ ) for any comparison of diagnostic tools and VAP diagnosis rates varied from 4% to 48% on the same patient set (151).

### Bronchoscopic Guided Protected Specimen Brushing and Bronchoalveolar Lavage

Bronchoscopic guided PSB and BAL both employ the use of bronchoscopy to reach the pulmonary segment(s) of interest. With these techniques, the amount and quality of secretions can be assessed visually at the (sub-) segmental level.

For BAL a known quantity of sterile physiologic saline solution (between 50 and 150 cc) is injected into the (sub-) segmental bronchus and retrieved after three to four respiratory cycles via suction aspiration into a sterile container attached to the bronchoscope (152). In order to obtain a representative specimen, one-fourth to one-third of irrigate must be recovered (152). The lavage fluid is sent for a cell count and differential as well as gram stain and quantitative culture. In prospective studies comparing bronchoscopically guided BAL results, with postmortem histopathologic evaluation sensitivities of  $>80\%$  and specificities of 75% to 100% with positive predictive values of up to  $\sim 95\%$  and negative predictive values of up to  $\sim 89\%$ , were found using quantitative culture cut-off levels between  $10^3$  and  $10^4$  CFU/mL (150). Gram staining of the BAL effluent was negative in  $\sim 94\%$  of patients without VAP and similar results were achieved using cell count and differential with cut-off points of 400,000 cells/mL ( $\geq 50\%$  neutrophils) (153). Other studies found similar sensitivities and specificities for BAL quantitative cultures when comparing it to various methods of clinical diagnosis but less sensitivity ( $\sim 75\%$ ) for initial Gram stain and differential cell count for the diagnosis of early VAP (positive predictive value 100%, negative predictive value  $\sim 75\%$ ) (152,154).

In PSB a special catheter containing a telescoping brush (covered by a coated tip) is advanced into the segment of interest. Pushing off the protective tip deploys the brush and a sample of the distal airway secretions is obtained. The brush is retracted back into the catheter and removed. Quantitative cultures from the brush specimen, using similar cut-off levels as those for BAL, have yielded 75–100% sensitivity and 90–100% specificity for the correct diagnosis of VAP when compared with histopathologic findings (150–165). Critics have argued that guided PSB and BAL are invasive, require a skilled operator, and are associated with significant cost.

### Nonbronchoscopic Protected Catheter Aspirate and Bronchoalveolar Lavage

Recently, non-bronchoscopic protected catheter aspirate and broncho-alveolar lavage have evolved as alternative diagnostic methods (166). Sensitivities for these blind sampling methods have been reported as being somewhat lower (61–72%) than those of the bronchoscopic PSB and BAL, but specificities ranged at a comparable 84–99% in the initial studies (167). Qualitative concordance of the predominant pathogen was demonstrated in 83–93% ( $\kappa > 0.8$ ) when comparing invasive with noninvasive PSB and BAL. Problems with these non-guided techniques are related to the inability to reliably direct the sampling tool to the area of interest and, in the case of BAL, to a higher rate of

**Table 3** Centers for Disease Control Definition of Nosocomial Pneumonia 2002

	Main Criterion <sup>a,b</sup>	Sub Criterion
Criterion 1	Patient has rales or dullness to percussion on physical examination of the chest and at least one sub criterion	New onset of purulent sputum or Change in character of sputum Organisms cultured from blood Isolation of an etiologic agent from a specimen obtained by transtracheal aspirate, bronchial brushing, or biopsy
Criterion 2	Patient has a chest radiographic examination that shows new or progressive infiltrate, consolidation, cavitation, or pleural effusion and at least one sub criterion	New onset of purulent sputum or change in character of sputum Organisms cultured from blood Isolation of an etiologic agent from a specimen obtained by transtracheal aspirate, bronchial brushing, or biopsy Isolation of a virus or detection of viral antigen in respiratory secretions Diagnostic single antibody titer (IgM) or fourfold increase in paired sera (IgG) for pathogen Histopathologic evidence of pneumonia

<sup>a</sup>Pneumonia must meet at least one of the main criteria

<sup>b</sup>*Comments:* Expecterated sputum cultured are *not* useful in the diagnosis of pneumonia but may help identify the etiologic agent and provide useful antimicrobial susceptibility data. Findings from serial chest x-rays may be more helpful than a single x-ray.

*Source Notes:* Nosocomial infection is defined as a localized or systemic condition (*i*) that results from adverse reaction to the presence of an infectious agent(s) or its toxin(s) and (*ii*) that was not present or incubating at the time of admission to the hospital (see reference below). The information used to determine the presence and classification of an infection should be a combination of clinical findings and results of laboratory data and other tests.

*Source:* From Ref. 234.

inadequate sampling (return of inadequate fluid amount, differential cell count demonstrates >5% bronchial epithelial cells) (147,155,168–170).

✎ **To avoid therapy delay, several studies suggest the use of an initial Gram stain obtained via guided or non-guided BAL or PSB as guide to initiate therapy. Sensitivity and specificity are slightly lower than those of quantitative cultures, but positive and negative predictive values are between 70% and 90% (152,160,171).** ✎

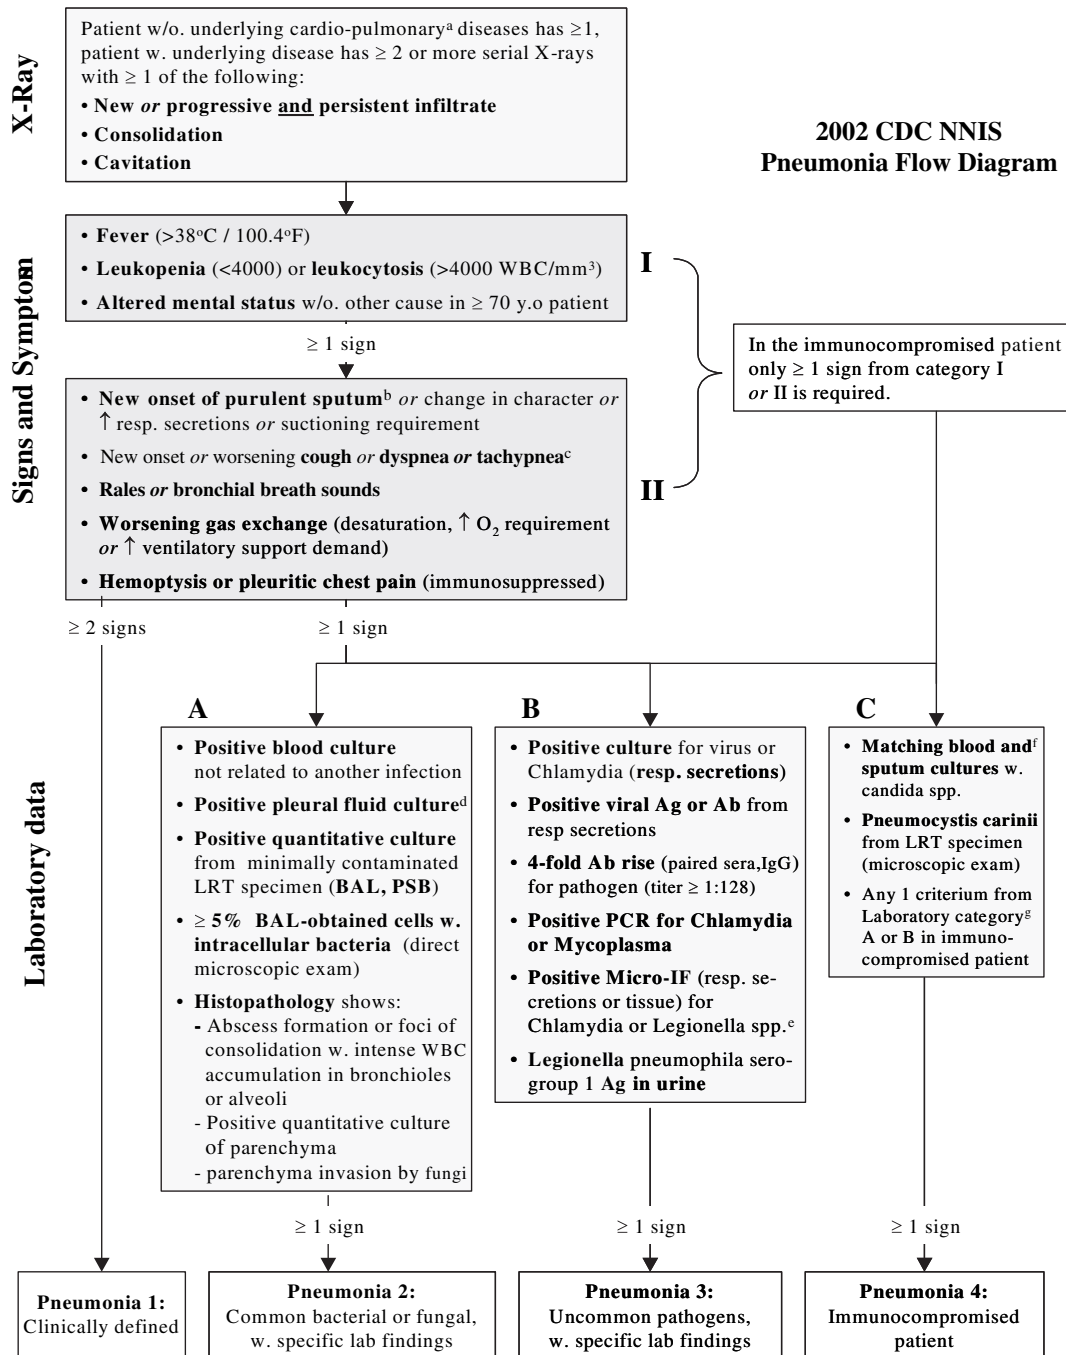

In today's clinical practice a uniform consensus as to which criteria to use for the diagnosis of NP and VAP has not been reached. It is recognized that the early correct diagnosis and initiation of appropriate antibiotic therapy improves outcome (171,172). Similarly, over-diagnosis and indiscriminate use of antibiotics are associated with increased cost and complications. An evidence-based assessment of diagnostic tests for VAP in 2000 concluded that insufficient high-level evidence was available to indicate that quantitative testing produced better clinical outcomes than empiric treatment, and recommended formal outcome research with randomized, controlled trials to assess various diagnostic and management strategies for VAP (171). However, a recent prospective randomized multi-center study from France compared "invasive" (bronchoscope guided) BAL to standard clinical criteria (including suction catheter aspirate) for diagnosis of pneumonia in 413 patients (164). The use of an invasive diagnostic strategy was associated with a decreased mortality at day 14 (16.2% vs. 25.8%,  $p = 0.022$ ); decreased mean Sepsis-related Organ Failure (SOFA) occurs at day 3 and 7, and decreased antibiotic use at day 14 with more antibiotic-free days at day 28 ( $11.5 \pm 9.0$  vs.  $7.5 \pm 7.6$ ,  $p < 0.001$ ) (164). The Canadian Critical Care Trials Group documented similar reductions

of antibiotic usage in a prospective multi-center study on 92 patients receiving mechanical ventilation (173). In that study no difference in ICU length of stay but a decrease in mortality (18.5% vs. 34.7%,  $p = 0.03$ ) were noted. These studies also demonstrated that the clinical diagnosis of VAP could not be confirmed by microbiological data from invasive diagnostic techniques in 22% to 60% and that the initial antibiotic therapy was inadequate in 24–39% of those patients with confirmed VAP (most often due to resistance of Gram negative pathogens to 3rd generation cephalosporins) (173). A Spanish study demonstrated no difference in outcome regardless of the method of microbiological diagnosis (174).

### CDC NNIS Pneumonia Flow Diagram

In an effort to resolve some of the above issues and to create a common language that can be used to compare the results of future studies, the CDC, through the NNIS, has developed a new pneumonia flow diagram that incorporates classic (clinical) diagnostic elements, PSB and BAL as well as the immune status of the host to define four types of pneumonia (175,176) (Fig. 4).

✎ **Invasive diagnosis with BAL or PSB may not be necessary in the normal host that has clear clinical evidence of VAP, an absence of other potential sources of infection, and who responds appropriately to a course of antibiotic therapy. Invasive diagnosis should be considered early in patients that have equivocal clinical signs, in the immunocompromised host, in patients with evidence of severe infection, in patients with ARDS and suspected VAP, in patients who develop late VAP and those who do not respond to therapy.** ✎

**Figure 4** 2002 CDC NNIS Pneumonia Flow Diagram.

<sup>a</sup>Cardio-pulmonary diseases to be considered: congestive heart failure, interstitial lung disease, bronchio-pulmonary dysplasia, respiratory distress syndrome, chronic obstructive pulmonary disease, smoke inhalation, pulmonary injury, etc.

<sup>b</sup>Purulent sputum contains  $\geq 25$  PMNs and  $\leq 10$  epithelial cells per low power field; pure qualitative clinical description is insufficient. A single notation of change in character is not meaningful, repeated notations in a 24 hours period are more indicative of an infectious process

<sup>c</sup>In adults, tachypnea is  $>25$  breaths/min.

<sup>d</sup>Scant or watery sputum is often seen with pneumonia due to viruses and mycoplasma; influenza and RSV may produce copious sputum.

<sup>e</sup>Few bacteria may be seen on stains from resp. secretions from patients with pneumonia due to *Legionella* spp., mycoplasma or viruses.

<sup>f</sup>Semiquantitative or nonquantitative cultures of sputum obtained by aspiration or lavage are acceptable; when sputum and blood cultures are matched, specimen needs to be obtained within 48 hours of each other.

<sup>g</sup>Immunocompromised patients are those with neutropenia ( $<500\text{WBC}/\text{mm}^3$ ), leukemia, lymphoma, HIV infection w.  $\text{CD}_4$ -counts  $<200$ , post splenectomy, post organ transplantation, on cytotoxic chemotherapy, on high dose steroids ( $>40$  mg Prednisone/day or its equivalent) (See Volume 2, Chapter 52).

**Abbreviations:** Ab, antibody; Ag, antigen; BAL, bronchoalveolar lavage; CDC, centers for disease control; IF, immunofluorescence; LRT, lower respiratory tract; PSB, protected brush specimen; PCR, polymerase chain reaction.

## ACUTE RESPIRATORY DISTRESS SYNDROME AND VENTILATOR-ASSOCIATED PNEUMONIA

The diagnosis and therapy of VAP in patients with ARDS is particularly difficult. These patients often require high levels of ventilatory support for prolonged periods of time. They demonstrate diffuse patchy bilateral pulmonary infiltrates on plain chest films. CT scanning is only moderately accurate in differentiating ARDS-related infiltrates from pneumonia with 70% true negative and 60% true positive ratings when evaluated by skilled radiologists (141,142). Fever and leukocytosis from SIRS or an underlying infectious process (often the inciting event for the development of ARDS) are exceedingly common, and a significant proportion of these patients have received prior/concomitant antibiotic therapy. Similarly, patients with ARDS often develop inflammatory-type respiratory secretions and bacterial tracheo-bronchitis, making the interpretation of standard endotracheal aspirate Gram stains and cultures difficult (139).

In a multi-center study by the ARDS Study Group, the incidence of VAP (diagnosed by invasive techniques) among ARDS patients was about 60% higher than that of non-ARDS patients (36.5–55% vs. 23–28%) receiving mechanical ventilation (135). **In ARDS, the combination of an altered local immune response, loss of alveolar wall integrity, and collapse or consolidation of parenchyma with subsequent under-ventilation of these areas are thought to act synergistically in predisposing these patients to the development of VAP.** Pneumonia may develop in several different lung areas at the same time and 40% of patients develop bilateral bacterial growth (137).

Patients with ARDS often require prolonged periods of mechanical ventilation. The incidence of late pneumonia as well as recurrent episodes of infection is high. Only ~10% of the first episodes of VAP occur (or are diagnosed) before day 7 of mechanical ventilation (mean 9.8 +/- 5.7 days) (138). Non-fermenting Gram-negative rods and problem pathogens like (multi-drug resistant) *Pseudomonas* spp., *Acinetobacter*, and *Staphylococcus* spp. are found in over 50% of these patients (144). Patients with bilateral involvement are more likely to have polymicrobial growth and  $>10^5$  CFU/mL in the BAL fluid (140).

It is unclear as to what extent the development of VAP influences the overall outcome of ARDS. Some authors suggest no significant differences in overall mortality whereas others found ARDS mortality increases by a factor of 1.5–2 in patients with VAP (138). We believe it important to maintain a high level of suspicion for VAP in patients with ARDS that develop clinical signs of infection or fail to improve gradually with intensive medical support. Invasive diagnostic methods should be employed early to ensure diagnosis. Empiric antibiotic therapy should cover the common drug resistant pathogens and should be tailored according to culture results as soon as possible (4).

### RISK ASSESSMENT

#### Host-Related Factors

Independent risk factors for the development of VAP include host related factors, like age greater than 65, a higher degree of severity of the acute illness (i.e., APACHE II  $>20$ , odds ratio 4.8), evidence of immunosuppression (i.e., diabetes, steroid use, moderate to severe malnutrition, HIV, bone marrow diseases and organ transplantation), and

significant pre-existing cardiac, renal, vascular, or pulmonary co-morbidity (3).

### Admission Diagnosis

An admission diagnosis of trauma (particularly head trauma), thoraco-abdominal surgery, or significant burns increase the risk for VAP by a factor of 3–5 (177). Other factors, soon after or during admission, that increase the risk of VAP include the need for emergent intubation (odds ratio 6.4) or re-intubation (odds ratio 2.9) during the course of the illness and frank aspiration before or during the intubation process (odds ratio 12.7) (178). The development of initial severe respiratory failure ( $\text{PaO}_2/\text{FiO}_2 < 200$ , odds ratio 3.5), severe acute lung injury (ALI), and ARDS raises the risk of VAP in a similar fashion (179).

### Tracheostomy, Central Lines, Oral Nasoenteric Tubes, Prior Use of Antibiotics

In a large prospective study on 3171 patients admitted to the medical and surgical ICU, the placement of a tracheostomy (odds ratio 6.7) and multiple central venous catheters (odds ratio 4.2) also increased the risk for development of VAP (180). Likewise the presence of oral or nasoenteric feeding tubes and prior use of systemic antibiotic therapy has been linked to the development of VAP (see previous paragraphs) (181–184).

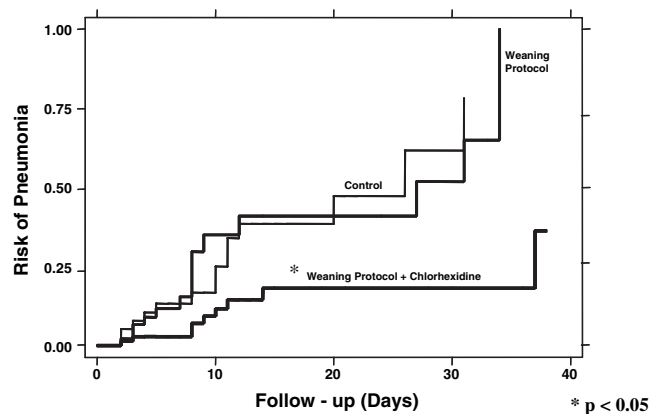

### Duration of Mechanical Ventilation

VAP risk is not static but increases with the duration of mechanical ventilation. Daily hazard rates are quoted between 1.3% and 3.3% and overall risk approaches 100% after 30 days of ventilation (Fig. 5) (179).

Most of these factors cannot be altered acutely in any given patient, but knowledge of the patient's potential risk should heighten the clinician's vigilance to minimize additional risk and employ available preventive strategies.

## MICROBIOLOGY AND ANTIMICROBIAL THERAPY

**The mainstay of therapy in NP and VAP is adequate systemic antibiotic coverage. The antibiotics used**

**Figure 5** Ventilator-associated pneumonia and duration of mechanical ventilation. Cox regression analysis of the risk for development of ventilator-associated pneumonia in relation to the duration of mechanical ventilation. *Source:* From Ref. 116.

should be bactericidal to the suspected pathogen(s), and reach adequate tissue levels in the lung. ⚡ In general it is believed that a large portion of the pathogens responsible for VAP is acquired endogenously, mostly from the patient's enteric Gram negative flora (185).

In 1995 the American Thoracic Society published a set of guidelines for the (initial empiric) treatment of NP, based on the severity of infection, presence of risk factors for specific organisms, and timing of NP occurrence (186). Although the concept may be valid and is still used throughout the country, there are several problems with these guidelines: the original recommendations do not include data derived from the multiple studies on invasive diagnostic techniques, the original selection of antibiotics is outdated since many new agents have been Food Drug Administration (FDA) approved, microbial resistance patterns have shifted, and no specific recommendations regarding duration of therapy were made.

A decade later the updated 2005 Guidelines for the Management of Adults with Hospital-acquired Pneumonia, Ventilator-associated Pneumonia, and Healthcare-associated Pneumonia was published (4). These guidelines are evidence-based and were prepared by an expert committee sponsored by the American Thoracic Society (ATS) and the Infectious Diseases Society of America (IDSA) (4).

⚡ There is a striking difference in the prevalence of individual pathogens between countries, hospitals, and even individual patient care units within each hospital. ⚡ Moreover, studies and aggregate data from the NNIS (Table 4) demonstrate an alarming increase in drug resistant pathogens in the United States (4,6,185).

Patient-related factors, including preexisting pulmonary disease, immune status, type of surgery, prior antibiotic exposure, the timing of the VAP (early vs. late), as well as the severity of the infection, all further influence the spectrum of most likely pathogens (4,186–190).

Inadequate initial therapy (even when begun early) is associated with worse outcomes (191). Therefore, it is of utmost importance to know the patient's clinical history,

severity, and timing of VAP, and locale-specific data prior to making the choice for empiric therapy. Other factors that must be considered include the patient's allergies and cross-allergenicity of certain antibiotic classes, the patient's hepatic and renal function (for dose adjustments), potential interactions of certain antibiotics with other medications, and specific contraindications (i.e., pregnancy, neuromuscular disease, cardiac disease) for certain agents (see Volume 2, Chapter 53 for specific antibiotic guidelines).

In general, antimicrobial therapy is begun empirically when clinical suspicion of pneumonia arises in the ventilated patient. Several studies have demonstrated that early therapy improved outcome (192). Although there is no clear cut-off point, the data suggests that the maximum benefit is achieved when therapy is begun within 8–12 hours of the initial diagnosis (suspicion). Delays of >48 hr have been associated with increased mortality (4,191,182). The current antibiotic guidelines for VAP are summarized in Table 5.

### Early Ventilator-Associated Pneumonia

⚡ Early VAP (occurrence in less than 5–7 days), particularly in trauma patients, is associated most commonly with *Streptococcus pneumoniae* (SP), *Haemophilus influenzae* (HI), Enteric gram-negative bacilli (GNB) and Methicillin Sensitive Staphylococci (MSSA). A prolonged hospital stay prior to intubation and exposure to (broad-spectrum) antibiotics are linked to a higher incidence of *Pseudomonas aeruginosa* (PA), *Acinetobacter* spp., other resistant staphylococci (MRSA) and, possibly, vancomycin resistant *Enterococcus* spp. (VRE). ⚡ In absence of these factors, monotherapy with a β-lactum/β-lactamase inhibitor (with or without antipseudomonal activity), 2nd or 3rd-generation cephalosporin (with or without antipseudomonal activity), newer generation quinolone, or carbapenem all demonstrate equal success rates (4,6,185–189,193).

**Table 4** Ventilator-Associated Pneumonia: Microbial Isolates and Resistance

Organism isolates	NNIS aggregate data			
	1984	1986–89	1990–96	1999
<i>Pseudomonas aeruginosa</i>	17	17	17	18
<i>Staphylococcus aureus</i>	13	16	19	18

**Table 5** Therapy of Ventilator-Associated Pneumonia According to Severity, Risk Factor, Onset, and Most Likely Pathogens

Severity of illness <sup>a</sup>	Risk factors <sup>b</sup>	Onset	Most likely organisms	Core antibiotics
Mild/moderate	Yes	Any time	<i>Pseudomonas aeruginosa</i> (and related species) w. prolonged ICU stay, steroids, prior antibiotics, structural lung disease)	Antipseudomonal cephalosporin (ceftazidime, cefepime) or Antipseudomonal carbapenem (imipenem, meropenem) or B-lactam/B-lactamase inhibitor (piperacillin/tazobactam) PLUS Antipseudomonal fluoroquinolone (ciprofloxacin, levofloxacin) or Aminoglycoside (gentamicin, tobramycin, amikacin)
			Anaerobes- w. recent abdominal surgery or witnessed aspiration	Metronidazole clindamycin is only useful for anaerobic infections above the diaphragm (see Volume 2, Chapter 53)
			<i>Staphylococcus aureus</i> w. coma, head trauma	+/- Vancomycin or linezolid until MRSA excluded; +/- Rifampin
			<i>Legionella</i> on high-dose steroids	Azithromycin or levofloxacin
	No	Any time	Enteric gram-negative bacilli (Non-Pseudomonal) <i>Enterobacter spp.</i> <i>Escherichia coli</i> <i>Klebsiella spp.</i> <i>Proteus spp.</i> <i>Serratia marcescens</i> <i>Haemophilus influenzae</i>	Ceftriaxone or ampicillin/sulbactam or ertapenem
	Yes	Any time	Gram-positive organisms <i>Staphylococcus aureus</i> (MSSA)- <i>Streptococcus pneumoniae</i> <i>Pseudomonas aeruginosa</i> (and related species.) <i>Acinetobacter spp.</i>	Vancomycin plus antipseudomonal fluoroquinolone (levofloxacin, moxifloxacin) See mild/moderate; Positive risk factors
Severe	No	Late onset	<i>Staphylococcus aureus</i> (MRSA)	
		Early onset	See: mild/moderate; no risk factors	

<sup>a</sup>Definition of severe hospital-acquired pneumonia:

Admission to the intensive care unit with:

Respiratory failure (need for FiO<sub>2</sub> >35% to maintain SaO<sub>2</sub> >90% or need for mechanical ventilation

Severe sepsis w. hypotension (SBP <90 mmHg or DBP <60 mm Hg, requirement of pressors >4 hr) and/or endorgan dysfunction (i.e., acute renal failure w. urine output <20 ml/hr for >4 hr)

Rapid radiographic progression, multilobar pneumonia, or cavitation of a lung infiltrate

<sup>b</sup>Patient-related risk factor include severe acute/chron. illness, coma, malnutrition, prolonged hospitalization, hypotension, smoking, COPD, diabetes mellitus, alcoholism, renal failure, advanced age.

<sup>b</sup>Infection control-related risk factor include poor infection control measures, lack of hand washing/universal precautions.

<sup>b</sup>Intervention-related risk factor include medications (sedatives, steroids, antibiotics, antacids, H<sub>2</sub>-blockers), thoraco-abdominal procedures, intubation, nasogastric tubes, and others.

Source: Modified from Guidelines for the management of adults with hospital-acquired, ventilator-associated, and healthcare-associated pneumonia. Am J Resp Crit Care Med 2005; 171:388–415.

### Late Ventilator-Associated Pneumonia Due to Problem Pathogens

In presence of the above factors and with late VAP (occurrence more than 10–14 days), the initial antibiotic coverage should include activity against pseudomonas and take local resistance patterns into strong consideration.

According to a recent international consensus conference, the high prevalence of resistant PA, *Klebsiella pneumoniae* (KP), *Acinetobacter spp.* and *Enterobacter spp.* in these patients may be better treated initially with a combination regimen (aminoglycoside or quinolone plus an anti-pseudomonal extended spectrum β-lactam or carbapenem) (194).

This recommendation has been made despite the lack of large prospective trials comparing mono- to combination therapy with regard to efficacy and outcomes, using clinical and invasive microbiological data (194).

### **Pseudomonas**

VAP due to *Pseudomonas aeruginosa* is associated with a high mortality (195–197). The organism produces several exotoxins and causes invasive infections (195–197,198). The most recent NNIS data demonstrate an alarming 30–50% increase in resistance to the most commonly used antibiotics (Table 4) (6). Monotherapy may lead to a higher incidence of resistance and higher mortality rates in pseudomonal VAP. To date there is still considerable debate as to which combination regimen is best. Aminoglycosides have good bactericidal activity and a prolonged post-antibiotic effect but a narrow therapeutic range, poor penetration into lung parenchyma, and decreased activity with lower pH (abscess) (193). These factors may be responsible for the synergistic advantage found in vitro which is not as obvious in vivo. On the other hand, the combination of  $\beta$ -lactam and quinolone does not demonstrate similar synergistic effects in vitro, but has similar efficacy in vivo (199). Fluoroquinolones reach high levels in most tissues, including lung, pulmonary immune cells and respiratory secretions (200). Antipseudomonal cephalosporins (e.g., ceftazidime or cefepime) and carbapenems have been reserved by most clinicians as second line agents for specific indications. With multi-drug resistant strains of *Pseudomonas aeruginosa*, the use of polymyxin B and/or colistimethate (colistin) may be the only alternative (201). Bacterial eradication may take a long time and overall outcome in resistant pseudomonas cases is worse (197–203).

### **Acinetobacter**

Similar to PA, VAP due to *Acinetobacter baumannii* (AB) is challenging due to extensive resistance (up to >70% to any of the mainstream antibiotic agents) and high mortality rates (198,204–208). The prevalence of this pathogen is highly different between individual units; AB VAP occurs predominantly in patients with significant pre-existing lung disease and after prior antibiotic exposure; it should be suspected mainly in late VAP, with failure to respond to standard treatment regimen and patients with severe infections. Septic shock in these patients is thought to be associated with production of a cell wall endotoxin (204). Like pseudomonas, acinetobacter has the ability to survive in a wide variety of contaminated materials and easily spreads among patients. Treatment must be individualized according to microbiologic data, as soon as possible; most authors agree on the use of combination regimen. Isolation of these patients is important to prevent spread.

### **Extended Spectrum Beta-Lactamase Producing Klebsiella pneumoniae**

Extended Spectrum Beta-Lactamase (ESBL) producing KP is a problem directly related to the extensive use of 3rd-generation cephalosporins (particularly ceftazidime) in the ICU (209,210). Whereas resistance was prevalent in 2% of strains in 1989, to date it has risen five fold. ESBL confers resistance to essentially all 3rd generation cephalosporins, extended-spectrum penicillins and the monobactam, aztreonam. Recent data demonstrates emerging resistance to the quinolones as well (208). In these cases carbapenems become the drug of choice; however, the first

reports on resistance to these drugs are already emerging (209). Interestingly, efforts to reduce the use of ceftazidime (and other 3rd generation cephalosporins) have led to dramatic reductions (from 20–40% to 0–14%) in KP multi-drug resistance over a relatively short time period (207–210).

### **Anaerobes**

Anaerobes may be found in up to 35% of NP but the incidence of VAP is significantly lower (1.1–3.5%). Although it is important to pay attention to adequate sampling (PSB sampling has been recommended) and proper transport (<30 min) and processing of the specimen to avoid false negative results, routine therapy for VAP does not need to include specific anaerobic coverage (211–213).

### **Methicillin-Resistant Staphylococcus**

MRSA is encountered mainly in patients with prior colonization, prolonged hospital stay or duration of mechanical ventilation (>7 days), prior exposure to antibiotics or steroid therapy and significant pre-existing lung disease (COPD) (214). Prior antibiotic exposure and significant COPD were the factors most often associated with MRSA infection (215). The overall incidence of MRSA in VAP is 15–18% (NNIS) and primary empiric therapy with vancomycin or linezolid is probably warranted in patients with the above-mentioned risk factors (6,186,188,195,207, 214–217). A recent prospective study in 340 patients with gram-positive VAP documented that *S. aureus* was the most frequent pathogen isolated, and 68% were MRSA (218). In a double blind study of MRSA VAP with patients randomized to linezolid versus vancomycin, with aztreonam for Gram-negative coverage (219). The cure rates in clinically evaluable patients were 57% for linezolid-treated patients and 60% for vancomycin-treated patients. Although this study demonstrated the relative equivalence of the two drugs, lack of clinical response after five to seven days of treatment using therapeutic levels of vancomycin warrants a switch to linezolid.

Interestingly, patients with altered mental state (i.e., head trauma) are at increased risk of developing (early) infections with MSSA, which is better treated with the semi-synthetic penicillins oxacillin or nafcillin (6,220).

### **Candida spp.**

*Candida* spp. is often recovered in the respiratory specimen of critically ill ventilated patients who have received prior antibiotic therapy. In non-immunosuppressed patients candida seldom causes VAP even when recovered in high colony numbers. One of the important modes of therapy in candidal colonization/suspected infection is to remove foreign bodies (central venous lines, urinary catheters, ETT) and reduce or stop systemic broad-spectrum antibiotics as soon as feasible. Routine antifungal coverage is not warranted, unless the patient is neutropenic or otherwise significantly immunosuppressed (uncontrolled diabetes, high-dose corticosteroid therapy, HIV) or candida is found in multiple sites (i.e., urine, abdominal, blood). Fluconazole (at appropriate doses) will treat all candida species except *C. krusei* and *C. lusitaniae* (194,221).

### **Duration of Antibiotic Therapy**

One of the most important questions regarding VAP treatment relates to the optimal duration of antibiotic therapy. Most studies report treatment courses between 7 and 14 days (4). Longer courses are usually related to selective

(resistant) pathogens or lack of overall patient improvement. Prolonged courses of antibiotic therapy and indiscriminate broad-spectrum coverage are linked to increased adverse effects from the drugs, increased cost, opportunistic infections with resistant bacteria and fungi, *Clostridium difficile* enterocolitis, and overall worse outcomes (4). However, short courses of therapy may be related to treatment failure or relapse, particularly with pathogens that are difficult to eradicate (PA, MRSA, AB, VRE).

In a randomized trial of patients with ventilator-associated pneumonia, Chastre et al. reported patients who received eight days of antibiotic therapy had fewer recurrences and less resistance overall than did patients who received 15 days of therapy (222).

In this context, the importance of obtaining unequivocal microbiological data (BAL or PSB) and adjustment of empiric therapy to local/individual resistance patterns and clinical response to therapy cannot be overemphasized. The adjustment (de-escalation of therapy) should be made as soon as culture results are available (within <72 hours of initiation of therapy).

## OUTCOMES

The development of NP and VAP is associated with significant morbidity and mortality. Crude mortality rates of 20–50% have been documented (4). Attributable mortality rates are reported to be ~30%, and patients that develop VAP demonstrate a 30–50% higher mortality (relative risk increase) than those who require mechanical ventilation but do not develop VAP (223). VAP significantly increases the duration of mechanical ventilation and ICU length of stay (mean two to seven days), and thereby the amount of resource utilization and cost (224). Studies investigating various strategies of VAP prevention (i.e., weaning protocols, chlorhexidine oral decontamination) have demonstrated a reduction in overall mortality by 35% to 60% related to similar decreases in the incidence of VAP in their respective patient populations (118,119,177).

The reported impact on outcome in studies investigating the use of early aggressive invasive diagnosis has been variable. Fagon et al. demonstrated in a large prospective multicenter trial that invasive diagnosis and management reduced death from any cause at day 14 (16 vs. 26%) as well as organ failure scores at days 3 and 7 (225). In that study the group managed by invasive diagnostic strategy had significantly more antibiotic-free days (11.5 vs. 7.5,  $p < 0.001$ ) compared to the clinical group. Several other studies have clearly demonstrated that delays in initiation of appropriate antibiotic therapy (for as little as 48 hr) increased crude mortality rates 20–30% (odds ratio 1.72) (164,172,174). In addition to the early initiation of antibiotic therapy, concentrations of drugs must be adequate, and the choice of antimicrobial agent must be appropriate for the organism(s) present. Indeed, most studies have shown a 50% or more reduction in mortality when appropriate antibiotics are used compared to inadequate therapy (Fig. 6).

To improve outcomes it is important to combine several strategies in the diagnosis and therapy of VAP: in the normal host and in absence of significant confounding factors (i.e., ARDS, significant chronic lung disease, prolonged intubation, prior antimicrobial therapy, or potential other sources of infection) the clinical diagnosis of VAP

**Figure 6** Therapy-dependent ventilator-associated pneumonia mortality. VAP-associated mortality (in %, y-axis) depending on inadequate or adequate systemic anti-microbial therapy. Source: From Ref. 236, 69, 71, 237.

and confirmation with qualitative endotracheal aspirate cultures may be adequate to guide therapy. In all other patients, particularly those with late or recurrent episodes of VAP, consideration should be given to early invasive diagnosis. The decision-making process for initial empiric antibiotic regimen should include microbial data for the specific unit location of the patient, the time point of occurrence (early vs. late), as well as prior patient-specific culture data and antibiotic usage when available. Antibiotic therapy should be combined with intensive chest physiotherapy and strategies designed to wean the patient off mechanical ventilation (4,223–225).

## EYE TO THE FUTURE

Future research in VAP is focused in three main areas: early accurate diagnosis of VAP with microbiology, reduction of duration of antimicrobial therapy for VAP treatment, and, most importantly, prevention of VAP.

### Early Accurate Diagnosis of Ventilator-Associated Pneumonia

Multiple studies have defined that both bronchoscopic and non-bronchoscopic BAL are significantly more sensitive and specific than non-quantitative endotracheal aspirate cultures in the microbiological diagnosis of pneumonia in mechanically ventilated patients. Non-bronchoscopic BAL is a simple, safe, inexpensive bedside procedure, and should be examined in a large multi-center trial to determine if it has equal sensitivity and specificity compared with bronchoscopic BAL. This would greatly simplify the optimal procedure for diagnosis of VAP, and would potentially become a standard for use in all future clinical trials in VAP. At present, VAP studies are a mix of those that use the CDC clinical definition for VAP versus bronchoscopic BAL, making these studies difficult to compare.

Significant advances have been made in the rapid detection of resistant organisms, such as MRSA. A rapid procedure, providing results in less than six hours, was recently reported using multiplex quantitative PCR for the identification of MRSA directly from sterile sites or mixed flora

samples, such as nasal swabs (226). A 96-well format assay allowed analysis of 30 swab samples per run and detection of MRSA with exquisite sensitivity compared to optimal culture-based techniques that require two to three days. New rapid diagnostic technology such as this will allow us to minimize overuse of antibiotics, and employ targeted antibiotic therapy, in attempts to prevent widespread antimicrobial resistance.

### Reduced Duration of Antibiotic Therapy for Ventilator-Associated Pneumonia Treatment

It is clearly evident from the research to date that it is imperative to prescribe initial appropriate antibiotic therapy in VAP treatment, but duration of therapy for VAP treatment remains controversial. Clinicians have commonly used arbitrary durations of antimicrobial treatment ranging from 10 to 21 days. Recent data suggest that other endpoints for defining duration of VAP treatment can be considered, such as the clinical pulmonary infection score (CPIS) (227). Serial measurements of CPIS in VAP patients may help define strategies to shorten duration of therapy for VAP.

### Prevention of Ventilator-Associated Pneumonia

Traditional strategies aimed at prevention of VAP include the use of ventilator weaning protocols to reduce duration of mechanical ventilation and the semi-recumbent position to decrease aspiration incidence. All ICUs should aim to achieve full compliance with these standards that have been documented to reduce VAP.

Recent studies have focused on other innovative strategies to reduce bacterial colonization (228). Modified endotracheal tubes with a port for continuous suctioning of accumulated secretions in the subglottic space (CASS, continuous aspiration of subglottic secretions) have demonstrated potential benefit in small studies, but a large multi-center randomized study has not yet been accomplished. The efficacy of silver-coated endotracheal tubes is being investigated, using silver and hydrogel technology that is commonplace in the use of urinary catheters, and has been associated with reduced incidence of urinary tract infections (229). This has been hypothesized to occur due to the antibacterial properties of silver and its ability to prevent bio-film formation (229). It is well known that bio-films harbor large concentrations of bacteria that display an inherent resistance to therapy with systemically administered antibiotics.

Similarly, other strategies to reduce bacterial colonization in the posterior pharynx have been investigated, including the use of chlorhexidine gluconate oral rinse and protegrins (230). Protegrins are extremely broad-spectrum antimicrobial peptides, active against many bacterial and fungal species, including those resistant to conventional antimicrobial drugs, by attaching to and destroying the integrity of the lipid cell membrane (230). The first protegrin to undergo clinical trial is iseganan hydrochloride oral solution, and is in phase II/III clinical trials for the prevention of VAP (230). Inhaled protegrins are also being investigated for the active treatment respiratory tract infections in cystic fibrosis patients (230).

Noninvasive positive pressure ventilation (NPPV) has been documented to reduce VAP in patients with acute respiratory failure caused by exacerbations of chronic pulmonary disease. Cost reduction associated with NPPV in this group is attributed to the prevention of VAP by avoidance

of endotracheal intubation (230). The benefit of NPPV for patients with acute nonhypercarbic hypoxemic respiratory failure is less clear, and more clinical studies are necessary in this area. The CDC and the Healthcare Infection Control Practices Advisory Committee have developed a comprehensive Guideline for the Prevention of Healthcare-associated Pneumonia 2003, which reviews all potential therapies for prevention of VAP and the available evidence supporting their use (232).

### SUMMARY

Hospital-acquired or nosocomial pneumonia is the second most common nosocomial infection in the United States and is associated with substantial morbidity and mortality. VAP significantly increases the duration of mechanical ventilation and ICU length of stay, and thereby the amount of resource utilization and cost. Most hospitalized patients who develop pneumonia have one or more risk factors, including ages above 65 yr, immunosuppression, altered sensorium, and significant pre-existing cardiac or pulmonary disease, or have undergone major thoraco-abdominal surgical procedures. The pathophysiology of VAP is complex and includes host-related, equipment-related, and microbial factors that promote colonization of the tracheo-bronchial tree, impaired clearance of microorganisms, and alteration of the local immune response, ultimately leading to pulmonary infection. The most important factors contributing to the development of VAP include oro-pharyngeal colonization and micro-aspiration, pulmonary de-recruitment and decreased clearance, prolonged mechanical ventilation, and development of ARDS.

Consensus regarding the diagnosis of ventilator-associated pneumonia has been difficult to reach in the past. The clinical diagnosis is based on the appearance of new infiltrates on plain chest radiographs, new or altered appearance of respiratory secretions, and general signs of infection (i.e., leukocytosis and fever). While this approach may be sufficient for the normal host and in absence of significant confounding factors (i.e., ARDS, significant chronic lung disease, prolonged intubation, prior antimicrobial therapy, or potential other sources of infection), pneumonia is often over diagnosed in critically ill patients, using clinical criteria alone. Protected specimen brushing, and bronchoscopic and nonbronchoscopic bronchoalveolar lavage (BAL) are significantly more sensitive and specific than nonquantitative endotracheal aspirate cultures in the microbiological diagnosis of pneumonia in mechanically ventilated patients and are becoming the standard of care for critically ill patients.

Organized strategies for the prevention of pneumonia in mechanically ventilated patients are of paramount importance, should address various aspects of the pathophysiology of VAP simultaneously, and include most importantly the use of ventilator weaning protocols to reduce duration of mechanical ventilation, the semi-recumbent position to decrease aspiration incidence, the use of improved oro-pharyngeal hygiene (chlorhexidine), and prevention of progressive pulmonary de-recruitment (chest physiotherapy, positioning therapy). Studies have demonstrated reduction in overall mortality by 35% to 60% using these strategies. All ICUs should aim to achieve full compliance with these standards that have been documented to reduce VAP.

The mainstay of therapy in NP and VAP is adequate systemic antibiotic coverage. The antibiotics used should

be bactericidal to the suspected pathogen(s) and reach adequate tissue levels in the lung. There is a striking difference in the prevalence of individual pathogens between individual patient care units within each hospital, and studies and aggregate data from the NNIS demonstrate an alarming increase in drug resistance and prevalence of the problem pathogens in the United States. Patient factors (i.e., pulmonary disease, type of surgery, immune status, and prior antibiotic exposure) and the timing of the occurrence (early vs. late) of VAP, as well as the severity of the infection, further influence the spectrum of most likely pathogens. Inadequate initial therapy, even when begun early, is associated with worse outcomes. Therefore, it is of utmost importance to know the patient's clinical history, severity and timing of VAP, and locale-specific data prior to making the choice for empiric therapy. Empiric therapy should be tailored to the patient-specific pathogens as soon as culture data are available. Duration of therapy for VAP treatment remains controversial; currently arbitrary durations of antimicrobial treatment range from 7 to 21 days. Recent data suggest that shorter duration of therapy may be feasible in uncomplicated VAP and that end-points such as serial measurements of the clinical pulmonary infection score (CPIS) may help define strategies to shorten duration of therapy for VAP (222).

## KEY POINTS

- ✂ Health care worker (HCW) cross contamination has been shown to play an important role in the pathogenesis of VAP.
- ✂ Endotracheal tube (ETT) bio-film formation and tracheal colonization have been acknowledged as potentially significant factors leading to (chronic) tracheo-bronchitis and subsequent lower airspace infection.
- ✂ Increased colonization of the esophagus and stomach with a bacterial shift towards pathogenic enteric gram negative species and candida has been demonstrated in critically ill patients.
- ✂ It is currently recommended to use agents that do not raise the gastric pH in patients with low to moderate risk of upper GI bleeding. Drugs that lower pH are recommended for patients at high risk of upper gastrointestinal bleeding.
- ✂ Recent studies have demonstrated significant reductions in VAP (37–69%) and mortality (40–45%) in critically ill surgical and cardiac surgery patients by improving oral hygiene through frequent suctioning of pooled secretions and the use of the topical disinfectant chlorhexidine.
- ✂ Pulmonary de-recruitment (atelectasis, alveolar collapse) begins early and is progressive in supine patients receiving mechanical ventilation.
- ✂ Duration of mechanical ventilation itself may be the single most important risk factor for the development of pneumonia.
- ✂ The clinical diagnosis of VAP is based on the appearance of new infiltrates on plain chest radiographs, new or altered appearance of respiratory secretions, and general signs of infection (i.e., leukocytosis and fever).
- ✂ To avoid therapy delay, several studies suggest the use of an initial Gram stain obtained via guided or non-guided BAL or PSB as a guide to initiate therapy. Sensitivity and specificity are slightly lower than those of quantitative cultures, but positive and negative predictive values are between 70% and 90%.

- ✂ Invasive diagnosis with BAL or PSB may not be necessary in the normal host that has clear clinical evidence of VAP, has an absence of other potential sources of infection, and responds appropriately to a course of antibiotic therapy. Invasive diagnosis should be considered early in patients that have equivocal clinical signs, in the immunocompromised host, in patients with evidence of severe infection, in patients with ARDS and suspected VAP, in patients who develop late VAP, and in those who do not respond to therapy.
- ✂ In ARDS, the combination of an altered local immune response, loss of alveolar wall integrity, and collapse or consolidation of parenchyma with subsequent under-ventilation of these areas is thought to act synergistically in predisposing these patients to the development of VAP.
- ✂ The mainstay of therapy in NP and VAP is adequate systemic antibiotic coverage. The antibiotics used should be bactericidal to the suspected pathogen(s), and reach adequate tissue levels in the lung.
- ✂ There is a striking difference in the prevalence of individual pathogens between countries, hospitals, and even individual patient care units within each hospital.
- ✂ Early VAP (occurrence <5–7 days), particularly in trauma patients, is associated most commonly with *Streptococcus pneumoniae* (SP), *Haemophilus influenzae* (HI), enteric Gram negative bacilli (GNB) and methicillin sensitive Staphylococci (MSSA). A prolonged hospital stay prior to intubation and exposure to (broad-spectrum) antibiotics are linked to a higher incidence of *Pseudomonas aeruginosa* (PA), *Acinetobacter* spp., and other resistant Staphylococci (MRSA) and, possibly, vancomycin resistant *Enterococcus* spp. (VRE).

## Indwelling Vascular Catheter–Related Infection and Sepsis

Michael G. Seneff and Ahmet Can Senel

Department of Anesthesiology and Critical Care Medicine, George Washington University Medical Center, Washington, D.C., U.S.A.

### INTRODUCTION

Vascular catheterization is the most common procedure performed in critically ill patients (1). Sites of catheterization include the peripheral veins, central veins, large systemic arteries, and pulmonary arteries. Insertion of peripheral venous catheters is usually performed by nonphysician support staff and managed by protocol that includes removal within 72 hours. Limiting peripheral venous catheters to 72 hours or less has virtually eliminated these catheters as a significant source of infectious complications (2,3).

Indwelling central venous catheters are indispensable in caring for the critically ill and are inserted in the majority of patients admitted to the ICU. However, their use comes with the cost of several important complications including catheter-related infection (CRI) and sepsis (4). A developing evidence base supports the use of catheter management protocols. However, many ICUs still do not have modern protocols governing insertion technique, maintenance of catheters, duration of catheterization, or indications for removal. Surveys of catheter management demonstrate a continued wide diversity of practice between institutions, and among ICUs within the same institution, and even among practitioners in the same ICU (5). For example, practices such as routine guidewire exchanges and change of catheter site after 72–96 hours still occur, even though these practices have been shown not to decrease, and in some cases increase, infectious and mechanical complications (6). We believe this diversity in clinical management, frequently involving techniques and practice patterns at odds with a large evidence base, is a result of a concentration on the art (and not the science) of insertion, unstructured methods of teaching, under-appreciation of risks, and habitual physician behavior. This approach can lead to less than optimal ICU management.

Vascular catheterization is an art and a science, but any individual with a reasonable amount of dexterity can learn to insert catheters. Management of catheters in a given patient is a more difficult, decision-making task and requires a physician well versed with recent methodological and technological advances. CRI prolongs hospital stay and increases cost; in the worst case the patient may suffer significant morbidity and even mortality. In this chapter, we focus primarily on percutaneously inserted central venous catheters because they are associated with the highest infectious complication rate. Appropriate, arterial catheters and pulmonary artery catheters (PACs) are also discussed. Surgically implanted central venous catheters and peripherally inserted central catheters are also placed in ICU patients,

but usually for special situations in the chronically critically ill and the interested reader is referred elsewhere for a review of these catheters (7,8). We first define and review the epidemiology of CRI, followed by a discussion of the pathophysiology of and ways to prevent CRI. We then discuss the treatment of established CRI, provide a look at future developments, and conclude with a plea that every ICU director study the literature, establish strict catheter protocols, and monitor adherence in their own units.

### DEFINITIONS, INCIDENCE, AND IMPACT OF CATHETER-RELATED INFECTION

Part of the problem in communication regarding CRI is the disparity in definitions and methods of diagnosis. When does catheter colonization become catheter infection? What's the best method of diagnosing catheter infection? Are blood cultures drawn through central catheters valid? Although controversies still exist, some uniformity and agreement has emerged regarding important concepts. **☞ Semi-quantitative catheter segment cultures are easier to perform, but less specific than quantitative culture techniques for diagnosis of CRI. ☞**

Of several methods exist for catheter segments and hubs, including direct gram staining (9), acridine-orange staining (10–12), qualitative broth culture (13), semi-quantitative catheter segment culture (14), and quantitative catheter cultures (15); the latter two are the most commonly utilized and documented in published studies. Rolling a catheter segment on an agar plate performs semi-quantitative cultures, while submerging the catheter segment in broth performs quantitative cultures. Semi-quantitative cultures are generally easier to perform, but are less sensitive and less specific for diagnosing true CRI and bacteremia (16), due in part to the fact that quantitative cultures sample both the external and intra-luminal parts of the catheter. Both of these techniques involve removal of the catheter. However, the “paired” quantitative blood culturing technique has been developed for diagnosis of CRI without removing the catheter, as might be indicated in a patient with limited access. This technique involves paired blood samples, one obtained through the central catheter and the other from a peripheral venipuncture site. Approximately 1.0 ml of the drawn blood is then added to a molten agar pour plate. The number of colonies of bacteria growing on the pour plate from each sample is compared. In some studies, time elapsed before the culture becomes positive is also evaluated (17,18).

## Definitions

The spectrum of CRI includes catheter colonization, catheter infection, and catheter-related bacteremia (CRB), as described in Table 1. The term catheter-related sepsis is typically reserved for patients with sepsis [i.e., systemic inflammatory response syndrome (SIRS) due to infection] caused by CRI.

Catheter colonization is defined as  $\geq 15$  colony forming units (CFU) on semi-quantitative or  $\geq 10^3$  on quantitative culture of the intradermal or distal catheter segment, in the absence of accompanying signs of inflammation at the catheter site. Catheter infection (also referred to as local CRI) is defined as  $\geq 15$  CFU with accompanying signs of inflammation, such as erythema, warmth, swelling, and tenderness. Local CRI can be limited to the exit site and involve the pocket of a totally implantable device or the subcutaneous tunnel of a surgically implanted catheter. Catheter-related bacteremia is present when a peripheral blood sample and a catheter segment culture are positive for the same organism, in a patient with clinical symptoms of bloodstream infection and no other apparent source of infection. If paired quantitative blood cultures are being utilized, catheter infection is considered present if the central catheter

sample is positive and the peripheral sample negative, while CRB is diagnosed if the colony count from the central catheter is five to tenfold greater than the peripheral blood colony count (19).

## Incidence of Catheter-Related Infection

It is difficult to define the true overall incidence of CRI because it is impacted by so many different variables, including type of ICU, type and composition of catheter, duration of catheterization, method of insertion, and site of insertion. That is part of the reason CRI rates vary greatly between reports and institutions, but some estimates are possible, and all of the figures are staggering. Utilizing the above definitions, CRI occurs in 3% to 9% of all percutaneously inserted catheters in the ICU, and 90% of these are related to central venous catheters. This translates into between two and eight episodes of infections per 1000 central catheter days, the most relevant benchmark (20,21). Arterial catheters have a much lower incidence of infection, whereas specialty catheters, such as hemodialysis catheters, are associated with an increased incidence of infection. Pulmonary artery catheter infection rates are similar, assuming they are removed within 72–120 hour (21).

**Table 1** Definitions of Catheter-Related Infection

Infection Type	Definition
Catheter colonization	$> 15$ colony forming units (cfu) (semiquantitative culture) or $> 10^3$ (quantitative culture) of a catheter segment (or hub) without associated clinical symptoms of infection
Catheter infection	
Exit-site infection	Erythema, tenderness, warmth, induration, or purulence involving only the catheter skin exit site
Pocket infection	Erythema, tenderness, and/or necrosis of the skin over the reservoir of a totally implanted device and/or purulent exudate in the subcutaneous pocket
Tunnel infection	Erythema, tenderness, warmth, and induration involving the subcutaneous tract of a tunneled catheter
Bloodstream infection	
Infusate-related	Growth of the same organism from infusate and from separate percutaneous blood cultures, with no other identifiable source of infection. Often an unusual gram negative organism in an epidemic setting
Catheter(device)-related	Growth of the identical organism on a catheter segment and from a separate percutaneous blood culture in a patient with clinical symptoms of infection and no other identifiable source

## Magnitude of Morbidity from Catheter-Related Infection

Approximately 5 million central venous catheters are inserted annually, accounting for 15 million central venous catheter days, which means there are between 150,000 and 450,000 episodes of CRI each year. On average, CRI, and especially CRB, are associated with considerable morbidity, including an attributable mortality of zero to 30%, prolonged hospitalization (up to 7 days), and thousands of dollars (one estimate as much as \$ 50,000 per episode) in increased costs (22–26).

### ♣ Seventy per cent of nosocomial bloodstream infections occur in patients with central venous catheters. ♣

An analysis of the data by Wenzel and Edmond is particularly eye opening (27). They report that of the 200,000 nosocomial bloodstream infections (NBSI) that occur annually, 70% occur in patients with central venous catheters. Assuming an attributable mortality of 10% to 30%, NBSI represent the fourth to thirteenth leading cause of death in the U.S., a large percentage of these directly a result of central venous catheters. They also put into perspective the importance of measures proven to reduce CRI and NBSI, estimating that the use of new catheter technologies (antiseptic or antibiotic-coated and impregnated) could result in 4,000–9,000 lives saved annually (Table 2) (27,28). By their estimates, simple measures such as increased hand-washing could save between 1000–2000 lives annually (27,29). Even using the most conservative figures, it is obvious that every ICU, and especially surgical and trauma units where CRI rates usually trend higher (30), should have strict catheter protocols and strategies in place to minimize the incidence of CRI.

## PATHOPHYSIOLOGY OF CATHETER-RELATED INFECTION/SEPSIS

♣ Most CRI is initiated by skin (site) colonization, followed by migration down the catheter tract, involving the bio-film

**Table 2** Estimate of Potential Number of Lives Saved Using New Catheter Technologies

Attributable mortality rate (%)	Expected central venous catheter-related deaths from blood stream infection	No. of deaths assuming new catheters prevent 45% of deaths	No. of lives saved
15	10,500	5755	4745
20	14,000	7700	6300
25	17,500	9625	7875
30	21,000	11,550	9450

Note: See text for details.

### surrounding the catheter and ultimately infection of the catheter tip, bacteremia, and metastatic infection. ✎

The pathogenesis of CRI has been better elucidated in recent years. Most CRI (60–75%) is initiated by skin colonization, followed by migration of the infecting organism around the catheter through the intra-dermal tract (30–34). The organism(s) then become part of a bio-film coating the catheter, and once the catheter and tract are involved, quickly migrate to the catheter tip. Once infected, the catheter acts as an intra-vascular source of infection with potentially continuous bacteremia and risk for metastatic infection. Colonization of the hub and intra-luminal migration of bacteria may be more important in long term catheters, but represents the etiology of CRI in only about one fourth of infected percutaneous catheters (35–37). Secondary infection of catheters from bacteremia of another source, or contaminated infusate, occurs much less frequently.

An understanding of the pathophysiology explains many clinical features of CRI and why certain preventive strategies are effective. Catheters associated with thrombosis are more likely to be infected because the clot is part of the biofilm, supports growth, and impedes defense mechanisms (38–40). Triple lumen catheters have a higher rate of CRI than single lumen catheters, but it is not three times higher and may be more related to disease severity (41,42). Catheters inserted through or adjacent to a highly contaminated or abnormal skin site, such as burns or tracheostomies, have a higher incidence of infection. Finally, any intervention that more thoroughly sterilizes the skin site (chlorhexidine) (43), impedes migration of bacteria (silver-impregnated cuffs) (32,44), prevents formation of a bio-film (catheter composition, heparin), or inhibits bacterial growth on the catheter (antiseptic and antibiotic coated and impregnated catheters) (45) logically should reduce the overall incidence of CRI. Most of the recent advances in catheter maintenance discussed below were developed with the primary pathogenesis of CRI in mind.

## PREVENTION OF CATHETER-RELATED INFECTION

✎ Simple measures of prevention such as handwashing with an alcohol-based solution or gel could save 1000–2000 lives annually. ✎

Strict adherence to hand-washing and aseptic technique remains the cornerstone to prevention of CRI (46,47). Catheters inserted under suboptimal conditions (such as in

an emergency) should be removed as soon as feasible (within 24 hours at the latest). Additional strategies shown to minimize CRI are summarized in Table 3, and discussed in greater detail below.

### Operator Education and Standardization

Numerous studies have demonstrated the effectiveness of educational and quality improvement programs for physicians and nurses in reducing CRI (5,48–50). These programs educate caregivers about recent improvements in infection control and lead to standardization in technique and catheter maintenance. Whether hospital- or specifically ICU-based, these programs should be mandatory for any physician inserting catheters, and updated on an annual basis. At our hospital, we incorporate a catheter education program during hospital house-staff orientation, reinforce concepts during ICU rotation with specific lectures and supervision, and monitor continuously for compliance. Likewise, an active surveillance program for CRI and overall infection control is instrumental in early recognition of CRI. Each institution should have their CRI rates expressed in per 1000 catheter days to measure the impact of institutional

**Table 3** Steps to Minimize Catheter-Related Infection

Strict adherence to catheter insertion and maintenance protocols
Site preparation with chlorhexidine-based preparation
Appropriate site selection, avoiding heavily colonized or anatomically abnormal areas; use subclavian veins for anticipated catheterization of >5 days
Maximal barrier precautions during catheter insertion
Use of antiseptic or antibiotic impregnated/coated catheter for anticipated duration of >4 days
Remove pulmonary artery catheters/introducers after 5 days
Use multilumen catheters only when indicated, remove when no longer needed
Avoid routine guidewire exchanges
Use surgically implantable catheters or peripherally inserted central catheters for anticipated long term (>2–3 weeks) catheterization
Hospital-wide CRI reduction education programs
Active infection control and quality improvement programs

Note: Strategies demonstrated to decrease the incidence of CRI. See text for details.

protocols, new catheter technologies, and for comparison to national benchmarks (21).

### Strict Indications for Central Access Limits Catheter-Related Infection

The best way to prevent CRI is not to insert a central venous catheter. Central and arterial catheters are overutilized and often placed for convenience or as an automatic/habitual behavior. Indications for gaining central venous access are shown in Table 4, and should be followed closely. The table is important as much for what is not listed as what is. Fluid resuscitation alone is a less robust indication for central venous catheters because it can be accomplished quicker in emergencies using peripheral catheters. Determination of CVP as a sole indication for central venous catheters is controversial, given the limitations of CVP as a reflection of intravascular blood volume. Pulmonary artery catheters are probably also overutilized, and should be reserved for established indications (51). Most importantly, patients should be monitored daily as to continued need for central venous catheters, arterial catheters, or PAC, and these catheters should be withdrawn immediately when no longer indicated.

### Site Selection

✎ The sub-clavian approach is preferred for limiting CRI, because it can be performed (or supervised) safely by experienced operators and is associated with a lower incidence of CRI than jugular or femoral catheters. ✎

Although there are many technical variations, most central venous catheters and PACs are inserted with a sub-clavian, jugular, femoral, or antecubital (peripherally inserted central catheters) approach, and arterial catheters with a radial, ulnar, femoral, dorsalis pedis, or brachial approach. Which site is chosen in any given patient depends on many variables, including operator experience, indication for catheterization, presence or absence of pulmonary disease, and local skin conditions (Table 4). Whenever possible the sub-clavian approach is

preferred for moderate to long duration catheterization, because it can be performed (or supervised) safely by experienced operators and is associated with a lower incidence of CRI than jugular or femoral catheters (52–56). We reserve the jugular approach for shorter duration use and typically remove after 5–7 days. We utilize the femoral vein mainly for emergency resuscitation and temporary hemodialysis. The lower incidence of CRI with sub-clavian catheters is likely due to the lower baseline skin colony counts, and because the area is easier to maintain, and farther away from potentially highly contaminated sites, such as a body orifice or airway appliance. Whether peripherally inserted central catheters have a lower rate of CRI in the critically ill is controversial (57) but they are generally much less useful in the acute setting and usually reserved for rehabilitation and chronic care (58).

Infectious considerations have no bearing on the choice of arterial catheterization site. Arterial catheters have a low overall incidence of significant infection, and there is not a substantial difference between sites (59–61). We reserve the use of brachial catheters to specialized situations or in patients with limited arterial access (62).

### Barrier Protection During Catheter Insertion

Maximal barrier protection, including gloves, gown, and mask for the operator and a large sterile body drape for the field, regardless of the site of catheterization and area in the hospital (i.e., operating room *vs.* ICU), reduces the overall rate of CRI for central venous catheters (63,64). This rule needs to be strictly enforced, especially in academic centers where house officers frequently have their own ideas about the need for gowns and drapes. Peripheral arterial catheters can be inserted using gloves (after excellent hand-washing) and local aseptic technique during insertion, but we recommend maximal barrier protection for insertion of femoral arterial catheters (63). The emergency department or resuscitation suite should change catheters placed in the field within 24 hour.

**Table 4** Indications, Site Selection, and Recommended Duration of Central Venous Catheter

Indication for central venous catheter	Preferred site	Recommended duration
Central venous access for vasoactive agents, caustic medications, concentrated agents, inability to perform peripheral catheterization	SV	Indefinite, change for specific indication
Total parenteral nutrition—long term	SV SV (surgically implanted)	Indefinite
Preoperative preparation	IJV or SV	Indefinite
Acute renal replacement therapy	IJV or FV	Change to new site after 7 days
Emergency airway management	FV or SV	Change FV catheters ASAP
Transvenous pacemaker	R IJV	Change to new site after 7 days
Inability to lie supine	FV	Change to new site after 7 days
Cardiopulmonary arrest	FV or SV	Change FV catheter ASAP
Pulmonary artery catheterization	RIJV L SV	Change to new site after 5 days
Coagulopathy	IJV, EJV, FV SV <sup>a</sup>	Change to new site after 7 days

<sup>a</sup>SV catheters can often be placed safely in patients with coagulopathy, but the clinical situation should dictate choice. Recommendations are based on the literature and authors' experience. See text for details.

Abbreviations: FV, femoral vein; IJV, internal jugular vein; R, right; L, left; SV, subclavian vein.

### Skin Site Preparation and Care

Proper skin cleansing/antiseptics of the insertion site are one of the most important measures for preventing CRI. Commonly used antiseptics are 10% povidone-iodine, 70% alcohol, tincture of iodine, and 2% aqueous chlorhexidine. Although comparative data is not extensive, it appears that 2% aqueous chlorhexidine is the superior agent in preventing central venous and arterial CRI (43,65). We use a Chloraprep® One-Step applicator that is a combination of 2% chlorhexidine and 70% isopropyl alcohol. Proper application involves repeated back and forth strokes for 30–60 sec, and then drying for 30 sec.

During catheter maintenance, there are many potential measures to reduce CRI, but most have not been definitively shown to be effective. Application of antimicrobial ointments to the catheter site at the time of insertion or dressing change is a common practice, but has not convincingly decreased CRI and may increase fungal contamination (66,67). A recently developed chlorhexidine patch that can be applied to the catheter site was effective in reducing epidural catheter colonization and may be effective for vascular catheters (68). The type of dressing used probably has little bearing on the incidence of CRI (69). Transparent dressings that allow moisture to evaporate are not associated with a lower CRI rate than gauze and tape, but they are more versatile, secure the site better, permit visual inspection, and do not have to be changed as frequently. Other maintenance issues, such as routine tubing and administration set changes, stopcocks versus needle-less systems, type of infusate or flush, and in-line filters, probably have no significant bearing on CRI (as long as sterile technique is maintained for entering system) and their use should be dictated by institutional protocols (21).

### Catheter Types and Technology

Catheter type is correlated with incidence of CRI (70). In general, specialty catheters such as temporary dialysis and PAC introducers have higher CRI rates due to host and treatment related factors. These catheters generally must be removed sooner than central venous catheters (Table 4). Triple lumen catheters have higher rates than single lumen, although not three times higher, and should only be placed when actually needed for optimal patient care (41). However, it is a frequently quoted fallacy that the use of single lumen catheters is needed for total parenteral nutrition or the infusion of a special drug. Single lumen catheters are rarely indicated in the SICU because most patients require several lines and to insert several single lumen central lines actually would increase the complication rate (mechanical and infectious) as compared to using multiport central venous catheters.

🔗 **New catheter technologies that incorporate antibiotic-bonding or impregnation, or infection resistant materials, reduce CRI and allow for longer duration of catheterization.** 🔗

New catheter technologies that reduce the rate of CRI include antiseptic-bonded and impregnated catheters, antibiotic-impregnated catheters, and most recently, catheters designed with a trimetal (silver, carbon and platinum) compound inherently resistant to infection (46,71–75). Most of the discussion regarding these new catheters is whether they are cost-effective and which technology reduces CRI the most, but it cannot be denied that they do effectively reduce CRI rates and can safely remain in place longer (53,76,77). Concerns regarding the risks of allergic reactions or induction

of resistance have so far not nearly outweighed the benefits of reduced CRI (78,79). Impregnated catheters protect both the inner and outer surface, and logically will be most effective, but available evidence does not definitively justify one catheter type or manufacturer over another. However, in our opinion, available data strongly support the routine use of one of these catheters for prolonged catheterization (more than 3 days). Indeed, in other institutions and ours, the use of catheters has been strongly cost-effective with a significant drop in CRI rates (77) (data on file).

### Duration of Catheterization

Obviously, individual factors and situations impact on the CRI risk for any given catheter, and risk/benefit decisions to withdraw or leave catheters in place must be individualized. A single lumen catheter placed in the SV utilized expressly for TPN and no other purpose can remain for weeks, while a triple lumen catheter placed in the IJV in a shocked patient with multiple infusions is at risk for significant CRI within a week. Any ICU can decrease its episodes of infection per 1000 catheter days by using all preventive strategies and routinely changing the catheter site every three days, but this is neither practical nor cost-effective, and will increase noninfectious complications. Still, for infection control, it is important that each ICU have guidelines governing, *in general*, the duration of catheterization and other decisions, such as when it is appropriate to change over a guide-wire.

🔗 **Colonization of the skin site initiates most CRI, and in the presence of adequate site care, colonization is not necessarily going to necessarily be time-dependent, prevented by guide-wire exchanges, or change to another site.** 🔗 The presence of guidelines standardizes care, sets a baseline on which recommendations for changes can be made, and acts as a benchmark for continuous quality improvement. Luckily, recently completed clinical trials provide an adequate evidence base to make recommendations. These trials have demonstrated that (i) SV catheters have a lower incidence of CRI than FV or IJV catheters (33,52,55,56,80); (ii) routine guidewire exchanges do not prevent, and may increase, CRI (6); (iii) scheduled changes of catheter site (e.g., at 3 or 7 days) does not lower overall complications (81,82); (iv) the use of preventive strategies safely prolongs the duration of catheterization at any given site (53,83); and (v) there is not a linear association between duration of catheterization and risk for CRI (84). When one remembers the pathophysiology of CRI, these results are logical.

Critical care physicians and surgeons are strong willed, and habits die hard, thus, not all ICUs have adapted guidelines incorporating all the above evidence. However, it is important that every ICU have well delineated and publicized guidelines for catheter duration that are enforced and monitored (Table 4). Guidelines should be dynamic and reassessed frequently, and changes implemented in a quality improvement program that is based on valid infection control data (48–50,83).

### DIAGNOSIS AND TREATMENT OF CATHETER-RELATED INFECTION

Inevitably, even with best practices, CRI occurs and will require evaluation and treatment. CRI can be uncomplicated

and resolve with removal of the catheter, or associated with catastrophic complications such as shock, septic thrombophlebitis, or endocarditis, requiring weeks of antibiotics. Management and decision making is complex because there are invariably potential non-catheter sources of fever and infection, and patients may be at high risk for catheter change or replacement. In this section, we review the diagnosis and treatment of CRI, again concentrating on percutaneously inserted central venous catheters, since they constitute 90% of all relevant CRI (43). Arterial catheters, perhaps because of the high flow, are much less likely to be the source of CRB, but the principles discussed here also apply to their management (85). Cuffed, tunneled, and peripherally inserted central catheters are specialized catheters intended to remain in place longer, and although the diagnosis of CRI is made in a similar fashion, decisions to remove these catheters are a bit more complex. In general, long term catheters may not require removal for uncomplicated CRI, but should be removed if associated with shock, septic thrombosis, endocarditis, recurrent bacteremia, or with candida and gram negative infection (19,21).

## Pathogens

### Gram-Positive Cocci

#### Coagulase-Negative Staphylococci

Coagulase negative staphylococci, especially *S. epidermidis*, are the quintessential microbial pathogens associated with device-related infections (Table 5). Staphylococci constitute the most frequent cause of CRI because these organisms are ubiquitous in the ICU, exist in the normal skin flora, and elaborate a slime factor that enables them to thrive on the surface of catheters (34,86). CRIs due to coagulase-negative staphylococci often present with fever alone, are sometimes associated with inflammation at the insertion site, and rarely are complicated by severe sepsis (87,88). Treatment approaches vary among institutions, and there are no randomized clinical trials that offer strong guidance (89). Clearly, some of these infections will resolve with removal of the catheter only, but many experts recommend treatment with an appropriate antibiotic such as vancomycin or alternatively, linezolid (these organisms are almost always methicillin-resistant) for 5–7 days (19). Patients who develop recurrent bacteremia, have prosthetic heart valves, infection induced organ failure, or other complications require a longer duration of therapy.

#### *Staphylococcus aureus*

☞ Recently completed studies suggest that low risk patients with CRI caused by *Staphylococcus aureus* can be safely treated with 10–14 days of antibiotic therapy. ☞ *S. aureus*

constitutes the second most common cause of CRI in critical care units, and is far more consequential than coagulase-negative Staphylococcal infections. *S. aureus* infections of percutaneously inserted central venous catheters mandate removal of the catheter and appropriate antibiotic therapy (90,91). Many of these infections are caused by methicillin resistant *S. aureus* (MRSA) (92,93), and longer durations of antibiotic therapy are frequently indicated. The primary decision is whether to treat with 7 to 14 days (short course) or 28 to 42 days (long course) of therapy. Recently completed studies suggest that low risk patients, identified by a physiologic response to therapy within 48 to 72 hours (fever defervescence and white blood cell count decreased organ function stable or improving, and no valvular abnormalities by echocardiogram) can be safely treated with 10 to 14 days of appropriate therapy (19,94–97). For MSSA, nafcillin alone is usually adequate, whereas vancomycin or linezolid is required for MRSA. For vancomycin intermediate sensitive (VISA) or resistant (VRSA) *S. aureus*, linezolid or daptomycin should be used. The addition of rifampin is usually not necessary for uncomplicated, low-risk patients.

High risk patients are individuals who do not respond quickly to therapy, have persistent bacteremia, evidence of metastatic infection, septic thrombosis, indwelling prosthetic material, or are immuno-compromised. High-risk CRI should be treated with an extended duration of antibiotics, usually 28 days. Infective endocarditis, best diagnosed using transesophageal echocardiogram (TEE) (96), usually requires 6 weeks of therapy, frequently with the addition of rifampin for at least part of the time (19).

#### Enterococci

☞ VRE is usually identified in patients with prolonged, complicated ICU stays who have received multiple courses of antibiotics. ☞ Enterococci are as frequent a cause of CRI as *S. aureus* and perhaps more important because of the emergence of vancomycin-resistant enterococci (VRE) (98). Vascular catheters are the most frequent source of VRE bacteremia in the ICU, and although these infections are usually not highly virulent, they are problematic because of infection control issues. VRE is usually identified in patients with prolonged, complicated ICU stays and multiple courses of antibiotics (99). Treatment is not standardized, and there are no randomized controlled studies to guide therapy. We usually treat low risk patients by removing the catheter, treating with 14 days of linezolid, and documenting sterile blood and stool cultures. High-risk patients warrant longer durations of therapy, and

**Table 5** Common Pathogens Causing CRI and Associated Mortality Rates

Pathogen	1986–1989 (%)	1992–1999 (%)	Crude mortality (%)
Coagulase-negative Staphylococci	27	37	21
<i>S. aureus</i>	16	13	25
<i>Enterococcus</i> spp.	8	13	32
<i>Candida</i> spp.	8	8	40
Gram-negative rods	19	14	37

Note: Most frequent organisms causing CRI.

Source: Adapted from Ref. 29.

consultation with an infectious disease expert is frequently indicated (100–102).

### Gram-Negative Organisms

Catheter-related infection due to gram-negative organisms is not common but is increasing in frequency, especially in immunocompromised patients with tunneled catheters. Gram-negative infections of percutaneous catheters mandate removal of the device and antibiotic therapy for 10 to 14 days (low risk patients) or 4 to 6 weeks (high risk). Gram negative infections of surgically implanted and other tunneled catheters do not necessarily mandate removal of the catheter, and management should be individualized, based on the physiologic status of the patient and early response to therapy (19). However, we almost always remove catheters infected with gram-negatives, because of their virulence, difficulty in clearing these organisms, and the high rate of recurrence.

### Fungal Species

☞ **Some of the patient factors that increase the likelihood of fungal-related CRI are abdominal surgery, total parenteral nutrition, hyperglycemia, extended length of stay, and exposure to multiple antibiotics.** ☞ *Candida* is the most common fungal source of CRI (103). Anti-fungal therapy is mandatory for all instances of CRI caused by *Candida* species. On occasion, when the catheter tip but not peripheral blood is positive for *Candida albicans*, antifungal therapy may not be necessary—but we treat all of these patients to avoid the late recurrences which may have devastating consequences (104–109). Patient factors that increase the likelihood of fungal-related CRI are abdominal surgery, total parenteral nutrition, hyperglycemia, extended length of stay, and exposure to multiple antibiotics.

Treatment of fungal CRI involves removal of the catheter and treatment with antifungal therapy for 14 days beyond the date of the last positive blood culture. The biggest decision regarding therapy is whether to use amphotericin with all of its attendant complications, or fluconazole, which is better tolerated but carries a greater risk of resistance. *Candida tropicalis* and *C. krusei* are inherently resistant to fluconazole, and in some hospitals, as much as 20–40% of *albicans* are resistant.

High risk, hemodynamically unstable, and previously fluconazole-treated patients should initially be started on amphotericin or an echinocandin until cultures and sensitivities are available to guide therapy. In patients with renal insufficiency, lipid preparations of amphotericin are appropriate. When fluconazole is used, we favor doses at least as high as 400 mg daily, the dose found to be as effective as amphotericin dosed at 0.5 mg/kg/day (106). Newer antifungal agents, such as caspofungin, are significant advances with high potency and low side effects, and will likely be increasingly utilized for CRI caused by *Candida* species, especially as an alternative to lipid preparations of amphotericin.

### Unusual Pathogens

☞ **Some unusual organisms, such as *Corynebacterium JK-1*, *Malassezia furfur*, *Candida parapsilosis*, and *Mycobacteria species*, are uniquely associated with CRI, usually in the setting of long-term catheterization in immunocompromised patients.** ☞ When an unusual pathogen is isolated from a catheter tip, it often represents a contaminant

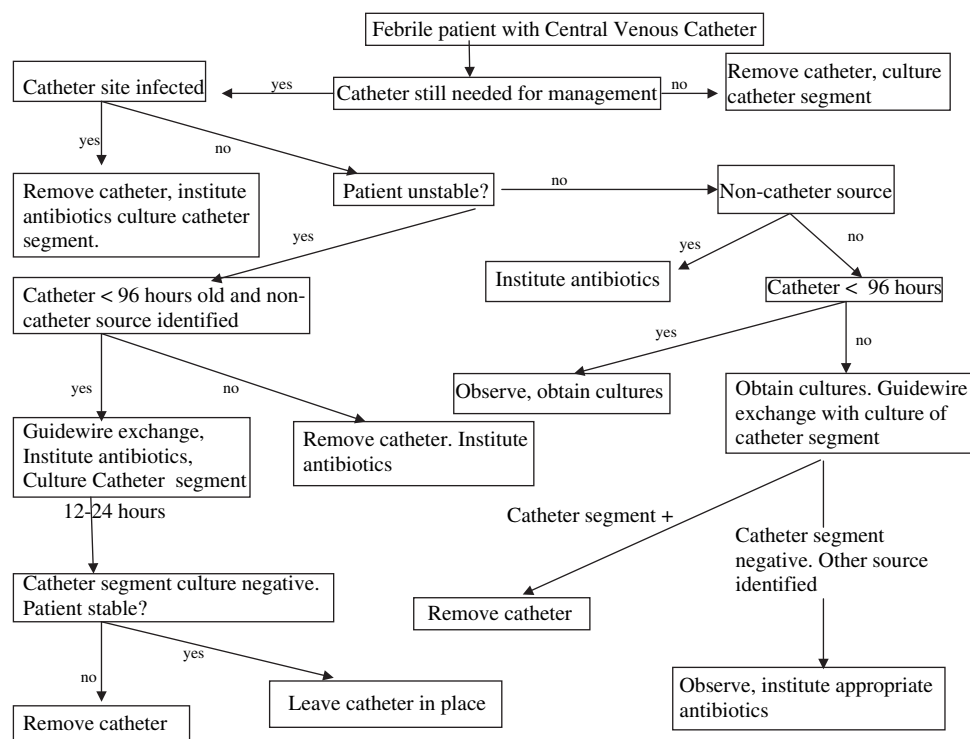

unless it is an organism known to be associated with CRI. Obviously, if catheter-related bacteremia is identified, any organism should be regarded as a pathogen and treated appropriately, including removal of the catheter and initiation of appropriate antibiotic therapy (110–116).

### Management of the Febrile Catheterized Patient

Because it is such a frequent occurrence, management of the febrile patient with one or more indwelling vascular catheters deserves special comment (Fig. 1). The majority of fevers in catheterized patients are not secondary to CRI but rather the myriad of other potential causative factors in ICU patients (117). In general, management decisions should be individualized and the decision to discontinue a catheter is impacted by the duration of catheterization (CRI is very unusual in catheters less than 96 hour old inserted under sterile conditions), type of catheter (non-tunneled catheters are easier to remove than tunneled/surgically implanted catheters), and physiological status of the patient (fever alone versus organ dysfunction/shock) (117). Figure 1 summarizes our approach to the febrile patient with non-tunneled catheters, and we discuss below what changes to this approach are necessary when surgically implanted catheters are involved. ☞ **The decision to discontinue a catheter is impacted by the duration of catheterization (CRI is very unusual in catheters less than 96 hour old inserted under sterile conditions), type of catheter (non-tunneled catheters are easier to remove than tunneled/surgically implanted catheters), and physiological status of the patient (When in doubt—pull it out!).** ☞

For catheters inserted by surgery or interventional radiology (Permacath, Quinton, Mediport, etc.) the approach is similar, but a more concentrated effort at catheter salvage is warranted. Evidence of complicated device infection, such as tunnel infection, port abscess, or extensive cellulitis, mandate catheter removal and 7 to 14 days of antibiotic therapy; likewise, evidence for systemic or metastatic infection also require removal of the catheter and a longer course of antibiotics, as much as 4 to 6 weeks for septic thrombosis and infective endocarditis (118). In our experience, CRI due to non-staphylococcal organisms almost always requires catheter removal, although in rare instances and only when the patient is stable, the organism can be cleared with the catheter in place utilizing antibiotic lock therapy (19). Uncomplicated CRI caused by *S. aureus* can sometimes be cleared without catheter removal, but relapses are common and the clinician must be vigilant for recurrent bacteremia and systemic complications (97). In the presence of uncomplicated infection due to coagulase-negative staphylococcus, the catheter can be retained if there is no evidence of persisting or relapsing bacteremia.

Catheter colonization occurs when the catheter tip or segment is positive for more than 15 cfu. but blood cultures remain negative. Again, it is difficult to make general recommendations and each episode should be evaluated individually. Coagulase negative staphylococcus generally does not need to be treated, but other pathogens should be respected and, if necessary, treated with a relatively short course (5–7 days) of appropriate antibiotics. Repeat blood cultures should be drawn to ensure clearance of the pathogen. If the catheter was exchanged over a guide-wire and the old catheter segment is positive, the new catheter should be removed.

**Figure 1** General approach to the patient with fever and central venous catheter(s). Many exceptions apply. Catheter segment can be tip or intradermal. See text for details.

## EYE TO THE FUTURE

A zero incidence of CRI is a holy grail that will be difficult to obtain. However, improvements to catheter technology, site preparation, insertion technique, and catheter management protocols have resulted in trends of longer catheterization durations with fewer infectious complications. In addition, advancements in non-invasive technologies have decreased the frequency of central catheterization requirements, thereby exposing fewer patients to its risks (119–121). Future improvements in catheter technology will likely center on novel infection and thrombosis-resistant materials, and development of new anti-microbial strategies (122–125). Barrier devices, such as the collagen cuff and chlorhexidine patch, will see improvements in design, and concomitant increases in utilization (32,68,126). Site decontamination will be improved by greater availability of user friendly, existing antiseptics, and undoubtedly, development of new, broader spectrum and longer-acting preparations (65). Insertion techniques that may further reduce CRI include emphasis on the sub-clavian route, subcutaneous tunneling for internal jugular and femoral catheters, and changes to standardized kits, such as sutureless securement devices, needle-less systems, and bloodless syringes (21,127–130).

Perhaps the greatest challenge in the future, and an area for which there may be the biggest impact, is preventing the emergence of resistant organisms. Vascular catheters are one of the most important sources of VRE, MRSA, VISA, VRSA and fluconazole-resistant candida (especially non-albicans species) (46), and it is likely that other resistant pathogens will appear in the future.

Prevention of resistant organisms in the modern day ICU is a complex exercise that involves all aspects of catheter insertion and management, including institutional antibiotic policies. Rapid and accurate diagnosis of CRI will lead to more timely, earlier, appropriate use of antibiotics, measures which are proven to reduce infectious morbidity and mortality (131–132). Equally as important, an ability to rapidly exclude CRI will also reduce the amount of antibiotic empiricism, and decrease the overall exposure to antimicrobials. The accurate diagnosis of CRI may be improved by better culture techniques and, potentially, by the use of specific serum markers (133–138). Better institutional-wide infection control programs incorporating new technologies will improve physician compliance with existing protocols, and allow for more rapid adoption of emerging technologies. As advances occur, it will ultimately remain the responsibility of the treating physician to incorporate these changes into daily practice, with an overall goal of lessening the aggregate burden of infectious diseases, while likewise limiting other complications and cost.

## SUMMARY

Infections caused by invasive devices continue to be an important nosocomial complication in critically ill patients. It is the mandate of all physicians practicing in ICUs to minimize this expensive and sometimes fatal event. Technological improvements have dramatically reduced the incidence of CRI, and it is likely that there will be additional developments in catheter composition, site preparation, and barrier

devices that will further reduce the incidence of CRI. However, physician practices continue to be the greatest source of CRI, which is inexcusable and must be a result of under-appreciation of factors leading to the development of CRI. Every critical care unit should have strict catheter insertion and maintenance policies in effect, based upon the most recent evidence-based literature (Table 4). An active infection control program monitors CRI and benchmarks to regional/national standards, and measures the impact of changes or quality improvements. When CRI does occur, rapid diagnosis and appropriate therapy limits the impact of infection and reduces the likelihood of emergence of resistance. Treatment should be individualized based on virulence of the organism, patient physiology, catheter type, and presence of complications. It is only through the implementation of a comprehensive catheter insertion and management protocol, as reviewed in this chapter, that ICU managers can begin to approach the ideal of a zero incidence in device related infection.

### KEY POINTS

- 🔑 Semi-quantitative catheter segment cultures are easier to perform, but less sensitive than quantitative culture techniques for diagnosis of CRI.
- 🔑 70% of nosocomial bloodstream infections occur in patients with central venous catheters.
- 🔑 Most CRI is initiated by skin (site) colonization, followed by migration down the catheter tract, involving the biofilm surrounding the catheter, and ultimately infection of the catheter tip, bacteremia, and metastatic infection.
- 🔑 Simple measures of prevention, such as hand-washing with an alcohol-based solution or gel, could save 1000–2000 lives annually.
- 🔑 The subclavian approach is preferred for limiting CRI, because it can be performed (or supervised) safely by experienced operators and is associated with a lower incidence of CRI than jugular or femoral catheters.
- 🔑 New catheter technologies that incorporate antibiotic-bonding or impregnation, or infection resistant materials, reduce CRI and allow for longer durations of catheterization.
- 🔑 Colonization of the skin site initiates most CRI, and in the presence of adequate site care, colonization is not necessarily going to be time-dependent, prevented by guidewire exchanges, or change to another site.
- 🔑 Recently completed studies suggest that low risk patients with CRI caused by *Staphylococcus aureus* can be safely treated with 10–14 days of antibiotic therapy.
- 🔑 VRE is usually identified in patients with prolonged, complicated ICU stays who have received multiple courses of antibiotics.
- 🔑 Some of the patient factors that increase the likelihood of fungal-related CRI are abdominal surgery, total parenteral nutrition, hyperglycemia, extended length of stay, and exposure to multiple antibiotics.
- 🔑 Some unusual organisms, such as *Corynebacterium JK-1*, *Malassezia furfur*, *Candida parapsilosis*, and *mycobacteria species*, are uniquely associated with CRI, usually in the setting of long-term catheterization in immunocompromised patients.
- 🔑 The decision to discontinue a catheter is impacted by the duration of catheterization (CRI is very unusual in catheters <96 hour old inserted under sterile

conditions), type of catheter (non-tunneled catheters are easier to remove than tunneled/surgically implanted catheters) and physiological status of the patient (*When in doubt-pull it out!*).

## Abdominal Infections in Trauma and Critical Care

Bruce Potenza

Division of Trauma, Burns, and Critical Care, Department of Surgery, UC San Diego Medical Center, San Diego, California, U.S.A.

Jason Marengo and Sara Minasyan

Department of Surgery, UC San Diego Medical Center, San Diego, California, U.S.A.

### INTRODUCTION

In a busy surgical intensive care unit (SICU), 25% to 40% of the patients present with or develop intra-abdominal disease (including infections) requiring medical or surgical attention. Patients with suspected intra-abdominal pathology may have signs and symptoms referable to a primary intra-abdominal process or referred pain secondary to medical disease (1).

Some patients admitted to the SICU with a primary diagnosis of an intra-abdominal infection can be managed with medical therapy alone. Common examples include: (i) the cirrhotic with spontaneous bacterial peritonitis; (ii) fulminant pancreatitis; and (iii) nonperforated diverticulitis. However, most will need antibiotics and decompressive or operative therapy. Some can be treated by interventional radiologic procedures for decompression or drainage of localized suppurative disease process, such as those seen with a pelvic abscess or complicated cholecystitis and ascending cholangitis. Some patients will need operative therapy. Deciding which patient requires operative intervention, determining the timing, and selecting which operation is to be performed are challenging decisions.

The development of sepsis or low cardiac output states can result in splanchnic hypoperfusion. Resuscitation and treatment of the underlying circulatory dysfunction often resolves the end-organ ischemia. Conversely, if the patient does not demonstrate signs of clinical improvement, concern over continued intestinal ischemia may prompt surgical intervention.

Other patients admitted to the surgical critical care unit are recent postoperative cases. These patients may develop complications as a direct consequence of their operative procedures, resulting in an intra-abdominal infection (2). Examples include failure of the primary surgical procedure, an anastomotic leak or breakdown, a complication of surgery such as a small bowel obstruction, unanticipated complication of the surgical procedure such as an enterotomy, or colotomy with leak or devascularization of a mesenteric segment of the bowel. Patients may also develop medical complications while recovering from their surgery. These include acalculous cholecystitis, pancreatitis, ileus, bowel obstruction, and gastrointestinal bleeding (Table 1).

Not all intra-abdominal infections are created equal. Intra-abdominal infections that are community-acquired have lower morbidity and mortality associated with them than hospital-acquired infections (3). Factors contributing to

increased mortality include the nature of the abdominal complication, physiologic status of the host, comorbid disease, and microbiology of the infectious process (4). Christou et al. reported a 32% mortality rate in patients who developed a postoperative intra-abdominal complication. If the patient required a reoperation, the mortality increased to 42% (5). If patients developed secondary peritonitis due to a prior surgical procedure, the mortality rate was 50% (6). The development of tertiary peritonitis in a postoperative patient increases the mortality rate to 60% (7). Other factors adding to the morbidity include advancing age, male gender, shock, poor nutritional status, multisystem organ failure, emergency surgical procedures, and multiple surgical procedures (8).

The traditional presentation of abdominal infections and other diseases is often altered in critically ill patients due to changes in a patient's neurologic status from traumatic brain injury (TBI), drug intoxication, or the development of metabolic disorders (liver or renal failure), or due to the administration of sedatives, analgesics, or neuromuscular blockade (NMB) drugs. The altered mental status from trauma or critical illness makes obtaining the chief complaint and historical information difficult as well.

Distracting postoperative pain and pain associated with trauma can also mask or delay the recognition of abdominal distress. The use of NMB drugs, and/or presence of spinal cord injury (SCI) also hinder the practitioner's ability to accurately examine the patient's abdomen for signs of peritonitis. **☞ The first clues to the development of an intra-abdominal infection may be the new onset of fever, leukocytosis, intolerance to oral feedings, abdominal distension, or deterioration in the patient's hemodynamic status (7). ☞**

Intra-abdominal infection remains an important clinical entity. **☞ Familiarity with the normal postoperative course as well as the timing and presentation of postoperative complications assist in the management of critically ill patients. ☞** Prompt recognition and correction of these problems may mitigate untoward effects and lead to a better outcome. This chapter will discuss the pathophysiology, diagnosis, and methods of treatment of intra-abdominal infections. The concept of source control will be discussed, as it pertains to intra-abdominal infections and disease.

### PERITONEAL PHYSIOLOGY AND BACTERIAL CLEARANCE

The peritoneal membrane is the natural barrier between the abdominal cavity and the blood-soft tissue interface of the

**Table 1** Etiologies of Abdominal Infection

Primary peritonitis
Spontaneous bacterial peritonitis
Peritoneal dialysis catheter infection
Childhood spontaneous peritonitis
Perforated abdominal viscous
Appendicitis
Diverticulitis
Strangulated bowel
Strangulated hernias
Volvulus
Trauma
Ischemia based on a vascular etiology
Gastrointestinal tumor erosion into adjacent abdominal organs
Tertiary peritonitis
Nosocomial infection
Opportunistic infection
Retroperitoneal abscess
Psoas abscess
Osteomyelitis of the spine
Solid organ infection
Liver or splenic abscess
Bacterial or protozoan
Pancreatitis
Pyelonephritis
Post operative complications: anastomotic breakdown or leak
GI or GU infection
Pyelonephritis
Tubo-ovarian abscess
Pelvic inflammatory disease
Septic abortion

Abbreviation: GU, genitourinary.

surrounding abdominal support structures. In the healthy adult, the peritoneal surface closely approximates the total body surface area of skin, measuring approximately 1.7 cm (2). The peritoneum is divided into the visceral (covering the internal structures of the abdomen) and the parietal peritoneum, which covers the outer lining of the abdomen. This peritoneal membrane is composed of mesenchymal cells (9). The peritoneal lining is semipermeable, consisting of multiple small fenestrations that permit the passage of fluid and small solutes into and out of the peritoneal cavity. These fenestrations, located within the basement membrane, permit the bidirectional passage of fluid and small solutes (10). The bidirectional flow is influenced by the solute concentration, temperature, vasoactive compounds, local perfusion, and volume of the peritoneal fluid.

A small amount of intra-abdominal fluid (50–100 mL) is normally found within the abdominal cavity. This fluid acts as a lubricant between visceral and parietal structures and assists with the intraperitoneal immunologic function. The predominant cells found within the fluid consist of macrophages (50%) and lymphocytes (40%). The constant motion of the diaphragm exerts a gentle counterclockwise movement of this fluid within the abdomen. Fluid initially found in the infrahepatic area will migrate in this pattern until it has moved inferiorly through the pelvis and then superiorly into the left upper quadrant.

✎ **The peritoneum acts as a semipermeable membrane allowing for the passage of both fluid and solutes.** ✎ Intra-abdominal and intravascular hydrostatic

pressure and oncotic pressure gradients effect movement of intra-abdominal fluid. The movement of fluid into and out of the peritoneal cavity is a dynamic process.

Lymphatic drainage occurs via the peritoneal-lymphatic complex at the undersurface of the diaphragm. This complex is composed of peritoneal mesothelial cells with intervening stomata, which cover a fenestrated basement membrane and the inner layer of the lymphatic endothelium. The degree of opening at the stomata varies with diaphragmatic movement, and changes with intrathoracic and intraperitoneal pressure. The presence of valves in the draining lymphatics prevents reversal of flow back into the abdominal cavity. The constant motion of the diaphragm facilitates the passage of these substances into the thoracic duct (11). Thus, there is a constant movement of fluids and solutes throughout the abdomen at any time (3).

Histologically, these mesenchymal cells are filled with extensive rough endoplasmic reticulum and multiple cytoplasmic lipid inclusions, which support the active metabolic function of the peritoneum (12). The peritoneum is very biochemically active, secreting interleukin-1 (IL-1), and interleukin-6 (IL-6), monocyte attractant proteins, transforming growth factors, granulocyte, monocyte, and macrophage colony stimulating factor.

Contamination from a viscous perforation results in a bacterial challenge to the abdomen. The key goals in the management of these patients is to prohibit further intra-abdominal contamination, obtain source control, administer antibiotic therapy to prevent secondary infection, and perform definitive therapy for the underlying intra-abdominal disease process.

The initiation of the inflammatory response of the abdominal cavity generates an intense cascade of cellular events, which effectively attempt to contain the site of infection (13). The immune response to infection includes both humeral and cellular activation. The increased permeability of the peritoneal membrane facilitates an influx of polymorphonuclear cells, cytokines, and fluid. Macrophages secrete proinflammatory products. Within 24 to 48 hours, levels of IL-1, IL-6, and tumor necrosis factor alpha (TNF- $\alpha$ ) can be measured in the peritoneal fluid.

The coagulation cascade is also amplified. Fibrinogen and prothrombin are released into the peritoneal cavity. In addition, the release of tissue thromboplastin, by stimulated mesenchymal cells, promotes the conversion of fibrinogen to fibrin. As the fibrin polymerizes, the viscous fluid promotes the development of adhesions and thick fibrinous peel. Bacteria become trapped within the reticulum. The development of an ileus places the bowel wall in close proximity to the site of infection, permitting the adherence of omentum or loops of small and large bowel, which may wall off an infection. If successful, the infectious process will be sequestered, permitting phagocytosis of bacteria by macrophages and polymorphonuclear cells (14–16). If the area of infection can be sequestered, then an abdominal abscess will form; however, if the host is unable to contain the area of infection then a diffuse peritonitis may occur.

Systemic manifestations, such as fever (Volume 2, Chapter 46) and leukocytosis (Volume 2, Chapter 57) develop. Inflammation of the somatic nerves within the peritoneal membrane due to abdominal distension or peritoneal irritation will lead to subjective complaints of abdominal tenderness. The physiologic alterations of diffuse peritonitis are similar to those that are seen with a 50% total body surface area burn. Rapid exudation of fluid and solutes into the peritoneal cavity result in the decrease of circulating

intravascular volume. An initial rise in the systemic vascular resistance and secondary tachycardia develop in order to augment cardiac output. The picture of uncontrolled abdominal infection is likely to follow a predictable course.

After the initial infectious insult and the inability of the host to control the infection, a hyperdynamic phase develops. Oxygen delivery is increased. Cutaneous vasodilatation and erythema is noticed, signifying the typical “warm phase of shock.” As the systemic inflammatory response worsens, sepsis and systemic inflammatory response syndrome (SIRS) can progress to septic shock. If the infection is not controlled by antibiotics, surgery, or drainage, then a hypodynamic phase develops. Worsening systemic vascular resistance, poor tissue perfusion, and the uncoupling of the ATP cytochrome system renders the cells incapable of handling the oxygen. Microcapillary and intracellular shunting occurs, resulting in systemic acidosis and septic shock (17). If this is not reversed, multisystem organ dysfunction (MODS) or death can occur.

## ABDOMINAL INFECTIONS FOLLOWING TRAUMA AND SURGERY

### Scope and Pathophysiology

Intra-abdominal infections are an important complication in critically ill, postsurgical, and trauma patients (18,19). These infections range from an isolated intra-abdominal abscess to diffuse infectious peritonitis. These conditions may have a primary focus emanating from the abdomen or may be due to a local, regional, or hematogenous spread. The host may respond with traditional signs of infection, progress to SIRS, or develop frank sepsis (20–22).

✎ In a study of 2457 consecutive surgical infections at the University of Virginia, 10% (252/2457) were due to intra-abdominal infections (23). ✎ The leading sources of abdominal infection were the colon (29%), the stomach (21%), the hepatobiliary tract (16%), and the small bowel (15%). Mortality was directly related to or was complication of the infectious process in 25% (614 patients) with surgical infections. Twenty-four percent of the cultured organisms demonstrated resistance to typical antibiotic regimens. Organisms with a high resistance rate included *Staphylococcus epidermidis* (67%), *Staphylococcus aureus* (49%), and *Pseudomonas aeruginosa* (51%) (24). Treatment failures and mortality were higher in the patients infected with resistant bacteria.

Bochud et al. (25), reported an abdomen source of sepsis in 27% (2430/9000) of the patients in intensive care. In another study of 465 patients with an intra-abdominal infection, 72% presented with primary abdominal pathology, whereas a nosocomial intra-abdominal infection occurred in 28%. Barie et al. (27), described the colon as the etiologic agent in 50% of all abdominal infections in the ICU. A localized process resulting in an intra-abdominal abscess was seen in 22% of the patients. Those patients who developed a diffuse peritonitis were sicker, older, and had a higher rate of MODS (1).

### Factors Promoting Abscess Formation

Although bacteria resistance is one factor that contributes to treatment failure, the status of the host plays an important role in treatment success or failure. If the host is not capable of controlling or sequestering an infection, spread may occur by direct extension into contiguous tissues. This may result in a larger abscess or erosion into a contiguous

organ. In the latter instance, a fistula may develop (entercutaneous, colocutaneous, colovaginal, or colovesical) fistula. A disseminated infection may occur if an abdominal source of infection is not controlled, resulting in a systemic inflammatory response or sepsis (28).

Certain physiologic environments hinder the host's ability to fight infection. Local and regional perfusion abnormalities, due to hypotension, impair the delivery of cell mediators of inflammation as well as the clearance of bacterial-laden leukocytes. The presence of an intra-abdominal hematoma acts as a good culture medium. Antibiotic penetration into an abscess cavity is impaired and efficacy is reduced due to the acidic environment of an abscess cavity. Necrotic tissue may be a nidus for bacterial growth while hindering phagocytosis.

### Role of Antibiotics and Source Control

Once the diagnosis of an intra-abdominal infection has been made, the selection of an appropriate therapeutic regimen is essential. Antibiotics, percutaneous drainage, or surgery of an infected intra-abdominal infection are the mainstay of therapy (Fig. 1). The application of these modalities remains challenging. Appropriate antibiotic selection, length of therapy, microbial resistance patterns, and combination versus mono drug regimens remain as the key issues to this therapeutic arm. Does the patient have an identifiable abscess collection? Does the abscess require drainage? How should the abscess cavity be drained, percutaneously or surgically? (29).

In most patients with a contained small intra-abdominal abscess, a combination of antibiotics with either percutaneous drainage or surgery is the preferred modality of treatment. A favorable response to the outlined treatment plan may yield a resolution of the intra-abdominal infection; however, continued fever, leukocytosis, and abdominal pain may herald an incompletely treated intra-abdominal infection, which may need more intervention. Due to the high likelihood that many intra-abdominal infections derive their source from a perforation or discontinuity of the gastrointestinal tract, therapy must be directed to the primary etiologic anatomic area. One of the key concepts of intra-abdominal infection management is source control. If there

**Figure 1** Percutaneous drainage of anterior abdominal fluid collection (arrow).

is an ongoing intra-abdominal contamination from a perforated viscus, there can be neither control of the infection nor eradication of the disease.

### Imaging for Intra-abdominal Processes

✎ **Adjunct imaging studies are critical to the diagnosis of intra-abdominal infections, postoperative complications, or missed traumatic injuries.** ✎ These studies may include the acute abdominal radiograph series, ultrasound (US), computerized tomography (CT), magnetic resonance imaging (MRI), and nuclear scanning. Which of these modalities is best for a specific patient is predicated on many considerations. Familiarization and knowledge of relative perioperative complications and time of presentation facilitate appropriate use of these diagnostic modalities.

The acute abdominal series (flat plate, upright, or lateral decubitus films) may demonstrate free air, ascites, renal or hepatobiliary stone disease, or bowel obstruction. However, it has limited utility in critically ill patients. US, on the other hand, is portable, noninvasive, reproducible, and carries no radiation risk to the patient. Specific pathology, such as hepatobiliary disease (acute cholecystitis, cholangitis, and pancreatitis) are imaged well by US. Extra or intrahepatic ductal dilatation can be identified suggesting biliary outflow obstruction. Biliary stones greater than 2 mm in diameter can be visualized in the common bile duct. Cholelithiasis, abnormal gall bladder wall thickening ( $\geq 3.5$  mm), gall bladder wall enhancement, and pericholecystic fluid are suggestive of gall bladder pathology. Repeat US examination can delineate structure-specific changes, such as organ size, dilatation, luminal diameter, and wall thickness. US is also useful in the diagnosis of free fluid and acute appendicitis (30). Renal evaluation for obstruction or intraparenchymal abscess is also accomplished with US. Doppler US can be utilized to evaluate vascular flow or obstruction.

✎ **The abdominal CT scan has greatly advanced our ability to diagnose intra-abdominal pathology (31).** ✎ The delineation of anatomic structures continues to improve with each advancing generation of scanners. Multidetector scanning with 16, 32, or 64 slides per revolution yields improved definition and resolution of intra-abdominal pathology. Adjacent structure review and analysis aids the clinician in the planning of interventional procedures.

In addition to soft tissue and intra-abdominal pathology, abdominal CT scanning is useful to study vital retroperitoneal structures, such as the major vessels, the kidney, and the pancreas. In patients with acute pancreatitis who are not progressing as expected in the SICU, an abdominal CT scanning may demonstrate the complications of the disease. CT findings may demonstrate the presence of pancreatic inflammation, peripancreatic abscess, pseudocyst, or evidence of pancreatic necrosis. Retroperitoneal abscess or vascular abnormalities are also best visualized by CT scanning. Finally, bowel obstruction or compromise is also well-imaged by CT.

A pelvic CT is useful when intra-abdominal pathology is suspected within the pelvis and mandatory when peritonitis or abscess location is being evaluated. In this area, transabdominal US is limited due to the distance between the abdominal wall and deeper pelvic pathology. Often gas within the superiorly resting bowel will obscure deeper abdominal pathology. Transrectal and transvaginal US are methods to circumvent these problems, and are used in the diagnosis and management of deep pelvic pathology. CT of

the area of concern will provide a detailed picture of the underlying disease process and surrounding anatomy (32).

Arterial and venous phase CT angiography is now available at most institutions. Determination of vascular integrity, perfusion characteristics, or occlusion of vessels is now possible with faster scanning techniques. Both arterial and venous flow protocols exist to image during the appropriate vascular phase. In addition to vascular integrity, organ perfusion can be determined. Areas of focal perfusion defects suggest local thrombosis or embolism. Multiple areas of poor perfusion suggest low cardiac output that may be due to a cardiac etiology, hypovolemia, or shock.

A clinical example of the utility of abdominal CT scanning in ICU patients was performed by Velmahos et al. This was a prospective study to determine if an intra-abdominal infection was responsible for the clinical deterioration in 86 critically ill trauma patients (33). The patients had unexplained fever ( $>38.0$ ), leukocytosis ( $>12,000$ ), and abnormal Swan-Ganz readings, suggestive of sepsis or a clinical suspicion of an ongoing intra-abdominal process. Eighty-two percent of these patients were postoperative patients from abdominal exploration. Major surgical findings included gastric trauma, small intestine perforation (46%), or colonic perforation (19%), with intraperitoneal fecal contamination. Forty-five of these patients had abnormal (initial) CT scans with 41 patients having their management changed based on the CT scan. Thirty-five had CT-guided drainage of fluid collections. Thirty had positive bacterial cultures representative of an intra-abdominal abscess. Three patients underwent a second abdominal operation and three patients had their antibiotic regimen changed. The mean time for a CT scan was nine days. Overall the abdominal CT demonstrated a sensitivity of 97.5% and a specificity of 87.5%. Forty patients underwent a second abdominal CT scan. Eight patients had their management altered or avoided a second abdominal exploration. Fifteen patients underwent a third abdominal CT. Two patients underwent CT-guided aspiration with one requiring abdominal exploration. Most of the patients who developed an intra-abdominal infectious complication did so by the ninth postoperative day.

Nuclear medicine techniques have a limited role in the diagnosis and management of patients with intra-abdominal pathology (34). Nuclear medicine uses radionuclide agents, such as Technetium-99 (Tc-99) sulfur colloid scintigraphy, to demonstrate the function of an organ in question. Evaluation of hepatobiliary integrity and function can be performed in this fashion.

Radionuclide scanning can also be utilized on recently transplanted organs to evaluate tissue blood flow through the demonstration of normal versus pathologic perfusion patterns. However, solid organ transplants are currently most commonly evaluated with ultrasound. Abnormalities may suggest arterial or venous anastomotic problems due to thrombosis inflow or outflow obstruction.

✎ **The use of radionuclide scanning with Gallium-67 citrate or Indium-111 to detect areas of active inflammation or infection are less commonly used today, due to the advancements in multisliced CT scanning.** ✎ However, in selected patients these scans may be used to either identify an area of increased uptake, suggestive of a pathologic process, or monitor the treatment plan to eradicate an infectious process.

MRI offers improved visualization of soft tissue and vascular structures (35). When gadopentetate dimeglumine is used for contrast, the risk of contrast administration nephrotoxicity or allergic reaction can be avoided. A

magnetic resonance cholangiogram may be performed to evaluate the hepatobiliary system in lieu of the more invasive endoscopic retrograde cholangiogram. Expense, unavailability of 24-hour accesses, difficult radiographic interpretation for the average physician, and the need for long scanning times in areas that offer little ability to administer ICU care make this a second-line diagnostic tool.

## DEFINITIONS

### Source Control

☞ **Local source control is paramount in order to manage intra-abdominal infections; without it, fluid resuscitation, antibiotic therapy, and critical care are unlikely to succeed (36).** ☞ Although source control may be specific for each abdominal infection, the principles remain constant (37). Perforations of hollow organs must be repaired or diverted. Ongoing ischemia must be reversed with the reestablishment of adequate perfusion. Discrete collections of infected material (abscesses) must be drained percutaneously or surgically. Devitalized or necrotic tissue must be considered for resection.

### Abscess Cavity

An abscess is a collection of infected material, cellular debris, and components of leukocytes that are contained within a fibrinous capsule. The abscess may be located within the proper abdominal cavity, soft tissue or bone. Its characteristics are determined by the material within the abscess cavity, viscosity, and complexity, as determined by loculations. The location of the abscess contributes to the ability to percutaneously or surgically drain the cavity. The abscess cavity may remain as a singular entity, enlarge, or fistulize into a surrounding organ if not treated appropriately. Abscess cavities tend to be relatively protected by the fibrinous capsule that had formed to sequester the infection. Within the cavity are bacteria, necrotic tissue, and pus. The fibrinous capsule also hinders antibiotic penetration, and the antibiotic entry into the deeper areas of large abscess cavity is the poorest of all. As abscess cavities enlarge or become multiloculated, alternative methods of management become necessary (38).

### Phlegmon

Phlegmon is the term used to describe a collection of tissues that have been inflamed and now has the characteristics of an amorphous tissue collection. The tissue is not infected by definition, but may become infected by hematogenous seeding or seeding from an adjacent organ. An example of this is the retroperitoneal pancreatic phlegmon that occurs with necrotizing pancreatitis. It is often difficult to determine if a phlegmon is infected. Fine needle aspiration may assist in this decision.

### Devitalized Tissue

Necrotic or traumatized tissue that is unlikely to repair itself represents the tissue that should be removed in the face of an infection. This tissue has the potential to be a "safe harbor" for bacteria due to poor perfusion. Antibiotic penetration and activity is impaired as well as native, immune, and phagocytic activities. This tissue most often needs to be débrided or excised.

### Unencapsulated Free Purulent Fluid

Free infected fluid within the abdomen is seen when the host is unable to sequester or encapsulate a collection of suppurative fluid due to ongoing purulent drainage or host immunoincompetence. The result may be a freely flowing collection of pus located within a dependent portion of the abdomen or pelvis.

### Soft Tissue Infections

The infection of soft tissue may involve the superficial layers of the epidermis and dermis, as in cellulites, or involve deeper structures such as a superficial abscess within the layers deeper, than the dermis. Once the infection has spread deeper it may extend to the fascial layer and track the infection along this layer causing necrotizing fasciitis. If the infection goes deeper it may enter into the muscle compartment and result in a localized abscess cavity or an infectious myonecrosis.

### Fistula

This represents a tract usually lined with pseudoepithelium, which connects a perforation in a hollow viscous with another structure. The fistula may track to a second structure and result in a colovesical or rectovaginal fistula. It may also track to the soft tissue through the epidermis to form an enterocutaneous or colcutaneous fistula.

### Foreign Body Infection

Foreign body infections can occur following implantation of materials or shrapnel from external penetration during trauma or from infection secondary to an implantable biocompatible device. Examples of the latter include heart valves, peritoneal dialysis catheters, stents, and orthopedic implants. Two modes of therapy exist for these devices. One can attempt to eradicate the infection with antibiotic therapy or one can remove the device. The latter can be done if the antibiotic therapy does not succeed. Some devices can be removed easily and replaced at a later date when the infection has subsided. Other devices such as heart valves are difficult to replace and must be immediately replaced. These considerations as well as the species of the infecting organism must be taken into account when managing patients with infected implantable devices.

## SOURCE CONTROL STRATEGIES

☞ **Source control is the process by which a site of infection (intra-abdominal or otherwise) is controlled so that further contamination of the surrounding tissues ceases.** ☞

Options of drainage, diversion, and definitive management of the infection vary with the organ injured or infected, the degree of infection, and the physiologic condition of the host (Table 2). The initial therapy may only serve the temporary goal of controlling the infection. After additional resuscitation, antibiotics and intensive care therapy, definitive treatment can be more safely accomplished in the physiologically stronger host (28). Systemic antibiotics and drainage may control the infection and permit a definitive procedure to be performed at a later time when the situation has been optimized. In this case, a one-stage colonic resection with primary anastomosis may be performed in patients successfully managed with percutaneous drainage. On the other hand, diffuse abdominal soilage with peritonitis due to uncontrolled infection may require source control of the

**Table 2** Source Control Strategies

Strategy	Examples
Drainage	
Percutaneous	Cholecystostomy, liver abscess drainage Perforated diverticulitis with localized abscess
Surgical	Diffuse peritonitis or suppuration Abscess inaccessible to percutaneous drainage
Diversion	Ileostomy or colostomy
Debridement/ peritoneal toilette infection	Pancreatitis with necrosis, soft tissue
Deciding on the extent of surgery	Can the patient tolerate a definitive procedure Do they need a temporizing procedure to Control of gastrointestinal spillage Peritoneal toilette vs. a definitive procedure
Device removal	Removal of peritoneal dialysis catheter
Definitive care	Diverticulitis with perforation (peritoneal toilette, bowel resection, and colostomy vs. primary repair)

initial problem and an abdominal washout at one or more settings. This is seen when the host is not capable of sequestering the infectious process. In this situation a definitive procedure may need to be delayed due to the degree of tissue inflammation and adhesions that one may encounter during a definitive procedure. Postponing may permit a resolution of the intense inflammation and permit safer operative dissection at a later date. "Time and Mother Nature are the surgeon's two greatest allies, and many a seemingly impossible situation can be converted to one that is merely a challenge by careful patience" (39).

### Drainage

Drainage can be accomplished surgically or percutaneously. Recent advances in interventional radiologic techniques now make percutaneous drainage of deep-seated intra-abdominal or solid organ abscesses a viable option. Criteria for the use of percutaneous drainage include accessibility to the abscess via the percutaneous route. Relative contraindications to percutaneous drainage include the sites generally inaccessible to catheter drainage (i.e., include interloop abscesses), the presence of continued leakage into the abscess cavity from an uncontrolled gastrointestinal perforation, or the presence of multiloculated abscess or one that has a highly viscous fluid or cellular debris (40).

### Diversion

The need to divert a source of infection is dependent upon the organ injured, the location of the injury, the physiologic condition of the patient, and knowledge of the natural history of the problem. Most diversion procedures are done on the gastrointestinal tract; however, diversion of the genitourinary tract is also performed. The gastrointestinal tract may be obstructed, perforated, infarcted or involved with an inflammatory process, making definitive therapy, including excision, difficult if not dangerous.

Diversion with a loop ileostomy will prevent distal movement of gastrointestinal succus into an area of perforation. Similarly proximal large bowel diversion will prevent a distal perforation from continued leakage. In certain situations, the distal pathology may remain if the involved area is so inflamed as to make operative resection dangerous. More often, the distal lesion is resected and a diverting small bowel or large bowel stoma is created. At a later date, when the inflammation and infection have resolved, a primary anastomosis is performed similar to what is done in a two-set procedure for perforated diverticulitis.

### Debridement and Peritoneal Toilette

Indications to surgically debride the source of abdominal infection include the presence of diffuse peritonitis with free fluid that is suspected to be purulent, an abscess that is inaccessible to percutaneous drainage, and a complex abscess defined as one with multiple loculations, highly viscous material, or full of cellular debris. In these situations surgical debridement and peritoneal toilette is carried out. **☞ The intent of peritoneal toilette is to drain the abscess, debride devitalized tissue, and remove gross fecal material and foreign bodies.** ☞ The goal is to reduce the burden of infected and devitalized tissue so the host's defense mechanisms will be able to eradicate the remaining infection. Free-flowing infected peritoneal ascites or pus is suctioned and irrigated.

There appears to be no benefit to attempt to remove fibrinous material from the partial or visceral surfaces of the abdomen and its contents. Clearly necrotic or devitalized tissue should be removed. At the end of the case, the abdomen should be suctioned so that large amounts of fluid do not remain. Although one can anticipate postoperative ascites to develop, leaving lavage fluid has the theoretical disadvantage of inhibiting macrophage function as well as other important advantageous inflammatory processes.

In staged procedures, the patient's initial physiology may be so deranged and tenuous that a prolonged procedure would adversely affect the outcome. Similar to damage control in the trauma setting, an initial debridement lavage and diversion (if necessary) is performed. Re-exploration within the next 24 to 48 hours is undertaken for a second look, lavage, and debridement. Staged abdominal repair is performed in situations where source control has not been possible at the initial operative settings. The abdomen is left open, that is, without closure of the fascia or skin. A temporary closure is placed, thus saving the fascia for the final operative procedure and closure (41).

No irrigation technique seems to be superior to another. A key point to remember is that in order for the abdominal immunologic defense mechanisms to work, there should be no residual irrigation fluid. Leaving irrigant fluid would simulate an ascites situation where it is known that the host's defense mechanisms are diminished. The macrophage in particular does not function well in an ascitic fluid medium. The addition of antibiotics to the irrigant has not been shown to be superior to simple saline solution. If one is going to lavage or irrigate the abdomen then the best method is to use multiple small aliquots of irrigate and then suction the fluid rather than the usual "pour and agitate" technique seen in most operating rooms.

### Removal of Implanted Devices

The rationale to remove these sources of infection is dependent upon a number of factors. These include the etiology of

the infecting organism and the likelihood of a therapeutic response and resolution with antibiotic therapy, the morbidity of removing the devices, and the ability of the host to survive without the device.

✎ **The presence of a foreign body significantly lowers the quantity of micro-organisms needed to produce infection (42).** ✎ Depending upon the timing of the infection, certain organisms predominate. Early graft infections are typically *S. epidermidis*. This organism is known for its propensity to produce a biofilm layer on a prosthetic device, which becomes adherent to the organism. Eradication of this infection becomes more difficult in this situation as the organism is “protected” within this layer from phagocytosis (43).

### Determining the Extent of Surgery

The extent of the surgical procedure is determined by the underlying pathophysiology, the patient’s condition, and knowledge of the natural history of the surgical disease. Early in the course of a surgical disease it may be possible to operate and achieve source control, as well as correct the primary problem. In the later stages of a disease time course, tissue inflammation, adhesions, or complex abscess formations may make it difficult if not unwise to attempt a curative and definitive procedure on the patient. The operative time spent with tedious lysis of adhesions, in order to separate component anatomic structures, may be prohibitive in a critically ill patient. The added operative time may tax the patients’ underlying physiologic reserve, add to the perioperative fluid requirements, and may result in excess blood loss due to the highly inflamed nature of the hostile abdomen. In other patients, comorbid disease and poor physiology may render a definitive procedure unsafe. In these instances, temporizing measures of repair, diversion, or exclusion of an injured segment without definitive reconstruction may be warranted.

### Definitive Care

Definitive care simply encompasses all of those therapeutic modalities, medical and surgical, which will be utilized in the overall treatment of the patient. Although many patients will have a stepwise approach to the eradication of their intra-abdominal infection, the sum total of these will leave the patient free of infectious disease with restored intra-abdominal continuity or semi, or permanent diversion (Table 3).

## ANTIBIOTIC THERAPY FOR INTRA-ABDOMINAL INFECTIONS

In most cases of intra-abdominal infections of surgical patients the use of antibiotics is an adjunct of therapy. Control of the source of infection by drainage, debridement, diversion, or resection is the essential component of the treatment plan. ✎ **The choice of antibiotics is predicated upon thoughtful consideration of the patient’s surgical infection in conjunction with the patient’s underlying physiologic state as well as comorbid disease.** ✎ The benefits of appropriate antibiotic usage include eliminating causative bacterial pathogens, prevention of the spread of disease to distant sites, prevention of recurrent infection, and shortening the time for the patient to resolve the signs and symptoms of disease. The main questions to be answered, which aid in the determination of antibiotic treatment, include the following: (i) What is the etiology of the surgical infection? (ii) What are the likely bacterial pathogens associated with the disease process? (iii) How long has the infection been active? (iv) What is the degree of contamination or spread of the disease? (v) Is the infection community or hospital acquired? (vi) What are the antibiotic susceptibility and resistance patterns at your hospital? (vii) What is the duration of antibiotic therapy? and (viii) What are the potential side effects and medication interactions that might affect antibiotic selection? In an era where there is increasing bacterial resistance to antibiotic therapy, judicious and appropriate use of these agents, in addition to sound surgical practice, afford the best outcomes for these patients. It cannot be stressed that the successful treatment of an intra-abdominal infection is predicated upon adequate source control.

✎ **Significant factors that have been shown to increase patient morbidity and mortality include a higher severity of illness age greater than 50, an [acute physiology and chronic health evaluation (2nd edition) APACHE II] score of >8, poor nutritional status, significant cardiovascular disease, inadequate source control, and the presence of multidrug-resistant organisms (44).** ✎ When there is an intra-abdominal perforation, how the patient’s defense mechanisms are able to cope with the infection fundamentally defines the outcome. Patient outcome is better if the contamination is small and the patient is able to localize the infection into an abscess rather than if the spillage is large and diffuse. Patients with generalized peritonitis have a two-fold increase in death than if the patient has a confined intra-abdominal abscess (21). In a study by Merlino et al. (45), 70% of those patients with localized

**Table 3** Source Control Options in Common Intra-abdominal Infections

Disease	Temporizing	Definitive care
Perforated peptic ulcer	Omental patch Omental patch with HSV	Vagotomy/ pyloroplasty
Perforated gallbladder	Cholecystostomy	Cholecystectomy
Perforated stomach	Oversewing	Wedge resection
Perforated intestine	Resection and exclusion	Resection, ostomy, or primary repair

With abscess	Percutaneous drainage	Surgical drainage, resection with ostomy, or primary repair

Abbreviation: HSV, highly selective vagotomy.

Source: From Ref. 150.

intra-abdominal abscess were treatment successes, whereas those patients who presented with diffuse peritonitis had a treatment failure rate of 70%. Treatment failures may result in a worsening of the patient's clinical condition. This in turn may lead to a prolonged hospitalization due to an additional antibiotic course, reoperation, multisystem organ failure, and (rarely) death (46). Those factors known to increase the likelihood of developing sepsis include age greater than 40 years, perforation of a hollow viscus (nonappendiceal), the presence of diffuse peritonitis, and pre-existing organ dysfunction (47). In a study by Mulier et al., all patients died in whom source control of a gastrointestinal perforation failed. Likewise, all patients died if source control was achieved, but clinical signs of peritonitis did not resolve (48).

☞ **The microbiology of intra-abdominal infections has remained remarkably stable over the last 30 years.** ☞ The choice of antibiotics is directed by the type and expected microbiology of the infection. Gram-positive, gram-negative anaerobic, and aerobic organisms abound in the gastrointestinal and gynecologic tract; however, the anatomic location determines the specific makeup and concentration of the microbe flora. The normal upper gastrointestinal tract has only  $10^3$  organisms proximal to the ligament of Treitz. In patients on antacid therapy, the microflora is colonized with up to  $10^6$  organisms including *Enterobacteriaceae* and *Candida albicans*.

Distal to the ligament of Treitz, the bacterial counts increase, and the predominant microflora changes from gram-positive organisms to enteric gram-negative rods and anaerobic bacteria. Once the terminal ileum and cecum are reached, logarithmic increases in the concentrations of gram-negative and anaerobic organisms occur. Movement into the colon alters the microflora to predominantly gram-negative organisms. Within the colon, over 400 discrete bacterial species can be isolated. Concentrations of microbes within the large bowel reach  $10^{12}$  to  $10^{13}$  mL bacteria per gram of feces. In the large bowel the concentration of facultative anaerobes reach  $10^{12}$ , whereas the concentration of anaerobic organisms concentrations are  $10^6$ . *Escherichia coli* constitute less than 0.1% of the intracolonic flora; however, with a colonic perforation, the concentration of *E. coli* rapidly increases in the peritoneum to levels of 33 times that found in the intracolonic. This is due in part to the endotoxin, adherence characteristics, and virulence of *E. coli* within the peritoneum. Fifty percent of abdominal cultures after colonic perforation will demonstrate the presence of *E. coli*. It is important to note that of all the bacterial species found within the colon only a small number are actually found in the culture. This may be in part due the virulence of the organism as well as the local intra-abdominal conditions, such as local tissue oxygen tension and the inability of the less virulent organism to coexist with rapid proliferation of *E. coli* and other gram-negative organisms (49).

As seen with obstruction, gastrointestinal stasis will promote overgrowth of bacteria irrespective of the location of the obstruction. Bacterial colony concentration and representative species are altered, setting the stage for a more virulent inoculum, if there is a perforation. Familiarity with the most likely microbes involved in the infectious process is important in the choice of antibiotic therapy. The distinction between a community-acquired versus a hospital-acquired intra-abdominal infection is also important. Hospital-acquired infections, due to postoperative surgical complications or due to complications of other medical disease processes, have a different bacteria profile than

community-acquired intra-abdominal infections. The microbiology of hospital (nosocomial) infections demonstrate a more resistant microflora including *P. aeruginosa*, *Enterobacter*, Enterococci, and *Proteus* species, as well as methicillin resistant *S. aureus* and candida (50). The choice of empiric antibiotic therapy in this group should be broader than in the community-acquired group. Consideration of antifungal therapy should be given in the setting of chronic illness, surgical relapse, or in the face of an immunosuppressed patient.

☞ **The use of antibiotics directed against anaerobic bacteria (*Bacteroides fragilis*) in colonic perforation is an established principle.** ☞ These anaerobic antibiotics do not change the short-term morbidity of the patient, but rather decrease the change in the development of a late abdominal abscess formation (51).

The predominant antibacterial agents for treatment of intra-abdominal infections include the semisynthetic penicillins, cephalosporins, carbapenems, quinolones, and anaerobic agents such as clindamycin and metronidazole. Vancomycin and newer agents for use with methicillin-resistant staphylococci include linezolid, tigecycline, and daptomycin (see Volume 2, Chapter 53). Therapy with aminoglycosides has been declining due to the use of other less toxic antimicrobial agents.

Single-agent coverage is reserved for shorter duration of therapy as well as less serious infections. These agents tend to be either semisynthetic penicillin with beta-lactamase inhibitors, such as piperacillin/tazobactam, or a cephalosporin, such as cefoxitin. They afford broad aerobic and limited anaerobic antimicrobial coverage. Broader spectrum agents such as the carbapenems are reserved for serious intra-abdominal infections. These include meropenem and imipenem. Combination therapy provides additional coverage for anaerobes with the addition of clindamycin or metronidazole to any of the other antibiotics. Synergistic antipseudomonal coverage includes semisynthetic penicillin or a third-generation cephalosporin plus a quinolone or an aminoglycoside. The Society for Surgical Infections has recommended single- and double-coverage antimicrobial regimens for intra-abdominal infections, which are listed in Table 4. They have also developed broad guidelines for who should receive antibiotics, as well as the duration of

antibiotic therapy for intra-abdominal infections. Those patients for whom antibiotic therapy is recommended for  $\leq 24$  hours include the following: (i) patients with iatrogenic or traumatic enteric perforations with peritoneal contamination, who are able to be operated upon within 12 hours, (ii) patients with gastroduodenal perforation operated on within 24 hours, (iii) patients with acute or gangrenous appendicitis or cholecystitis without perforation, and (iv) patients with transmural bowel necrosis without bowel perforation, peritonitis, or abscess formation. In these patients a single dose of preoperative antibiotics are indicated. A second group of patients for whom antibiotic therapy would be indicated for  $\geq 24$  hours include those patients with established surgical intra-abdominal infections or more extensive intraoperative findings than the former described group of patients (52–55).

The efficacy of the overall treatment plan should yield an improvement in the patient's overall condition. Although there is no definitive duration of antibiotic therapy, the improvement of the clinical course, resolution of leukocytosis, a normalization of temperature, and return of their gastrointestinal function are good markers of infection control. Those patients may have their antibiotics ceased 24 to 48 hours after these markers have been achieved. In the patient with a favorable clinical response a total time of antibiotic therapy should be no longer than five to seven days.

In those patients with compromised immune systems, a longer time frame should be established. In some patients (i.e., a periappendiceal abscess), a shorter course may be sufficient. Use of antibiotics in trauma where there has been abdominal contamination is dependent upon the amount and duration of spillage. Typically the duration of time is short unless the injury has been missed and the patient's infection is well established. Trauma patients with a perforation of a hollow viscus and surgical repair within 12 hours, show no benefit from antibiotic therapy for longer than 24 hours of antibiotic therapy (52). A course of 24 hours of antibiotics appears to be as good when compared to a three- to five-day course of antibiotics. In trauma patients with established infections such as those with missed intra-abdominal injuries, therapy should be carried out for five to seven days as in other established gastrointestinal perforations (52,54,56). Lack of clinical response, suggested by persistent fever, leukocytosis, prolonged fluid requirements, and gastrointestinal dysfunction suggest ongoing infection and the need to be reevaluated after five to seven days of appropriate treatment. Complicated intra-abdominal infections with ongoing contamination, organ infection (pancreatitis), or an open abdomen may need prolonged antibiotic therapy. The duration in this group of patients is dictated more on the clinicians' impression as to patient progression or deterioration.

Whether or not there is a need to culture all peritoneal fluid or aspirate remains a debated topic (57,58). Reasons for the routine use of intra-abdominal cultures would be to identify bacteria that are not suspected in the infectious process or to identify resistant bacteria to the treatment regimen (58,59). Those who oppose the use of routine cultures claim that the bacteria profile of the intra-abdominal infection can be predicted with a great degree of certainty, and routine cultures are neither sensitive nor specific enough to guide therapy.

There may be subsets of patients where routine intra-abdominal cultures may be efficacious. These include immunocompromised patients, hospitalized patients, patients already on antibiotics who then present with an intra-

abdominal infection, patients who develop postoperative abdominal complications, or patients who fail to clear their initial intra-abdominal infections. Intraoperative cultures can assist in appropriate antibiotic selection. There is a 15% to 20% incidence of resistant bacteria found in an intra-abdominal infection, and knowledge of this fact along with sensitivities of the organism may alter antibiotic therapy. Routine cultures of intra-abdominal fluid remain an unresolved issue; perhaps a middle-of-the-road approach to selective culturing of infected abdominal fluid in higher risk patients may be of benefit.

Certain bacteria and fungi are sometimes present in the intra-abdominal cultures. The significance of these organisms remains a pertinent question for the practitioner. Organisms such as Enterococci, Candida, and methicillin-resistant *S. aureus* are common isolated bacteria. Enterococcus has been found in 5% to 20% of patients with peritonitis; yet, large-scale studies have described successful treatment for intra-abdominal infections without specific antibiotic coverage for Enterococci (60,61). In most instances, it functions as a copathogen rather than the active infectious agent. In community-acquired abdominal infections, there appears to be no role for antimicrobial coverage for Enterococci (60,62). Hospital-acquired (nosocomial) infections, such as those seen in postoperative patients, are circumstances where Enterococci may play an active role and are not simply co-pathogens (63–65). Recent studies have demonstrated an increased risk of postoperative complications and a higher mortality rate in subgroups of patients with Enterococci cultured (66). These include patients with peritonitis who are immunocompromised, a prosthetic heart valve, severe sepsis, prior cephalosporin therapy, or persistent intra-abdominal collection without clinical improvement (63,67). These patients may benefit from enterococcal antibiotic coverage. The choice of antibiotic should be driven by culture sensitivities and institutional protocols, but would include monotherapy with vancomycin, ampicillin, an aminoglycoside, or linezolid. Linezolid and daptomycin are newer agents for soft tissue infections with Enterococci (68).

The isolation of candida has been associated with an increase in morbidity as well as mortality in intra-abdominal infections (69). Yet in a large series of patients with *C. albicans* and intra-abdominal infection, there appeared to be no difference in clinical outcome if antifungal treatment of candida was undertaken (70). One explanation for this finding may be that what most cultures represented was colonization with candida, rather than a true infection with candida. Again, in subgroups of patients with intra-abdominal candida, the outcome seems to have been dependent upon early administration of antifungal therapy (71). Patients likely to be included in the latter group include those with recurrent gastrointestinal perforation, patients with postoperative complications of acute pancreatitis surgery, or patients with repeated positive intra-abdominal cultures (72). Present therapeutic strategies include fluconazole, amphotericin, or liposomal amphotericin for those patients with renal insufficiency.

In summary, the Surgical Infection Society guidelines aid in the choice and duration of antibiotic therapy (68). These include: (i) Those patients undergoing an elective gastrointestinal surgery should receive a bowel preparation. (ii) Patients in whom source control is achieved at the first operation can be treated for 24 hours and then discontinued (53). (iii) Trauma patients with a perforated abdominal viscus can be treated for 24 hours. (iv) Patients with an

established abdominal infection should undergo antibiotic therapy for five to seven days. If the patient develops signs or symptoms suggestive of an ongoing abdominal infection then prompt diagnostic workup should be initiated. (v) The use of antifungal therapy should be withheld unless the patient is at risk of development of a fungal infection.

## SPECIFIC ABDOMINAL INFECTIONS

### Peritonitis

There are three forms of peritonitis: primary, secondary, and tertiary. Primary peritonitis, also called spontaneous bacterial peritonitis (SBP), may be due to an inflammatory or infectious process. Secondary peritonitis is due to breakdown, perforation, or leak of an intra-abdominal hollow organ or viscus that permits contamination of the abdomen. Tertiary peritonitis is a latent infection seen in chronically ill or immunosuppressed critically ill patients. It tends to be due to atypical nonpathogenic organisms and is not due to a disruption of the gastrointestinal tract or other solid organs.

#### Primary Peritonitis

♣ SBP is infectious in origin and is usually seen in patients with cirrhosis and ascites (73). ♣ The ascites become infected without evidence of an intra-abdominal source. The bacterial flora typically has only one bacterial species, which is often due to gram-positive organisms, such as *Staphylococcus sp.* and *Streptococcus sp.*, or gram-negative organisms, such as *E. coli* or *Klebsiella*.

Speculation as to the source of the infection includes translocation through the gastrointestinal wall or hematogenous spread from distant foci, such as the genitourinary track or skin infection. Patients with indwelling peritoneal dialysis catheters may develop peritonitis due to a break in the sterile technique. The dialysis fluid may become infected during changing of the peritoneal dialysate or due to a dialysis catheter. A sterile form of primary peritonitis may be due to the presence of blood, bile, or urine within the peritoneum. Many episodes of blood or bile in the peritoneum do not lead to peritonitis. Release of pancreatic enzymes into the peritoneum during acute pancreatitis will most certainly result in peritoneal inflammation and abdominal pain. Granulomatous peritonitis is less common, but may result from an infectious source, such as tuberculosis, or from a chemical source, such as talc from surgical gloves.

The diagnosis of primary peritonitis is usually made by documentation of ascites, by physical examination or US. Paracentesis is performed and the fluid sent for cell count and culture. Leukocytes (WBC) of 500 or polymorphonuclear neutrophils (PMNs) of 250 or greater are diagnostic. Gram stain and culture will help direct appropriate antibiotic coverage. In the case of a peritoneal dialysis infection both systemic administration and intraperitoneal administration of antibiotics are the mainstays of treatment. If there is a true dialysis catheter infection, the treatment remains the same. Clinical response to antibiotic therapy is reflected by an improvement in the patients' condition and a clearing of purulent exudate from the peritoneal fluid within 48 to 72 hours. A negative peritoneal culture is obtained at the end of the treatment. In patients failing to improve, the peritoneal dialysis catheter must be removed.

The outcome of primary peritonitis in cirrhotic patients is variable and dependent upon whether this occurred in the outpatient setting or as an inpatient. In outpatient cirrhotic patients there is a 3.5% incidence of SBP

with a corresponding one-year survival of 67% (74). In a group of hospitalized patients the prevalence of SBP was 10% to 20% with an in-hospital mortality of 20% to 30% (75). The presence of acute renal failure increases the mortality rate to 58% if the renal failure is at steady state, versus nearly 100% for those patients with permanent renal failure (76–78).

### Secondary Peritonitis

♣ Secondary peritonitis is a result of a break in the intra-abdominal viscera integrity (13). ♣ Perforation or transmural necrosis of a hollow viscus may lead to spillage of gastrointestinal contents into the abdomen. These leaks may occur from perforated, gastric or duodenal ulcers, perforated small bowel, appendicitis, inflammatory bowel disease, ischemia, or diverticulitis. Spillage of gastrointestinal contents may occur due to abdominal trauma, operative procedures (enterotomies), or anastomotic leaks. Although gastric perforations may have low bacteria concentrations, progression from proximal to distal in the gastrointestinal tract demonstrates increasing bacterial counts and the presence of anaerobic microbes.

The diagnosis of secondary peritonitis is suspected in a patient with fever, leukocytosis, abdominal peritoneal findings, unexplained hypotension, or intolerance to oral nutrition. An abdominal radiograph may demonstrate pneumo-peritoneum, intestinal wall thickening, pneumocystis intestinalis, or thumb printing. In other patients, abdominal and pelvis CT scans may detect free fluid in the presence of free abdominal air, focal area of intestinal edema, pneumatosis intestinalis, or an abscess. Patients with a localized abscess may develop localized findings without systemic signs or symptoms of illness. They may be treated with percutaneous catheter drainage (66,79).

The initial therapy of the patients is fluid resuscitation. Secondly, control of the intra-abdominal source of infection is obtained. This may include a definitive procedure such as resection of the affected segment of sigmoid diverticulitis with primary anastomosis. Conversely, it may involve a temporizing measure with a diverting colostomy. The abdomen is then cleaned of any purulent material via controlled lavage. If there is no evidence of elevated intra-abdominal pressures, the fascia is approximated. The wound is left open to heal with a delayed primary closure, wet-to-dry bandages, or a vacuum-assisted closure. Lastly, the prevention of further intra-abdominal infection and faster resolution of active disease symptoms are facilitated by antibiotic administration (36,80). In patients with severe diffuse peritonitis, a single operation to control the source of infection was successful in 88% of the patients. In other patients reoperation at 24 to 48 hours or open abdominal management with repeated staged operative procedures is indicated.

In some patients, a single definitive operation is not possible. Declining physiologic reserve, hypothermia, coagulopathy, and acidosis are conditions where damage control surgical principles should be employed (81). In severely compromised patients, a shorter operative procedure, both in time and in scope, may be beneficial. The correction of hypotension, coagulopathy, and hypothermia could be accomplished in the SICU (82). In certain patients, abdominal edema due to fluid resuscitation and the systemic inflammatory response may limit the surgeon's ability to close the abdomen safely (Table 5).

In some patients, the degree of abdominal soilage and contamination is so great that a second-look operation with

**Table 5** Indications for Open Abdomen Management

Excessive bowel, peritoneal and soft tissue edema
Massive soft tissue loss to the abdominal wall
Inability to obtain source control
Need for a second look procedure (to assess bowel perfusion)
Damage control surgery (hypothermia, coagulopathy, or acidosis)
Abdominal compartment syndrome

further debridement and lavage may be indicated. Source control can usually be controlled with two to three operative procedures (80). At some point if the abdomen cannot be surgically closed, temporary mesh and skin grafting or a component closure may be necessary.

There is a cost to abdominal reexploration that can be measured in increased patient morbidity and mortality (83). Mortality rates for reoperation range between 30% and 52% (82). Each trip back to the operating room extolls a physiologic price on the patient. It has the potential to incite the second hit, which may trigger a broader inflammatory response such as SIRS. Patients who require additional operative interventions seem to do better with reoperation, based on demand rather than simply planned at some time interval. Those patients with a planned reoperation developed SIRS (21%) versus reoperation on demand patients (13%). Similarly, multisystem organ failure developed in 68% of patients with planned reoperation versus 39% if the reoperation was performed on demand (32,84,85). If a second-look operation is necessary, mortality is reduced if the procedure is undertaken within 48 hours of the first procedure.

Frequent abdominal reoperations are associated with the development of intense inflammation of the bowel and subject it to ongoing tissue trauma. The rate of intestinal fistulae formation, perforation, and anastomotic leaks increase with each subsequent operative procedure (86). This observation can be readily seen by the operating surgeon. The bowel becomes more edematous and adhesions grow denser with each operation. An intense serositis develops on the bowel wall. Dissection of free tissue plains within the abdomen becomes difficult. At this point, it is probably better to attempt to secure some type of abdominal closure rather than continue to reoperate, if possible (85,87).

The decision for temporizing surgery rather than definitive surgery is determined by intra-operative evaluation of the three key areas: (i) evaluation of the overall physiologic status of the patient, (ii) evaluation of the condition of the surgical anatomy, and (iii) knowledge of the natural history and course of the disease encountered.

### Tertiary Peritonitis

Tertiary peritonitis occurs in critically ill patients. These patients tend to be immuno-compromised or have been hospitalized for a long period of time. In the latter group of patients, they are often not clinically improving and have gone from one medical or surgical problem to the next, never seeming to fully recover (88). These patients have poor physiologic reserve and nutritional status. Tertiary peritonitis is not a common disease, but is often seen in patients who were originally seen with secondary peritonitis. In the medical ICU, patients may develop tertiary peritonitis without any antecedent operative therapy. The recovery in these patients is hindered by recurrent infections, which are dominated by nosocomial bacteria and opportunistic

infections. Mortality for this disease ranges from 30% to 60% (89).

The diagnosis of tertiary peritonitis is difficult to make (90). There are a paucity of clinical signs, symptoms, and findings to direct the clinician. Suspicion of tertiary peritonitis may be initiated by a gradual downward course of a patient without an obvious etiology, heralded by fever and leukocytosis. Fluid collections are aspirated and therapy directed by gram stain and culture. In these patients, *S. epidermidis*, *Pseudomonas* spp., and *Candida* spp. are frequent pathogens. These patients are succumbing to pathogens that are typically nonpathogenic to the immunocompetent host. Their ultimate demise is not due to the organisms, but to multisystem organ failure.

### Perforated Abdominal Viscous

The management of a perforated abdominal viscus follows the same basic treatment principle of source control. Perforations must be contained either through normal host defense mechanisms, drainage, or surgery. If there is to be spontaneous healing or sequestration of a perforation, the surrounding tissue must be of good quality so that an inflammatory reaction may develop and sequester the infection. All but small (3–5 mm) intra-abdominal abscesses should be considered for drainage. Diffuse peritonitis with accompanying free suppurative abdominal fluid most often requires operative intervention.

The most common etiologies of upper gastrointestinal sources of abdominal perforations are gastric and duodenal ulcers. Unfortunately, currently, many patients are on antacids that effectively bypass the stomach's natural defense mechanism. In these patients, the upper gastrointestinal contents are of higher bacterial concentrations and often contain atypical bacteria and fungi.

The diagnosis of an upper gastrointestinal perforation may be heralded by epigastric pain, fever, and leukocytosis. The pain is constant and may radiate into the posterior epigastrium or right upper and lower quadrants. Nausea and vomiting may accompany these symptoms. Physical examination may reveal abdominal pain or guarding in the epigastrium and right upper quadrant. Plain films of the abdomen, including upright and lateral decubitus films may reveal free intra-abdominal air. If a CT of the abdomen is performed, both free air and free fluid may be seen. Additionally, local tissue edema may be seen near the area of perforation. If oral contrast was administered it may be seen outside the confines of the stomach or duodenum.

🔧 **Primary repair of gastroduodenal ulcer perforation is dependent upon the etiology of the perforation.** 🔧 Simple perforated ulcers may be repaired by oversewing and Graham patch. More complex ulcers, such as giant ulcers or ulcers due to gastric cancer, may require resection and anastomosis. Definitive surgical anti-ulcer therapy needs to be weighed against this benchmark. More and more younger people are using nonsteroidal anti-inflammatory agents. The incidence of *Helicobacter pylori*-associated gastrointestinal perforation is rising. A study by Tokunaga et al. (91), and another by Ng et al. (92), discovered that 80% to 90% of patients with a perforated ulcer were found to test positive for *H. pylori*. In these patients simple oversewing with a patch and treatment with antibiotics effective against *H. pylori* was sufficient to control the disease process (92). Hydrogen pump inhibitors are very effective acid-reducing agents. In selected patients (the elderly or

critically ill) these pump inhibitors may be more beneficial than the morbidity of a larger resection.

Small bowel perforation is unusual and is often times a result of inflammatory bowel disease, obstruction, or trauma. Large bowel perforation is more common and includes the additional differential diagnosis of diverticulitis, volvulus, and malignancy. Within the colon the concentrations of anaerobic organisms increase so that one gram of stool contains  $10^{12}$  anaerobes and  $10^8$  aerobes (93).

Management is specific to the disease process. Ischemic or infarcted bowel is resected and usually reconstructed with a primary repair at the first operation if the patient's physiology permits it. Revascularization of mesentery vessels may be indicated in the presence of a proximal obstruction due to embolic or occlusive disease. Intestinal obstruction is relieved as adhesions are lysed or hernias reduced. If the bowel is viable then no gastrointestinal surgery is performed. Inflammatory bowel problems may present with bleeding, obstruction, or perforation.

Surgical repair is directed toward the correction of the underlying problem, with the understanding that most of the inflammatory diseases are chronic and recurring. Surgical repair of traumatic small bowel injuries are the mainstay after debriding any nonviable tissue from the site of injury. Primary repair of large bowel perforations has become the first line of therapy in patients who can tolerate the added time to the initial operation (94). In those patients who physiologically cannot tolerate a longer operation can be surgically temporized by leaving a segment of bowel in discontinuity to be repaired at a second-stage operation or by diversion ostomy (95).

### Intra-abdominal Infections Due to Trauma

The management of seriously injured patients is complex. Operative versus nonoperative strategies, use of adjunct angiographic procedures, and supportive critical care are commonplace in the management of these patients. Overall, 25% of postoperative trauma patients develop an intra-abdominal infection (Table 6). Surgical wound complications occur in 12% and intra-abdominal abscess formation develops in 9% of patients. The remaining patients develop

diffuse peritonitis, solid organ, or retroperitoneal abscesses. In the multicenter trial of the American Association for the Surgery of Trauma (AAST), 297 patients underwent laparotomy for bowel perforation, 19% (55) patients developed an intra-abdominal abscess, 9% (27) patients developed fascial dehiscence, and 4.3% (13) patients developed a colonic leak. Primary infectious sources include gross fecal contamination, hepatic, gastric, enteric, and colonic perforation. Intra-abdominal complications may also occur as a result of treatment, delay in diagnosis, or due to missed injuries. Sometimes, the gastrointestinal injury may not result in immediate perforation. Rather, ongoing tissue injury from ischemia, intramural hematoma or acute distension of a partial thickness bowel injury may result in a late complication. Medical complications, secondary to critical illness, such as pancreatitis or cholecystitis are seen in 14% of the cases (96). The nonoperative management of selected abdominal trauma is associated with the development of intra-abdominal complications.

Over the last 20 years, there has been a paradigm shift to the nonoperative management of liver injuries. Mortality from higher-grade injuries, the AAST Grade 4 and 5, has decreased. Yet, this has not come without a cost. Morbidity from the nonoperative management of liver injuries includes intra-abdominal complications (97,98). Bile leaks may progress to form a biloma, become infected, or develop diffuse peritonitis. Devitalized hepatic tissue may become infected and develop an intrahepatic or intra-abdominal abscess.

In a study by Wahl et al. (99), 33% (94/281) of patients with hepatic injuries developed an intra-abdominal complication. These complications were bile leak, liver abscess, or an intra-abdominal abscess. Patients who developed a complication had higher liver Abbreviated Injury Scores (AIS  $\geq 4$ ). Almost half of the patients who underwent operative therapy developed a liver-related complication. Fifty-three percent of the patients who underwent simple angiography and 60% of those with angioembolization developed a complication. In the nonoperative and nonprocedure group only 1.5% of the patients developed a complication. Presenting symptoms included unexplained fever, leukocytosis, or peritonitis. The diagnosis was confirmed with a hepato-iminodiacetic acid (HIDA) scan using Tc-99. The sensitivity and specificity of this test were both 100%. Treatment consisted of laparoscopic drainage or abdominal washout and placement of a closed suction drain.

Complications increase with increasing severity of hepatic injury. Patients with AAST Grade 3 liver injuries experience a 4.7% chance of developing an intra-abdominal infection. This increases to 21% with Grade 4 injuries and 63% of Grade 5 injuries (100,101). Options of treatment include percutaneous drainage, endoscopic retrograde cholangiography (ERCP) with stent placement, laparoscopic drainage, and washout or open exploration.

Splenic injuries do not have the same complication profile. Here, recurrent hemorrhage rather than infection appears to be the main complication with nonoperative management. Those patients managed nonoperatively, and who undergo angiography, seem to have a slight increase in the risk of developing an infectious complication. Recently, there have been case reports and small series of splenic abscess formation (6%) after angioembolization of ongoing splenic hemorrhage (102).

From a surgical standpoint, one of the most dreaded complications has been the breakdown or leak of a gastrointestinal primary repair or anastomosis. The stomach, due to the rich vascular supply, tolerates repair well. Caveats to

**Table 6** Traumatic Etiologies of Abdominal Infections

Incomplete peritoneal toilette with residual peritoneal contamination
Continued lack of source control
Gastrointestinal anastomosis leak
Gastrointestinal repair leak
Gastrointestinal fistula
Gastrointestinal ischemia with perforation
Hepatic abscess due to trauma
Infected biloma
Missed injury with continued peritoneal contamination
Soft tissue infection
Postoperative intra-abdominal abscess
Postoperative pancreatitis or leak with infection
Infected vascular prosthesis
Infectious complications due to open abdomen management
Tertiary peritonitis
Retained foreign body infection (bullet, explosive fragments)
Incomplete tissue debridement
Delayed gastrointestinal perforation after blunt trauma

obtaining a good repair are adequate debridement of the injured tissue, standard repair techniques, and postoperative gastric decompression. Leak rates are less than 6%.

The evolution from diversion colostomy to primary repair of colon injuries has been a slow process. During World War II, both British and American surgeons performed these procedures as a standard of care for battlefield colonic injuries. With improved technique, antibiotics, rapid evacuation, and perioperative care, surgeons gradually tested primary repair of the colon. From 1949 to 1990, there were 26 studies examining this premise. Leak rates from the primary closure of traumatic colonic injuries were 1.3% (20/1507). Leaks from resection and anastomosis were 5.7% (19/335). Some of these studies were retrospective and many not randomized. In four prospective studies, where patients received primary colonic repair without exclusionary criteria, there were no leaks in the simple suture repair group and there was a leak rate of 3.7% in the resection and anastomosis group (103). In a large multicenter trial of 297 patients with colonic injury, an abdominal complication occurred in 24% of the cases (104). There was no statistical difference between the primary anastomosis (22%) and the diversion group (27%). Independent risk factors for the development of an abdominal complication included severe fecal contamination, transfusion of RBCs of  $\geq 4$  units in the first 24 hours or single-agent antibiotic prophylaxis. Current recommendation is to consider primary gastrointestinal repair or resection and anastomosis in most trauma patients. In a study by Sasaki et al. (105,106), there was no difference in septic complications in the primary repair group versus the diversion colostomy group.

With these statistics in mind it is important to put this knowledge in a conceptual postoperative timeframe. Behrman et al. (107), examined the temporal frame of development of the intra-abdominal infection after a leak. In 222, intestinal repairs were done in 171 patients. There were 11 complications (5%) that occurred in 11 patients. There were four duodenal, four small bowel, and three colon-failed repairs that were diagnosed on an average on postoperative day 15. The four duodenal leaks (4 of 12) were in primary enterorrhaphies with associated pancreatic injury. The small and large bowel leaks all occurred in patients with resection and primary anastomosis. In three of the four small bowel leaks the patients had developed abdominal compartment syndrome. Overall complications were associated with more seriously ill patients, with higher blood transfusion and fluid requirements during the initial resuscitation and operation.

Missed abdominal injuries are seen at variable rates in the literature (0.3–31.4%) (108,109). The higher missed injury rates were reported by institutions with relatively low volume; less than 200 patients per year (110). Other institutions reported a much lower incidence. Buduhan et al. (111), reported an abdominal missed injury rate of 1.6% which was a splenic laceration. Data from our own institution examining over 13,000 patients over a 12-year period, revealed an overall missed injury rate of 3% (all anatomic areas). Missed abdominal injuries were diagnosed in 0.5% (65 patients). Most of these missed abdominal injuries were due to a false initial read on the CT of a solid organ (liver and spleen). This did not impact on immediate care as these were managed nonoperatively. Other abdominal injuries resulted in 38% of (22/65) of patients requiring operative intervention. These included small bowel perforations (11), diaphragm (9), splenic injury (1), stomach (1), and perforated duodenal ulcer (2). Thus 0.3% of all the trauma

patients admitted to our center had missed abdominal injury (stomach, bowel, or duodenal) that had the potential to cause an intra-abdominal infectious process (112).

### Acute Appendicitis

Complicated cases of appendicitis may send a patient to the SICU with a diagnosis of abdominal sepsis. Acute appendicitis begins with obstruction of the lumen of the appendiceal orifice. Secondary bacterial overgrowth occurs with distension of the appendix.

Simple appendicitis can become a suppurative appendicitis. In addition, a perforated appendicitis can develop into a periappendiceal abscess. Diffuse peritonitis may occur in a patient who is unable to sequester the suppurative process. This may be seen in the immunoincompetent or elderly patient. These patients are at risk of developing sepsis due to an uncontrolled intra-abdominal source. Complicating the diagnosis sometimes is a redundant sigmoid colon with diverticula. This situation may resemble acute diverticulitis; however, the management of these two conditions in the early stages is very similar. Although US imaging may demonstrate a distended appendix, CT scans better delineate the anatomy of the disease process. The sensitivity of the abdominal CT was 94% with a sensitivity of 95%. US had a sensitivity of 86% with a sensitivity of 81% (113). Radiographic findings on CT for acute appendicitis include appendiceal wall thickening  $>5$  mm, periappendiceal inflammation or fat streaking, nonfilling of the appendix, the presence of a fecalith, or a periappendiceal mass or abscess.

Simple appendicitis and suppurative appendicitis are treated surgically by appendectomy. An appendiceal abscess is typically drained percutaneously or treated operatively. Perforated appendicitis is managed operatively unless there is a periappendiceal abscess. Localized abscesses may be drained percutaneously. If the abscess cavity is small and adjacent to the appendix, both may be operatively resected. On the other hand, if there is a complex picture of inflamed bowel and a large abscess then percutaneous drainage may be more beneficial. Early operation on stable patients with this ileocecal inflammation has been shown to increase the likelihood of complications and more extensive operative intervention. Appropriate antibiotics include second-generation cephalosporins or quinolones or semisynthetic penicillin. Improvement in the patient's condition at 48 hours should be demonstrated. If not, rescanning for an undrained abscess or operation is necessary. Complex abscesses or regional peritonitis is best managed by operation. A patient with an appendiceal phlegmon is probably best treated conservatively with antibiotics and an interval appendectomy at six weeks (114). However, if patients do not undergo interval appendectomy, only 20% go on to develop signs and symptoms of a second episode of appendicitis. The majority of these cases will present within one year of the first episode and tend to be uncomplicated (115). Therefore, there are advocates of watching and waiting rather than performing an interval appendectomy. If this management strategy is utilized in patients over the age of 40, then screening colonoscopy is recommended at a later date to exclude other significant colonic pathology such as colon cancer or inflammatory bowel disease.

Appendectomy can be performed via the open technique or laparoscopically. In patients whom the diagnosis is not known for certain, the laparoscopic approach affords the opportunity to visually explore the abdomen (116).

### Acute Cholecystitis

Over 90% of the patients with acute cholecystitis have associated cholelithiasis. The remaining patients have acalculous cholecystitis, a disease primarily of critically ill patients. Calculous cholecystitis is secondary to cystic duct obstruction with secondary gall bladder dilatation.

Signs and symptoms of acute cholecystitis include right upper quadrant pain and referred pain to the right scapula and back. There may be associated nausea and vomiting. The pain tends to be unremitting in contradistinction to biliary colic that waxes and wanes, but subsides typically in six hours.

US is the primary diagnostic procedure as it is noninvasive, quick, and offers no risk to the patient. Typical findings include cholelithiasis, a distended gall bladder (>5 mm) with wall thickening (>3.5 mm), and pericholecystic fluid (32). In some cases, there may be mucosal wall separation or intramural air. A HIDA scan will demonstrate nonvisualization of the gall bladder. Care must be used in the interpretation of a nonvisualized gall bladder in a fasting critically ill patient. The gall bladder may be contracted due to disuse and not pick up the technetium contrast material and give a false positive result (117).

✂ **Acalculous cholecystitis is rarely seen outside of the SICU. It typically occurs in very ill patients who have been receiving parenteral nutrition.** ✂ The pathophysiologic mechanism of acalculous cholecystitis appears to be an alteration to the microcirculation of the mucosa of the gall bladder wall. This in turn leads to gall bladder wall ischemia, inflammation, bacterial invasion, necrosis, and possibly perforation (118). Risk factors for this process include recent hypotension, as seen with septic and burn patients, or prolonged biliary stasis (total parenteral nutrition). The diagnosis of this condition is more difficult to make and is often inferred. A critically ill patient who suddenly decompensates without an obvious cause, a newly developed intolerance to feedings, development of an ileus and unexplained fever or leukocytosis should prompt consideration of acalculous cholecystitis. Serum chemistries may be misleading with relatively normal liver function tests. Only a mild-to-moderate leukocytosis may be present.

A right upper quadrant US may demonstrate all the findings seen with calculous cholecystitis, except for the stones (Fig. 2). More often, the only ultrasonic finding will be a distended gall bladder. The additional finding of a thickened gall bladder wall (>3.5 mm) is supportive evidence for acalculous cholecystitis. Serial USs may demonstrate an enlarging gall bladder with some pericholecystic fluid or some slough in the gall bladder.

Surgical treatment is the mainstay for both acalculous and calculous cholecystitis. Both open surgical as well as laparoscopic surgical approaches have been utilized (119). Due to the intense inflammatory nature of this process one needs to exercise caution and sound surgical judgment when utilizing the laparoscopic approach. Conversion to an open surgical procedure may be indicated in patients in whom the anatomy is distorted or the inflammation prohibitive for a safe dissection (120).

Antibiotics are administered in the perioperative period and consist of a second-generation cephalosporin. If the patient is stable, laparoscopic cholecystectomy with cholangiography as indicated should be carried out. Patients whose symptoms have been present for longer than three to four days may have a very inflamed gall bladder that would make operative resection difficult. In these patients, a delayed surgical procedure after antibiotics and a cooling

down period may make a laparoscopic procedure feasible. Conversion rates of <2% are seen in acute cholecystitis of less than two days duration. More advanced cholecystitis is associated with an 11% to 32% conversion rate to open cholecystectomy (121).

In those patients with an intense inflammatory reaction of the gall bladder, partial cholecystectomy is an alternative. Here the posterior wall of the gall bladder can be left on the liver and it is safer to dissect the gall bladder in a retrograde fashion from the fundus toward the neck. Transection of the gall bladder is performed when it is deemed too treacherous to dissect further. Attempts to perform a cholangiogram through the proximal gall bladder may be of benefit in these circumstances. Otherwise, the remaining gall bladder wall is oversewn and a closed suction drain is placed in the Morison's pouch. If the gall bladder cannot be sutured, the placement of a drain should suffice in the absence of common bile duct obstruction. In the case of an obstructed common bile duct, an ERCP can be employed postoperatively to clear the duct.

**Figure 2** Acalculous cholecystitis. (A) Acalculous cholecystitis-distended gallbladder with pericholecystic fluid and edema. (B) Percutaneous drain placed demonstrating collapsed gallbladder (arrow).

If a patient is critically ill, and has acalculous cholecystitis, consideration of a percutaneous drainage of the gall bladder is possible. A note of caution is that the ischemia to the gall bladder walls may lead to necrosis and eventual perforation. ⚡ **The presence of gall bladder wall necrosis may be missed on both CT and US; therefore, if a percutaneous drain is placed, the patient needs to be observed closely over the next two to three days to ensure clinical improvement.** ⚡ Antibiotics are generally continued for a 7 to 14-day course in these patients. If the patient improves an interval cholecystectomy can be performed (122).

### Acute Cholangitis

Acute cholangitis is an ascending infection of the hepatobiliary tree caused by obstruction of the common bile duct. The resulting stasis of bile behind an obstruction is fertile material for bacteria to colonize. Biliary obstruction may be acute or more indolent. The most common cause of obstruction in North America is due to choledocholithiasis (30–60%) (123). Hemobilia may be seen in trauma and transplant patients, leading to occlusion of the bile duct due to the RBC. Biliary strictures due to malignancy, ischemia, sclerosing cholangitis, or recurrent episodes of pancreatitis may cause obstruction. Malignant strictures are associated with infected bile in 25% to 33% of the cases. Infection of the biliary tree may also follow manipulation from ERCP. Common bile duct stents as well as biliary decompressive tubes may become infected. Extrinsic compression of the common bile duct may be seen with pancreatic cancer, gastric cancer, duodenal hematomas, and lymphomas. Patients who have undergone a biliary decompressive surgery with a choly-enteric anastomosis are at an increased risk for biliary infection.

Signs and symptoms are manifested by Charcot's triangle of right upper quadrant pain, jaundice, and fever. In 15% of the patients a more severe ascending cholangitis is seen with accompanying hypotension and mental status changes. The addition of the mental status changes and septic picture along with Charcot's triad, form the Reynold's pentad (124).

Laboratory tests demonstrate an elevated WBC (12,000–22,000), total and direct bilirubin, alkaline phosphatase, [alanine aminotransferase (ALT) also known as serum glutamic pyruvic transaminase (SGPT)] and [aspartate aminotransferase (AST) also known as serum glutamic oxaloacetic transaminase (SGOT)]. The degree of hyperbilirubinemia is proportional to the length of time and completeness of the obstruction. Diagnostic tests include US, HIDA scan, and CT scan. US is usually the first test of choice. The US typically demonstrates a dilated common bile duct with associated intrahepatic ductal dilatation. There is usually evidence of cholelithiasis, and choledocholithiasis may be demonstrated. Stones >2 mm can be visualized by the US, if imaged in the appropriate plane.

A HIDA scan will demonstrate filling of the liver and gall bladder without emptying of the Tc-99 into the duodenum. CT scans are beneficial when malignancy is suspected. Magnetic resonance cholangiopancreatography (MRCP) also visualizes the hepatobiliary tree, but a secondary test is usually reserved for patients who cannot tolerate an ERCP. An ERCP is both diagnostic and therapeutic in most cases.

Biliary stones can be retrieved with a basket or crushed. A sphincterotomy may be done to accommodate the passage of larger stones or a stent may be placed if a stricture is present to relieve the infected obstruction. Biopsies may be taken if there is suspicion of

cholangiocarcinoma or ampullary carcinoma. The most common bacteria found in these infections are *E. coli*, *Klebsiella pneumoniae*, and *Enterococcus faecalis*. In two-thirds of the cases there is a mixed flora. Anaerobes are uncommonly found in this type of infection.

⚡ **Treatment of ascending cholangitis is a medical emergency and requires prompt decompression.** ⚡ Antibiotic therapy should be started with a broad-spectrum antibiotic, such as second- or third-generation cephalosporin or semi-synthetic penicillin. Septic patients may benefit from dual antibiotic coverage. A quinolone may be started in the penicillin-allergic patient. Fluid resuscitation should be instituted immediately. Seventy percent to 85% of the patients will respond favorably to this initial treatment. After 24 to 48 hours of clinical improvement, ERCP is attempted to relieve the obstruction. This management scheme is successful in 85% to 90% of the cases. Cannulation of the common bile duct and identification of the obstruction are diagnostic.

In patients in whom there is no clinical improvement in 24 hours, surgical decompression with cholecystectomy and common bile duct exploration should be considered (125). Morbidity and mortality are greatly increased in this patient population and correspond to the patient's underlying physiologic state [and approach 30% to 40% (126)]. Those patients who present in shock with comorbid disease are at higher risk. These patients are quite ill and typically require an open procedure rather than a laparoscopy. If surgical decompression is unsuccessful, placement of a T-tube for drainage also affords the interventional radiologist a chance to retrieve a stone in six weeks, when the T-tube track may be sequentially cannulated and dilated. Outcomes of mild-to-moderate ascending cholangitis are excellent. Severe cholangitis or a poor host has significant morbidity and mortality associated with this disease. Patients in septic shock have a 20% to 25% mortality rate associated with this disease (127).

### Acute Diverticulitis

The presence of fever, leukocytosis and CT evidence of free fluid, abscess, hemoperitoneum or micro deposits of free air around the inflamed colon signify a more serious case of diverticulitis (128). Advanced diverticulitis may present with a localized abscess, peritonitis, or fistula formation. The latter may present as colocutaneous, colovaginal, colovesical, or coloenteric fistula. ⚡ **Patients with diverticulitis who are unable to sequester the infection can develop peritonitis.** ⚡ Indications for operative care of diverticulitis include: (i) diffuse peritonitis, (ii) unresolving obstruction, (iii) fistula, (iv) symptomatic stricture, (v) failure to improve on medical therapy, (vi) recurrent attacks, (vii) inability to exclude carcinoma, (viii) bleeding, and (ix) immunosuppression (129). Patients may be admitted to the SICU with newly diagnosed diverticulitis after percutaneous drainage of an abscess or in the perioperative period. These patients are typically elderly and have a more advanced disease. Their needs include ongoing fluid resuscitation, control of heart rate, ventilation, or general supportive critical care measures. Patients returning from the operating room will have undergone resection of the affected segment of colon, drainage, and debridement of the surrounding abscess cavity and a diverting colostomy with a Hartman's procedure. In selected patients, primary colonic anastomosis in the setting of an unprepped bowel may be considered (130). Choosing the proper patients for a primary repair is

dependent upon the patient's physiologic state, nutritional state, and added operating time (36,95). The abdomen may be left open with only a fascial closure.

## OTHER INTRA-ABDOMINAL INFECTIOUS PROCESSES

### *Clostridium difficile* Colitis

*Clostridium difficile* is a gram-positive, spore forming, anaerobic bacillus. The primary source of infection is nosocomial. It is estimated that 20% to 30% of patients will test positive for *C. difficile* after admission to the hospital, compared to 2% of healthy individuals in the community. The spores from *C. difficile* are resistant to oxygen, desiccation, and many disinfectants facilitating the nosocomial transmission of *C. difficile* via the fecal-oral route.

In order for clinical *C. difficile* colitis to develop, alterations in the normal colonic microenvironment must be changed to favor this proliferation of *C. difficile*. Antibiotics are the most common cause for this alteration. Although all medications have been associated with *C. difficile* colitis, including vancomycin and metronidazole, those most commonly linked are clindamycin, cephalosporins, quinolones, amoxicillin, and ampicillin. Antibiotic factors associated with clinical disease include the dose and frequency of antibiotic use, route of administration (oral most associated), and the bactericidal effect of the antibiotic to anaerobes.

♣ **Only one-third of the hospitalized patients who become colonized with *C. difficile* will go on to have clinical manifestations of colitis (131).** ♣ Fifty percent of all colonized patients will harbor the toxigenic strains. The host immune system is thought to play a significant role in who becomes symptomatic. Significant correlation has been found between high levels of IgG Anti-Toxin A and asymptomatic carriers. Higher levels of anti toxin IgG may play a role in lessening risk of onset and/or clinical severity of the patient's disease (132). The pathogenicity of the *C. difficile* strain is also an important factor. *C. difficile* becomes pathogenic when it acquires the ability to produce Toxin A or Toxin B. These toxins incite an inflammatory reaction in the lamina propria, and recruit proinflammatory cells (133).

Risk factors of clinical disease are: duration of hospital stay, an ICU admission, use of multiple antibiotics, and duration of antibiotic exposure. Increased age and severity of underlying illness were also found to be important and correlated with an eight-time increase in the likelihood of clinical infection. *C. difficile* colitis occurring in the absence of antibiotics has also been reported in the chemotherapy and Hirschsprung disease population.

Given that antibiotics are one of the leading risk factors for developing *C. difficile* colitis, prolonged surgical antibiotic prophylaxis should be avoided. Antibiotics continued postoperatively versus a single or three-dose prophylaxis regimen have been found to significantly increase the incidence of *C. difficile* infections. Prophylaxis preop with metronidazole has not been found to be effective in protection against *C. difficile*.

The spectrum of clinical disease varies widely. As previously discussed there is a significant hospitalized population who becomes colonized with pathogenic strains of *C. difficile*, but remain asymptomatic. These patients are without clinical symptoms, and will require no further diagnostic testing or treatment.

Antibiotic-associated diarrhea is the most common clinical manifestation of intestinal *C. difficile* disease. This is usually manifested by watery nonbloody diarrhea without

true systemic signs of infection, such as fever or leukocytosis. Endoscopic findings vary from a normal to a mildly edematous-appearing colonic mucosa. These cases typically resolve after the offending antibiotic has been stopped. In more advanced clinical *C. difficile* colitis cases, the colon will demonstrate luminal inflammation, edema, and in severe cases, the classical pseudomembrane. These changes may endoscopically appear to be continuous or present as patchy areas of colonic involvement (134). These patients usually have watery mucoid diarrhea, and possibly hemocult positive stool. Frank blood is rare. Often patients complain of abdominal pain with distension and systemic signs (nausea, low grade fevers, leukocytosis, and fatigue). The preferential areas of colonic disease are usually limited to the sigmoid and rectum. In some patients, the colitis is limited to the cecum and right colon. These patients may present with abdominal distension, ileus, and minimal diarrhea.

Fulminant pseudomembranous colitis is a rare consequence of *C. difficile* intestinal infection. These patients may present with any combination of signs and symptoms from abdominal pain and watery diarrhea to abdominal distension and a paralytic ileus. In the most severe cases, patients may present with a toxic megacolon, signs of a systemic inflammatory response, tachycardia, and hypotension. *C. difficile* colitis should be considered in any patient who has recently received antibiotics and presents with toxic megacolon of unknown etiology. Cytomegalovirus (CMV) colitis must also be in the differential, especially if the patient is immunocompromised and presents with symptoms of pseudomembranous colitis with negative *C. difficile* toxin assays (135).

A suspicion of *C. difficile* colitis should be raised if antibiotics have been used in the last three months or if the patient has been hospitalized for greater than 72 hours. The gold standard diagnostic test is a stool sample cytotoxicity assay for Toxin B. This test is costly and requires several days for results. An ELISA for Toxin A or B is more rapid, with sensitivities and specificities similar to the gold standard. Endoscopic evaluation is indicated if significant disease is present and stool labs are repeatedly negative, or if a rapid diagnosis is required. ♣ **On endoscopy, the presence of pseudomembranes correlates with a >95% chance of *C. difficile* infection.** ♣ Flexible sigmoidoscopy or colonoscopy is indicated as 20% of pseudomembranes are beyond 25 cm from the anal verge. A CT scan of the abdomen will demonstrate a thickened colonic wall in involved regions, and may show pneumatosis or perforation in advanced cases.

No benefit has been found in the treatment of asymptomatic carriers with antimicrobials. Treatment of mild-to-moderate disease should focus on fluid and electrolyte replacement, discontinuation of antibiotic regimen, and avoidance of medications that impair gastrointestinal peristalsis (narcotics/antidiarrheal agents). Drugs that impair gastrointestinal motility impair the clearance of *C. difficile* toxin and allow more time for the toxin to incite an inflammatory reaction in the gastrointestinal tract. High-risk antibiotics should be discontinued if possible or substituted with those that are less likely to contribute to *C. difficile* colitis. Clinical improvement is seen in 15% to 25% of patients after discontinuing the inciting antibiotics.

If symptoms continue despite discontinuing or changing antibiotics, and *C. difficile* infection has been confirmed, then either metronidazole or vancomycin is indicated. Oral metronidazole is the first drug of choice with a dose of 500 mg TID for 10 to 14 days. In patients unable to take oral metronidazole, intravenous therapy should be attempted for a longer course of 14 days. Attempts to coadminister

oral metronidazole via a nasogastric tube can be undertaken. With this regimen, greater than 90% of cases of *C. difficile* will resolve. Metronidazole has been found to be therapeutically equivalent to vancomycin in the treatment of *C. difficile*, is less expensive, and carries a theoretically decreased risk of creating vancomycin resistant strains of Enterococcus. Oral vancomycin (125 mg TID) is indicated as a first line medication in pregnant females, children under ten, and those who fail a course of metronidazole.

The treatment of severe/fulminant pseudomembranous colitis is not standardized. Although this represents 3% to 5% of *C. difficile* associated disease, the mortality rate is 65%. Oral vancomycin is recommended as the initial pharmacologic intervention, along with fluid and electrolyte replacement, and discontinuing high-risk antibiotics as discussed above. Although vancomycin and metronidazole have been shown to be therapeutically equivalent, some feel that patients respond more rapidly to oral vancomycin. Because decreased gastrointestinal motility may interfere with drug delivery, many increase the dose of vancomycin to 500 mg every 6 hr and deliver it via a nasogastric or nasointestinal tube. A few small studies have also reported infusing vancomycin via colonic catheters during colonoscopy. Passive immunization with anti *C. difficile* toxin immunoglobulin has also been reported as effective, but needs further investigation via controlled studies.

Surgery is required in approximately 5% of *C. difficile* cases. Generally, these fall into the severe/fulminant category, which is initially unresponsive to medical treatment and in those patients who present with perforation. There is no consensus as to how long medical treatment should be continued before declaring failure and pursuing surgical options. If possible, a therapeutic course of 48 to 72 hours of medical treatment should be attempted if the patient's condition permits before proceeding onto a surgery. Some of these patients may present as an "acute surgical abdomen" and undergo a laparotomy prior to establishment of the *C. difficile* diagnosis. The most common complications in these patients who ultimately require surgery for fulminant colitis include toxic megacolon with perforation, volvulus, and complicated acute diverticulitis. Plain films often demonstrate dilated small or large bowel, mucosal edema with thumb printing, and intramural gas, which may be indistinguishable from obstruction or ischemic bowel. A CT scan is also usually unhelpful in establishing the diagnosis of *C. difficile* fulminant colitis. Bowel thickening with pericolic streaking and possible ascites may be present with a classic cloverleaf or accordion sign in 20% of the cases. Severity of clinical disease has not been found to correlate with CT appearance. Colonoscopy may be helpful in decompressing a dilated colon, but increases the risk of perforation.

At laparotomy, the external wall of the involved bowel may appear normal. Because of this deceptive appearance of "healthy bowel," some have been tempted to perform segmental resection with reanastomosis (136). Several studies, although with smaller number of patients, have found a decreased mortality rate with subtotal colectomy versus segmental resection or colostomy (137). The failure rate of subtotal colectomy has been reported to be 24% versus that of segmental resection and diverting stomas, which are 40% and 75%, respectively (138).

☞ ***C. difficile* will recur in 16% to 20% of patients who initially responded to treatment.** ☞ No difference in recurrence exists between patients initially treated with vancomycin versus metronidazole. Risk factors for recurrence include treatment with additional antibiotics and history of a

previous recurrence. Although recurrence may be due to reactivation of persistent *C. difficile* spores in the colon, approximately 50% of recurrences are a consequence of reinfection with a different *C. difficile* strain. These patients may simply be retreated with the same agent (metronidazole or vancomycin). Patients with a second relapse should be on vancomycin 125 mg QID for six weeks of therapy. Multiple recurrences are seen in 8% of the treated patients.

Anion-binding resins have also been used in the treatment of *C. difficile* colitis. Cholestyramine binds *C. difficile* toxin and helps with elimination of the toxin. Anion-binding resins also bind vancomycin, and should not be given within three hours of one another. Probiotics have also been investigated in an attempt to establish a colonic microenvironment, which limits *C. difficile* overgrowth. *Saccharomyces boulardii* has been found, in a recent European study of 124 patients, to significantly decrease recurrences of *C. difficile* in patients with a history of multiple recurrences when used in conjunction with vancomycin or metronidazole. No difference in recurrence rates was discovered when used in the patients' first episodes of *C. difficile*.

### Cytomegalovirus Colitis

CMV is a DNA virus belonging to the herpes family that is clinically active in critically ill patients with acquired immuno deficiency syndrome (AIDS) and organ transplantation. CMV is ubiquitous, and seropositivity for CMV ranges from 30% to 100% depending on the population studied (139). CMV is present in most bodily secretions including urine, feces, semen, saliva, breast milk, blood, cervical, and vaginal secretions. The initially asymptomatic inoculation and infection is followed by a period of latency that can last for the life of the patient if they remain immunocompetent. Immunosuppression or immunodeficiency allows for reactivation of the disease.

Patient populations found to be particularly at risk include AIDS and transplant patients, as well as patients on immunosuppression for inflammatory bowel disease (140). Ninety percent of patients with AIDS, at autopsy, have been found to have disseminated CMV. The most common infectious complication of solid organ transplant remains CMV, occurring in 60% to 70% of patients. Ten percent of these patients manifest clinical CMV colitis.

☞ **Symptomatic CMV infection rates for solid organ transplantation have been as follows; kidney (8%), liver (29%), heart (25%), and heart-lung transplant recipients (39%) (141).** ☞ The two major factors that seem to correlate with symptomatic CMV colitis in transplant patients include exposure to CMV prior to transplantation and the degree of immunosuppression after transplantation. Many transplant patients are placed on prophylactic antiviral regimens, such as ganciclovir 3 gm/day or acyclovir 3.2 gm/day for disease prevention (142).

☞ **Although CMV colitis typically presents with watery diarrhea, 30% of patients may have fever and weight loss without diarrhea and some may present simply with bloody stools and no diarrhea.** ☞ Associated symptoms are nausea, vomiting, fever, weight loss, and gastrointestinal bleeding. CMV infection of the colon causes vasculitis, and may result in bowel ischemia and a clinical presentation, which mimics surgical acute abdomen. Toxic megacolon, perforation, and hemorrhage have been reported as complications of intestinal CMV infection. The Wilson group reported that the most common reason for AIDS patients

receiving abdominal surgery was CMV colitis. Antiviral therapy has been effective in reducing the incidence of the most severe complications associated with CMV colitis and have made surgery for this disease uncommon.

CMV colitis may be difficult to distinguish from other causes of colitis. On endoscopy, friable mucosa, erythema, and isolated shallow or deep coalescing ulcers are present. Submucosal hemorrhage may also be present, and is a result of CMV-induced vasculitis. These lesions are usually patchy and limited to one region of the colon. Isolated right colonic lesions are reported in the literature from 13% to 40%, underscoring the importance of full colonoscopic evaluation versus sigmoidoscopy. Endoscopic biopsy with demonstration of CMV inclusion bodies is the gold standard of diagnosis (143). In addition, 25% of patients may have mucosa that appears grossly normal. Random biopsies of inflamed and noninflamed regions from the cecum, ascending, transverse, descending, and sigmoid are important. Although uncommon, CMV has been isolated from grossly normal bowel.

Biopsies typically demonstrate an inflammatory infiltrate consisting of leukocytes, lymphs, and plasma cells. Enlarged mucosal cells with basophilic intranuclear inclusions are pathognomonic for CMV. CMV cultures of stool have not consistently been found to be predictive of active infection and are not advised. Polymerase chain reaction of patient serum is the best method of diagnosis and monitoring therapy. CT scan generally shows nonspecific colonic thickening consistent with colitis, and is often a nonspecific diagnostic tool.

Most patients with CMV colitis are managed medically. Typically an initial treatment regimen includes ganciclovir (5 mg/kg IV q 12 hours). Improvements in histological samples have been seen within three weeks. Complete response to therapy is seen in about 90% of patients. If complete response is not achieved, Foscarnet (60–90 mg/kg IV TID) is initiated. The lowest recurrence rates in patients with AIDS-associated CMV colitis have been those on protease inhibitors. The “outcome of AIDS-associated CMV colitis in the era of potent antiretroviral therapy” was examined by Bini et al. (144). The patient population consisted of severely immunocompromised AIDS patients. Although rectosigmoid colon was most commonly affected, 29% on endoscopy had disease limited to the right side of the colon. Bini felt strongly that full colonoscopy was important in AIDS patients with chronic unexplained diarrhea or gastrointestinal bleeding. Recurrent CMV infection has been found in up to 75% of patients.

♣ **Indications for the surgical management of CMV colitis include perforation, massive gastrointestinal bleeding, and toxic megacolon.** ♣ Patients with mild signs of peritoneal irritation with no free air and strong likelihood of CMV colitis should initially be treated medically. Patients who require surgery should have segmental resection of the colon without reanastomosis at the initial surgery. Surgical mortality of AIDS patients undergoing emergency bowel resection was 28% on the first postoperative day. One-month mortality rose to 71%. Six-month mortality was 86%. Death was usually due to sepsis and *Pneumocystis carinii* pneumonia.

## Genitourinary Infections

Genitourinary infections that may present in the critically ill patient include simple urinary tract infections, perinephric abscess, acute focal bacterial nephritis, and renal abscess

(145). Urinary tract infections (UTI) present no differently than in noncritically ill patients and are suspected with a change in the color of the urine, cloudy sediment, or hematuria. Under normal conditions, the genitourinary tract is sterile. In the face of obstruction, secondary infection may develop. Urinalysis may demonstrate the presence of leukocytes, bacteria, or test positive for leukocyte esterase or nitrate, which are supportive evidence of an infection. Urine cultures confirm that the diagnosis may be classified as a solitary carbuncle or multifocal medullary abscess.

♣ **Ascending infections, pyelonephritis, and medullary abscess are usually accompanied by history of reflux, calculi, or obstruction due to previous surgery.** ♣ Urinalysis usually demonstrates pyuria and bacteria. Medullary abscess may present as acute pyelonephritis. Classically with this presentation, fever and leukocytosis continue after initiation of antibiotics (146).

Hematogenous spread of bacteria to the kidneys is also possible. Primary sources of infection include infected skin wounds, osteomyelitis, and use of contaminated intravenous devices via intravenous drug use or hemodialysis. Currently, the most common etiology of renal abscesses is ascending urinary tract infection usually associated with “renal tubular obstruction from previous infection or calculi” (147).

Clinical presentation usually includes fever, chills, flank pain, and occasionally weight loss and malaise. Important historical points are recent Staph infection (within last 1–8 weeks), recent history of urinary stasis, calculi, pregnant neurogenic bladder, and diabetes. Typically, renal abscess due to hematogenous spread presents with acute onset of fever, chills, flank pain without history of UTI, and usually demonstrates no growth on urine culture. The cutaneous Staph infection that leads to hematogenous seeding may occur up to eight weeks prior to the renal symptoms.

Urinary cultures correlate well with the etiologic agent of the renal abscess. Although pyuria and proteinuria are common, one-third of the urinalysis will be normal and 40% of urine cultures will have no growth. One-third of patients will have positive blood cultures, whereas anemia and azotemia are present in 40% and 25%, respectively.

Radiographic data may be helpful in establishing the diagnosis. Plain film is a nonspecific tool, but may demonstrate obliteration of the psoas shadow or enlargement of the kidney. A CT scan is the diagnostic procedure of choice and will best define the relationship of the abscess with the surrounding structures. The appearance of the infectious process will depend on its stage of development. In the early stages of infection, a “focal region of decreased attenuation” will be present. In the next few days, the focus of infection becomes walled off. When the chronic abscess is established, surrounding tissue planes are obliterated, Gerota’s fascia appears thickened, and the abscess is a “low attenuating mass with a ring of higher attenuation which represents the inflamed wall.” This is known as the ring sign. Generally, renal carbuncles appear as solitary space-occupying lesions, whereas medullary abscesses appear as small multifocal lesions or simply as a poorly functioning kidney.

Treatment of the infection depends on its size. Abscesses less than 3 cm that are discovered early may be treated with intravenous antibiotics and close observation. Percutaneous drainage becomes necessary when abscesses are 3 to 5 cm or if the patient is either immunocompromised or unresponsive to antibiotics and close

observation. Surgical drainage is required when abscesses are greater than 5 cm.

### Tubo-ovarian Abscess

Tubo-ovarian abscess (TOA) is a major complication of pelvic inflammatory disease. The history of prior pelvic inflammatory disease is elicited from 30% to 50% of the patients with a tubo-ovarian abscess. Tubo-ovarian abscess occurs most frequently in the third and fourth decades of life. Abdominal and pelvic pain present in greater than 90% of tubo-ovarian abscesses in the literature. This is usually accompanied by fever, chills, and occasional vaginal discharge and/or bleeding, and nausea. Twenty to thirty-five percent of these patients may present afebrile with a normal white count. The clinical picture of the tubo-ovarian abscess may be further complicated by some presenting as uncomplicated pelvic inflammatory disease. **♣ The key to diagnosis of tubo-ovarian abscess is “inflammatory adnexal mass.” Because physical exam alone may be inadequate, when suspicion arises, imaging test should be used. ♣**

US or CT is the most appropriate investigation for imaging a potential pelvic/intra-abdominal abscess. US will not only localize the mass, but also provide information as to its complexity. Transabdominal US has 90% sensitivity for diagnosing pelvic abscess. Endovaginal US has improved on both sensitivity and specificity. An additional use for US is its ability to determine efficacy of therapy once antibiotics or drainage has been employed.

In most patients, the tubo-ovarian abscess is composed of mixed aerobic and anaerobic bacterial flora. The predominant organisms discovered, in a recent study, by the Landers group included *E. coli* (37%), *B. fragilis* (22%), Prevotella (26%), aerobic streptococci, Peptococcus (11%), and Peptostreptococcus (18%). Although pelvic inflammatory disease is a key risk factor for tubo-ovarian abscess, *Neisseria gonorrhoeae* and *Chlamydia trachomatis* are rarely isolated from the tubo-ovarian abscess. Most infections are polymicrobial and contain anaerobes. Similar to intra-abdominal infections, it is the anaerobic bacteria that are responsible for abscess formation within the oviducts and ovaries.

With an unruptured tubo-ovarian abscess and concerns regarding future reproductive ability and maintenance of the hormonal axis, a conservative medical approach is initially pursued. If there is no clinical response to antibiotics (persistent fever, persistent leukocytosis), if the patient's condition worsens (increased size of tubo-ovarian abscess, increased sedimentation rate), or a suspicion of rupture exists in the first 48 to 72 hours, then surgery is indicated. In young nulliparous women, some allow for an additional 24 to 48 hours before declaring a failure of antibiotic therapy. The presence of an adnexal mass >8 cm and/or bilateral adnexal involvement were predictive of medical failure. Degree of leukocytosis, fever, and past history of pelvic inflammatory disease (PID) were not predictive of medical failure. Response to medical therapy ranges from 16% to 95% in the literature with a mean of 69.4% (148). Broad-spectrum antimicrobial agents with anaerobic coverage are indicated for these infections (149).

**♣ Indications for surgical management of TOAs include rupture and suspicion of rupture. Delay in treatment of TOA significantly increases mortality. ♣** The surgical approach to unruptured tubo-ovarian abscess includes extraperitoneal drainage, drainage via posterior colpotomy or vaginal colpotomy, total hysterectomy with bilateral adnexectomy, unilateral adnexectomy, percutaneous drainage, and laparoscopic drainage. Extraperitoneal drainage

requires the “adherence of parietal and visceral peritoneum” to be effective. This modality is infrequently used because better results have been achieved with laparoscopic and percutaneous techniques. Posterior colpotomy is used primarily for “fluctuant abscess in the midline, which dissects the rectovaginal septum and is firmly attached to the parietal peritoneum.” This specific indication has limited the number of tubo-ovarian abscesses, which would benefit from this procedure. A danger of peritoneal sepsis also exists as a potential complication from this approach. Vaginal colpotomy is rarely used and carries a high complication rate. Aggressive debridement with total hysterectomy and bilateral adnexectomy has been advocated by some. Unilateral adnexectomy is recommended to maintain fertility and a normal hormonal axis. Seventeen percent of patients after this procedure required additional surgery at a later date and 14% had subsequent intrauterine pregnancies. Studies that support this approach are retrospective and lack significant long-term follow-up.

CT-guided drainage is usually carried out via the transgluteal approach that often causes significant patient discomfort. Endovaginal and transrectal US guided drainage have demonstrated good results in the limited number of cases that have been reported. The additional benefit of CT and US are that they can later be used to evaluate the effectiveness of the therapeutic drainage. Reported cases of laparoscopic drainage are also encouraging, but are limited in number.

### EYE TO THE FUTURE

Better understanding of the perioperative course of a critically ill surgical patient affords the clinician the best opportunity to provide high quality care. Improved diagnostic equipment, such as abdominal CT scans with 32 and 64 arrays, produce a more comprehensive scan. Multiplanar scanning and computerized reconstruction will produce body images of a quality not yet achieved.

Antibiotic resistance is an ever-increasing problem. Clinicians will need to embrace evidence-based recommendations for surgical antibiotic therapy. These recommendations describe which patients would benefit from antibiotic therapy and specify the duration of therapy. The recommendations must become widespread, rather than each clinician basing antibiotic therapy on personal experience.

Source control will remain the cornerstone of abdominal infection control. Basic principles of drainage, diversion, debridement, and definitive care are essential to eradicate any infection. Patient physiology will continue to drive the intraoperative surgical decision-making. Whether the patient has the reserve to continue on the operating table or if the patient should undergo a temporizing procedure will remain a difficult and crucial question. Ultimately, patient care will depend upon thoughtful consideration of these choices often made under very difficult circumstances.

### SUMMARY

Intra-abdominal infections remain a significant problem. Knowledge of the normal and abnormal postoperative period is essential for the clinician taking care of critically ill patients. ICU patients are often unable to demonstrate

the typical signs and symptoms of intra-abdominal disease. Attention to the patient's progression in the perioperative period is essential, to notice subtle changes in the gastrointestinal function, which may be the only harbinger of abdominal disease.

The abdominal and pelvic CT have done more to aid in the diagnosis of an intra-abdominal infection than any other diagnostic modality. Often times, not only is the abdominal pathology visualized but important information concerning the adjacent structures is obtained. This facilitates better operative planning and patient management. In trauma patients, the delineation of bowel wall characteristics suggestive of injury are now becoming commonplace. Thin cuts through the hepatobiliary system aids in the diagnosis of injury. The use of the CT angiography to identify vascular flow within intra-abdominal organs and vessels greatly assists in our diagnostic abilities. Perfusion of organs, such as the pancreas in disease, is much better delineated so as to determine the viability of this organ.

Antibiotic selection and duration of antibiotic therapy is an important issue particularly in light of the increasing pattern of microbial resistance. Those patients for whom antibiotic therapy is recommended for  $\leq 24$  hours include the following: (i) patients with iatrogenic or traumatic enteric perforations, with peritoneal contamination, who are able to be operated upon within 12 hours; (ii) patients with gastroduodenal perforation operated on within 24 hours; (iii) patients with acute or gangrenous appendicitis or cholecystitis without perforation; and (iv) patients with transmural bowel necrosis, without bowel perforation, peritonitis, or abscess formation. In these patients single dose of preoperative antibiotics are indicated. A second group of patients for whom antibiotic therapy would be indicated for  $\geq 24$  hours include those patients with established surgical intra-abdominal infections or more extensive intraoperative findings than the former described group of patients.

The ultimate resolution of an intra-abdominal infection is predicated upon adequate source control. Methods include drainage, diversion, debridement, and definitive care. The choice of which modality to use is determined by the underlying disease process, likelihood of establishing source control, and patient physiology.

Paradigm shifts to the nonoperative management of solid organ injury has generated a new set of complications. High grade liver injuries (4–5) are associated with the formation of a bile leak, biloma, hepatic, or intra-abdominal abscess. Suspicion of these problems by day 4 postinjury should prompt the clinician for a workup, which may include an US or CT. Drainage and possible washout of bile collections is usually performed in these patients.

Missed injuries in trauma patients represent only a small area for which intra-abdominal infections occur. Constant vigilance to potential injuries that may present in a delayed fashion should be suspected in selected patients. Yet, it is clear that missed abdominal injuries that result in gastrointestinal perforation result in increased morbidity and mortality if there is a delay in diagnosis. If a patient unexpectedly deteriorates, appropriate diagnostic testing should be performed and resuscitative measures taken.

Other disease entities may cause intra-abdominal infection. These include colitis, genitor-urinary infection, and gynecologic infections. *C. difficile* colitis, in particular, is a great masquerader. Patients should be suspected with this disease in situations where they have been on long-term antibiotics or have long-term hospitalizations. The disease is readily treatable, however, when a toxic

colitis has developed, treatment options are limited and the end result may be a subtotal colectomy with diverting ileostomy.

Overall, a fundamental understanding of the perioperative course of a surgical patient and recognition of deviations from this is essential to provide critical care. Armed with this knowledge a physician can act upon subtle clinical signs and disease presentation to rapidly diagnose and treat an underlying intra-abdominal infection.

## KEY POINTS

- ✂ The first clues to the development of an intra-abdominal infection may be the new onset of fever, leukocytosis, intolerance to oral feedings, abdominal distension, or deterioration in the patient's hemodynamic status (7).
- ✂ Familiarity with the normal postoperative course as well as the timing and presentation of postoperative complications assist in the management of critically ill patients.
- ✂ The peritoneum acts as a semipermeable membrane allowing for the passage of both fluid and solutes.
- ✂ In a study of 2457 consecutive surgical infections at the University of Virginia, 10% (252/2457) were due to intra-abdominal infections (23).
- ✂ Adjunct imaging studies are critical to the diagnosis of intra-abdominal infections, Postoperative complications, or missed traumatic injuries.
- ✂ The abdominal CT scan has greatly advanced our ability to diagnose intra-abdominal pathology (31).
- ✂ The use of radionuclide scanning with Gallium-67 citrate or Indium-111 to detect areas of active inflammation or infection is less commonly used today, due to the advancements in multisliced CT scanning.
- ✂ Local source control is paramount in order to manage intra-abdominal infections; without it, fluid resuscitation, antibiotic therapy, and critical care are unlikely to succeed (36).
- ✂ Source control is the process by which a site of infection (intra-abdominal or otherwise) is controlled so that further contamination of the surrounding tissues ceases.
- ✂ The intent of peritoneal toilette is to drain the abscess, debride devitalized tissue, and remove gross fecal material and foreign bodies.
- ✂ The presence of a foreign body significantly lowers the quantity of micro-organisms needed to produce infection (42).
- ✂ The choice of antibiotics is predicated upon thoughtful consideration of the patient's surgical infection in conjunction with the patient's underlying physiologic state as well as comorbid disease.
- ✂ Significant factors that have been shown to increase patient morbidity and mortality include a higher severity of illness, age greater than 50, an APACHE II score of  $>8$ , poor nutritional status, significant cardiovascular disease, inadequate source control, and the presence of multidrug-resistant organisms (44).
- ✂ The microbiology of intra-abdominal infections has remained remarkably stable over the last 30 years.
- ✂ The use of antibiotics directed against anaerobic bacteria (*B. fragilis*) in colonic perforation is an established principle.
- ✂ SBP is infectious in origin and is usually seen in patients with cirrhosis and ascites (73).
- ✂ Secondary peritonitis is a result of a break in the intra-abdominal viscera integrity (13).
- ✂ Primary repair of gastroduodenal ulcer perforation is dependent upon the etiology of the perforation.

- 9 Acalculous cholecystitis is rarely seen outside of the SICU. It typically occurs in very ill patients who have been receiving parenteral nutrition.
- 9 The presence of gall bladder wall necrosis may be missed on both CT and US; therefore, if a percutaneous drain is placed the patient needs to be observed closely over the next two to three days to ensure clinical improvement.
- 9 Treatment of ascending cholangitis is a medical emergency and requires prompt decompression.
- 9 Patients with diverticulitis who are unable to sequester the infection can develop peritonitis.
- 9 Only one-third of the hospitalized patients who become colonized with *C. difficile* will go on to have clinical manifestations of colitis (152).
- 9 On endoscopy, the presence of pseudomembranes correlates with a >95% chance of *C. difficile* infection.
- 9 Treatment of ascending cholangitis is a medical emergency and requires prompt decompression.
- 9 Symptomatic CMV infection rates for solid organ transplantation have been as follows: kidney (8%), liver (29%), heart (25%), and heart–lung transplant recipients (39%) (162).
- 9 Although CMV colitis typically presents with watery diarrhea, 30% of patients may have fever and weight loss without diarrhea and some may present simply with bloody stools and no diarrhea.
- 9 Indications for the surgical management of CMV colitis include perforation, massive gastrointestinal bleeding, and toxic megacolon.
- 9 Ascending infections, pyelonephritis and medullary abscess are usually accompanied by history of reflux, calculi, or obstruction, due to previous surgery.
- 9 The key to diagnosis of tubo-ovarian abscess is “inflammatory adnexal mass.” Because physical exam alone may be inadequate, when suspicion arises, imaging test should be used.
- 9 Indications for surgical management of TOAs include rupture and suspicion of rupture. Delay in treatment of TOA significantly increases mortality.

## Sinusitis

Quyen T. Nguyen and Terence M. Davidson

Department of Otolaryngology–Head and Neck Surgery, UC San Diego Medical Center, and San Diego VA Healthcare System, San Diego, California, U.S.A.

### INTRODUCTION

Paranasal sinusitis is an important potential cause of fever in the intensive care unit (ICU) (1). The pathophysiology of sinusitis in the ICU setting is similar to that of outpatient sinusitis and is related to obstruction of the osteomeatal complex (OMC), or to disruption of normal mucociliary transport. This is true for the critically ill trauma patient who often has additional risk factors beyond simple inflammatory sinus obstruction, for example, structural injury and disruption of the sinus drainage system. Patients in the ICU often have complicating debilitating medical issues such as nosocomial colonization and immune suppression. Paranasal sinusitis in this setting may lead to severe complications including pneumonia, meningitis, and sepsis (2–5). Thus, when there is clinical concern of sinusitis in the ICU setting, it is evaluated and treated aggressively. This chapter will review the anatomy, pathophysiology, microbiology, diagnosis, and treatment of sinusitis in the critically ill patient. A typical case will be presented to illustrate the key points of diagnosis and treatment.

### ANATOMY

The paranasal sinuses consist of four paired pneumatized cavities of the skull and facial bones with ostia that drain into the nose (Fig. 1). These are named from top-medial to bottom-lateral as the frontal, ethmoid, sphenoid, and maxillary sinuses. The ethmoid sinuses are unique in that they are composed of 18 to 20 small air cells (like a honeycomb) rather than a single large cavity. The ethmoids are divided into anterior cells, which drain into the middle meatus, and the posterior cells, which drain into the superior meatus. The sphenoid sinus drains via the superior meatus. The frontal, maxillary, and anterior ethmoids all drain via the middle meatus. All of the paranasal sinuses are lined with ciliated pseudostratified columnar epithelial cells (6). The cilia of the sinus mucosa propel a mucus blanket of secretions, bacteria, and purulence toward the ostia. In normal adults, approximately 1500 cc of fluid is produced each day from the epithelium of the nose and paranasal sinuses. Mucociliary transport is estimated to be at a speed of 0.5 cm/min in normal conditions (7). The combination of a large fluid production and a healthy active

mucous transport system keeps the bacterial colony count low in normal healthy patients.

The most frequently diseased paranasal sinuses are those that drain into a small region in the middle meatus called the ethmoid infundibulum, a part of the OMC. This small space has a maximal volume of 2.88 cc (7) and contains multiple small narrow clefts that can be easily occluded and obstructed. Obstruction and consequent inhibition of the mucociliary transport system causes decreased ventilation, leading to stagnation of the secretions, resulting in an infection commonly called sinusitis.

### PATHOPHYSIOLOGY

The area of the middle meatus where the sinus ostia drain from the frontal, maxillary, and anterior ethmoid sinus is called the OMC. Nasogastric (NG) tubes can physically obstruct the ostia or paralyze the mucociliary transport system. The anterior ethmoid and maxillary sinuses are the most commonly involved paranasal sinuses in patients with nosocomial sinusitis. However, many patients with radiologic maxillary sinusitis also have abnormalities of the posterior ethmoid, frontal, and sphenoid sinuses.

#### Mechanical Obstruction

☞ **The single most important factor in the development of sinusitis is the disruption of the mucociliary transport system, typically from obstruction of the normal drainage pathways, the OMC of the paranasal sinuses.** ☞ In the intensive care setting, mucociliary transport from the paranasal sinuses is commonly obstructed in the nasal cavity by NG tubes or nasotracheal intubation. These tubes may directly obstruct the sinus ostium, or cause swelling of the nasal ostium via inadvertent trauma occurring during insertion (8). However, impaired mucociliary clearance or changes in the mucous composition in states of dehydration, chronic disease, and mechanical ventilation also lead to mucociliary stasis, obstruction of sinus ventilation, and impaired mucous outflow. Trauma to the nasal mucosa leads to mucosal edema and inflammation that can impair mucociliary clearance. Interestingly, no difference in sinusitis rates was seen in critically ill patients who were intubated via the nasal route compared to orally intubated patients (9). This is partly explained by the fact that most

**Figure 1** Superimposition of coronal computed tomographic image through paranasal sinuses on photograph of male patient. The paranasal sinuses occupy a large volume within the human head and produce a large amount of mucus each day. However, the drainage outflow from these sinuses must pass through narrow clefts that are easily obstructed. *Note:* The outflow tract (*arrow*) is in the superior medial aspect of the maxillary sinus; thus gravity has a limited role in the drainage of mucosal secretions. *Arrow*, maxillary sinus ostia through which mucus secreted by maxillary sinus mucosa must pass. *Abbreviations:* E, ethmoid sinus; IT, inferior turbinate; M, maxillary sinus; MT, medial turbinate.

of the orally intubated patients also had nasal tubes for GI decompression or enteral feeding.

### Non-mechanical Factors

The composition of the sinonasal mucus is sensitive to multiple factors. Changes in the mucous viscosity can affect mucociliary clearance (10). In acutely ill patients, dehydration, chronic disease, or mechanical ventilation may lead to thickened mucus, mucociliary stasis, and consequent sinusitis (11). Even in patients without nasal tubes, the supine position and limitation of head movements in the ICU setting impedes the natural sinus drainage facilitated by gravity (12). Furthermore, the supine position is associated with decreased venous drainage from the head and neck regions, leading to increased nasal congestion and mucosal edema, further obstructing mucociliary transportation. In the intubated patient, positive pressure ventilation may compound this problem by raising central venous pressure (5).

### Trauma-Related Risk Factors

Patients in the trauma ICU often have additional risk factors that predispose them to developing paranasal sinusitis. For example, craniofacial trauma can lead to the presence of blood and bony debris in the nose and paranasal sinuses, which predispose the patient to bacterial sinusitis. Furthermore, fractures of the facial bones may lead to mechanical obstruction of the OMC, with resultant development of ostial obstruction, mucous stasis, and sinusitis (13).

### Pre-existing Conditions

There are a number of additional pre-existing conditions completely unrelated to trauma or critical illness that increases the risk of sinusitis. These include anatomic abnormalities such as congenital choanal atresia, septal deviation, foreign bodies, and tumors. In addition, allergic rhinitis causes nasal mucosal swelling and predisposes the patient to sinusitis. Similarly, patients with prolonged and repeated infections, chronic or recurrent sinusitis may undergo changes in the mucosal lining of the sinuses. These patients may undergo replacement of the normal ciliated epithelium with stratified squamous epithelium that does not maintain normal sinus sterility and these patients are prone to congestion stagnation and exacerbation of the underlying sinus disease (14). Immuno compromised and out of control diabetics are not only prone to sinusitis but also fungal diseases such as mucormycosis.

## MICROBIOLOGY

### Bacterial Sinusitis

Community-acquired acute sinusitis is usually of viral origin. Additionally, less than 2% of all upper respiratory tract infections in adults are complicated by bacterial sinusitis (15,16). Thus, antibiotic treatment for community-acquired sinusitis is only recommended if symptoms persist for more than seven days, and in patients with clinical symptoms of purulent nasal secretions, maxillary facial or tooth pain, or tenderness (15).

When cultures are taken in patients with community-acquired sinusitis, only 15% demonstrate a viral origin, the remainder being caused by bacterial organisms. The most common bacteria cultured from community-acquired sinusitis are pneumococcus and *Haemophilus influenzae*, with almost no isolates from *Pseudomonas* spp, *Acinetobacter* spp, or *Escherichia coli* (15,16). This contrasts sharply with the findings in nosocomial sinusitis.

Sinus infection isolates from ICU patients have a distinctly different profile. ⚡ **Nosocomial sinusitis may be caused by both gram-negative bacilli and gram-positive cocci, with 20% being polymicrobial (14).** ⚡ Thus antibiotics with broad coverage directed at gram-positive as well as gram-negative bacteria with efficacy against *Pseudomonas* should be initiated when treating nosocomial sinusitis. More virulent, gram-negative bacilli (*Pseudomonas* spp., *Acinetobacter* spp., etc.) were found in 47% of cases of bacterial sinusitis documented with transnasal puncture, with *P. aeruginosa* being the most common. *Staphylococcus aureus* was found in 35% of the cases, and fungus in 8% (Table 1). Fungal sinusitis should be considered when the patient does not improve clinically despite removal of inciting agents and broad-spectrum antibiotic coverage.

### Fungal Sinusitis

In rare situations, usually involving immunosuppression, fungi may be the causative organisms. In the outpatient setting, fungal sinusitis is rare and usually caused by *Aspergillus* found in soil and decaying plant matter. Fungal sinusitis with *Aspergillus* is rarely invasive and is usually treated with immunotherapy and/or corticosteroids (17). However, in immune-compromised patients (e.g., patients in the ICU setting) and in patients with poorly controlled diabetes, fungal infection of the paranasal sinuses caused by *Mucor* and *Rhizopus* fungal species is extremely serious

**Table 1** Microbial Flora of Sinusitis

	Community-acquired (%)	Nosocomial (%)
<i>Streptococcus pneumoniae</i>	31	
<i>Haemophilus influenzae</i>	21	
<i>Moraxella catarrhalis</i>	2	
Group A streptococcus	2	
Anaerobes	6	
Viruses	15	
<i>Staphylococcus aureus</i>	4	35
Gram-negative bacilli ( <i>Pseudomonas</i> spp., <i>Acinetobacter</i> spp., <i>Escherichia coli</i> )		47
Fungus		8

Source: Adapted from Refs. 15, 16.

and often fatal (18). Granulocytopenic patients are most vulnerable to these invasive fungi. Thus, there should be a high index of suspicion for fungal sinusitis in patients in the ICU that do not respond to medical control, especially in the setting of granulocytopenia or periorbital inflammation (19).

## DIAGNOSIS

### Clinical Presentation

☞ **The usual clinical symptoms and signs of sinusitis seen in otherwise healthy outpatients may be missed in critically ill patients.** ☞ Acute sinusitis in the normal population usually presents with headache, facial pain, nasal obstruction, mucopurulent nasal discharge, malaise, and lethargy. Many ICU patients are sedated and analgesed to such a degree that fever, purulent nasal discharge, or air-fluid levels on sinus imaging may provide the first clinical indication of sinusitis. Interestingly, fever is present in less than 50% of patients with acute (community-acquired) sinusitis. Thus, the presence of fever and radiographic evidence of sinusitis does not necessarily indicate that sinusitis is the cause of fever in the ICU patient.

Nosocomial sinusitis is fairly common in the ICU setting, ranging from 5% to 35% of patients (20–25). Indeed, nosocomial pneumonia, sinusitis, and bloodstream infections are the most common infectious sources of fever in ICU patients (1). However, given the multitude of additional potential sources of fever, the presence of sinusitis alone does not mean that sinusitis is the cause of fever in the ICU patient (26).

☞ **An important risk factor for the development of sinusitis in the ICU setting is the presence of nasal tubes.** ☞ Unfortunately, in this patient population, localized symptoms of infection (headache, facial pain, malaise, and lethargy) are difficult to elicit and the presence of purulent discharge may only be present in a minority (~25%) of patients (5). When sinusitis is in the differential for fever, computed tomography (CT) scans are the most useful tool for imaging the paranasal sinuses, and is better than magnetic resonance imaging (MRI), which has false positives. Plain films have no value in the assessment of sinusitis.

### Diagnostic Significance of Fever

The Society of Critical Care Medicine defines fever in the ICU as a temperature of  $>38.3^{\circ}\text{C}$  ( $>101.0^{\circ}\text{F}$ ) (27,28). Any disease process that results in the release of proinflammatory cytokines IL-1, IL-6, and TNF- $\alpha$  may result in the development of fever (29). Thus infectious as well as a large list of noninfectious inflammatory conditions [including trauma, burns, and systemic inflammatory response syndrome (SIRS)] may result in a febrile response (see Volume 2, Chapter 46 for evaluation of febrile ICU patient).

Historically, especially in the preantibiotic era, increased body temperature has been shown to be associated with improved outcome (including survival) from infectious diseases (30–33). ☞ **The acute development of fever in a previously stable and afebrile ICU patient must immediately trigger a search for a treatable infection.** ☞ Indeed, infection is the most common cause of delayed morbidity in trauma patients. Furthermore, elevated body temperature is associated with a number of additional deleterious effects such as increased cardiac output, oxygen consumption, carbon dioxide production, and energy expenditure (34). Additionally, fever is associated with a worse neurologic outcome following traumatic brain injury (TBI) (35,36). Accordingly, these deleterious side effects far outweigh any potential benefit of fever in the ICU setting.

☞ **Sinusitis is only one of a host of infectious etiologies of fever in critically ill patients (see Volume 2, Chapter 46).** ☞ Unfortunately, many of the normal diagnostic clues to sinusitis will be absent in critically ill patients, due to sedation or neurologic injury. In the ICU setting, fever may be the only indication that sinusitis is present.

### Imaging Studies

One-third of patients with radiologic evidence of sinusitis (e.g., air-fluid levels or mucosal thickening in head CT) have clinically significant infectious sinusitis documented by bacterial cultures (22). Thus, the clinical importance of radiologic data in isolation is unknown, and should never be assumed to be the sole source of a fever in a critically ill patient until cultures are obtained and other sources of fever are excluded.

#### Plain Film Radiography

Plain film radiography was historically used in the outpatient setting for the diagnosis of acute sinusitis. Although the specificity of plain films is adequate, the sensitivity has been shown to be unacceptably low as compared to that of CT (37) and thus is not used as a tool in the diagnosis of sinusitis either in the clinic or in the ICU. Furthermore, as plain film radiography cannot clearly delineate the relationship between soft tissue and the bony sinus framework, it is not very helpful for diagnosis in the setting of bony trauma or anatomic abnormalities. However, some critically ill patients are too unstable to transport to the CT scanner; for these patients plain film radiography may be considered.

The four standard radiographic projections are as follows: occipitofrontal (“Caldwell’s view”), occipitomeatal (“Water’s view”), lateral, and submental vertex (axial view). Because the maxillary sinuses are most commonly involved, and are best seen on the Water’s view, some advocate this simple projection, rather than all four.

#### Computed Tomography

☞ **CT is the most useful radiographic method to evaluate the presence of sinusitis in the paranasal sinuses.** ☞ CT

is the preferred imaging study for paranasal sinuses because it clearly delineates the relationship between the soft tissue density of paranasal sinus mucosa, the integrity of the bony framework, and the presence or absence of air/fluid within the sinuses (38). Mucosal thickening, opacification, or air-fluid levels suggest infection (Fig. 2) (22). CT scans should be obtained, 5 × 5 mm with coronal views without contrast. Air-fluid levels on CT are not pathognomonic for acute sinusitis, because blood in the sinuses (resulting from head trauma) can also appear as an air-fluid level. Using sterile technique and a diagnostic threshold of 10,000 colony-forming units/milliliter (cfu/mL), sinus cultures should be obtained, when both clinical and radiologic evidence of sinusitis exists. ⚡ **Significant infection as diagnosed by positive sinus culture is only found in 38% of patients with radiologic (CT) evidence of sinusitis.** ⚡ Bacteremia with the same microbial flora was found in 17% to 25% of patients with nosocomial sinusitis (22).

### Sinus Ultrasound

Sinus ultrasound is another emerging technique that has been shown to be useful in the evaluation of acute sinusitis. A prospective trial comparing the accuracy of sinus ultrasound to that of standard sinus radiography revealed more than 92% sensitivity and specificity for the diagnosis of maxillary sinusitis in the outpatient setting (39) as well as in the ICU setting with mechanically ventilated patients (40). However, the use of sinus ultrasound in the diagnosis of sinusitis requires training and has not gained popularity in the United States, despite its common usage in other countries (39,40).

## Diagnostic Procedures

### Nasal Endoscopy

Nasal endoscopy is emerging as an important new tool in the evaluation of paranasal sinusitis. This technique has been shown to be both sensitive and specific in predicting a positive bacterial culture from paranasal sinusitis. In a prospective study involving 141 patients in the ICU, Skoulas et al. found that plain film radiography and CT scans were only 41% and 47% accurate, respectively, in predicting the presence of maxillary sinus purulence. However, the presence of purulent exudates emanating from the middle meatus seen by nasal endoscopy was 78% accurate in predicting a positive culture (41). Given the need to have a significant

clinical suspicion for sinusitis prior to confirming the diagnosis with an invasive procedure such as antral puncture and culture, nasal endoscopy is increasingly utilized.

### Antral Puncture

⚡ **The gold standard for the diagnosis of sinusitis is maxillary sinus puncture (antral puncture), aspiration, Gram stain, and culture (Fig. 3) (42).** ⚡ This technique involves accessing the maxillary sinus through the bony maxillary (canine) fossa, is invasive, time-consuming, and carries the risk of orbital hemorrhage, infection, and blindness (43,44). However, it has been shown that a change in antibiotic therapy guided by culture of maxillary sinus aspirate results in improved patient outcome (45). Thus, the question of when to perform maxillary sinus tap remains controversial. Recent studies suggest that nasal endoscopy should be performed first and antral punctures should only be performed if purulence is seen in the middle meatus (41).

## TREATMENT

### Removal of Intranasal Tubes and Promotion of Nasal Drainage

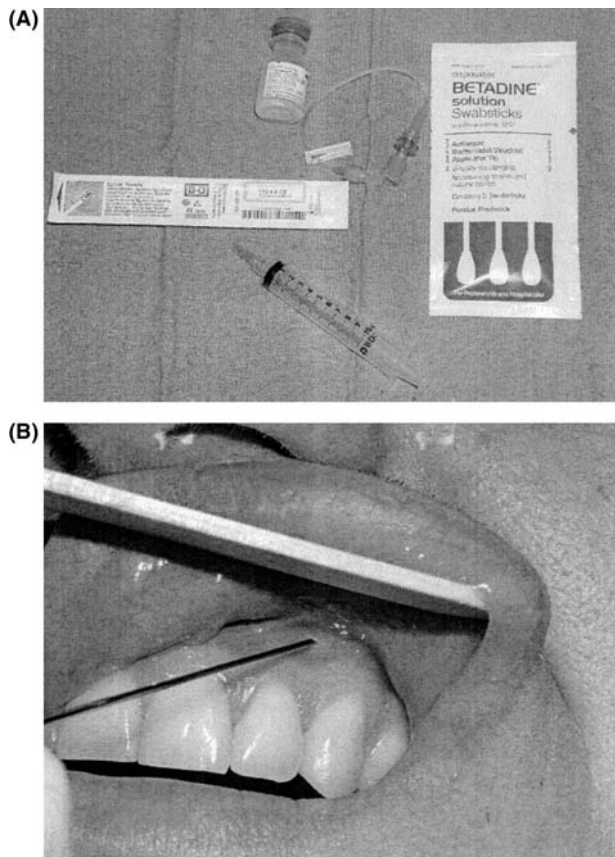

⚡ **The most important factor in treating nosocomial sinusitis in the ICU setting is the removal of inciting factors causing impairment of mucociliary transportation and paranasal sinus ventilation.** ⚡ Thus, if the patient has any foreign bodies within the nasal passages such as nasotracheal or NG tubes, these should be removed completely or switched over to the other nasal passage. This is a difficult decision for it may mean that if a patient is nasally intubated, one must transfer these tubes to the oral cavity or neck, that is, consider tracheostomy. If a patient requires enteral feeding, consider an orogastric tube, a cervicogastric tube, or a gastric feeding tube. To further facilitate mucociliary transport, mucosal congestion can be reduced with topical decongestants, elevating the head of the bed 30°, and improving hydration of the patient (both intravascular and with humidified oxygen if extubated).

### Antibiotics

Acute bacterial sinusitis is routinely treated in the outpatient setting with amoxicillin, doxycycline, or erythromycin (15).

**Figure 2** Coronal computed tomographic (CT) images of paranasal sinuses. On the left is a coronal CT image showing the maxillary (M) and ethmoid (E) sinuses in a healthy patient. Note that the sinuses are air-filled cavities (black) enclosed by bony walls (white). On the right is a coronal CT image showing paranasal sinuses in a patient with maxillary sinus mucosal thickening (small arrow) and ethmoid sinus opacification (large arrow).

**Figure 3** Sinus cavity aspiration equipment and technique. (A) The equipment necessary to perform a sinus aspiration: betadine swab, 18-gauge spinal needle, 10-cc syringe, intravenous tubing, and injectable sterile saline without preservatives. (B) Following infiltration with a local anesthetic/vasoconstrictor (lidocaine 1% with epinephrine 1:100,000), the superior gingivolabial groove at the level of the canine fossa is prepared with betadine. The 18-gauge spinal needle is advanced through the mucosa and bone superior to the root of the canine tooth, medial to the zygomatic buttress, and lateral to the piriform aperture. Advance the needle until the sinus mucosa is penetrated, and then remove the introducer. Aspirate a sterile sample for gram stain, culture, and sensitivities. Irrigate the sinus with sterile saline solution, which allows flow of purulent secretions through the natural ostium. Irrigation should commence only once the position of the spinal needle is confirmed to be in the antrum by aspiration of air or purulent fluid.

However, sinusitis occurring in the ICU requires broad-spectrum antibiotics due to the increased incidence of gram-negative and polymicrobial organisms. **Initial empiric antimicrobial therapy requires coverage of both gram-positive and gram-negative bacteria (with adequate pseudomonas coverage) (Table 2).** If clinical assessment reveals inadequate improvement following antibiotic therapy along with the removal of the inciting agents (nasotracheal/NG tubes), the antibiotic regimen can be changed either empirically or with guidance by nasal endoscopy, with culture or direct aspirate via antral puncture (46). As mentioned above, although direct aspirate via antral puncture has traditionally been the gold standard for establishing a diagnosis of bacterial sinusitis (15,45), multiple recent studies indicate that cultures obtained with swab via nasal

endoscopy are equally specific and sensitive as are cultures derived from antral punctures with direct aspiration (47,48).

### Surgery

As the majority of patients develop nosocomial sinusitis in the ICU setting as a consequence of foreign bodies blocking normal drainage of the paranasal sinuses, the removal of these foreign bodies is usually adequate treatment. Thus, all foreign bodies should be removed from the nasal cavities, topical decongestants used to minimize mucosal congestion, and adequate hydration insured. Surgery in the absence of invasive fungal sinusitis or central nervous system/orbital complication has a limited indication in the setting of ICU sinusitis. Antibiotics are used when deemed clinically indicated. Surgical drainage is rarely indicated in the setting of nosocomial sinusitis in the absence of anatomic abnormalities, sepsis, or secondary complications (49).

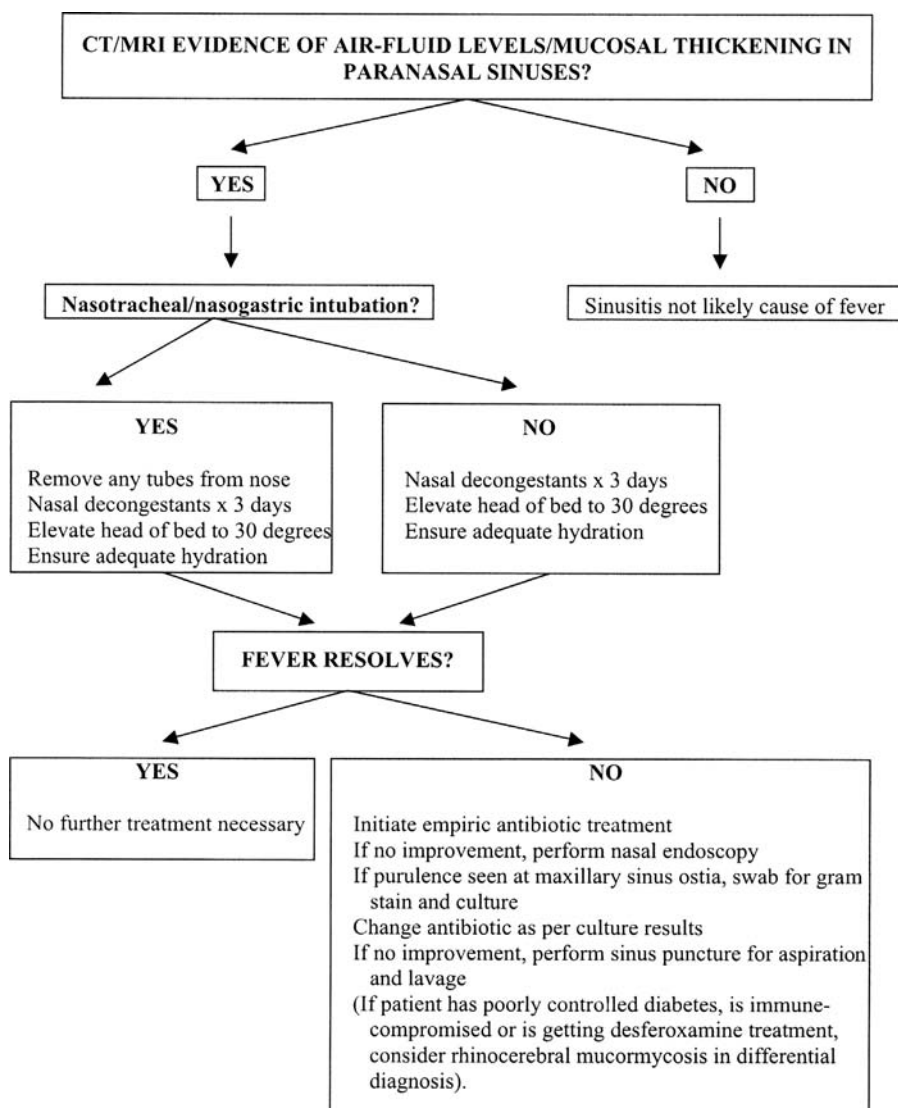

### CLINICAL PERSPECTIVE: CASE ANALYSIS

The clinical lessons described herein are further emphasized with the following case presentation. This is a typical critical care trauma patient with fever, upon whom an ear, nose, and throat (ENT) consult was obtained to rule out sinusitis. The patient is a 35-year-old male with closed head injury and fever of 39.2°C.

One week prior to consult, the patient was involved in a motor vehicle accident and suffered a closed head injury with subdural hematoma. The patient was intubated orally in the field because of loss of consciousness and brought to the hospital by the emergency medical services. Following surgical evacuation of the subdural hematoma, the patient remained intubated and was brought to the surgical ICU. Despite withdrawal of all sedatives, the patient remained unresponsive and ventilator-dependent. A soft, small-diameter NG tube was placed on the left side on hospital day 2 to initiate enteral nutrition. On hospital day 6, the patient developed fever of 39.2°C.

This patient is otherwise healthy without any significant prior medical or surgical conditions, has no history of prior sinusitis, is not taking any medication other than phenytoin for seizure prophylaxis, and is not allergic to medicines.

The physical examination reveals that the patient has a Glasgow Coma Scale (GCS) equivalent to 9-T. He can open his eyes spontaneously, can localize pain with all extremities, but does not follow commands, and cannot vocalize (endotracheal tube in place). His head, eyes, ears, nose, and throat examination reveals the craniotomy incision for evacuation of subdural hematoma; the wound is clean and dry, no obvious nasal discharge is noted, but left serous otitis media is noted with otoscope. An NG tube is seen passing through the left nare, the nasal mucosa is edematous, and no evidence of purulent discharge is detected. His extraocular muscles and pupillary examination are normal. The chest examination reveals diffuse rhonchi bilaterally. The heart examination is normal, the abdomen is soft and nondistended, there is no organomegaly, and he is tolerating his enteral nutrition. His extremity examination reveals a left antecubital IV without erythema or induration, a right radial arterial line, and there is no lymphadenopathy in either axilla. A Foley catheter is in place.

**Figure 4** Diagnostic and treatment algorithm for the febrile intensive care unit patient.

**Table 2** Antimicrobial Therapy for Sinusitis

	Community-acquired	Nosocomial
Primary treatment	Amoxicillin (500 mg PO tid × 10 d) Amoxicillin/clavulanic acid (875 mg/125 mg PO bid or 500 mg/125 mg PO tid × 10 d) Cefdinir (300 mg PO bid or 600 mg PO qd × 10 d) Cefpodoxime (200 mg PO bid)	Piperacillin and Tazobactam 3.375 gm IV q6 hr Imipenem (0.5 mg IV q6 hr) Meropenem (0.5 mg IV q6 hr)
Alternate treatment (resistant disease/penicillin allergy)	Levofloxacin (500 mg PO qd × 10 d) Moxifloxacin (400 mg PO qd × 10 d)	Amphotericin B (for mucormycosis) (0.8–1.5 mg/kg/d IV)

Abbreviations: IV, intravenously; PO, per OS (orally).

Source: Adapted from Refs. 15, 16.

His white blood cell count is 14.7% with 87% segmented neutrophils. His chest radiograph is clear except for a left lower lobe atelectasis, which comes and goes periodically. The abdominal CT from admission (one week ago) is negative. A sinus CT is ordered by the head and neck surgery consultant revealing both left maxillary and ethmoid sinuses' mucosal thickening and opacity, with an air-fluid level in the left maxillary sinus. Initial assessment by the ENT consultant (based upon above data, without culture data) was as follows: "Radiologic evidence of left maxillary and ethmoid sinusitis in febrile patient with NG tube in place." Suggestions to the critical care team included: (i) change NG tube to orogastric tube, (ii) start oxymetazoline topical decongestant for three days, and (iii) elevate head of bed to 30°.

Twenty-four hours following removal of NG tube and initiation of the oxymetazoline topical decongestant, the patient defervesced to 38.2°C. However, over the ensuing 48 hours, the patient became febrile again with Tmax of 39.4°C. Nasal endoscopy was performed revealing purulent material at the maxillary sinus ostia bilaterally. Following disinfection with betadine, maxillary sinus puncture was performed and aspirate sent for Gram stain and culture. Gram stain revealed Gram-negative bacilli and multiple polymorphonucleocytes. Intravenous ciprofloxacin was initiated. Cultures subsequently became positive for *P. aeruginosa*. Twenty-four hours following the initiation of antibiotics, the patient defervesced to 37.4°C and remained afebrile.

Lessons from the case report include: (i) Most patients with a nasal tube >72° will have air-fluid levels and (ii) nasal endoscopy is simple and noninvasive and should have been performed on the initial consultation. When purulent discharge is seen in the sinus ostia, cultures should be obtained and antibiotics started.

## EYE TO THE FUTURE

Although the gold standard in the diagnosis of paranasal sinusitis has been maxillary sinus puncture, aspiration, and culture, this technique is fairly invasive, time-consuming, and painful in the nonsedated patient. Recent advances in nasal endoscopy have shown that it is a useful tool for the diagnosis of paranasal sinusitis. The advantage of this non-invasive technique is that it can be performed quickly and is not operator-dependent. Further studies will be needed to confirm the correlation between nasal endoscopy and antral puncture. Continued development of endoscope technology has notably improved the image quality and ability to visualize the sinus ostia. Additional developments in ENT will improve the ability to diagnose and manage nasal sinusitis including continued development of imaging capabilities with both spiral CT scans and MRI. Increasing recognition of the morbidity of large nasal tubes in critically ill patients should also have a beneficial effect on lowering the incidence of disease. Ultrasonography may play a future role in the evaluation of paranasal sinusitis.

## SUMMARY

Paranasal sinusitis is a known cause of fever in the ICU. The pathophysiology of acute paranasal sinusitis is usually due

to decreased muciliary clearance leading to OMC obstruction, mucous stasis, and consequent infection. The treatment of paranasal sinusitis is fairly straightforward—eliminate the source of OMC obstruction (i.e., intranasal intubation) and improve intranasal mucous drainage (head elevation and topical decongestants).

Acute bacterial sinusitis in the community is chiefly due to *Streptococcus pneumoniae* and *H. influenzae* (50), whereas sinusitis in critically ill patients generally results from *S. aureus*, *Acinetobacter* spp., *Pseudomonas* spp., and, up to 8% of the time, fungi (Table 1). The majority of ICU patients with bacterial paranasal sinusitis respond appropriately to antibiotics.

The most common clinical dilemma involving sinusitis in the ICU revolves around determining in which patient sinusitis is a significant contributing factor to fever, when so many other conditions following trauma and critical care also elevate the temperature (Volume 2, Chapter 46). Increased use of nasal endoscopy and study of the correlation between CT scan images, surgical culture data, and antral culture may clarify the future therapy of this vexing condition.

## KEY POINTS

- ✎ The single most important factor in the development of sinusitis is the disruption of the mucociliary transport system, typically from obstruction of the normal drainage pathways, the OMC of the paranasal sinuses.
- ✎ Nosocomial sinusitis may be caused by both gram-negative bacilli and gram-positive cocci, with 20% being polymicrobial (14).
- ✎ The usual clinical clues of sinusitis seen in otherwise healthy outpatients may be missed in critically ill patients.
- ✎ An important risk factor for the development of sinusitis in the ICU setting is the presence of nasal tubes.
- ✎ The acute development of fever, in a previously stable and afebrile ICU patient must immediately trigger a search for a treatable infection.
- ✎ Sinusitis is only one of a host of infectious etiologies of fever in critically ill patients (see Volume 2, Chapter 46).
- ✎ CT is the most useful radiographic method to evaluate the presence of sinusitis in the paranasal sinuses.
- ✎ Significant infection as diagnosed by positive sinus culture is only found in 38% of patients with radiologic (CT) evidence of sinusitis.
- ✎ The gold standard for the diagnosis of sinusitis is maxillary sinus puncture (antral puncture), aspiration, Gram stain, and culture (Fig. 3) (42).
- ✎ The most important factor in treating nosocomial sinusitis in the ICU setting is the removal of inciting factors causing impairment of mucociliary transportation and paranasal sinus ventilation.
- ✎ Initial empiric antimicrobial therapy requires coverage of both gram-positive and gram-negative bacteria (with adequate pseudomonas coverage) (Table 2).

### INTRODUCTION

By their very nature, traumatic injuries commonly break down our most important barriers to infection: the external skin and endothelium of the gut, lung, and genito-urinary systems. Even in “closed” injuries such as bony fractures or head injuries, many of our supportive and resuscitative therapies violate these barriers, for example, placement of central venous catheters, endotracheal intubation, and surgical repairs. The experienced physician is mindful of the potential harm that may result from invasive interventions, as well as the anticipated benefits.

As we learn more about the immune system, we are discovering that major immunological changes are triggered by traumatic injury, some of which enhance the immune response, and others that seem to suppress it. Old ideas become new again as we marvel at the complexity of regulatory mechanisms involved in immunity, and strive to understand the variations of the immunological response to similar antigens under varying conditions. Other elements of treatment including antibiotics, nutrition, and ventilation strategies are also known to affect immunity.

This chapter reviews the human immune system and the effects of trauma, burns, and critical illness. The chapter also reviews the effect of some common systemic diseases on the immune system, including an illuminating section on autoimmunity, presently an area of intense research. Autoimmunity has been discovered to play an important role in otherwise idiopathic disorders such as inflammatory bowel disease, myasthenia gravis, rheumatoid arthritis, and other ailments previously known as “collagen vascular diseases.” A specific section is dedicated to human immunodeficiency virus (HIV) infection in trauma and critical care. Next, the most common infectious agents that afflict immunocompromised patients are surveyed, followed by a brief review of the considerations for immunosuppressed solid organ transplantation. Section “Eye to the Future” provides a glimpse at the considerable research ongoing in the area of immune modulation in trauma and critical care.

### REVIEW OF THE HUMAN IMMUNE SYSTEM

#### Anatomic Barriers

The first line of defense against infection includes the normal anatomic barriers of the skin, airway, and gut. These defenses are often disrupted by traumatic injuries or by invasive therapies intended to treat critically ill patients. Because of the physical barriers provided by keratinized epithelium, bacteria seldom survive in large numbers on the skin surface. In addition, the direct antibacterial effects of lactate and fatty acids in sweat and sebaceous secretions decrease the pH and generate an external surface that is hostile to most bacteria. An exception is *Staphylococcus aureus*, which often invades the hair follicles and sweat glands.

Protection is also provided by the antimicrobial mucous lining the inner surfaces of the body, including the gut and airway epithelium. Special antimicrobial protection factors such as immunoglobulin A (IgA) and complement also help kill invading microbes. Bactericidal factors are also provided by gastric acid, spermine and zinc in semen, lactoperoxidase in breast milk, and lysozyme in tears, nasal secretions, and saliva. Lactic acid produced by commensal organisms in the vagina also helps protect against pathogenic bacteria. Microbial invaders are often trapped in the mucus and removed mechanically by cilia, coughing, and sneezing. Other mechanical factors include washing by tears, saliva, and urine. Langerhans cells in skin, and dendritic cells in the interstitium of various tissues, are also constantly on the prowl for foreign invaders.

☞ **Once a pathogen has overcome the primary barrier of the skin, respiratory, gastrointestinal (GI), or genitourinary epithelium, the immune system must then combat the invader.** ☞

The natural or innate immunity process refers to the older, nonspecific immune system that involves recruitment and release of macrophages, neutrophils, natural killer (NK) cells, cytokines, some cellular receptors, and the complement system (1–3). Adaptive or acquired immunity involves recognition of specific antigen and confers both specificity and a “memory effect” by T- and B-lymphocytes. The acquired immune system can be further divided into the humoral and cellular immune systems, both of which communicate through the influence of cytokines. The complement system is also active in both cellular and

**Table 1** Leukocytes Involved in the Immune System

Cell type	Function	Surface marker	Special traits
T helper (Th)	Stimulate B-cells: provides specific and nonspecific cytokine signals for activation and differentiation	CD3+, CD4+, CD8–	MHC class II markers restrict activation Th2 activates B-cells, makes IL-4
	Activate macrophages: cytokines provide message for activation	CD3+, CD4+, CD8–	MHC class II markers restrict activation Th1 activates macrophages, makes interferon- $\gamma$
T cytotoxic (T <sub>C</sub> )	Lyse antigen expressing cells: such as those infected by virus, or allografts	CD3+, CD4–, CD8+	MHC class I markers restrict activity
T suppressor (T <sub>S</sub> )	Downregulates cellular and humoral immunity	Can be CD3+ or CD3– Usually CD4–, CD8+	
T regulator (T <sub>REG</sub> )	Suppresses T-cell-mediated inflammation	CD4+, CD25+	Diminishes autoimmunity
NK	Spontaneous lysis of tumor cells, Ab-dependent cellular cytotoxicity	Fc receptor for IgG	MHC class I markers restrict activity
NK T-cells	Amplify both cell-mediated and humoral immunity	CD4 +	Express a restricted subset of surface markers (V $\alpha$ )
B cells	Ab Production, and presents antigen to T-cells	Fc and C3d receptors MHC class II	Differentiate into plasma cells (which produce Ab)
Macrophages (monocytes)	Phagocytosis, secretion of cytokines to activate T-cells (e.g., IL-1), neutrophils	Macrophage surface antigens, and “armed” with Ab binding to Fc receptors	Express surface receptors for C3a, kill ingested bacteria by oxidative bursts
PMN (neutrophils)	Phagocytosis killing	Can be “armed” with Ab	Protective in parasitic infections, but adverse effects (e.g., granuloma) can occur

*Abbreviations:* Ab, antibody; C3a, activated third component of complement; IL, interleukin; MHC, major histocompatibility complex; PMN, polymorphonuclear; NK, natural killer.

humoral immunity, and serves as an interface between the innate and adaptive immune systems.

### Cellular Immunity

A large array of white blood cells (WBCs), or leukocytes, are involved in the immune system (Table 1). Cellular immunity is mediated by thymus derived (T) lymphocytes. The T-cells constitute approximately 65% of the circulating lymphocytes. Each T-cell is genetically programmed to recognize and bind to specific cell-bound antigens by way of an antigen-specific T-cell receptor (TCR). Each antigen-specific TCR is linked to a cluster of nonvariable polypeptides referred to as the CD3 molecular complex. The CD3 proteins are involved in signal transduction into the T-cell after the antigen-specific TCR binds antigen. In addition to CD3 proteins, T-cells express a variety of nonpolymorphic-function-associated proteins, of which CD4 and CD8 are particularly important.

👉 **The CD4 and CD8 proteins are expressed on two mutually exclusive sets of T-cells, and are co-receptors of T-cell activation.** 🦋 During antigen expression, CD4 molecules bind to the nonpolymorphic portions of major histocompatibility complex (MHC) class II molecules on the antigen-presenting cells. In contrast, CD8 molecules bind to the nonpolymorphic portions of MHC class I molecules. The CD4+ T-cells are referred to as helper T-cells, and the CD8+ T-cells are known as cytotoxic/suppressor T-cells. The CD4+ T-cells are the major regulators of cellular immunity. The CD4+ T-cells secrete cytokines influencing virtually every cell type in the immune system including other T-cells, B-cells, macrophages, and NK cells. 🦋 **The important regulatory role of CD4+ T-cells is evident when HIV infects the host and selectively kills CD4+ T-cells**

**(described subsequently).** 🦋 The CD8+ T-cells secrete cytokines as well, but are mainly cytotoxic cells.

The bone marrow derived (B) lymphocytes constitute approximately 15% of the peripheral circulating lymphocytes. In mature patients, they are found in the bone marrow, lymphocytes, spleen, tonsils, and extralymphatic organs (including Peyer's patches in the ileum). After antigen stimulation, B-cells transform into plasma cells and secrete immunoglobulins, which are the main mediators of humoral immunity.

🦋 **Immunoglobulin M (IgM) is present on the surface of all B-cells, comprising the antigen-binding component of the B-cell receptor.** 🦋 Like the T-cells, the B-cell receptor has antigen specificity, partly due to the IgM molecular structure. In addition to the IgM molecule, the B-cell has a nonpolymorphic transmembrane protein similar to the CD3 proteins of the TCR. B-cells have other nonpolymorphic receptors required for function including complement receptors, Fc receptors and CD40. Interestingly, the B-cell complement receptor (CD21) binds Epstein-Barr virus (EBV), explaining why EBV often infects B-cells. Additionally, the CD40 molecule is a member of the tumor necrosis factor- $\alpha$  (TNF- $\alpha$ ) family of receptors, and is instrumental in interactions between the CD4+ T-helper cells and B-cells. Activated T-helper cells express the CD40 ligand that binds CD40 expressed on B-cells, and are required for mature plasmacytes to secrete IgG, IgE, and IgA. Patients with a mutation in the CD40 ligand do not secrete sufficient immunoglobulins and have a defined immunodeficiency called X-linked hyper-IgM syndrome.

Macrophages are part of the mononuclear phagocyte system involved in both inflammation and immunity. 🦋 **The first cells to migrate to areas of injury following trauma are**

**the polymorphonuclear neutrophils (PMNs) with quantities peaking in the first 24 hours, followed by the macrophages, which reach their zenith at 72 hours.** ⚡ Macrophages play a key role in the immune response and, initially, the macrophages process and present antigens to T-cells. Additionally, in the presence of certain cytokines from the CD4+ T-cells, macrophages will kill tumor cells and other benign cells. Macrophages are also important in humoral immunity as they phagocytose bacteria and other microbes that have been opsonized (coated) by IgG or C3b (a factor in complement). Dendritic cells have antigen-presenting roles and are so-named because of the cytoplasmic extensions, extending from the main cell body. Langerhans cells are dendritic cells located in the epidermis that may be killed during severe burns. Dendritic cells are widely distributed within lymphoid tissues and within non-lymph interstitial space of tissues such as lung and heart. In the spleen and lymph nodes, dendritic cells are referred to as follicular dendritic cells and express IgG Fc receptors serving to trap antigen opsonized by these antibodies.

NK cells comprise approximately 10% of the peripheral lymphocytes. These NK cells are larger than most lymphocytes, they possess Fc receptors that bind to IgG and kill opsonized cells. However, NK cells have another method of seeking out and killing foreign cells. The NK cells have a receptor mechanism that recognizes MHC class I molecules (which are on the surface of all normal mammalian cells) and do not attack these. However, cells lacking the MHC class I molecule (e.g., bacteria, tumors) are attacked by perforating the cell membrane with a molecular punch called “perforin,” and injecting cell destructive proteins called “granzymes.” NK cells are part of the innate immune system. Additionally, NK cells may attack some host cells with MHC class I molecules associated with other surface molecules that indicate to the NK cells that the host cell has been infected by a virus. MHC class II molecules are restricted to lymphocytes, macrophages, and (antigen-presenting) dendritic cells.

Erythrocytes and platelets also have a role in the immune system, which is not often acknowledged. Both red blood cells and platelets have receptors for complement, and platelets in addition have IgG Fc receptors. Thus, they could play a role in clearing immune complexes and antigens that have been opsonized by complement.

## Humoral Immunity

Passive humoral immunity is conferred when preformed antibodies are obtained from an external source. This

occurs naturally during human gestation by the transfer of maternal IgG. Maternal IgG is gradually lost over the first year of life. Breast-fed babies also obtain maternal IgA affording local protection particularly to the gut. Beyond infancy, passive humoral immunity can be conferred by parenterally administered human immunoglobulin.

In contrast, active humoral immunity develops when the immune system encounters an antigen either due to natural infection or by vaccination. The relative serum concentrations and characteristics of separate classes of immunoglobulins are summarized in Table 2. Antigen may be categorized as thymus-independent (TI) type 1 or type 2 and thymus dependent (TD) based on its predominant mechanism of B-cell activation. TI-type 1 antigens are microbial or vegetable molecules that bind to B-cells and stimulate proliferation and differentiation of specific or nonspecific antibody responses. TI-type 2 antigens elicit predominantly antigen-specific antibody responses. Most protein and glycoprotein antigens encountered by the immune system are TD antigens. Two types of cellular interactions are required for antibody responses to TD antigens. T-cells must recognize antigen associated with MHC class II molecules on the surface of the antigen-presenting cell. Next, the B-cell and T-helper cell interact, and the B-cell internalizes antigen. Once the antigen is processed and associated with the MHC class II molecules, the T-helper cell is able to recognize appropriate cells to deliver its stimulating signal.

⚡ **When the host has pre-existing circulating antibodies due to vaccination or prior infection, microbial replication can be halted at the onset of infection.** ⚡ This secondary antibody response results from activation of a memory B-cell. Memory cells typically circulate widely and survive for long periods of time. Upon interaction with antigen, antibodies (predominately IgG, IgA, and IgE) are rapidly produced. In contrast, the primary humoral immune response (predominately IgM) may be too slow to protect against many pathogens (1).

## The Complement System

The complement system consists of a group of plasma proteins, which are essential for antibodies to achieve destruction of foreign cells, bacteria, and apoptotic cells. The complement proteins lack immunologic specificity, but comprise a highly complex cascade system consisting of 35 discrete proteins (12 of which are directly involved in the complement pathway, while the rest have regulatory functions) (4).

**Table 2** Structural and Biological Properties of Human Immunoglobulins

Property	IgG	IgA	IgM	IgD	IgE
Approximate mass (Da)	150,000	160,000 460,000	900,000 memb. 180,000	180,000	190,000
Serum concentration (mg/mL)	15	3.5	2.0	0.003	0.0005
Serum half-life (days)	23	6	5	2–8	1–5

The protein components of complement are numbered in the order of their discovery rather than the sequence in which they are activated. ⚡ **Although there is no immunologic specificity in complement activation, or in its effects, there are several immunological methods by which the complement system can be activated.** ⚡ Some complement components enhance the effects of antigen–antibody interactions (as occurs with opsonization), whereas others increase the inflammatory response by stimulating the release of vasoactive substances, and by stimulating chemotaxis of leukocytes (Table 3) (4).

Three biochemical pathways can activate the complement system (all converging at C3): (1) the classic pathway, (2) the alternative complement pathway, and (3) the mannan-binding lectin (MBL) pathway (4). All three pathways generate homologous variants of C3-convertase. The enzyme, C3-convertase initiates the membrane-attack pathway culminating with the assembly of the membrane-attack complex (MAC), the cytolytic endproduct of the complement cascade consisting of C5b, C6, C7, C8, and polymeric C9. The MAC pentamer inserts into the cell membrane and forms a transmembrane channel which causes osmotic lysis of the target cell.

### Classic Pathway

The classic complement pathway is initiated by antigen–antibody complexes involving IgM or IgG, either by binding to C1 at their Fc portions or by direct binding of C1 to the pathogen surface. The C1 complex is inhibited by C1-inhibitor. The C1 complex now binds to and splits C2 and C4 into C2a and C4b. C4b and C2a bind to form C3-convertase (C4b2a complex). Production of C3-convertase signals the start of the membrane-attack pathway (the final common pathway of all three activation routes).

### Alternative Pathway

The alternative pathway is more primitive than the classical pathway, and does not require the presence of antibody. Instead, C3 can be hydrolyzed directly by endotoxin, or following contact with bacterial cell wall constituents, aggregated IgA, or as a form of amplification feedback following activation of C3 by any of the three major complement pathways. In the alternative pathway, C3 is split into C3a and C3b. Some of the C3b is bound to the pathogen where it will bind to factor B; this complex will then be cleaved by factor D into Ba and the alternative pathway C3-convertase,

Bb. In other words, after hydrolysis of C3, C3b complexes to form C4b2a3b, which cleaves C5 into C5a and C5b. C5a and C3a are known to trigger mast cell degranulation and release histamine among other products (see Volume 1, Chapter 33). C5b, together with C6, C7, C8, and C9, form the MAC (C5b6789).

### Lectin Pathway

The lectin pathway is homologous to the classical pathway, but with the opsonin, MBL, instead of C1. This pathway is activated by binding MBL to mannose residues on the microbial cell walls, which activates the MBL-associated serine proteases, MASP-1 and MASP-2, which can then split C4 and C2 into C4b and C2a, which then binds together to form C3-convertase, as in the classical pathway.

### Complement Involvement in Immunologic Diseases

The complement system plays a role in numerous immunologic diseases including anaphylaxis, asthma, systemic lupus erythematosus (SLE), and various forms of arthritis, autoimmune heart disease, and multiple sclerosis. Additionally, deficiencies of the constituents in the terminal portion of the complement pathway predispose to infections, particularly meningitis, and infections due to encapsulated bacteria requiring opsonization for death (e.g., *Pneumococcus*, *Neisseria*, and *Haemophilus influenzae*) (4,5).

### Immunologic Regulation and Tolerance

Immune effector mechanisms are powerful processes that can lead to cell and tissue destruction; therefore, close control of immune system activation is essential. T-cells regulate both humoral and cellular effector mechanisms. The division of CD4+ helper T (Th) cells into two functional subsets, Th1 and Th2, is a paradigm for understanding how autoimmune inflammation is orchestrated by cytokines and chemokines. The cytokines interleukin (IL)-12 and interferon- $\alpha$ , secreted by antigen-presenting cells, promote proinflammatory and cytotoxic Th1 responses via secretion of interferon- $\alpha$  and TNF- $\alpha$ , whereas IL-4 promotes Th2 responses with activation of B-cells. Chemokines are chemotactic proteins secreted by various cell types and, through their interaction with specific receptors, direct the selective traffic of leukocytes throughout the lymphoid system and into inflammatory sites. Once activated, large numbers of

**Table 3** The Three Main Physiologic Functions of the Complement System

Function	Mechanism of action	Complement protein responsible for activity
Host defense against infection	Opsonization	Covalently bound C3 and C4 fragments
	Chemotaxis and leukocyte activation	Anaphylatoxins (C5a, C3a, and C4a); leukocyte anaphylatoxin receptors
Interface between innate and adaptive immunity	Lysis of bacteria and cells	MAC (C5b–C9)
	Augmentation of antibody response	C3b and C4b bound to immune complexes and to antigen; C3 receptors on B-cells and antigen-presenting cells
	Enhancement of immunologic memory	C3b and C4b bound to immune complexes and to antigen; C3 receptors on follicular dendritic cells
Disposal of waste	Clearance of immune complexes from tissues	C1q; covalently bound fragments of C3 and C4
	Clearance of apoptotic cells	C1q; covalently bound fragments of C3 and C4

Abbreviation: MAC, membrane-attack complex.

Source: From Ref. 4.

**Table 4** Gell and Coombs Classification of Immune-Mediated Hypersensitivity Reactions

Hypersensitivity class	Prototype disorder	Immune mechanism
I—Anaphylactic	Anaphylaxis, some forms of bronchial asthma	Formation of IgE (cytotoxic) antibody → immediate release of vasoactive amines and other mediators from basophils and mast cells followed by recruitment of other inflammatory cells
II—Cytotoxic	Autoimmune hemolytic anemia, erythroblastosis fetalis, Goodpasture syndrome	Formation of IgG, IgM → binds to antigen on target cell surface → phagocytosis or lysis of target cell by C8,9 fraction of complement or antibody-dependent cellular cytotoxicity
III—Immune complex	Arthus reaction, serum sickness, SLE, certain forms of acute glomerulonephritis	Antigen–antibody complexes → activated complement → attracted neutrophils → release of lysosomal enzymes and other toxic moieties. Failure of complement to clear
IV—Cell-mediated (delayed)	Tuberculosis, contact dermatitis, transplant rejection	Sensitized T lymphocytes → release of lymphokines and T-cell-mediated cytotoxicity

Abbreviations: Ig, Immunoglobulin; SLE, systemic lupus erythematosus.

cytokine-producing cells are produced; therefore, it is essential that the process be self-limited to avoid excessive injury.

The immune system is closely regulated by a process termed “tolerance.” In vertebrates, tolerance occurs at multiple levels. One of the most fundamental is the presence of “self”-markers on the native cell membranes, for example, the MHC class I binding structures described above. Cells without the MHC class I “self”-protein are attacked as foreign.

Another mechanism of negative regulation is activation-induced cell death, a form of apoptosis that eventually kills the cells (2). The complement system plays an integral role in the clearance of apoptotic cells and the immune complexes from plasmas and tissues. Some other negative feedback signals include prostaglandins produced by macrophages, transforming growth factor- $\beta$ , and IL-10, which deactivates macrophages, in turn decreasing cytokine production by T-cells. Disruption of any or all of these tolerance systems or other immune system control mechanisms leads to autoimmune disease (described further below).

✎ **Hypersensitivity reactions are exuberant, improperly regulated immunological responses to various antigenic molecules resulting in tissue injury to the host.** ✎

These have been classified into four major types by Gell and Coombs based upon the mechanism of tissue injury (Table 4). In Type I disease, the antigen triggers an IgE-mediated anaphylactic response (Volume 1, Chapter 33). Type II disorders involve the formation of antibodies against native tissues, so-called cytotoxic response, as seen in Goodpasture Syndrome. Type III hypersensitivity disease is caused by immune complexes that fail to clear properly, thereby causing tissue injury as seen with SLE. Type IV disorders involve delayed tissue injury that is mediated by sensitized T-lymphocytes.

## EFFECT OF TRAUMA, BURNS, AND CRITICAL ILLNESS ON IMMUNITY

### Overview of Immune Modulation Following Injury

The effects of severe trauma and burns are often manifest as an overwhelming “systemic inflammatory response syndrome” (SIRS) followed by a relatively immunodepressed state during which life-threatening infections may occur (6).

This period of recovery from systemic inflammation is called the “counter-regulatory anti-inflammatory response” (CARS). A traumatic insult typically initiates an inflammatory state that will establish a balance between the beneficial effects of controlled inflammation and potential injurious effects such as “adult respiratory distress syndrome” (ARDS) and “multi-organ dysfunction syndrome” (MODS) due to uncontrolled inflammation. The normal initial result of massive injury and shock can be an excessive inflammatory response; this is commonly called the “one-hit” model. In other cases, this response may result from a “two-hit” model where the patient receives a relatively mild initial inflammatory stimulus that would normally resolve, followed by a second hit such as a surgical procedure or an infection that leads to hyperstimulation of the immune system. In either case, the innate immune system including macrophages, leukocytes, NK cells, IL-8, and complement components are excessively activated leading to SIRS and MODS.

The opposite may also occur in which the initial inflammatory response is relatively mild yet the recovery response is marked by excessive immunosuppression. Patients may have inadequate neutrophil chemotaxis, phagocytosis, lysosomal enzyme content, and respiratory burst. This relatively immunosuppressed state following trauma likely contributes to an increased risk of infection following traumatic injury. The production of immunoglobulins and interferon falls and many patients become anergic. In the context of excessive CARS, infection and sepsis become more likely and mortality increases. The cytokine profile and interplay ultimately determines whether SIRS or CARS will manifest.

Several studies support the notion that the immune response is suppressed following severe trauma. There is evidence that levels of some naturally occurring anti-inflammatory mediators, such as soluble TNF- $\alpha$  receptor and IL-1 receptor antagonist are increased during the 14 days following severe traumatic injury. There were higher levels in patients with more severe injury, and patients with higher levels had higher mortality (7). Likewise, the ability of peripheral blood mononuclear cells to respond to endotoxin is reduced in severely injured patients. In these patients with an average injury severity score (ISS) of 39, release of proinflammatory cytokines (TNF- $\alpha$ , IL-1 $\beta$ , IL-6, IL-8, IL-12, and IFN- $\alpha$ ) in response to stimulation with

lipopolysaccharide was inhibited compared with healthy controls (8). It has been demonstrated previously that following burn injury, PMN function is impaired (9). Significant traumatic injury can influence leukocyte function and cytokine expression leading to both immunoactivation and immunosuppression. In fact, the optimal goal of therapy may be best understood in terms of the goal of restoring the balance between immunostimulation and immunosuppression (10).

As our ability to measure inflammatory mediators has improved, there have been many studies attempting to determine serum markers of patients at highest risk. For example, C-reactive protein is typically elevated within the first two days following traumatic injury. However, it is non-specific and has not been shown to predict complications (11). Another marker, procalcitonin, is produced in the thyroid and not detected in normal individuals. Although it is elevated after trauma or infection, there is no consensus on its usefulness as a marker (12). TNF- $\alpha$  is one of the central regulators in the acute phase response involved in leukocyte chemotaxis, fever, hypotension, and endothelial cell adhesion. Persistently elevated levels are associated with poor outcome. Its usefulness as a marker has been inconsistent and treatment with anti-TNF- $\alpha$  has not proven successful (13–15). IL-1 and IL-8 have also been unreliable as markers. IL-6 and IL-10 may be more reliable (16,17), and in one study the ratio of IL-6 to IL-10 was recommended as a useful marker to predict the degree of injury following trauma (18).

### Measures of Immunocompetence

Cell-mediated immunity is most commonly evaluated clinically by placing an anergy panel in which small quantities of common antigens are injected intradermally, to see if induration occurs within 48 to 72 hours. Common antigens used to assess cell-mediated immunity include proteins from tetanus toxoid, diphtheria toxoid, *Candida*, *Tricophyton*, *Streptococcus*, and *Proteus*. If no response occurs within 72 hours, the patient is said to be anergic, and is probably unable to mount an adequate immune response to foreign invaders. Many institutions have stopped performing these in conjunction with ppd testing, but anergy panels remain a clinically sound method to determine a patient's cell-mediated immune status.

Of the markers of cellular activity, monocyte human leukocyte antigen (HLA)-DR class II molecules seem to most consistently serve as an index of antigen-presenting capacity (19–21). HLA-DR class II molecules mediate antigen processing which allows cellular immunity to proceed. As an index of antigen-presenting capacity, it stands to reason that their decline and recovery rates are closely linked to clinical outcome. In fact, multiple measures of PMN function are altered in ways that would seem to increase the likelihood of infection (22). The infectious agents commonly found in these patients include opportunistic organisms such as *Pseudomonas aeruginosa*, *Staphylococcus epidermidis*, *S. aureus*, and *Candida albicans*. In many cases, the source of infection may be distant from the initial wound, further indicating that there is systemic dysfunction of the immune system.

One study of chest trauma demonstrated an aggressive inflammatory response locally at the source of the injury, followed by systemic immunosuppression (23). Therefore, the innate systemic phagocytic cells, particularly PMNs and monocytes, appear to become suppressed following traumatic injury (24).

Other cellular markers such as endothelial adhesion molecules (ICAM-1, L-selectin) and the CD11b leukocyte receptor have received some attention but results have been mixed (25,26). As other markers are characterized, the ability to predict and intervene before specific complications arise for a particular patient will likely be enhanced.

### Treatment-Related Immunomodulation

In addition to the disruption of barriers and tissues from the initial trauma and the response of the immune system to the inflammatory cascade, the treatments applied to traumatically injured patients can also influence infection risk. Something as simple as intravenous (IV) access can have a profound impact on the patient's infection risk due to type of access, location of placement, and line care both during and after placement (Volume 2, Chapter 49).

The timing of surgical intervention may have a profound effect on the immune response to trauma. In patients with limited orthopedic injuries, early total care allows rapid mobilization and restoration of function. However, in patients who are more severely injured, limiting primary surgery to only essential, life-saving interventions give the patient the best chance of recovery. Early surgical repair of bony fractures in these patients may be associated with a massively increased inflammatory response leading to SIRS, ARDS, and MODS (27–29). **Damage control surgery in severely injured patients was first applied to abdominal surgery (Volume 1, Chapter 21), and is now known to improve outcome for orthopedic trauma surgery as well (29).**

Severe traumatic injury is related to an increase in gut permeability (30–32), allowing translocation of gut flora into the systemic circulation (33,34). The gut has emerged as a target for immunomodulation; glutamine, arginine,  $\Omega$ -3 fatty acids, and nucleotides have been added to enteral feeding as a means to enhance the patient's immune response (35–37). Early enteral nutrition is an important element of prophylaxis against nosocomial infections (see Volume 2, Chapter 32).

Patients in the hospital, particularly in the intensive care unit (ICU), are sleep-deprived both in quantity and quality of sleep. Sedatives and narcotics are known to interfere with the quality of sleep as well. There appears to be a relationship, possibly involving the autonomic nervous and neuroendocrine systems, between sleep deprivation and the immune system that might lead to increased risk of infection (38).

Patients who are intubated are at increased risk for ventilator-associated pneumonia (Volume 2, Chapter 48). Treatment decisions, such as the timing of a tracheostomy, can influence the rate of infection and mortality (39). Ventilator settings with lower tidal volumes can reduce the inflammatory response in acute lung injury and has been shown to reduce mortality in the setting of ARDS (40,41).

Other commonly employed treatments have also been shown to have adverse effects on the immune system. Blood transfusions have been shown to correlate with an increase in infection rate in a dose-dependent manner (42,43), although there remains controversy if this is causal or a marker of injury severity (44). Hypertonic saline may even have an immunosuppressive effect, possibly beneficial in blunting the immune hyperstimulation typical of the acute phase of resuscitation (45). Many, if not all of the vasoactive agents that are used in critically ill patients, also have immunologic activity. The interactions of this therapy

**Table 5** Postsplenectomy Vaccination Guidelines

Vaccine name (bacterial species covered)	Adult dose	Pediatric dose	Optimum timing/comments
Pneumovax 23 (pneumococcal vaccine with antigens for 23 most common pneumococcal strains)	0.5 mL IM/SC	0.5 mL IM/SC (contraindicated for age <2 years)	For traumatic splenectomy: administer immediately upon arrival (prior to splenectomy). For elective splenectomy at least 2 weeks prior to scheduled surgery
MCV4-conjugate MPSV4-oid formulation [tetravalent meningococcal vaccine, including capsular polysaccharide antigens (groups A, C, Y, and W-135) of <i>Neisseria meningitidis</i> ]	0.5 mL SC	0.5 mL SC (contraindicated for age <2 years)	Same as above MCV4—licensed in 2005 confers longer lasting immunity. MPSV4—available since 1970s provides only short (<1 year) immunity
ActHIB, HibTITER, PedvaxHIB (Haemophilus B conjugate vaccine)	Not indicated	Age and Hib titer dependent (see package insert)	Initial Rx is same as above, but requires repeated doses per schedule

*Abbreviations:* HIB, *Haemophilus influenzae*-type B; IM, intramuscular; MCV4, meningococcal tetravalent conjugate vaccine; MPSV4, meningococcal tetravalent polysaccharide antigen vaccine; SC, subcutaneous.

*Source:* Data for pneumococcal, meningococcal, and hemophilus from Refs. 145–147.

with the patient's immune system is only beginning to be understood (46).

Agranulocytosis, a syndrome characterized by severe neutropenia, was first reported to be associated with medication exposure in 1934 (47). A host of pharmacologic agents, for example, antibiotics, antidysrhythmics, and anti-seizure medications, can cause marrow suppression and agranulocytosis (see Table 6 in Volume 2, Chapter 57) (48,49). Severe neutropenia ( $<0.5 \times 10^9$  neutrophils/L) is a life-threatening disorder, rendering the patient unable to battle infection. The agents most frequently implicated are antibiotics, antithyroid drugs, antiplatelet agents, and neuroleptic and antiepileptic agents, although drug-induced agranulocytosis is a rare event with an incidence around 3 to 12 cases per million population (for a more complete list and explanation, see Volume 2, Chapter 57) (49). Risk increases with increasing age and drug exposure and appears to be more common in women than men (50). Treatment with hematopoietic growth factors such as granulocyte colony-stimulating factor has been shown to shorten the duration of neutropenia (51).

### Splenectomy—Special Case of Immune Component Removal

The spleen is the most commonly injured intra-abdominal organ (see Volume 1, Chapter 27), and a missed splenic injury is the most common cause of preventable death in trauma patients (see Volume 1, Chapter 42). The optimal management of splenic trauma has shifted during the last two decades from nearly uniform splenectomy to an emphasis on spleen salvage (52). Part of the reason for this trend is the decreased post-trauma morbidity observed with properly staged nonoperative treatment. Another major factor driving nonoperative management of spleen injuries is the increasingly recognized immunological importance of the organ (especially in children <5 years of age) (52–54).

The most worrisome infectious complication following splenectomy is overwhelming postsplenectomy sepsis (OPSS). Chronic thrombocytosis (see Volume 2, Chapter 55) is the most common long-term effect of splenectomy, but it is clinically benign. Though relatively rare, OPSS has a high mortality (50%) (52). ⚠ **The risk of OPSS is particularly high following splenectomy in children under five years of age (especially infants splenectomized for trauma, with reported infection rates of >10%) (53).** ⚠ Infection most commonly occurs with encapsulated organisms (*Streptococcus pneumoniae*, *Neisseria meningitidis*, *Haemophilus influenzae*-type B). Encapsulated organisms are problematic because the spleen is integral in the removal of opsonized microbes such as these bacteria (54). Early antibiotic therapy is essential to avoid death from a rapidly progressive infection.

Protection against OPSS involves vaccination and less commonly antibiotic prophylaxis (Volume 2, Chapter 53). The optimal timing of vaccination has long been a subject of debate. Shatz et al. demonstrated that a 14-day delay in vaccination after emergent splenectomy resulted in improved antibody response, but that total postvaccination IgG levels were not significantly different from normal control subjects regardless of the time of vaccination (1, 7, or 14 days following splenectomy). The better functional antibody responses occurred against the serogroup and serotypes studied with delayed (14-day) vaccination, but not all serotypes were studied (55). In a follow-up study, antibody response was not improved any further by delaying vaccination to 28 days (56).

Although the antibody response may be better two weeks after splenectomy, if a delayed vaccination strategy is used, many patients would be discharged home from the hospital prior to receiving vaccination, and either missed immunization completely due to loss to follow-up, or develop infection prior to immunization. Many trauma surgeons in North America (44.1%) vaccinate their patients within the first week after emergent splenectomy, chiefly for this reason (57).

**Table 6** Autoimmune Diseases with Immunomodulating Treatments in Use or Being Developed

Disease	Autoimmunological mechanism of disease	Treatment(s)
Myasthenia gravis	Antibodies nicotinic Ach receptors in muscle disrupt transmission at the NMJ	Anticholinesterase drugs (e.g., pyridostigmine, neostigmine), thymectomy (improves 80%), plasmapheresis
Multiple sclerosis	Anti-myelin antibodies	Interferon $\beta$ -1a (inhibits IL-12)
SLE	Auto-antibodies to numerous structures including DNA, nuclei, immune complex nephritis, etc (due to IL-2 inhibition)	Steroids, and other immunosuppressive therapies. Soon, may have IL-2 boosting therapy for defective cells. Administration of complement may be therapeutic (SLE is more common and severe in complement deficiencies)
Rheumatoid arthritis	Auto-antibodies to numerous structures including synovium. TNF- $\alpha$ activated macrophages contribute to synovial inflammation	Methotrexate and blockade of TNF- $\alpha$ receptor (etanercept) or a monoclonal antibody against TNF- $\alpha$ (infliximab)
Inflammatory bowel disease	CD4 + CD45RO+ T-cell migration into inflamed mucosa elevated IL-2, IL-7, IL-10 production	Corticosteroids; aminosalicylates; anti-TNF- $\alpha$ agent (infliximab); inhibition of leukocyte migration into inflamed intestine by blocking integrins (cellular adhesion molecules)
Psoriasis	T-lymphocyte-based immunopathogenesis with Munro microabscesses below the stratum corneum	Alefacept, efalizumab, and etanercept, monoclonal antibodies, cytokines, and fusion proteins (see text for explanation)
Pemphigus	IgG anti-BM auto-antibodies, anti-BPAG <sub>1</sub> , and anti-BPAG <sub>2</sub> produced, and T-cells are	Immunosuppressive agents (e.g., azathioprine, mycophenolate mofetil, or cyclophosphamide), plasmapheresis to remove anti-BPAG <sub>1</sub> and anti-BPAG <sub>2</sub>
Addison's disease	21-Hydroxylase auto-antibodies impair adrenocortical function (takes years)	Corticosteroid replacement (targeted immunosuppressive regimens being developed)
Type 1A diabetes	Anti-insulin antibodies as well as transglutaminase auto-antibodies	Immunosuppressive regimens

*Abbreviations:* Ach, acetylcholine; BPAG<sub>1</sub>, bullous pemphigoid antigen<sub>1</sub>; BPAG<sub>2</sub>, bullous pemphigoid antigen<sub>2</sub>; CD45RO, markers on cell surface; CD4 + CD45RO+ T-cell, T helper cell with CD4 marker; IL, interleukin; NMJ, neuromuscular junction; SLE, systemic lupus erythematosus; TNF- $\alpha$  tumor necrosis factor alpha.

✎ **The current vaccination recommendations for traumatic splenectomy patients call for administration of indicated vaccines as soon as possible, preferably prior to splenectomy (58).** ✎ Pneumococcal vaccine should be administered at least two weeks before an elective splenectomy. If the above time frames are not practical for various reasons, the patient should be immunized as soon as possible after recovery and before discharge from the hospital to minimize the possibility that the patient will be lost to follow-up prior to vaccination (58).

The three commonly administered vaccines used in the post-traumatic splenectomy patient are summarized in Table 5. Pneumococcal vaccine (Pneumovax 23) contains capsular polysaccharide antigens of 23 pneumococcal types, comprising 98% of pneumococcal disease isolates (59). As one might predict, the most virulent pneumococcal serotypes tend to be the least immunogenic. Unfortunately, vaccine efficacy is poorest in younger patients, who are at higher risk. However, under ideal conditions in a healthy immunocompetent host, the vaccine offers a 70% protection rate.

Amoxicillin is recommended for antibiotic prophylaxis against encapsulated bacteria in asplenic children, especially for the first two years after splenectomy (60). Patients who are allergic to penicillin should be offered erythromycin. Some investigators advocate continuing antibiotic prophylaxis in children for at least 5 years after splenectomy or until aged 16 (61). However, long term antibiotics are less frequently utilized.

## PRE-EXISTING IMMUNOSUPPRESSIVE MEDICAL DISEASES

It is intuitive that known immunosuppression should adversely affect outcome in traumatic injury, and this is often the case. Disorders of the immune system can result from hypersensitivity reactions, such as anaphylaxis (Volume 1, Chapter 33), or from numerous triggers for SIRS (Volume 2, Chapter 63). Autoimmune diseases and immunodeficiency syndromes are also debilitating. Additionally, several important systemic diseases (including diabetes, renal failure, and liver failure) impair the native immune system, and will be briefly reviewed here.

### Diabetes

It has long been known that hyperglycemia and diabetes predispose patients to infection (see Volume 2, Chapter 60). However, the role of diabetes and hyperglycemia in trauma-associated infections is just now becoming elucidated. In a large retrospective review of the Pennsylvania trauma registry over a two-year period, the group of patients with a history of diabetes had an increased risk of sepsis (odds ratio, 1.61) (62).

Several immunological mechanisms are distorted by hyperglycemia and diabetes. The release of IL-1 and oxygen radicals by macrophages and neutrophils is inhibited, and phagocytosis by macrophages is impaired (63). Conversely, tight glycemic control improves the leukocyte oxidative burst and phagocytic activity (64). Therefore,

it is not surprising that tight glucose control with IV insulin in diabetic critically ill postoperative open-heart cardiac surgery patients demonstrated a reduced incidence of deep sternal wound infections (0.8% vs. 2% for subcutaneous insulin injections) (65) and decreased mortality overall (66,67). **✎ The incidence of bacteremia is reduced by almost 50%, and sepsis-associated mortality is similarly reduced when critically ill patients are intensively treated with exogenous insulin to maintain normoglycemia. ✎**

The link between hyperglycemia and increased risk of serious infections, regardless of a previous history of diabetes, was provided only recently (see Volume 2, Chapter 60). Improved capacity to clear bacterial invaders with euglycemia was observed in a novel rabbit model of prolonged critical illness (68). In this study, Weekers et al. (68) demonstrated that aggravation of insulin resistance and hyperglycemia likely plays a role in the reduced phagocytosis capacity and impaired bacterial killing of monocytes, and that this can be ameliorated with insulin administration and tight blood sugar control. Diabetic patients have additional stigmata that may increase their risk of infection such as arteriolar sclerosis which decreases tissue perfusion to various vascular beds. However, titrating insulin to maintain tight blood glucose control at normal levels appears to markedly enhance the immune system of critically ill patients.

### Renal Failure

Chronic renal failure (CRF), particularly in patients who are hemodialysis-dependent, results in considerable immunosuppression (69,70). Additionally, these patients have decreased perfusion to numerous tissue beds, and increased blood sugar, both of which favor microbial growth rather than host defense. Furthermore, these patients require specialized vascular access that can readily become seeded with infection with bacteremia (71).

**✎ Immune dysfunction in patients with renal failure involves both cellular (PMNs, T-cells, B-cells, dendritic cells), and humoral systems (alterations in complement, immunoglobulin levels, and cytokines) (72). ✎** The accumulation of both low- and high-molecular-weight uremic toxins (e.g., *p*-cresol, guanidine compounds, oxidation products, and granulocyte inhibitory proteins) are believed to be causal. Additionally, the secondary hyperparathyroidism associated with CRF is also thought to play an immuno-inhibitory role. With the frequent co-morbidity of malnutrition, the immune system is even more profoundly impaired.

Of the known uremic retention solutes, *p*-cresol dose dependently decreases PMN function by depressing the respiratory burst activity at concentrations commonly found in CRF patients (73,74). The toxicity of *p*-cresol is greater in the setting of hypoalbuminemia, a common problem following trauma and critical illness (75). Additionally, a factor removed by continuous ambulatory peritoneal dialysis but not by conventional hemodialysis was found to inhibit the function of PMNs in CRF patients (76). Whether these "toxic factors" are cleared by continuous renal replacement therapies has not yet been fully established.

Intracellular calcium plays an important role in many cellular functions, and increased cytosolic calcium is associated with secondary hyperparathyroidism of CRF, and with alterations in PMN function (77). Interestingly, normalization of cytosolic calcium by treatment with a calcium channel blocker (verapamil) resulted in improved PMN function without influencing the elevated parathyroid levels (78).

### Liver Failure

**✎ The immune system is altered in liver failure due to chronic inflammation, decreased production of proteins including complement with increased circulating TNF- $\alpha$ , and increased production of cytokines by the Kupffer cells. ✎** Accordingly, bacterial infection is a frequent complication of cirrhosis, particularly in those patients with GI bleeding or ascites (79). Additionally, these patients often have other co-existing disease such as malnutrition and diabetes that further impair their immunologic response. Infection in patients with fulminant hepatic failure is a major source of mortality as 44% to 80% of patients with fulminant hepatic failure develop bacterial infections. Empiric broad-spectrum antibiotics should be initiated on clinical suspicion of infection (80).

Bacterial and fungal infections are common in acute liver failure for a number of reasons. Patients with acute liver failure have diminished serum opsonic activity (81), faulty PMN leukocyte function (82), and impaired cell-mediated and humoral immunity (especially alcoholic cirrhosis) (83). Bacteremia is common because patients are comatose, have numerous indwelling catheters, and may be receiving H<sub>2</sub>-receptor blockers, steroid therapy, or broad-spectrum antibiotics. In one prospective study of 50 patients, 80% had culture-proven infection, and in half of the remaining patients, infection was suspected (though cultures were negative) (84). Gram-positive organisms, mainly streptococci and *S. aureus*, predominate in acute liver failure, suggesting that the entry through the skin is more important than GI entry (the pathway of Gram-negative organisms) (85). Regular microbial surveillance and aggressive treatment of presumed infection are essential, since prophylactic antibiotic regimens have shown little benefit (86). A finding of disseminated fungemia is particularly ominous (87).

### Autoimmune Diseases

**✎ Autoimmune diseases result from a failure of immune tolerance; it fails to recognize native cells and tissues as "self," instead treating these structures as though they are foreign invaders. ✎** Damage occurs to native cells and organs due to activation of T-cells and/or B-cells, in the absence of an ongoing infection or other discernible cause (88). There are a number of known ways in which tolerance of self-tissues is bypassed and autoimmune disease occurs. Genetics is involved, and there is an increased incidence in females (approximately 75% of autoimmune diseases) (89). However, environmental triggers are also exceedingly important (and almost universally required). A typical environmental trigger is infection. For example, following Group A Streptococci infection, patients may develop rheumatic fever due to cross-reaction between the bacterial antigens and myocardial tissue. Additionally, viral infections can lead to gene insertions or immunogenic circulating proteins that can trigger immune cross reactivity. Some autoimmune diseases such as pemphigoid may result as a paraneoplastic syndrome (90). Finally, several putative autoimmune diseases may have an immunological component that is not antiself. For example, women with scleroderma who have had children have significantly higher levels of fetal WBCs circulating in their blood decades after pregnancy than do mothers without the disease (89). Perhaps, scleroderma will eventually become re-categorized as graft-versus-host disease.

Because autoimmune diseases can cause significant organ failure, it is not uncommon for these patients to become critically ill. When such patients are injured, their course is complicated by their unique organ system dysfunction and immunological dysregulation. Moreover, the heavy use of glucocorticoids potentiates overall immunosuppression. A complete review of these processes is beyond the scope of this text, and the reader is referred to a recent review by Davidson and Diamond for a more comprehensive discussion (88). Table 6 summarizes briefly the selected autoimmune diseases.

While the best remedy is treating the root cause of autoimmune disease (i.e., blocking the specific cytokines or chemokines produced by improperly regulated T- or B-cells), symptomatic relief is particularly important when the structure attacked by the immune system involves the central nervous system (CNS), or neuromuscular junction (e.g., myasthenia gravis). Plasma exchange and administration of IV immunoglobulin (IVIG) are both effective in many autoimmune neurologic diseases (91). However, the specificity of IVIG can vary, and the proper patient selection in terms of initiation and duration of long-term maintenance requires additional randomized clinical trials. Clinical symptom relief for myasthenia gravis is provided by administration of anticholinesterase drugs, such as pyridostigmine and neostigmine. Psoriasis is an example of an autoimmune disease where immunomodulation has been employed at several levels of the disease including: (i) inhibition of T-cell activation; (ii) depletion of pathogenic T-cells (high-affinity IL-2 receptor or CD4); (iii) inhibition of key adhesion molecules, for example, selectins or integrins [Integrins are adhesion molecules that confer mechanical stability between the cells and their environment (92). They also act as cellular sensors and signaling molecules. Adhesion molecules can be inhibited by drugs such as efalizumab, a monoclonal antibody that interferes with adhesion mediated by leukocyte-function-associated antigen 1]; (iv) inhibition of key inflammatory cytokines (the monoclonal antibodies infliximab and adalimumab, as well as the fusion proteins etanercept and oncept all focus upon TNF- $\alpha$ ); and (v) shifting the cytokine milieu dominated by Th1 cells to a milieu weighted with Th2 cells, thus alleviating psoriasis by minimizing the IL-10 and IL-4 levels (93). There are no current studies reviewing the morbidity and mortality of pre-existing autoimmune diseases in trauma patients, but those with pre-existing organ dysfunction will have a more complicated course.

### Elderly

Elderly patients who sustain traumatic injuries and burns have a higher mortality. One reason commonly cited is their compromised immune response (94–97). The elderly are also at increased risk for diabetes, renal insufficiency, liver insufficiency, and malnutrition, all associated with immune impairment. In addition, there is considerable evidence that both chronic and acute ingestion of ethanol causes suppression of the immune response as well as impaired intestinal immunity and barrier function (98,99).

☞ **With regard to malnutrition, a recent mouse perforated bowel study showed that malnutrition was an independent risk factor for infection and mortality (100).** ☞

## HIV/AIDS AND TRAUMA OR CRITICAL ILLNESS

### Brief Review of HIV/AIDS

The acquired immunodeficiency syndrome (AIDS) is a profound immunosuppression state resulting from infection

with HIV, causing opportunistic infections, secondary neoplasms, and neurological manifestations. The virus is transmitted inside infected CD4+ T-cells and macrophages. Clinically, the disease is spread sexually or through blood or blood products as encountered by IV drug abusers.

Two genetically distinct but related forms of HIV (HIV-1 and HIV-2) have been isolated from patients with AIDS. HIV-1 is the predominant source of AIDS in the United States, Europe, and Central Africa (where it likely originated from the chimpanzee) (101). HIV-2 is more prevalent in West Africa, where it likely emerged from the sooty mangabey monkeys indigenous there (102).

HIV infection targets the immune system along with the CNS. ☞ **The CD4 molecule is a high affinity receptor for HIV, explaining the tropism of the virus for CD4+ T-cells and other CD4+ cells (i.e., monocytes/macrophages, and Langerhans cells/dendritic cells). The loss of these cells leads to profound immunosuppression, primarily cell-mediated immunity.** ☞

Early in the disease, HIV colonizes the lymphoid organs (spleen, lymph nodes, tonsils) producing over 100 billion viral particles per day, and killing one to two billion CD4+ T-cells daily. Initially, the immune system can regenerate the dying T-cells, and the CD4+ T-cell loss appears deceptively low. The Center for Disease Control classification of HIV stratifies patients into three categories on the basis of CD4+ T-cell counts: CD4+  $\geq$ 500, 200 to 499, and  $<$ 200 cells/ $\mu$ L. Patients in the first group are usually asymptomatic, those with levels from 200 to 499 are associated with early symptoms, and levels below 200 are associated with severe immunosuppression; the last group is conventionally considered to have AIDS.

The HIV epidemic continues to expand globally, especially in third world countries (103). The U.S. statistics demonstrate that AIDS- and HIV-related deaths peaked in 1993, but that the prevalence of HIV continues to increase (104). Indeed, in December 2004, the estimated prevalence of HIV infected individuals was near one million persons (including 180,000–280,000 who do not know they are infected) (105).

### Trauma and Critical Illness Involving HIV+ Patients

As the prevalence of HIV increases, traumatologists will become increasingly involved in the care of HIV-positive (HIV+) patients. A recent study of HIV infection in trauma patients demonstrated a prevalence of 0.3% (106). Most other North American trauma centers have reported a higher prevalence of HIV infection ranging between 0.96% and 4.3% (107,108). In one study, male patients from an urban area who were victims of interpersonal violence had an HIV prevalence of 3.5% (107).

HIV and AIDS can undoubtedly affect outcome in trauma patients. Much has been written about the prevalence of HIV infection in trauma patients, however, little is known about how the infection affects morbidity and mortality in these patients. Similarly, the stresses of trauma may affect the progression of HIV disease, yet little is actually known about these relationships either. Indeed, no randomized prospective trials have been conducted in trauma patients to evaluate the effects of HIV disease.

Patients who were identified as being immunosuppressed (AIDS, HIV+, routine steroid use, transplants, or active chemotherapy) comprised a smaller group, but their risk of sepsis was markedly increased (odds ratio, 4.43) (62). In other studies, HIV+ patients have been more likely

to develop infection after bony fracture (109), and HIV+ burned patients were more likely to develop systemic infections with higher associated mortality (110). In contrast, those patients who did not develop infection had similar length of stay and recovery characteristics as non-HIV+ patients, also the case in a study of nonburn traumatic injury (106). Another study showed no increased mortality in burned patients with HIV infection compared with previously healthy controls (111).

A recent Pennsylvania trauma outcome study (PTOS), retrospectively evaluated the status of HIV disease in trauma (106). PTOS reported some anticipated results, for example, that the majority of HIV+ patients were male, with a mean age of 39 years. The study also showed higher rates of penetrating trauma among HIV+ patients than in control patients, a pattern previously reported by others (112,113).

However, PTOS has made a first estimation at quantifying the various risk factors and co-morbidities. Compared with age-matched controls, HIV+ trauma patients were significantly more likely to suffer from chronic drug and alcohol use; neurologic disorders; renal, pulmonary, GI, and liver disease; non-HIV hematologic disease; and a history of psychiatric diagnosis (all  $P < 0.01$ ) (106).

The HIV+ status was also associated with significantly longer hospital length of stay (10.2 days vs. 6.8 days for controls,  $P = 0.001$ ). Additionally, HIV+ patients spent more days in the ICU ( $P < 0.02$ ), and were more likely to remain in the ICU for  $>7$  days (106). These observations are partly explained by the greater overall number of complications in the HIV+ group.

Although there was no overall statistical difference in mortality between the two groups (3.6% vs. 3.1%,  $P = 0.6447$ ), infection/sepsis and pulmonary complications were associated with significant mortality in HIV+ patients. HIV+ patients also underwent more thoracostomies (7.5% vs. 4.4%,  $P < 0.03$ ) and exploratory laparotomies (7.0% vs. 2.4%,  $P < 0.001$ ) (106).

The greater proportion of pulmonary complications in HIV+ patients occurred despite lack of significant difference in abbreviated injury scale score for the chest between the two groups. In a separate study by Rosen et al. (114) involving 63 HIV+ patients admitted to an ICU, 44% of those patients required mechanical ventilation, with a 57% associated mortality.

The PTOS study authors speculated that the incidence of post-traumatic complications may be related to the greater frequency of pre-existing conditions in the HIV+ trauma population. Although exact diagnoses are not reported in the PTOS database, HIV+ patients had nearly double the rate of pre-existing pulmonary disease compared with control patients. In the Rosen study of HIV+ ICU patients, 16 of 25 patients who died had primary pulmonary diagnosis and 3 of 25 died as a result of sepsis (114). In another study, mortality with a pleural effusion was two times higher for HIV+ patients with pleural effusion than for those without effusion (115). Others showed that the incidence of bacterial infectious complications in trauma patients was tied to increasing ISS and not the CD4 count (116).

HIV+ patients in the PTOS study underwent more operative procedures than the control group, and had nearly twice the frequency of exploratory laparotomy and chest tubes, and more frequent laparoscopy and thoracotomy (106). Hebra et al. (117) examined the types of procedures performed on 150 HIV+ patients admitted to the hospital for various surgical procedures (including trauma,

general surgical, orthopedic, cardiac, thoracic, and vascular procedures). They found that nearly half of 30 operations performed on their patients were performed to treat AIDS-related complications or to facilitate the workup of AIDS patients (117). In contrast, a study in burn patients showed similar number of procedures in HIV+ and control groups (118). The disparity of these results (especially without reporting absolute CD4+ T-cell numbers) emphasize the current inability to predict the relative detrimental outcome weight that HIV+ status connotes for various injuries.

Although the overall HIV+ patient mortality was not statistically different from the control group in the PTOS study, the operative mortality for HIV+ patient was 5.6%. Other studies agree with this finding, with mortality rates ranging from 3.8% to 5% (116,119). Additionally, having the stigmata of AIDS increases mortality (118,119). In a small study involving 10 general surgical patients with AIDS who underwent emergency laparotomy, Burack et al. (120) reported a 70% mortality in the postoperative period.

Although it has been suggested that major surgery or trauma can advance a patient's HIV stage as measured using the World Health Organization HIV clinical staging system (120–122), PTOS did not investigate this phenomenon. Other significant limitations of this study include its retrospective nature, inability to distinguish asymptomatic HIV from symptomatic AIDS, and lack of information on CD4+ count and retroviral or antimicrobial therapies used.

### HIV Drugs During Trauma and Critical Care

Complex treatment regimens are frequently required to manage unique infectious diseases and medical problems in HIV+ patients (123). However, there have not been any recent reviews in medical management for the HIV+ trauma patient in a decade (124).

The most common current therapy for HIV+ patients include the protease inhibitors that block the protease enzyme used by HIV to infect new cells. Protease inhibitors can reduce the amount of virus in the blood and increase CD4+ T-cell counts. In some cases, these drugs have improved CD4+ T-cell counts, even when they were very low or zero.

With the advent of protease inhibitors in combination with other drugs, the number of HIV+ patients who became ill from opportunistic infections, or died from AIDS, dropped by about 70%. However, some HIV strains have become resistant to protease inhibitors. Thus, it is recommended that protease inhibitors be taken in combination with at least two other anti-HIV drugs. This is called highly active anti-retroviral therapy or HAART, which increases the anti-HIV effect, and helps prevent resistance.

Nine Food and Drug Administration (FDA) approved protease inhibitors are available: darunavir (Prezista<sup>®</sup>), indinavir (Crixivan<sup>®</sup>), lopinavir/ritonavir (Kaletra<sup>®</sup>), ritonavir (Norvir<sup>®</sup>), saquinavir (Fortovase<sup>®</sup> and Invirase<sup>®</sup>), nelfinavir (Viracept<sup>®</sup>), and atazanavir (Rayataz<sup>®</sup>), tipranavir (Aptivus<sup>®</sup>), and fosamprenavir (Lexiva<sup>®</sup>).

Because of the rapidly expanding array of anti-HIV drugs, and the rapidity with which research results are changing in this area, any recommendations regarding the general treatment of HIV+ patients is likely to become quickly obsolete. Accordingly, readers are referred to the latest recommendations from the International AIDS Society—USA Panel (123). In addition, when HIV+ patients are admitted to the trauma unit or surgical ICU, it is

**Table 7** Categories of Micro-organisms Responsible for Sepsis in Immunocompromised Patients According to Various Etiologies of Impaired Immunity

Cause of impaired immune status	Gram-positive bacteria	Gram-negative bacteria	<i>Listeria, Legionella, Mycobacteria</i>	CMV and other HSV	Respiratory viruses	<i>Candida</i> species	Aspergillus and other molds
Sepsis	++	+	–	+/-	+/-	++	+
Glucocorticoids	+	+	++	+/-	+/-	+++	++
Neutropenia	++	+++	–	–	+	+++	++
HIV/AIDS	++	++	++	+	+/-	++	++
Solid organ transplant	+	+	+	+++	+	+++	+++
HSCT	+	+	+	+++	+++	++	+++

*Abbreviations:* CMV, cytomegalovirus; AIDS, autoimmune deficiency syndrome; HIV, human immunodeficiency virus; HSCT, hematopoietic stem cell transplant; HSV, herpes simplex virus; –, not a significant problem; +, occasional problem; +/-, may become a problem; ++, significant problem; +++, major problem.

*Source:* From Ref. 125.

recommended that an HIV specialist be immediately consulted to assist with the decisions regarding antiretroviral, and other immunological therapy.

### INFECTIOUS DISEASES IN THE IMMUNOCOMPROMISED

A consensus document was published in 2004 by an international group of critical care and infectious disease experts containing management guidelines for sepsis associated with immunosuppressive medications (125). The most commonly described infectious complications of immunosuppressive therapy are summarized in Table 7. The most common immunosuppressant medications are corticosteroids, cytoreductive agents such as methotrexate, immunophilin-binding agents such as tacrolimus, mycophenolate, anti-TNF agents, and other monoclonal antibodies and fusion proteins. Agents are commonly used in combination making the exact risk of infection for any one agent or patient difficult to discern. Nevertheless, patterns of infection have been noted and Table 7 shows the likely categories of micro-organisms for different types of patients.

It is very important to make the correct diagnosis to appropriately direct therapy at the causative organism. The preferred methods for diagnosis of the common pathogens infecting immunocompromised patients are summarized in Table 8. Interestingly, various categories of immunosuppressive drugs are associated with a specific set of infectious organisms that are normally suppressed by pathways they disrupt (Table 9). Finally, treatment recommendations based upon the status of the patient are given in Table 10.

It is useful to recognize that no unique combination of antibiotics is universally appropriate in this setting. The prevalent pathogens in a given ICU and antibiotics currently being administered must be put into the context of the patient's immunocompromised status and infectious symptoms. Prompt initiation of adequate antimicrobial coverage is of utmost importance; any delay results in worse outcome for the patient (126–129). Therefore, most experts in the management of immunocompromised patients tend to use very broad-spectrum coverage initially when dealing with severe sepsis of unknown origin in this patient population. Once the pathogens have been accurately identified, the coverage can be tailored more specifically. The reader is referred to Volume 2, Chapter 53 for a more complete review of the antimicrobial options.

### TRANSPLANTATION AND TRAUMA

Although the number of trauma patients presenting with a history of organ transplantation is small, these patients have a more complicated interaction between immunosuppression and inflammation than others. The risk of infection is related to the patient's overall immune state, including patient factors and medication effects, and the intensity of exposure to potential pathogens (130). In the hospital, these patients may become infected more easily from exposure to pathogens from other patients as well as contamination of air, water, or equipment in the building. Given the fact that steroids are the mainstay of most immunosuppressive regimens following transplant, these patients are at increased risk for osteoporosis and bony fractures (131–134). It is reasonable to assume that transplant recipients will be a small, but regular clientele on the trauma service. The typical timing of certain types of infection after transplant is reviewed below.

1. *First month following transplantation* ⚡ **During the first month after solid organ transplantation, the infections usually encountered in transplant recipients are the same as those found in a typical surgical population (135).** ⚡ Like other cases, the most important factors determining the incidence of infections are the type of operation, the technical skill applied to the operation, and the postoperative care of the patient. Duration of vascular access, use of drainage catheters, duration of intubation, and presence of indwelling stents, devitalized tissue, or fluids will all increase infection risk. Although uncommon, primary infection may be transmitted from the donor with the allograft. Opportunistic infections are also uncommon during the first month after transplant. If opportunistic infections occur during the first post-transplant month, it likely indicates significant environmental exposure, immunosuppressive state prior to transplant, or pre-existing infection in the donor or recipient (130).

2. *Second through sixth month following transplantation* ⚡ **After the first month, the immunomodulating viruses can become clinically significant, in addition to residual agents from prior infections and events.** ⚡ The combination of sustained immunosuppression and viral infection with cytomegalovirus (CMV), EBV, hepatitis B virus (HBV), hepatitis C virus (HCV), or HIV makes infection with opportunistic infections *Pneumocystis carinii*, *Aspergillus*, *Candida*, and *Listeria monocytogenes* more likely. This time period is when immunosuppression is typically at the highest.

**Table 8** Diagnostic Methodology for Selected Pathogens in Immunocompromised Patients

Suspected pathogen	Method of diagnosis	Alternate diagnosis	Comments
<b>Bacteria</b>			
Fastidious or unusual bacteria	Two to three BCs using aerobic and anaerobic bottles containing resin or charcoal neutralization particles	Standard aerobic, anaerobic BC bottles	Prolonged (i.e., 7–14 days incubation required)
<i>Legionella</i> species	BAL or sputum Cx. <i>Legionella</i> may not be seen in Gram stain or DFA of respiratory secretions	Urinary antigens PCR promising, but no standardized assay available	Urinary antigen detects only <i>Legionella pneumophila</i> serotype 1
<i>Nocardia</i>	Modified acid-fast stain or GMS of respiratory secretions or tissue Bx	Blood culture (note these may frequently be negative)	Beaded branching gram-positive bacilli should raise suspicion
<i>Mycobacterium tuberculosis</i>	Fluorochrome stain of BAL or sputum; amplification of rRNA or DNA using TB rapid broth Cx (Bactec, BactAlert, ESP systems)	Transbronchial Bx in case of negative BAL; bone marrow Bx if disseminated “miliary” TB	Disseminated TB may have skin lesions amenable to Bx. QuantiFERON-TB®Gold (QFT) can measure TB proteins in blood
Nontuberculous mycobacteria	Sputum/BAL in case of lung lesions	BC (isolator or rapid mycobacterial bottle); Bx of skin lesions	Bone marrow Cx is not more sensitive than BC, but may allow for earlier Dx
<b>Fungi</b>			
<i>Pneumocystis jirovecii</i> (formerly <i>Pneumocystis carinii</i> )	Direct fluorescence antibody from induced sputum or BAL	Silver stain from induced sputum or BAL	PCR may be more sensitive, particularly in non-HIV patients
<i>Candida</i> species	Bx of suspicious lesions; 2–3 aerobic BCs plus Cx of catheters	Funduscopy exam may be suggestive; CT scan helpful in chronic disseminated candidiasis	BCs may be negative in acute, and are typically negative in chronic disseminated candidiasis
<i>Cryptococcus neoformans</i>	EIA detection of cryptococcal antigen in serum or CSF	Two to three BCs; CSF India ink and Cx	
<i>Histoplasma capsulatum</i>	Stain of tissue Bx, two lysis-centrifugation (isolator) BCs	EIA detection of histoplasma antigen in urine; two aerobic BCs	Urine antigen positive only in disseminated disease
Mold infections ( <i>Aspergillus</i> species, <i>Fusarium</i> species, etc)	BAL; biopsy of any suspicious lesion; sputum, tracheal aspirate, bronchial brush	Plasma galactomannan antigenemia (but this cross reacts with some other molds such as <i>Penicillium</i> )	Isolation of molds from sputum indicates high risk of invasive disease—not to be ignored
<b>Viruses</b>			
CMV	CMV antigen detection, CMV PCR, shell vial from BAL	Viral Cx; cytopathic effect seen in cells from BAL suggests pneumonia	CMV antigen in the blood, and CMV PCR in the BAL does not mean CMV is causing disease
EBV	Quantitative PCR in blood (also useful for monitoring viral load)	Bx with immunohistochemistry is required for Dx of EBV lymphoproliferative disease	EBV causes lymphoproliferative disease in some transplant patients
Human herpes virus 6	PCR (preferably quantitative) detection of DNA in CSF	Serology (usually EIA) for IgM antibody; IgG only confirms previous infection	Detection of human herpes virus 6 by PCR in serum does not mean there is active disease
Adenovirus	Direct immunofluorescence staining and cell Cx (or shell vial) of secretions; BAL or blood PCR	Electron microscopy of respiratory secretions	Disseminated infection is Dx'd when adenovirus is found in the blood by PCR or if isolated from three different body sites

(Continued)

**Table 8** Diagnostic Methodology for Selected Pathogens in Immunocompromised Patients (*Continued*)

Suspected pathogen	Method of diagnosis	Alternate diagnosis	Comments
Parasites			
<i>Toxoplasma gondii</i>	PCR detection of DNA in blood, BAL, or lung tissue; cysts may occasionally be seen on Giemsa staining of lung or other tissues	Serology—IgM often negative, presence of IgG only confirms previous infection	Ninety percent of toxoplasmosis disease in critical illness is reactivation; septic shock can occur in AIDS and transplant patients
<i>Strongyloides</i> hyperinfection	First-stage “filariform” larvae in BAL, sputum, and feces; detection of adult larvae and eggs in intestine Bx (obtained by EGD)	Serology; migration test of larvae by plating stool on blood agar plate	The clinical syndrome of <i>Strongyloides</i> hyperinfection includes recurrent polymicrobial bacteremia with enteric bacteria

*Abbreviations:* AIDS, acquired immunodeficiency syndrome; BAL, bronchoalveolar lavage; BC, blood culture; Bx, biopsy; CMV, cytomegalovirus; CSF, cerebral spinal fluid; CSF, colony-stimulating factor; CT, computed tomography; Cx, culture; DFA, direct fluorescent assay; Dx, diagnosis; EGD, esophago-gastroduodenoscopy; EIA, enzyme-linked immunoassay; GMS, Gomori methenamine silver; IgM, immunoglobulin M; PCR, polymerase chain reaction; rRNA, recombinant RNA; TB, *Mycobacterium tuberculosis*.

*Source:* From Ref. 125.

3. *Beyond 6 Months* Most transplant patients are maintained on minimal long-term immunosuppressive therapy with good allograft function after 6 months. The most common infection in these patients is respiratory and is generally similar to what is seen in the general community. Opportunistic infections are rare unless there has been an unusually intense exposure (130). A small group of patients will have ongoing viral infection with human papilloma-virus, HBV, HCV, CMV, or EBV. The most challenging patients are those who develop recurrent or chronic rejection requiring an escalation in the use of immunosuppressive agents and a corresponding increased risk of chronic viral infections. These patients are very prone to opportunistic infections and must be guarded carefully.

A few other considerations in transplant recipients are worth mention. Transplant patients who are seronegative for varicella-zoster virus should receive varicella immune globulin and antiviral prophylaxis if exposed to varicella-zoster virus. These people are at risk for developing chronic active infection if exposed. The use of prophylactic therapy such as trimethoprim-sulfamethoxazole during the first 4 to 12 months after transplantation has markedly reduced the incidence of *P. carinii*, other respiratory infections, and urinary tract infections. When antibiotics are needed for transplant patients, the interactions with the immunosuppressive regimen must be carefully considered. Some combinations are particularly problematic and can cause excessive toxicity. Aggressive modes of diagnosing infection in immunocompromised patients are warranted, such as bronchoalveolar lavage for pulmonary infiltrates (136), because the patient's presentation may be altered due to their immunocompromised status. Consultation with experts in transplantation and infectious disease may be very helpful.

## EYE TO THE FUTURE

An area of great promise is that of human genomics and the possibility of identifying patients at high risk for either excessive immunoactivation or immunosuppression at the time of presentation after traumatic injury occurs (137,138).

This may permit patient-specific interventions to modify the natural response to the patient's benefit (139). In fact, it is already known that gender can play a role in outcome after traumatic injury. It seems that females are immunologically in a better position to recover from a septic insult than males (62,140).

Some of the potentially promising new treatment options are interference with MIF, HMGB1, C5a, or TREM-1 signal transduction pathways and an inhibition of apoptosis (141). These interventions, or others, may improve the prognosis of septic patients in the future. Simple measures including thorough irrigation and debridement of contaminated wounds will likely continue to be a mainstay of therapy, just as proper immunizational prophylaxis against tetanus continues to be important (142).

The relationships between the neuroendocrine and immune systems is another area of future interest as we learn how these systems interact (143). Indeed, some are attempting to develop a unifying theory of post-traumatic inflammation with the hope that this might better guide our research efforts and make sense of the many components. One such theory is based on the nutritional needs of cells following traumatic injury (144). Early immunonutrition may alter the cytokine balance preventing SIRS and/or CARS. It is hoped that this type of immunity-based thinking will improve the treatment of our patients, by giving rise to new ideas and therapies.

## SUMMARY

Traumatic injuries disrupt natural barriers to infection. Immunocompetent patients who sustain these injuries are likely to experience an acute inflammatory response that is proportional to the degree of tissue destruction, followed by a more prolonged immunosuppressed state. Patients suffering trauma with a pre-existing immunosuppressed state may not have as exuberant of an initial inflammatory response, but are at increased risk of infection and involvement of atypical organisms.

**Table 9** Association Between Immunosuppressive Drugs and Specific Infections

Agent	Mechanism of action	Infection	Comments
Corticosteroids	Prevents release of IL-1 and IL-2 from macrophages; inhibits phagocytosis by macrophages and PMNs; prevents T-cell proliferation and Ig production	Bacterial infection most common; HSV, fungi ( <i>Candida</i> , <i>Aspergillus</i> , <i>Cryptococcus</i> , <i>Pneumocystis</i> ), and <i>Strongyloides</i> superinfection	No increased risk with <10 mg of prednisone equivalent per day or <700 mg cumulative; aspergillosis risk after allogeneic BMT increases with $\geq 1$ mg/kg prednisone equivalent for $\geq 1$ week
Calcineurin inhibitors [Cyclosporine A (CsA), Tacrolimus]	CsA binds to cyclophilin-A; tacrolimus binds to FKBP12; inhibiting calcineurin and decreasing IL-2 gene transcription and T-cell proliferation	No specific association with severe infection	Role of CsA and tacrolimus alone is difficult to quantitate, but appear to be associated with the smallest risk of infection compared with other agents
Sirolimus (rapamycin)	Inhibits lymphocyte proliferation	Decreased risk of CMV infection compared with CsA and tacrolimus	One study reported increased risk of invasive aspergillosis
Cyclophosphamide	Inhibits lymphocyte proliferation	Bacterial complications of neutropenia, herpes zoster	
Azathioprine	Inhibits lymphocyte proliferation	Bacterial complications of neutropenia	No difference in infection rate between methotrexate with azathioprine in rheumatoid arthritis
Mycophenolate (MMF)	Antilymphoproliferative agent (purine synthesis inhibition)	Increased incidence of CMV disease, VZV	No increase in bacterial or fungal infections; less frequency of <i>Pneumocystis</i>
Methotrexate	Inhibits lymphocyte proliferation	<i>Histoplasmosis</i> , <i>Listeria</i> , <i>Pneumocystis</i>	<i>Pneumocystis</i> is the most common opportunistic infection associated with methotrexate
Anti-TNF- $\alpha$ agents (etanercept, infliximab)	Infliximab is a chimeric Ab against human TNF- $\alpha$ , and can fix complement and lyse target cells; etanercept is a modified soluble TNF- $\alpha$ receptor	Bacteremia, <i>Listeria</i> , tuberculosis, cryptococcosis, aspergillosis, CMV	Severe infection most common with infliximab; also, diminished signs and symptoms of infection until they are very advanced
Anti-CD25 antibodies (daclizumab, basiliximab)	Blocks high-affinity IL-2 receptors	No increase in bacterial, fungal, or viral infections	Delayed wound healing described by manufacturer
Purine analogues (2-chlorodeoxyadenosine, fludarabine)	Inhibits DNA synthesis	<i>Cryptococcus</i> , <i>Listeria</i> , herpes virus	Used in hematologic malignancies (themselves immunosuppressive)
Alemtuzumab (campath)	Anti-CD52, targets T- and B-lymphocytes, monocytes	Respiratory virus, adenovirus, CMV	Reactivation of CMV is common; CMV disease is rare except with HSCT

**Abbreviations:** BMT, allogeneic bone marrow transplantation; CMV, cytomegalovirus; CNV, choroidal neovascularization; FKBP, FK-site binding protein; HSCT, hemopoietic stem cell transplantation; HSV, herpes simplex virus; IL, interleukin; PMN, polymorphonuclear neutrophil; TNF, tumor necrosis factor; VZV, varicella-zoster virus.

The balance between the inflammatory and immunosuppressive responses can also be affected by the type and timing of therapeutic interventions employed, including surgery, transfusion, and IV access choices. Indeed, each of these interventions primarily intended to treat the patient with traumatic injuries can increase the likelihood of associated infectious complications.

A significant number of patients are at increased risk of infectious complications due to immunocompromise-related illness such as renal failure, liver failure, diabetes, HIV, malignancy, autoimmune disease, malnutrition, or therapies

including use of steroids, chemotherapy, or splenectomy. These patients deserve special attention in regards to infectious complications. Broad-spectrum antibiotic coverage should be started without delay in immunocompromised patients who demonstrate evidence of sepsis.

Understanding the balance between inflammation and immunosuppression following trauma will likely lead to improved treatment modalities. The current goals of therapy may be best approached in terms of restoring appropriate balance between immunostimulation and immunosuppression.

**Table 10** Immunocompromised States and Empirical Antibiotic Recommendations

Cause of immunosuppression	Pathogens causing severe sepsis	Recommended empirical antimicrobials <sup>a</sup>	Comments
Neutropenia	Enteric gram-negative bacilli, <i>Pseudomonas aeruginosa</i> , viridans group streptococci, <i>Candida</i> species	Carbapenem or cefepime or piperacillin/tazobactam + a quinolone or aminoglycoside ± vancomycin	Antifungal coverage should be added if shock develops late in the course of neutropenia or if there is evidence of <i>Candida</i> colonization
Splenectomy	<i>Streptococcus pneumoniae</i> , <i>Haemophilus influenzae</i> , meningococcus, others	Third generation cephalosporin + vancomycin	Patients should be vaccinated against encapsulated organisms (Table 6)
HIV/AIDS	<i>P. aeruginosa</i> , <i>Staphylococcus aureus</i> , <i>S. pneumoniae</i> , <i>Salmonella enteritidis</i> , <i>Cryptococcus neoformans</i> ; rarely: <i>Toxoplasma gondii</i> , <i>Helicobacter</i> , <i>Mycobacterium tuberculosis</i>	Ceftazidime or fluoroquinolone + vancomycin ± amphotericin B lipid formulation	Stage of disease and associated risk factors also to be considered: IVDA is risk factor for <i>S. aureus</i> ; Neutropenia for <i>Pseudomonas</i> ; only advanced AIDS increases risk for septic shock due to <i>Cryptococcus</i> and <i>Toxoplasma</i>
Solid organ transplant—early	Surgical site source: gram-negative bacilli (including <i>Pseudomonas</i> ), <i>S. aureus</i> , and VRE	Antipseudomonal beta-lactam + linezolid	
Solid organ transplant—late	Pathogens related to defect in cell-mediated immunity (e.g., <i>Legionella</i> , <i>Listeria</i> , etc.)	Fluoroquinolone ± vancomycin	
HSCT—pre-engraftment	See “neutropenia” above	See “neutropenia” above	See “neutropenia” above
HSCT—early (<day 100)	Without GVHD: catheter-related <i>Staphylococcus epidermidis</i> , <i>S. aureus</i> , nonfermentative gram-negative bacilli; with acute GVHD: enteric gram-negative bacilli, fungi	Too diverse for sole recommendation; combination therapy appropriate in septic shock	When considering antifungal coverage, septic shock is more commonly caused by <i>Candida</i> sp., than with mold infections; consider azole-resistant <i>Candida</i>
HSCT—late (≥100 days)	Chronic GVHD: combination of splenectomized and steroid-recipients	Third generation cephalosporin + vancomycin	Consider specific immunosuppressive agents being used

<sup>a</sup>These recommendations are based upon expert opinion and present a logical empirical approach. Local microbial resistance patterns, or known colonization with resistant pathogens should also be considered.

Abbreviations: AIDS, acquired immunodeficiency syndrome; GVHD, graft-versus-host disease; HIV, human immunodeficiency virus; HSCT, hematopoietic stem cell transplant; IVDA, intravenous drug abuse; VRE, vancomycin-resistant enterococcus.

Source: From Ref. 125.

## KEY POINTS

- ☞ Once a pathogen has overcome the primary barrier of the skin, respiratory, GI, or genito-urinary epithelium, the immune system must then combat the invader.
- ☞ The CD4 and CD8 proteins are expressed on two mutually exclusive sets of T-cells, and are co-receptors of T-cell activation.
- ☞ The important regulatory role of CD4+ T-cells is evident when HIV infects the host and selectively kills CD4+ T-cells.
- ☞ Immunoglobulin M (IgM) is present on the surface of all B-cells, comprising the antigen-binding component of the B-cell receptor.
- ☞ The first cells to migrate to areas of injury following trauma are the polymorphonuclear neutrophils (PMNs) with quantities peaking in the first 24 hours, followed by the macrophages, which reach their zenith at 72 hours.

- ☞ When the host has pre-existing circulating antibodies due to vaccination or prior infection, microbial replication can be halted at the onset of infection.
- ☞ Although there is no immunologic specificity in complement activation, or in its effects, there are several immunological methods by which the complement system can be activated.
- ☞ Hypersensitivity reactions are exuberant, improperly regulated immunological responses to various antigenic molecules resulting in tissue injury to the host.
- ☞ Damage control surgery in severely injured patients was first applied to abdominal surgery (Volume 1, Chapter 21), and is now known to improve outcome for orthopedic trauma surgery as well (29).
- ☞ The risk of OPSS is particularly high following splenectomy in children under five years of age (especially infants splenectomized for trauma, with reported infection rates of >10%) (53).

- 9 The current vaccination recommendations for traumatic splenectomy patients call for administration of indicated vaccines as soon as possible, preferably prior to splenectomy (58).
- 9 The incidence of bacteremia is reduced by almost 50%, and sepsis-associated mortality is similarly reduced when critically ill patients are intensively treated with exogenous insulin to maintain normoglycemia.
- 9 Immune dysfunction in patients with renal failure involves both cellular (PMNs, T-cells, B-cells, dendritic cells), and humoral systems (alterations in complement, immunoglobulin levels, and cytokines) (72).
- 9 The immune system is altered in liver failure due to chronic inflammation, decreased production of proteins including complement with increased circulating TNF- $\alpha$ , and increased production of cytokines by the Kupffer cells.
- 9 Autoimmune diseases result from a failure of immune tolerance: it fails to recognize native cells and tissues as "self," instead treating these structures as though they are foreign invaders.
- 9 With regard to mortality (100).
- 9 The CD4 molecule is a high affinity receptor for HIV, explaining the tropism of the virus for CD4+ T-cells and other CD4+ cells (i.e., monocytes/macrophages, and Langerhans cells/dendritic cells). The loss of these cells leads to profound immunosuppression, primarily cell-mediated immunity.
- 9 During the first month after solid organ transplantation, the infections usually encountered in transplant recipients are the same as those found in a typical surgical population (135).
- 9 After the first month, the immunomodulating viruses can become clinically significant, in addition to residual agents from prior infections and events.

### INTRODUCTION

Infections occurring in the intensive care unit (ICU) almost always involve nosocomial organisms, which are more resistant and more virulent than those typically acquired in the community. Nosocomial infections develop in approximately 24% of medical ICU patients, and 31% of surgical ICU patients (1), increasing morbidity (2), and prolonging hospital stay (3).

Trauma related injuries are the second largest source of health care costs in the United States (US) (3), and account for a significant portion of morbidity and mortality in all regions of the world (4,5). Infections in trauma patients can increase mortality up to three-fold (6).

The principles of antimicrobial use and the mechanisms of antibacterial resistance are reviewed in the first two sections of this chapter. Next, the factors increasing the risk of infectious disease following trauma and critical care are reviewed. The remainder of the chapter reviews the important clinical considerations for the various antimicrobial drugs currently in use.

All antibiotics must be evaluated in terms of their antimicrobial spectra, toxicities, and pharmacokinetic and pharmacodynamic attributes. Susceptibility results of antimicrobials reflect *in vitro* properties and do not always correlate with clinical results. Hence the reader is advised to consider many factors during antimicrobial selection (7). Several antibiotic choices are usually effective in the treatment of most infections. The recommendations listed here reflect the perspectives of two infectious diseases physicians and an infectious diseases pharmacist specialist.

### PRINCIPLES OF ANTIMICROBIAL USE

☞ **Antimicrobial selection for trauma and critical care is based on the following seven considerations: (i) whether the antibiotics are planned for prophylaxis or treatment of an established infection; (ii) the anatomic site of infection; (iii) whether the infection is community-acquired or nosocomial; (iv) best guess of the most probable causative microorganism (based upon geographical and institutional isolate profiles); (v) the patient's innate immunological status; (vi) the severity of the infection and general condition of the patient; and (vii) financial cost.** ☞

### General Rules for Selecting Single vs. Multiple Antibiotics

On some occasions, a single antibiotic is appropriate, for example, the treatment of cellulitis with cefazolin. However, there are several circumstances where combination antimicrobial treatment should be employed. The first is the prevention of the emergence of resistant organisms while on therapy; an example is the absolute necessity to use an anti-staphylococcal agent, like nafcillin, in combination with rifampin to prevent the emergence of rifampin-resistant mutations, which are single-step mutations to full resistance in the gene that encodes the bacterial RNA polymerase, the rifampin site of action. A second example is with polymicrobial infections (e.g., intraperitoneal and pelvic infections). The flora causing these infections includes gram-negative enteric rods, a multiplicity of different obligately anaerobic species, as well as enterococci and, occasionally, yeast. A third circumstance where antimicrobial combinations is in empiric therapy where early aggressive treatment improves survival and mixed microbial infection is probable, for example, necrotizing fasciitis.

### Antibiotic Synergy vs. Antagonism

In order to use combinations of antimicrobial drugs properly, the prescriber should be familiar with the concepts of antibiotic synergy and antagonism. Synergy occurs when the use of one antibiotic enhances the antimicrobial activity of another. In general, synergy occurs when the agents of any particular combination act on different biochemical pathways of the microorganism or act sequentially along the same metabolic pathway; an example of the first is the use of ampicillin (or vancomycin) and gentamicin against enterococci. Aminoglycosides are ineffective as single drugs in treating gram-positive organisms because they cannot penetrate the thick peptidoglycan cell wall to reach their site of action at the ribosome within the bacterial cytoplasm. The combination of ampicillin (or vancomycin) and gentamicin is synergistic for enterococci because ampicillin (and vancomycin) damage the bacterial cell wall (as their antimicrobial mechanism of action) thereby allowing the aminoglycoside to penetrate into the cell. Clinical studies have shown that the addition of gentamicin to ampicillin significantly improves outcome in patients with enterococcal endocarditis, even though enterococci are relatively resistant to ampicillin (8). Similar effects are noted with the combination of antistaphylococcal

penicillins (or vancomycin) combined with an aminoglycoside against *Staphylococcus aureus*, but the magnitude of the effect is less. Another clinical example of synergism involves the use of anti-pseudomonal beta-lactams such as piperacillin or ticarcillin in combination with aminoglycosides to treat serious infections with *Pseudomonas aeruginosa* (9).

The combination drug trimethoprim-sulfamethoxazole (Bactrim or Septra) is an example of synergism resulting from using two antibiotics that act sequentially in the same pathway. Sulfamethoxazole acts first and trimethoprim (TMP) second in the microbial pathway for de novo synthesis of folic acid, which is necessary for synthesizing precursors for DNA and other molecules involved in bacterial intermediary metabolism. For treating fungi, 5-FC is not used alone because of the development of rapid resistance. However, the combination of 5-FC and amphotericin is synergistic in vitro, and this combination is commonly used clinically to treat cryptococcal meningitis (10).

Antagonism occurs when the combination of antibiotics is less effective than either agent alone. For example, the use of bacteriostatic drugs such as tetracycline or chloramphenicol that inhibit protein synthesis generally decrease the effectiveness of beta-lactam drugs that act on the cell wall (11). Another example of antagonism in vitro involves the use of azoles like fluconazole in combination with amphotericin. Ergosterol, a sterol in the fungal plasma membrane, is the target site of amphotericin; azole drugs inhibit the enzyme necessary for ergosterol synthesis and decreases the amount of ergosterol present in the plasma membrane, thereby decreasing the target of action for amphotericin and making it potentially less effective.

## MECHANISMS OF ANTIBIOTIC RESISTANCE

Factors influencing the emergence of resistance in microorganisms include: (i) the indiscriminant use of broad-spectrum antibiotics in medicine, (ii) the widespread use of antibiotics in animal husbandry and fisheries, (iii) prolonged hospitalizations, (iv) the increasing numbers of immunocompromised patients, (v) international travel, and (vi) medical progress resulting in increased use of invasive procedures and devices.

Bacteria evade antimicrobial action by diverse mechanisms. These mechanisms include changes in permeability of the bacterial cell wall and plasma membrane to the antibiotic, antibiotic efflux from bacterial cells, inactivation of the antibiotic (usually enzymatically), modification or elimination of the target site(s) for the antibiotic, and the development of auxotrophs (bacterial strains with growth requirements different from those of the wild-type strains) which can bypass steps inhibited by antibiotics. Understanding the general mechanism of resistance has clinical relevance when choosing a specific antibiotic for a specific organism. For example, methicillin-resistant *S. aureus* (MRSA) is resistant to beta-lactam agents by virtue of possessing an altered penicillin-binding protein (PBP), the target of all beta-lactams. Therefore, combination products increasing the duration of beta-lactam activity with a beta-lactamase inhibitor, (e.g., piperacillin/tazobactam or ampicillin/sulbactam) will not demonstrate any activity against MRSA (12–17).

✦ **A primary tenet of antimicrobial therapy is to use the narrowest spectrum antibiotic possible, rather than a broad-spectrum agent.** ✦ Empiric treatment (prior to the final identification of specific microorganisms) is by necessity broad-spectrum, and the antibiotic selection is based upon several features. These include the location where the suspected infection developed (e.g., community vs. hospital-acquired),

the anatomic site involved (e.g., oropharynx vs. colon), suspected organisms (based on prior literature and local experiences), the local antibiotic sensitivity and resistance patterns, the current gram stain and prior culture results, patient allergies, renal/hepatic function, and other clinical factors. Emergent, empiric antimicrobial treatment is indicated in only a few situations, including, for example, suspected sepsis, bacterial meningitis, some fulminant pneumonias (i.e., *Bacillus anthracis*) and some severe soft-tissue infections (i.e., necrotizing fasciitis). There is usually adequate time for a thorough clinical evaluation of a patient in other circumstances, including the collection of adequate specimens (for gram stain and culture) prior to the institution of antibiotics. Fever alone in a clinically stable patient can result from either an infection or a myriad of other causes (e.g., major trauma, burns, surgery, hematoma in soft tissue or subarachnoid blood, etc.), and frequently does not require antimicrobial therapy. (Volume 2, Chapter 46) Hence the dictum “antibiotics are not the antipyretic of choice.”

Prophylactic antibiotic use in surgery should be limited to proven indications and duration. A good example of this principle are the recently published guidelines for the appropriate use of vancomycin to reduce the emergence of vancomycin-resistant enterococci (VRE) and possible vancomycin-resistant *S. aureus* (VRSA) (16). These guidelines discourage the use of vancomycin except for limited situations, which include: (i) severe beta-lactam allergy, (ii) infections caused by gram-positive cocci that are resistant to beta-lactams, (iii) empiric use in circumstances where there is a high institutional prevalence of MRSA, (iv) life threatening infections until definitive culture results return, and (v) the oral treatment of *Clostridium difficile* colitis (only when there is a failure of metronidazole) (16).

## RISK FACTORS FOR INFECTIONS IN TRAUMA AND CRITICAL CARE

Many factors increase the infection risk in trauma and critical illness. Defects in the mucosal and skin surfaces after trauma allow microbes to bypass initial defenses. Chest tubes, endotracheal tubes, catheters, and drains facilitate pathogen entry. Devitalized tissues and obstruction of drainage ports (e.g., sinusitis) increase the bacterial count, impair the normal self-cleansing of bacteria, and decrease the ability of white blood cells (WBC) to have access to bacteria—all serving to increase the risk of infection. Within a few days, patients lose the normal protective skin and gut flora and become colonized with nosocomial organisms, which subsequently cause hospital-acquired infections with microbes that are often resistant to many antibiotics.

The most basic question to be answered by the physician contemplating antibiotics in a critically ill patient is whether the patient is in fact infected. The cardinal signs and symptoms of infection (elevated WBC count, fever, hyperdynamic state), and inflammation (rubor et tumor cum calore et dolore [from Celsus]—redness and swelling with heat and pain) are also common accompaniments of acute trauma, and therefore, do not necessarily indicate an infection (18). These signs can persist for days after admission, especially with multiple fractures, burns, or diffuse soft tissue injury. Further complicating infection evaluations in this patient population are patient care devices, limited mobility, and ventilators. Another clinical conundrum is deciding whether a patient is colonized or actually infected, once organisms have been isolated. This can be especially problematic when the culture isolate was derived from suctioned sputa or previously placed drains.

Infection control measures are vitally important to mitigate the spread of resistant organisms. ✎ **As Ignaz Phillip Semmelweis discovered 150 years ago, the most important means of preventing the transmission of microorganisms from one patient (via the doctor or nurse) to another patient is strict hand washing (and now, the use of clean disposable gloves).** ✎

Bacterial organisms commonly responsible for infections in trauma and critically ill patients are divided into three main classes: aerobic gram positive, aerobic gram negative, and anaerobic. The common gram-positive pathogens and the currently recommended antibiotics for these organisms are listed in Table 1. The recommendations provided in this and other tables in this chapter reflect general sensitivity and resistance patterns as of the publication of this textbook, and local conditions may be different.

Organisms causing infections in trauma patients have changed over time. ✎ **At present, the majority of infections occurring in hospitalized trauma patients are due to gram-positive organisms (19), for example, MRSA and VRE, and to a lesser extent, multi-resistant gram-negative rods (20).** ✎ This is in sharp contrast to a few decades ago where gram-negative organisms prevailed.

Gram-negative organisms include many of the enteric bacteria and some of these are developing extended spectrum beta lactamases (ESBLs), especially the so called

“SPACE” organisms (*Serratia* spp., *Pseudomonas* spp., *Acinetobacter* spp., *Citrobacter* spp., *Enterobacter* spp). The common gram negative aerobic bacteria, along with the antimicrobial drugs of choice, are summarized in Table 2.

With appropriate antibiotic use, fungal infections are still rare in trauma injured patients, excluding catheter-related urinary tract infections. Judicious prophylactic antibiotic use in the trauma setting is generally accepted practice in specific situations (21–24).

✎ **Penetrating intra-abdominal injury, perforated abdominal viscera, and open fractures all warrant antibiotic prophylaxis (22–25).** ✎

Infections involving the mouth and gastrointestinal tract (including most intraabdominal abscesses) involve anaerobic bacteria, in addition to aerobic gram-positive and gram-negative organisms. The common anaerobic pathogens involved in trauma and critical care are summarized in Table 3. In general, infections involving anaerobic organisms that occur above the diaphragm, or in the vagina, can be treated with clindamycin or metronidazole. However, those occurring from organisms native to the colon (e.g., *Bacteroides fragilis*) are best treated by metronidazole.

A complete survey of infectious and non-infectious sources of fever is provided in Volume 2, Chapter 46. Sepsis and SIRS are reviewed in great detail in Volume 2, Chapters 47 and 63, respectively. The most common

**Table 1** Antimicrobial Drugs of Choice Against Aerobic Gram-Positive Bacteria

Microorganisms	Drug of choice	Alternative agents
<i>Staphylococcus aureus</i>		
Non-penicillinase-producing	Penicillin	Vancomycin, cephalosporin
Penicillinase producing	Nafcillin, oxacillin	Vancomycin, cephalosporin, erythromycin, clindamycin
MRSA	Vancomycin <sup>a</sup>	Linezolid, quinupristin/dalfopristin, tigecycline
VISA	Daptomycin <sup>b</sup>	Quinupristin/dalfopristin, linezolid
VRSA	Daptomycin <sup>b</sup>	Quinupristin/dalfopristin, linezolid
Alpha-streptococci ( <i>Streptococcus viridans</i> )	Penicillin	Cephalosporin
Beta-streptococci (A, B, C, G)	Penicillin	Cephalosporin, erythromycin
<i>Streptococcus bovis</i>	Penicillin	Vancomycin, cephalosporin
<i>Streptococcus pneumoniae</i> (pneumococcus)		
PCN-susceptible (MIC <0.1 mcg/mL)	Penicillin or amoxicillin	Cephalosporin, erythromycin, azithromycin, clarithromycin, levofloxacin, moxifloxacin, carbapenems, clindamycin, tetracycline
PCN-intermediate resistance (MIC = 0.1–2 mcg/mL)	Penicillin or ceftriaxone, cefotaxime	Levofloxacin, gatifloxacin, moxifloxacin, clindamycin, vancomycin
PCN-high-level resistance (MIC >2 mcg/mL)	Meningitis: vancomycin + ceftriaxone or cefotaxime other indications: vancomycin + ceftriaxone or cefotaxime, linezolid, levofloxacin, gatifloxacin, moxifloxacin	Carbapenems, quinupristin/dalfopristin
<i>Enterococcus</i> spp.		
Serious infection	Ampicillin + gentamicin or streptomycin	Vancomycin + gentamicin or streptomycin; linezolid; quinupristin/dalfopristin
Uncomplicated UTI	Ampicillin	Nitrofurantoin; ciprofloxacin, levofloxacin; fosfomycin
VRE	Linezolid	Daptomycin; quinupristin/dalfopristin

<sup>a</sup>Some studies show that linezolid was superior to vancomycin for ventilator associated pneumonia due to MRSA. However, the doses of vancomycin in these studies were subtherapeutic.

<sup>b</sup>Daptomycin contraindicated in pneumonia (surfactant inhibits daptomycin). For pneumonia, due to VISA, or VRSA use quinupristin/dalfopristin, or linezolid. *Abbreviations:* MIC, minimum inhibitory concentration; MRSA, methicillin-resistant *S. aureus*; PCN, penicillin; UTI, urinary tract infection; VISA, vancomycin intermediate sensitive *S. aureus*; VRE, vancomycin-resistant enterococcus; VRSA, vancomycin-resistant *S. aureus*.

**Table 2** Antimicrobial Drugs of Choice Against Aerobic Gram-Negative Bacteria

Microorganisms	Drug of choice	Alternative agents
<i>Acinetobacter</i> spp.	Imipenem, meropenem	Aminoglycoside, ciprofloxacin, cotrimoxazole, ceftazidime
<i>Aeromonas</i>	Cotrimoxazole	Aminoglycoside, imipenem, fluoroquinolone
<i>Enterobacter</i> spp.	Imipenem, meropenem	Aminoglycoside, ciprofloxacin, cotrimoxazole, cefepime
<i>Escherichia coli</i>	Ceftriaxone, cefotaxime	Aminoglycoside, imipenem, meropenem, ceftazidime, cefepime, cotrimoxazole, fluoroquinolone, aztreonam, piperacillin/tazobactam
<i>Haemophilus influenzae</i>	Second- or third-generation cephalosporin	Fluoroquinolone, cotrimoxazole
<i>Klebsiella pneumoniae</i>	Ceftriaxone, cefotaxime	Aminoglycoside, carbapenems, ceftazidime, aztreonam, cefepime, cotrimoxazole, fluoroquinolone, piperacillin/tazobactam
<i>Legionella</i> spp.	Azithromycin or a fluoroquinolone ± rifampin	Doxycycline ± rifampin, cotrimoxazole, erythromycin
<i>Proteus mirabilis</i>	Ampicillin	Cephalosporin, cotrimoxazole, aminoglycosides, carbapenem, fluoroquinolone, aztreonam
Other <i>Proteus</i> spp.	Ceftriaxone, cefotaxime, ceftazidime, cefepime	Imipenem, meropenem, fluoroquinolones, piperacillin/tazobactam, cotrimoxazole, aminoglycoside
<i>P. aeruginosa</i>	Ceftazidime + an aminoglycoside or cipro	Carbapenems, cefepime, aztreonam, levoflox, piperacillin
<i>Salmonella</i> spp.	Fluoroquinolone or ceftriaxone	Cotrimoxazole
<i>Stenotrophomonas maltophilia</i>	Cotrimoxazole	Fluoroquinolone
<i>Serratia</i> spp.	Carbapenem	Aminoglycoside, aztreonam, third- or fourth-generation cephalosporin, cotrimoxazole, piperacillin/tazobactam, fluoroquinolone

sources of infection in trauma and critical care also have specific chapters dedicated to them, including ventilator associated pneumonia (Volume 2, Chapter 48), indwelling catheter related infections (Volume 2, Chapter 49), abdominal sources of infection (Volume 2, Chapter 50), and sinusitis (Volume 2, Chapter 51). The remainder of this chapter reviews the antimicrobials most frequently used for trauma and critical care.

## PENICILLINS

### History/Description

Dr. Alexander Fleming discovered penicillin in 1929, while working on unrelated influenza research. Fleming happened upon his discovery when he observed that one of his staphylococcal culture plates became contaminated with

a mould, and that surrounding the fungi was a ring-like bacteria-free zone. Fleming subsequently diluted the mould more than 800 times, and still it retained the antibacterial effect. With the assistance of a mycologist colleague, the mould was identified as a *Penicillium*, and Fleming subsequently named the antibacterial active substance penicillin. His publication in 1929 describing this research received little attention until World War II, when penicillin use became widespread. In 1945, Fleming received the Nobel Prize for his discovery. Since that time, penicillin and its derivatives have remained the drug of choice for many bacterial infections, and modifications of its chemical structure has led to the development of numerous other beta-lactam derived antimicrobials (26–28).

### Mechanism of Action, Pharmacology, Administration, and Dosage

Penicillin and other beta-lactam related antibiotics (e.g., cephalosporins, monobactams, and carbapenems) all have similar mechanisms of action, primarily targeting the peptidoglycan cell wall; these actions are characterized by enzymatic inhibition of cell wall synthesis and turnover with the resultant destruction of bacteria through autolytic enzymes. For the available penicillin agents, modifications of the side-chain results in a wide variety of pharmacokinetic properties and antimicrobial activities (Table 4).

Most penicillin antibiotics are widely distributed however, penetration across the blood-brain barrier and into the cerebrospinal fluid (CSF) and into the vitreous humor is poor, and levels are significantly lower than serum concentrations, except in the presence of inflammation. Therefore, relatively high doses of penicillins are required to treat infections in these “protected” sites.

**Table 3** Antimicrobial Drugs of Choice Against Anaerobic Bacteria

Microorganisms	Drug of choice	Alternative agents
<i>Prevotella melanogenica</i>	Penicillin G; or clindamycin	Metronidazole
<i>Bacteroides fragilis</i>	Metronidazole	Carbapenems, ceftaxitin, ampicillin/sulbactam, piperacillin/tazobactam
<i>Clostridium perfringens</i>	Penicillin or clindamycin	Metronidazole, carbapenems, chloramphenicol
<i>Clostridium tetani</i>	Metronidazole	Penicillin, a tetracycline
<i>Clostridium difficile</i>	Metronidazole	Vancomycin (oral)

**Table 4** The Penicillins: Selected Dosing and Need for Adjustment Based Upon Renal or Hepatic Dysfunction

Penicillin sub-type	Typical adult IV dose range and intervals	Requires dose adjustment for renal insufficiency (CrCl <30 mL/min)	Requires dose adjustment for hepatic failure
Aqueous crystalline penicillin G	1–4 million units every 4–6 hr	Yes	No
Ampicillin	1–2 g every 4–6 hr	Yes	No
Ampicillin/sulbactam	1.5–3 g every 6–8 hr	Yes	No
Piperacillin	3–5 g every 4–8 hr	Yes	No
Piperacillin/tazobactam	3.375–4.5 g every 4–6 hr	Yes	No
Oxacillin	1–2 g every 4–6 hr	Yes	No
Nafcillin	1–2 g every 4–6 hr	Yes	No

Abbreviation: IV, intravenously.

### Antimicrobial Activity/Spectrum/Resistance

Differential bacterial cell wall permeability, binding site affinity and susceptibility to bacterial enzymes (e.g., beta-lactamases) account for the various susceptibility patterns among different penicillins, and other beta-lactams (Tables 1–3). Bacterial production of beta-lactamases, which enzymatically destroy beta-lactam antibiotics, represent the most common mechanism of antimicrobial resistance. Gram-positive organisms usually secrete beta-lactamases extracellularly, whereas gram-negative organisms secrete small quantities of beta-lactamases within the periplasmic space. There are several types of beta-lactamases, each with various binding affinities to enzymes required for the reproduction of specific microorganisms. With this in mind, the development of beta-lactamase inhibitors, in combination with specific penicillins, provides the rationale for the clinical use of combinations (i.e., ticarcillin-clavulanate, piperacillin-tazobactam, and ampicillin-sulbactam).

Narrow-spectrum penicillins, such as penicillin G or ampicillin, remain the drug of choice for most streptococci, enterococci, and oral anaerobic bacteria. The semi-synthetic penicillins, such as nafcillin or oxacillin, were designed specifically for *S. aureus* and have neither anaerobic nor enterococcal activity, and have reduced streptococcal activity. They also lack activity against gram-negative rods. Extended spectrum penicillins, (e.g., piperacillin, mezlocillin, and ticarcillin) have improved activity against not only *P. aeruginosa* but also against additional community and hospital-acquired gram-negative rods. ⚡ **The addition of a beta-lactamase inhibitor to beta-lactam antibiotics produces efficacy against beta-lactamase-producing organisms such as *S. aureus*, *Escherichia coli*, and most anaerobic bacteria. However, these combination products add no additional activity against *P. aeruginosa* and have no activity against MRSA.** ⚡ MRSA specifically lack the binding proteins for these beta lactams, and are intrinsically resistant regardless of the concentration or duration of high drug levels of beta lactams.

### Adverse Effects and Drug Interactions

Hypersensitivity reactions are the most common adverse effects encountered with the use of penicillins. These reactions range from minor, such as rash, to potentially life-threatening such as anaphylaxis (Volume 1, Chapter 33). A few unique adverse effects are seen with specific penicillins, such as platelet dysfunction with piperacillin and a

high incidence of rash with ampicillin and amoxicillin. The management of adverse effects and allergy testing is discussed below (Beta-Lactam Allergy). No clinically important drug interactions occur with the penicillins.

### Therapeutic/Clinical Uses

Because of their long history of clinical safety, efficacy, and availability, the penicillins are frequently used in the critically ill patient. As seen in Table 1–3, the penicillins are the drugs of choice for many infections commonly encountered in these patients.

## CEPHALOSPORINS

### History/Description

Cephalosporins are a group of natural and semi-synthetic compounds that are structurally similar to penicillins and have been in clinical use since the 1960s. The cephalosporins are categorized into first-to-fourth “generation,” based upon antimicrobial spectrum. Table 5 lists the four generations of cephalosporins (29–32).

### Mechanism of Action, Pharmacology Administration, and Dosage

Cephalosporins, like penicillins, enzymatically inhibit bacterial cell wall synthesis. Therapeutic cephalosporin concentrations are reached in many body sites; however, cefazolin and cephalothin do not provide adequate enough concentrations in the CSF to treat bacterial meningitis. However, several of the third and fourth generation cephalosporins reach sufficient concentrations in the CSF for therapeutic utility. These include ceftriaxone, cefotaxime, ceftizoxime, ceftazidime, and cefepime. Table 5 delineates the dosing considerations for the most commonly used cephalosporins. Uniquely, among the cephalosporins, ceftriaxone has the longest half-life and may be dosed on a once-daily basis in most clinical circumstances.

### Antimicrobial Activity/Spectrum/Resistance

⚡ In general, as one selects a second, third, or fourth generation cephalosporin, there is increased activity against aerobic gram-negative bacteria and less activity against gram-positive organisms. ⚡ Although ceftriaxone, ceftizoxime, and cefotaxime retain excellent gram-positive activity, the cephalosporins, as a class, do not have activity against

**Table 5** The Cephalosporins: Selected Dosing and Need for Adjustment Based Upon Renal or Hepatic Dysfunction

Cephalosporin generation and sub-type	Typical adult IV dose range and intervals	Requires dose adjustment for renal insufficiency (CrCl <30 mL/min)	Requires dose adjustment for hepatic failure
First generation			
Cephalothin	1–2 g every 4–6 hr	Yes	No
Cefazolin	1–2 g every 8 hr	Yes	No
Second generation			
Cefoxitin	1–2 g every 6 hr	Yes	No
Cefuroxime	0.75–1.5 g every 8–12 hr	Yes	No
Third generation			
Cefoperazone	1–2 g every 12 hr	Yes	No
Cefotaxime	1–2 g every 4–8 hr	Yes	No
Ceftriaxone	1–2 g every 12–24 hr	Yes	No
Ceftazidime	1–2 g every 8 hr	Yes	No
Fourth generation			
Cefepime	1–2 g every 12 hr	Yes	No

Abbreviation: IV, intravenously.

enterococci, MRSA, or *Listeria monocytogenes*. For activity against *P. aeruginosa*, the use of ceftazidime or cefepime is usually required. Because of their broad activity against most aerobic gram-positive cocci (except enterococci), and gram-negative bacilli (except *P. aeruginosa*), the third generation cephalosporins (ceftriaxone, cefotaxime and ceftizoxime) are commonly used in the critically ill patient.

The first generation cephalosporins, such as cefazolin, have a wide-range of activity against almost all aerobic cocci, including MSSA (but not enterococci or MRSA) and some gram-negative bacilli (with the exception of *P. aeruginosa* and some other gram-negative rods).

☞ **The cephamycins, specifically cefoxitin and cefotetan, have unique broad-spectrum activity against most anaerobic organisms. However, there are increasing resistant forms of *B. fragilis*.** ☞ *B. fragilis* resistance has risen to such a degree that both the Infectious Disease Society of America and the Surgical Infection Society now recommend against these drugs as single agents for intra-abdominal infections (23,24,33).

### Adverse Effects and Drug Interactions

The adverse effects of the cephalosporins are similar to those of the penicillins. Additionally, certain drug–drug interactions occur with cephalosporins and cephamycins, which have a methyl-thio-tetrazole side chain (cefotetan, cefoperazone, cefamandole, and moxalactam). This class of cephalosporins can produce a disulfiram-like reaction when administered with alcohol. In addition, these antibiotics can prolong the INR via inhibition of vitamin K metabolism.

### Therapeutic/Clinical Uses

The third generation cephalosporins (ceftriaxone, cefotaxime, and ceftizoxime) have broad activity against most aerobic gram-positive cocci and gram-negative bacilli, (except *P. aeruginosa*), and are very commonly used for empiric therapy for Ventilator-associated pneumonia (VAP) in critical care units. Ceftazidime also has excellent activity against *P. aeruginosa* but only marginal activity against gram-positive cocci.

Advantages of the cephalosporins include their relatively low toxicity, especially compared to the aminoglycosides, their activity against certain hospital-acquired, multi-drug resistant bacteria, and the opportunity to administer a single agent rather than multiple antibiotics. Cephalosporins are not superior to the older, narrow-spectrum, and less-expensive antimicrobials. Thus, extended-spectrum cephalosporins are rarely the drug of choice for any infection. In addition, the emergence of resistance during therapy with these newer cephalosporins has been shown, including VRE, MRSA, and *C. difficile* through selection pressures.

## OTHER BETA-LACTAM ANTIBIOTICS AND ADVERSE REACTIONS

### Monobactams

Aztreonam is a synthetic monocyclic B-lactam (monobactam) antibiotic, and was the first approved for clinical use in the US (34,35). Monobactams differ structurally from penicillins and cephalosporins because of their monocyclic rather than a bicyclic nucleus; this novel structure explains why aztreonam has little cross-allergenicity with the bicyclic B-lactams. Although skin rashes have occurred occasionally with the use of aztreonam, the drug has been given safely to patients with immediate-type hypersensitivity reactions (e.g., anaphylaxis and urticaria) to both penicillins and cephalosporins (36). Other adverse effects are similar to those of other B-lactam drugs.

☞ **Aztreonam is devoid of antibacterial activity against gram-positive and anaerobic bacteria.** ☞ Aztreonam is clinically effective against most facultative aerobic Gram-negative bacilli. The spectrum and potency of aztreonam is similar to the third generation cephalosporin ceftazidime (37) as both contain the same 2-aminothiazolyl with a propyl-carboxy addition to its side-chain (38). Aztreonam adequately crosses the blood brain barrier and is highly active against *Haemophilus influenzae* and *N. gonorrhoeae* (including beta-lactamase-producing strains), and against most of the Enterobacteriaceae (including *E. coli*, *Klebsiella*,

**Table 6** Monobactams and Carbapenems (Beta Lactam-like Drugs): Selected Dosing and Need for Adjustment Based Upon Renal or Hepatic Dysfunction

Beta lactam-like drug classification and name	Typical adult IV dose range and intervals	Requires dose adjustment for renal insufficiency (CrCl <30 mL/min)	Requires dose adjustment for hepatic failure
<b>Monobactams</b>			
Aztreonam	1–2 g every 8 hr	Yes	No
<b>Carbapenems</b>			
Imipenem/cilastatin	0.5–1.0 g every 6–8 hr	Yes	No
Meropenem	0.5–1.0 g every 6–8 hr	Yes	No
Ertapenem	1 g every 24 hr	Yes	No

Abbreviation: IV, intravenously.

*Proteus*, *Serratia*, *Shigella*, and *Salmonella* species). Aztreonam is slightly less potent than imipenem or ceftazidime against *P. aeruginosa*. The usual dosage of aztreonam is 1 to 2 g intravenously given every eight hours. Refer to Table 6 for selected dosing and route of administration.

### Carbapenems

Carbapenems are a class of antimicrobials created by a simple substitution of a sulfur atom for a carbon atom of the beta-lactam nucleus, and the addition of a double bond to the 5-member ring comprising the penicillin nucleus (7). The first clinically available carbapenem for use in the United States was imipenem, released in 1985 followed a decade later by meropenem (released in 1996) and shortly thereafter ertapenem. Imipenem is marketed as a combination drug with cilastatin (which inhibits the renal hydrolysis of imipenem). Meropenem and ertapenem, the other currently available carbapenems, are not combined with cilastatin.

🔑 **Carbapenems are the class of antibiotics with the greatest activity spectrum of any class of antibiotics for systemic use in humans. They are active against gram-positive (except MRSA), gram-negative, and anaerobic bacteria. These agents (except ertapenem) are particularly useful for hospital-acquired infections where bacterial resistance (other than MRSA and VRE) may be a concern.** 🔑

Similar to the beta-lactam agents (especially the cephalosporins) the carbapenems have no activity against MRSA, *Enterococcus faecium*, and *Legionella* spp. In addition, the carbapenems have no activity against *Stenotrophomonas* (formerly *Pseudomonas*) *maltophilia*. The activity of ertapenem does not include *P. aeruginosa* or *Acinetobacter* spp., two organisms commonly involved in hospital-acquired infections. The carbapenems, imipenem and meropenem, are considered the drugs of choice for extended-spectrum beta-lactamase (ESBL) producing organisms.

The mechanism of action is similar to that of other beta-lactam antibiotics and the toxicities are similar. In addition, imipenem is associated with an increased risk of seizures when administered in large doses to patients with renal insufficiency, a side effect caused by the cilastatin component (which decreases the seizure threshold). Refer to Table 6 for selected dosing, route of administration, and need for dose adjustment for the carbapenems. The pharmacology of meropenem has recently been reviewed (7,39).

### Beta-Lactam Allergy

Beta-lactam antibiotics are the most common class of antibiotics associated with adverse reactions partly because they are the most frequently used class of antibiotics. It was previously estimated that 1% to 10% of patients receiving penicillins will develop an adverse effect (40). However, that estimate was probably high, and the incidence of potentially life-threatening anaphylactic reactions is far lower (41).

Beta-lactam allergies are classified as immediate, accelerated, or delayed. Immediate reactions are of rapid onset occurring usually <30 minutes after administration, with the clinical manifestations of laryngeal edema, bronchospasm, hypotension, urticaria (hives), pruritus, and occasionally, anaphylactic shock. These reactions are IgE-mediated (Volume 1, Chapter 33).

Accelerated reactions occur from 1 to 72 hours after antibiotic administration, with the clinical manifestations of urticaria and angioedema. Delayed reactions are those occurring 3 days to several weeks after exposure, with rash being the most common, but they may also include serum sickness, hemolytic anemia, interstitial nephritis, arthralgias, and urticaria. Only the immediate and accelerated reactions have major clinical significance in terms of antibiotic selection.

Patients with a history of an immediate or accelerated reaction to penicillins manifesting as laryngeal edema, hypotension, urticaria, and/or angioedema, should not receive penicillins or any other beta-lactam antibiotics. In the event that a patient must be given penicillin, a penicillin skin test should be performed for patients with accelerated reactions, and if positive, then desensitization is required. If negative, these agents may be given cautiously. 🔑 **Patients with a history of penicillin allergy due to rash or pruritus only occurring more than 3 days after administration are no more likely to have any allergic reaction to a cephalosporin than patients without a history of penicillin allergy and can safely receive cephalosporins.** 🔑

Recent studies indicate that the incidence of cross-reactivity to cephalosporins in penicillin-allergic patients is probably not more than two percent (42). Cross-reactions between penicillins and carbapenems occur much more frequently. 🔑 **There is up to a 50% chance of developing a rash to carbapenems in patients with a history of rash to penicillins.** 🔑 Aztreonam, a monobactam, does not appear to have any cross-reactivity in patients with immediate reactions to beta-lactams and is a useful therapeutic option when an antibiotic possessing excellent gram-negative rod activity is indicated in a beta-lactam allergic patient. 🔑 **Aztreonam is**

considered a safe alternative in patients allergic to penicillins or cephalosporins requiring gram-negative coverage, and vancomycin is the recommended choice when these patients require gram-positive coverage. ⚡

## AMINOGLYCOSIDES

### History/Description

Aminoglycosides are naturally occurring antibacterial compounds produced by members of the Actinomycetes family that are filamentous bacteria that resemble fungi. Streptomycin (derived from *Streptomyces griseus*) was discovered in 1943, followed in 1963 by gentamicin (derived from *Actinomycetes* spp.), and tobramycin (derived from *Streptomyces tenebrarius*). The use of aminoglycosides has declined in recent years due to nephrotoxicity and the development of less toxic alternatives. However, the ability to dose these medications once daily and the relatively low level of resistance keeps the aminoglycosides in the clinical arena as a useful class of antibiotics (43,44).

### Mechanism of Action, Pharmacology, Administration, and Dosage

Aminoglycosides bind to the 30S ribosomal subunit of bacteria, thereby inhibiting protein synthesis. The ability of aminoglycosides to reach ribosomes, which are intracellular, is facilitated by the concurrent use of antibiotics that inhibit the synthesis of the bacterial cell wall, such as the beta-lactam antibiotics and vancomycin. This synergistic activity accounts for the clinical use of combination of an aminoglycoside with a penicillin beta-lactam or vancomycin for serious enterococcal infections.

The aminoglycosides exert concentration-dependent killing. They also have a prolonged post-antibiotic effect that allows for once-daily dosing in many patients. Aminoglycosides have poor oral absorption and therefore are administered parenterally. Changes in the extracellular fluid compartment, as in congestive heart failure, ascites, or dehydration, will alter the volume of distribution and necessitate dosage modifications. Aminoglycosides have negligible protein binding. The average half-life for aminoglycosides in patients with normal renal function is approximately two hours. Aminoglycosides are significantly removed by hemodialysis but to a much lesser extent via peritoneal dialysis. Aminoglycosides do not cross the blood brain barrier, even in the presence of inflamed meninges.

A loading dose is often administered in the critically ill; 1.5 to 2 mg/kg for gentamicin or tobramycin and 7.5 to 15 mg/kg for amikacin (Table 7). Interpatient variability in volume of distribution and renal function in the critically

ill population necessitates monitoring of aminoglycoside concentrations in the serum. Ideally, peak concentrations should be obtained 30 minutes after a 30-minute infusion. Trough concentrations should be drawn as close as possible prior to the start of the next dose. Recent studies suggest that single daily dosing is at least as effective as traditional dosing (due to the prolonged post-antibiotic effect) and may be less toxic (because the kidneys are allowed some recovery time between doses, when the blood concentration is low) (45).

### Antimicrobial Activity/Spectrum/Resistance

Aminoglycosides are active against aerobic gram-negative bacilli and certain mycobacteria (including *Mycobacterium tuberculosis*) and have in vitro activity against many Staphylococcus species. Despite in vitro activity, aminoglycosides are not useful as single agents in treating gram-positive infections. However, aminoglycosides can be used synergistically with either beta-lactams or glycopeptides in patients with either *S. aureus* or enterococcal infections. *Burkholderia* (formerly *Pseudomonas cepacia*) and *Stenotrophomonas* (formerly *Pseudomonas* or *Xanthomonas*) *maltophilia* are typically resistant to all aminoglycosides. This rather narrow spectrum of activity is reflected in Tables 1 and 2 showing aminoglycosides as mainly alternative agents to first-line therapy.

The most common mechanism of aminoglycoside resistance is the production of plasmid-mediated aminoglycoside-modifying enzymes. Resistance of enterococci to gentamicin was first reported in the United States 15+ years ago. A survey of eight United States tertiary-care hospitals demonstrated that 25% of enterococci had high-level resistance to gentamicin. These organisms are generally resistant to all other aminoglycosides, but occasionally are susceptible to streptomycin.

### Adverse Effects and Drug Interactions

⚡ All aminoglycosides are nephrotoxic and ototoxic and can prolong the duration of neuromuscular blockade drugs. ⚡ Aminoglycosides are reabsorbed by the proximal tubule accumulating in the renal cortex. This accounts for the nephrotoxicity, which is reportedly most common for gentamicin and least common for streptomycin, with amikacin and tobramycin being intermediate. Clinical nephrotoxicity does not usually occur until after at least 1 week of therapy, and is nonoliguric. Nephrotoxicity is typically reversible; however, ototoxicity (either vestibular or auditory) is generally permanent. Potentiation of neuromuscular blockade may also occur with the aminoglycosides, even after copious peritoneal irrigation with an aminoglycoside

**Table 7** Aminoglycosides: Selected Dosing and Need for Adjustment Based Upon Renal or Hepatic Dysfunction

Aminoglycoside drug name	Typical adult IV dose range and intervals	Requires dose adjustment for renal insufficiency (CrCl <30 mL/min)	Requires dose adjustment for hepatic failure
Gentamicin	1.5–2.5 mg/kg q12 hr or 5 mg/kg q24 hr	Yes	No
Tobramycin	1.5–2.5 mg/kg q12 hr or 5 mg/kg q24 hr	Yes	No
Amikacin	7.5 mg/kg q12 hr or 15 mg/kg q24 hr	Yes	No
Streptomycin	10–15 mg/kg q24 hr	Yes	No

Abbreviation: IV, intravenously.

(Volume 2, Chapter 6). It is treated primarily by supportive means (airway protection or ventilation).

The ototoxicity seen with furosemide is additive when administered concomitantly with aminoglycosides. Bumetanide is less ototoxic and should be considered when concomitant use of aminoglycosides and diuretics are needed.

Age greater than 60 and co-administration of other nephrotoxic drugs can exacerbate the nephrotoxicity due to aminoglycosides. Examples of these drugs include: amphotericin B, vancomycin, parenteral bacitracin, capreomycin, cidofovir, cisplatin, cyclosporine, foscarnet, ganciclovir, IV pentamidine, polymyxin B, streptozocin, or tacrolimus.

## Therapeutic/Clinical Uses

### Gentamicin

Gentamicin is used alone primarily for urinary tract infections. It is also typically used in conjunction with extended-spectrum penicillins for nosocomial infections caused by *Enterobacter* spp. and *P. aeruginosa*. Combination therapy including an aminoglycoside with agents that provide gram-positive or anaerobic activity is frequently used in potentially polymicrobial infections when gram-negative rods may be playing a role. An aminoglycoside is used in combination therapy with either ampicillin or vancomycin for several different types of endocarditis, most commonly those that are due to enterococci.

### Tobramycin

Tobramycin has essentially the same parenteral uses as gentamicin. It has greater activity against *Acinetobacter* spp. and *P. aeruginosa* but less activity against *Serratia marcescens* than gentamicin does. If organisms are resistant to gentamicin, they will likely be resistant to tobramycin. Inhaled tobramycin has been associated with improved pulmonary function and decreased hospitalization in patients with cystic fibrosis.

### Amikacin

Amikacin is useful primarily for organisms that are resistant to gentamicin and tobramycin. It is also used in combination with other antibiotics, for example, for infections due to *Nocardia asteroides* and occasionally for infections due to *M. tuberculosis* or *M. avium* complex.

### Streptomycin

Streptomycin is sometimes used (as part of combination therapy) in the treatment of multidrug-resistant tuberculosis

and may be useful in the treatment of some gentamicin-resistant enterococcal infections. It is also the drug of choice for several potential bacterial agents in bioterrorism, such as tularemia and plague, although gentamicin can be used alternatively.

## TETRACYCLINES AND GLYCYLCYCLINES

### History/Description

The tetracyclines were isolated from *Streptomyces* spp., first used clinically over 50 years ago. ♂ **Tetracycline has a broad spectrum of activity against gram-positive, gram-negative, and anaerobic bacteria as well as rickettsiae, mycoplasma, chlamydiae, protozoa, actinomycetes, and even certain viruses.** ♂ Tetracyclines are infrequently used in the ICU setting. However, when they are employed, it is usually to combat pneumonia due to presumed or known "atypical" agents (Table 8). Doxycycline and, to a lesser extent, minocycline are the most commonly used drugs of this class. The tetracyclines are still commonly used for community acquired pathogens, and have recently been reviewed in depth (46,47).

### Mechanism of Action, Pharmacology, Administration, and Dosage

The tetracyclines are similar in mechanism of action to aminoglycosides, as both antimicrobials inhibit bacterial protein synthesis at the ribosomal level. However, in regard to spectrum of activity, the tetracyclines more closely resemble the macrolides. The tetracyclines are typically bacteriostatic rather than bactericidal. Tetracycline is excreted in the urine and should be avoided in renal insufficiency, because high concentrations of the accumulated drug are hepatotoxic. In contrast to tetracycline, doxycycline, and minocycline are eliminated through hepatobiliary processes and can be used in patients with renal insufficiency.

Doxycycline and other tetracyclines can be administered either parenterally or orally, and because of the long half-life, can be administered once or twice daily. Refer to Table 9 for tetracycline dosing and need for dose adjustment.

### Antimicrobial Activity/Spectrum/Resistance

The tetracyclines are currently utilized for the empiric treatment of community-acquired pneumonia because of their activity against both many pyogenic bacteria and "atypical" organisms, such as *Mycoplasma* spp., *Chlamydia* spp., or *Legionella* spp. They also have utility in the treatment of infections

**Table 8** Antimicrobial Drugs of Choice Against Atypical Organisms

Microorganisms	Drug of choice	Alternative agents
<i>Mycoplasma pneumoniae</i>	Azithromycin or a tetracycline	Fluoroquinolone, erythromycin, clarithromycin
<i>Chlamydia psittaci</i>	Fluoroquinolone or doxycycline	Chloramphenicol
<i>Chlamydia pneumoniae</i>	Azithromycin or tetracycline	Fluoroquinolone, erythromycin, clarithromycin
<i>Ehrlichia</i> spp.	Doxycycline	
<i>Rickettsia</i> spp.	Doxycycline	Chloramphenicol, rifampin, fluoroquinolone
<i>Borrelia burgdorferi</i> (Lyme disease)	Amoxicillin or doxycycline	Ceftriaxone, cefotaxime, azithromycin, clarithromycin
<i>Leptospira</i>	Penicillin	A tetracycline, ceftriaxone
<i>Treponema pallidum</i> (syphilis)	Penicillin	Ceftriaxone, a tetracycline, erythromycin
<i>Actinomyces</i> spp.	Penicillin	A tetracycline, erythromycin, clindamycin
<i>Nocardia</i> spp.	Co-trimoxazole	A tetracycline, carbapenem, linezolid

**Table 9** Antibacterial Agents: Requiring Selected Dosing and Need for Adjustment Based Upon Renal or Hepatic Dysfunction

Misc. drug name	Typical adult IV dose range and intervals	Requires dose adjustment for renal insufficiency (CrCl <30 mL/min)	Requires dose adjustment for hepatic failure
Mimocycline	100 mg every 12 hr	No	±
Doxycycline	100 mg every 12 hr	No	±
Erythromycin	0.5–1 g every 6 hr	No	±
Azithromycin	0.25–0.5 g every 24 hr	No	No
Clarithromycin	500 mg orally every 12 hr	Yes	No
Clindamycin	600 mg every 8 hr	No	No
Metronidazole	500 mg every 8–12 hr	No	Yes
Quinupristin/dalfopristin	7.5 mg/kg every 8 hr	No	±
Linezolid	600 mg every 12 hr	No	±
Vancomycin	15 mg/kg every 12 hr	Yes	No
Daptomycin	4–6 mg/kg every 24 hr	Yes	No
Rifampin	600 mg every 24 hr	No	Yes
Tmp/sulfamethoxazole	5 mg/kg of tmp every 8–12 hr	Yes	±
Aminoglycosides	Table 7	Yes	No
Tigecycline	100 mg once followed by 50 mg every 12 hr	No	Yes

Note: ± indicates although specific dosage guidelines are not available, a reduced dosage may be necessary.

Abbreviations: Tmp, trimethoprim; IV, intravenously.

due to *Brucella* spp., rickettsiae, chlamydiae, syphilis, *Borrelia burgdorferi* (the agent of Lyme infection), *Vibrio* spp., *Yersinia* spp., *Francisella tularensis*, *Leptospira* spp., and genital infections. The tetracycline group is also useful in the treatment of some nontuberculous mycobacterial infections (such as *Mycobacteria marinum*). Tetracyclines were originally the only drugs available to treat VRE, however, linezolid, daptomycin, and quinopristin/dalfopristin have been recently used as well.

### Adverse Effects and Drug Interactions

The tetracyclines are generally well tolerated with two important exceptions: photosensitivity and discoloration of developing teeth and bones in children. Minocycline is also associated with vestibular toxicity and a blue-tinged hyperpigmentation of the skin and mucous membranes.

Milk, antacids, iron supplements, and probably other agents with divalent cations decrease the gastrointestinal absorption of orally administered tetracyclines and should be ingested several hours before or after the administration of tetracycline (which is best taken on an empty stomach). These oral divalent cations have less effect on the oral absorption of doxycycline and minocycline.

### Therapeutic/Clinical Uses

As a result of the broad spectrum of the tetracyclines as noted above, these agents are useful in a wide variety of infections; however, they are rarely indicated as the drug of choice in the critically ill patient except for the treatment of rickettsial infections and pulmonary infections due to “atypical” agents (Table 8).

Tigecycline, a glycine derivative of minocycline, received FDA approval for skin and skin structure infections and complicated intra abdominal infections in 2005. Like the tetracyclines, tigecycline has a broad spectrum of activity (48,49). It is active against gram-positive organisms,

gram-negative aerobes, anaerobes, and “atypical” organisms like Chlamydiae and Mycoplasma. It also has activity against organisms that are tetracycline resistant and is also active against MRSA, MRSE, VRE, and penicillin-resistant pneumococci. A notable gap in its spectrum is a lack of activity against *P. aeruginosa*, which could limit the use of tigecycline in the treatment of nosocomial infections, especially HAP. However, since it is much more potent than other tetracyclines, which are bacteriostatic, tigecycline will likely find use in non-pseudomonal HAP. The major side effect noted in early phase trials is nausea and vomiting in patients (20–35%). Tigecycline is only available as an intravenous preparation due to poor oral bioavailability. Its potential place in the therapeutic armamentarium is yet undefined.

## MACROLIDES

### History/Description

Erythromycin was the first clinically available macrolide antibiotic, and was introduced clinically in the 1950s. Erythromycin is derived from the soil fungus, *Streptomyces erythreus*. Modifications of the erythromycin chemical structure have led to two new macrolides (azithromycin and clarithromycin). Both azithromycin and clarithromycin possess better gastrointestinal tolerability and a somewhat broader spectrum of activity than erythromycin, although at a greatly increased cost. The macrolides are reviewed in several recent articles (50–52).

### Mechanism of Action, Pharmacology, Administration, and Dosage

The macrolides all act at the ribosome by inhibiting RNA-dependent protein synthesis. Azithromycin and clarithromycin are acid-stable and well absorbed from the gastrointestinal tract, irrespective of the presence of food.

Erythromycin, which is inactivated by stomach acids, requires enteric coating to increase its efficacy. All macrolides are rapidly absorbed and concentrate well within tissues, including phagocytes. The high concentration of macrolides within phagocytes serves as a delivery system of the drug to the site of infection. ⚡ **Azithromycin has an extremely long intracellular dwell time, permitting once daily (or less often) dosing.** ⚡ Indeed, azithromycin is often used once weekly for the prophylaxis of mycobacterial infections in patients with AIDS.

Various erythromycin products are available for both oral and parenteral administration. Intravenous administration of erythromycin is associated with thrombophlebitis, and intramuscular injections should be avoided due to pain. Oral and intravenous azithromycin are also available. A parenteral form of clarithromycin is currently not available. Dosing guidelines are shown in Table 9.

### Antimicrobial Activity/Spectrum/Resistance

Erythromycin, clarithromycin, and azithromycin all have bacteriostatic activity against gram-positive organisms, such as *Streptococcus pneumoniae* and some *S. aureus*. These agents also have good in vitro and clinical activity against Mycoplasma, Legionella, syphilis, and chlamydiae. Of note, both clarithromycin and azithromycin have activity against some mycobacteria (including *M. avium* complex) and *Helicobacter* spp. Erythromycin lacks activity against *H. influenzae*, whereas both azithromycin and clarithromycin are efficacious against this agent. The macrolides are frequently used in patients with allergies to beta-lactams, especially for infections due to gram-positive bacteria. However, they have very limited activity against MRSA and enterococcus, and a significant proportion of *S. pneumoniae* are resistant to the macrolides in some locales.

### Adverse Effects and Drug Interactions

Gastrointestinal intolerance is a frequent complication of oral erythromycin products, whereas the other macrolides tend to be much better tolerated. One advantage of azithromycin over the other macrolides is the absence of clinically significant drug–drug interactions involving the cytochrome P-450 system (CP450) (Volume 2, Chapter 4).

### Therapeutic/Clinical Uses

Macrolides are commonly used for community-acquired pneumonias and in patients who are allergic to penicillins. The promotility side effect of low-dose erythromycin is increasingly utilized as a promotility agent in critically ill patients with gastroparesis.

## LINCOSAMIDES (CLINDAMYCIN)

### History/Description

Clindamycin, a lincosamide derivative, has been in clinical use since the mid-1960s. Although clindamycin is associated with *C. difficile* colitis, it remains one of the mainstays in the treatment of serious anaerobic infections, and as an alternative agent for some *S. aureus* infections (51,53,54).

### Mechanism of Action, Pharmacology, Administration, and Dosage

Clindamycin inhibits RNA-dependent protein synthesis acting at the ribosomal level (infusion similar to macrolides). Although oral and intravenous preparations of clindamycin

penetrate most body tissues (including lung, liver, bone, and extra-cranial abscesses), it does not easily cross the blood-brain barrier or enter the CSF, even when the meninges are inflamed. Thus, metronidazole, which fully penetrates the CSF, should be used for any CNS infections involving anaerobic organisms (other than CNS toxoplasmosis—which can be treated with clindamycin). Dosing guidelines are shown in Table 9.

### Antimicrobial Activity/Spectrum/Resistance

Clindamycin has a spectrum of activity that includes many anaerobes, especially oral flora; some aerobic gram-positive cocci, including most strains of pneumococci; other streptococci; *S. aureus*; *Pneumocystis carinii*; and *Toxoplasma gondii*. Clindamycin has no activity against enterococci and has limited activity against most MRSA. The majority of aerobic gram-negative bacilli are intrinsically resistant to clindamycin. Most intestinal *Bacteroides* spp., especially of *B. fragilis* are resistant to clindamycin (55). Clindamycin, therefore, should not be a first-line antianaerobic agent to treat infections below the diaphragm.

### Adverse Effects and Drug Interactions

Clindamycin exerts a direct muscular depressant effect, and may prolong the duration of neuromuscular blockage (56). Diarrhea is a common side effect of clindamycin, even in the absence of colitis, and the potential for the development of *C. difficile* colitis makes the use of this antibiotic complicated, limiting its use to severe infections with clear indications for use.

Clindamycin has no clinically significant drug–drug interactions.

### Therapeutic/Clinical Uses

Clindamycin is used most commonly for infections outside of the CNS (except cerebral toxoplasmosis) that are thought to include anaerobes, especially *B. fragilis* and other penicillin-resistant anaerobes. Clindamycin is utilized in some pulmonary infections, especially aspiration pneumonia that is community-acquired and also as a useful alternative to penicillin.

Clindamycin has been successfully used in the treatment of pelvic inflammatory disease (PID) for years. This success probably relates to the fact that vaginal anaerobic flora are more similar to oral anaerobes than to colonic anaerobes in general. However, if the PID infection involves *B. fragilis*, metronidazole is a better choice. Although sexually transmitted pathogens can cause PID, these infections tend to become polymicrobial, involving aerobes and anaerobes. Clindamycin is frequently used with other antibiotics that have gram-negative bacillary activity. Since clindamycin is a protein synthesis inhibitor and can act even when cells are in stationary phase, it has utility in the treatment of bacterial toxidromes and in situations such as necrotizing fasciitis. ⚡ **Because of its gram-positive and anaerobic coverage, clindamycin is useful (with combination gram-negative therapy) for necrotizing fasciitis, most oral and vaginal anaerobic infections, and diabetic foot infections, which tend to be polymicrobial and virulent.** ⚡

## METRONIDAZOLE

### History/Description

Metronidazole is a nitroimidazole drug first synthesized in the 1950s and was originally recognized as being effective

against certain protozoa. In the 1960s metronidazole was recognized to also possess excellent anaerobic antimicrobial activity (53,57). ⚡ **Metronidazole is indicated for the treatment of serious polymicrobial infections involving anaerobes (e.g., necrotizing fasciitis and infections involving contamination from the GI tract). Importantly, other agents with aerobic gram-positive and gram-negative coverage must be co-administered.** ⚡

### Mechanism of Action, Pharmacology, Administration, and Dosage

Metronidazole enters the cell by passive diffusion where its nitro group is reduced by electron transport proteins with low redox potential. This process produces metabolites that alter the helical structure of DNA and subsequently causes cell death (58).

Metronidazole is rapidly absorbed in the gut. Indeed, serum levels are similar following oral and intravenous administration. Although metronidazole is almost completely absorbed after oral administration, critically ill patients should receive therapy via the intravenous route until stable (59). When the patient is stable, and the gut is functional, administration should be converted to the enteral route for cost saving since it is nearly 100% bioavailable. The liver metabolizes metronidazole into a water-soluble metabolite, and both this metabolite and the un-metabolized metronidazole are excreted in the urine. No dosage adjustment is required in those with renal insufficiency, but dosage should be reduced in patients with hepatic insufficiency. Therapeutic drug levels are attained in most tissues; excellent levels are found in the CSF.

In severe anaerobic infections, metronidazole is administered as a loading dose of 15 mg/kg intravenously followed by 7.5 mg/kg every six to eight hours. This typically equates to 1 g followed by 500 mg every six to eight hours.

### Antimicrobial Activity/Spectrum/Resistance

Metronidazole is active against certain protozoa, including *Trichomonas*, *Giardia*, and *Entamoeba* however; its primary role in the critically ill patient is as an extremely active agent against obligate anaerobic bacteria and is the antimicrobial agent most reliably active against *B. fragilis* (60). Resistance has been reported in Europe and Africa but is very uncommon (53). When metronidazole resistance does occur, it is most commonly attributable to the presence of one of the five known *nim* nitroreductase genes (61). Metronidazole resistance had not previously been reported in *B. fragilis* isolates from the Western Hemisphere, recently a serious infection involving a metronidazole-resistant *B. fragilis* isolate was recovered from a patient in Seattle, Washington in 2004 with the *nimA* nitroreductase gene (61).

### Adverse Effects and Drug Interactions

The most severe adverse effect seen with metronidazole, although rare, involves the central nervous system and may include seizures, encephalopathy, cerebellar dysfunction, and peripheral neuropathy (57). More commonly, metronidazole causes minor gastrointestinal side effects such as nausea, diarrhea, a metallic taste, stomatitis, and dry mouth (57). Alcohol should be avoided while receiving metronidazole because it can induce a disulfiram-like reaction (57,62). Metronidazole inhibits the metabolism of warfarin and will prolong the prothrombin time and INR in patients taking coumarin-type anticoagulants (63).

### Therapeutics/Clinical Use

In general, as a result of its spectrum of activity, metronidazole is extremely useful in most anaerobic infections with the important exceptions of those due to *Actinomyces* spp. and *Propionibacterium acnes* (57). The excellent penetration of metronidazole into all tissues combined with its bactericidal activity makes it effective for the treatment of most serious anaerobic infections (57). Many serious anaerobic infections are polymicrobial, therefore, additional agents with better coverage against gram-positive aerobes and gram-negative organisms are also necessary. ⚡ ***B. fragilis* is probably the most frequently encountered clinically significant anaerobe where metronidazole should be considered the drug of choice, especially in intra-abdominal infections (57).** ⚡ Metronidazole is also the drug of choice for the treatment of pseudomembranous colitis due to *C. difficile* (54). Oral vancomycin is an alternative in seriously ill patients with pseudomembranous colitis.

### QUINUPRISTIN/DALFOPRISTIN (SYNERCID®)

#### History/Description

The evolution of multi-drug resistant bacteria, including MRSA and VRE faecium, has created a pressing need for effective alternative antibiotics, hence the utility of the streptogramins (i.e., quinupristin/dalfopristin), linezolid, and daptomycin.

The streptogramins are a family of compounds isolated from *Streptomyces pristinaespiralis*. The family is divided into group A and group B based on molecular structure. Dalfopristin is a derivative of a group A streptogramin, and quinupristin is a group B streptogramin. These two streptogramins have been combined in a commercially available injectable form at a 30:70 weight-to-weight ratio. Individually, these compounds demonstrate only modest in vitro activity. However, the combination is synergistic. Unfortunately, in vitro studies also demonstrate that the combination of quinupristin and dalfopristin is not bactericidal against all species and strains of common gram-positive organisms.

Quinupristin/dalfopristin, a combination product known as "Synercid," has demonstrated activity against most strains of aerobic gram-positive microorganisms, both in vitro and in clinical infections, including; *E. faecium* (vancomycin-resistant and multi-drug resistant strains only), *S. aureus* (both MSSA and MRSA), and *Streptococcus pyogenes* (group A beta-hemolytic streptococci) (64,65). This compound is bacteriostatic against *E. faecium* and bactericidal against strains of methicillin-susceptible and methicillin-resistant *Staphylococci* spp. Importantly, dalfopristin/quinupristin has no activity against *Enterococcus faecalis*. A post-antibiotic effect has been demonstrated for *S. aureus*: seven hours for methicillin-susceptible strains; five hours for methicillin-resistant strains. Since the mode of action of streptogramins differs from other classes of antibacterial agents, there is no cross-resistance.

### Mechanism of Action, Pharmacology, Administration, and Dosage

Quinupristin and dalfopristin bind to sequential sites located on the 50S subunit of the bacterial ribosome. Dalfopristin binding causes a conformational change in the ribosome that subsequently increases the binding of quinupristin. The binding of both agents to the ribosome constricts the exit channel on the ribosome through which nascent polypeptides

are extruded; proper functioning of the ribosome is blocked and transfer RNA (tRNA) synthetase activity is inhibited leading to a decrease in free tRNA within the cell. Without these tRNAs, the bacterial cell cannot properly incorporate amino acids into peptide chains leading to bacterial cell death.

Quinupristin/dalfopristin undergoes hepatic metabolism, and both compounds have active metabolites. However, no increase in adverse events has been reported in patients with hepatic impairment, and no dosage reduction is required in these patients. The parent drugs and major metabolites are eliminated primarily by fecal excretion (75%) with a small portion of unchanged quinupristin and dalfopristin (15–19%) eliminated renally. In patients with a creatinine clearance <29 mL/min, a 30% increase in the combined AUC of quinupristin/dalfopristin and their metabolites has been observed, but the manufacturer has not established guidelines for dosage reduction. The manufacturer's recommended intravenous dose of quinupristin/dalfopristin in adults is 7.5 mg/kg given over 60 minutes every eight hours preferably through a central line.

### Antimicrobial Activity/Spectrum/Resistance

Resistance to the streptogramins has been reported (66,67). The most common expression of bacterial resistance to streptogramins is through conformational alterations in ribosomal target binding sites. However, it appears that multiple point mutations are required for drug resistance to this combination product to develop.

### Adverse Effects and Drug Interactions

The most common adverse effects with quinupristin/dalfopristin are infusion-site reactions. Non-infusion related reactions including nausea, diarrhea, vomiting, rash, headache, pain, and pruritus were reported with similar frequency as comparator antibiotics in one trial. Elevations in liver enzymes (2–7%), increases in total and direct bilirubin (1–5%), thrombocytopenia (2%), and decreases in hemoglobin of <8–mg/dl (2.6%) have also been reported.

Quinupristin/dalfopristin is an inhibitor of Cytochrome P450 (CP450) 3A4 enzyme. One study demonstrated a two-fold increase in cyclosporine levels within two to five days of concomitant use. Caution is recommended when concomitantly administering other agents that are eliminated via the CP450-3A4 isoenzyme pathway with quinupristin/dalfopristin (Volume 2, Chapter 4).

### Therapeutic/Clinical Uses

Quinupristin/dalfopristin is the most expensive parenteral antibacterial currently on the market. ⚡ **The greatest utility of quinupristin/dalfopristin, daptomycin, and linezolid is in the management of patients with multi-resistant enterococci (VRE) or MRSA infections for which limited alternatives exist.** ⚡ The treatment of VRE infections has been recently reviewed (68,69).

## LINEZOLID (ZYVOX®)

### History/Description

Linezolid is one of a new class of synthetic antibiotics known as fluorinated oxazolidinones (70,71). This drug is designed to target MRSA; it also provides good activity against other gram-positive organisms, including penicillin-resistant

pneumococci and VRE (72). This drug now provides an alternative to vancomycin therapy in an oral formulation.

### Mechanism of Action, Pharmacology, Administration, and Dosage

Linezolid inhibits bacterial protein synthesis by interfering with translation. Linezolid binds to a site on the bacterial 23S ribosomal RNA of the 50S subunit; this action prevents the formation of a functional 70S initiation complex, an essential step in the bacterial translation process. The action of linezolid is considered to be bacteriostatic against Staphylococci and Enterococci, but is bacteriocidal against the majority of Streptococcal strains tested.

Following oral administration, absorption of linezolid appears to be rapid with a peak plasma concentration ( $t_{max}$ ) of one to two hours (73). The oral bioavailability is approximately 100% and as such linezolid may be administered orally or intravenously without dosage adjustment (73). Linezolid is distributed extensively to various tissues. Linezolid appears to partition into the central nervous system at a CSF: serum ratio of 0.65:1; it has been used to successfully treat ventriculoperitoneal shunt infections caused by VRE or coagulase-negative Staphylococci. Of major importance in critical care, linezolid penetrates into bronchoalveolar lavage fluid and lung tissue more effectively than vancomycin (74).

The recommended adult dosage is 600 mg intravenous or orally every 12 hours for all indications except uncomplicated skin and soft-tissue infections, for which the recommended dosage is 400 mg orally every 12 hours. Elimination of linezolid is primarily (65%) nonrenal. Clearance is mediated by non-enzymatic chemical oxidation, which results in the formation of two major inactive metabolites, which are excreted renally (75).

Dosage adjustments are not necessary in renal insufficiency or mild to moderate hepatic dysfunction. Approximately 30% of a dosage of linezolid is removed by hemodialysis. For this reason, patients should receive their linezolid doses post-dialysis.

### Antimicrobial Activity/Spectrum/Resistance

Soon after linezolid became FDA-approved in the US, reports of linezolid-resistant VRE organisms were identified at several institutions. Resistance with linezolid has been observed in 15 patients with enterococcal infections, and a vancomycin-resistant strain of *E. faecium* with reduced susceptibility to linezolid (MIC = 8 mg/mL) has been isolated. Preliminary reports suggest that most cases of resistance to linezolid occur when the drug is used for prolonged periods of time in patients with prosthetic devices. Resistance to linezolid is usually associated with single-point mutations in 23S rRNA. Studies suggest the frequency of spontaneous resistance to linezolid is  $<10^{-9}$ .

### Adverse Effects and Drug Interactions

The most frequently reported adverse events with linezolid in one study were diarrhea (8.3%), nausea (6.6%), headache (6.4%), and vomiting (4.3%). In another study, tongue discoloration (2.5%), oral candidiasis (2.3%), and injection-site pain (1.4%) were also reported. Thrombocytopenia (platelet count <75% of the lower limit of normal and/or baseline) was reported in 2.4% of patients who received linezolid in clinical trials. Linezolid-related thrombocytopenia appears to be associated with prolonged duration of

therapy (>2 weeks) and is generally reversible on discontinuation.

Linezolid is metabolized via oxidation of its morpholine ring, independent of CP450 activities. It is 31% protein bound; therefore, interactions via displacement from protein binding sites are unlikely. Linezolid is a weak, reversible inhibitor of human monoamine oxidase A. Consequently, it has the potential to interact with adrenergic and serotonergic agents, leading to hypertensive crises (Volume 2, Chapter 17) and serotonin syndrome (Volume 1, Chapter 40 and Volume 2, Chapter 46). Mean increases in systolic blood pressure of 32 and 38 mmHg have been observed in normotensive subjects taking linezolid concomitantly with pseudoephedrine and phenylpropanolamine, respectively.

### Therapeutic/Clinical Uses

Linezolid is an expensive drug; one day of linezolid costs roughly the same amount as 500 days of either doxycycline or co-trimoxazole. Although this antibiotic represents the first in a unique class of antibiotics (the oxazolidinones), more clinical experience and formal pharmacoeconomics data should be obtained prior to its widespread clinical use. Linezolid should be reserved for the treatment of documented serious VRE or MRSA infections, or when oral therapy is an option. Since it appears to achieve high levels in the lungs, it may soon become the drug of choice to treat MRSA pneumonia (74).

## VANCOMYCIN

### History/Description

Vancomycin is a bactericidal glycopeptide derived from the soil fungus *Streptomyces orientalis* and was first introduced in 1956. Within two years, vancomycin use was superseded by methicillin and cephalothin, which had fewer side effects. In the late 1970s, MRSA began to emerge, and vancomycin returned to the clinical arena to treat these threats. Recent improvements in manufacturing have increased its purity and reduced the nephrotoxicity of vancomycin (75–78). However, the histaminereleasing effect responsible for “red man” syndrome and hypotension during administration still persist. Teicoplanin, a related compound, is at least as efficacious and less toxic. Teicoplanin has been used for years in Europe, but it is not currently available in the US.

♣ **Vancomycin is most often used parenterally to treat MRSA, empirically in life-threatening infections, and orally for *C. difficile* colitis.** ♣

### Mechanism of Action, Pharmacology, Administration, and Dosage

Vancomycin exerts its effect by binding to the precursor units of bacterial cell walls, known as peptidoglycans, inhibiting their synthesis. This binding occurs at a different site of action from that of penicillin. The net result is an alteration of bacterial cell wall permeability. In addition, RNA synthesis is inhibited. Gram-negative organisms are not sensitive to vancomycin, because porin channels in their cell wall do not accommodate the large, bulky vancomycin molecule.

Vancomycin is about 55% protein bound. Vancomycin penetrates most body tissues including the brain when the meninges are inflamed. Vancomycin also distributes well into pericardial, pleural, ascitic, and synovial fluids. Intravenous vancomycin is primarily excreted unchanged by the kidneys. Vancomycin has poor oral bioavailability with oral

doses remaining intraluminal in the intestine until eliminated in the feces; this also explains its oral use in *C. difficile* colitis. Vancomycin has a half-life of approximately six hours in a patient with normal renal function. However, in anuric patients, the half-life can be prolonged to approximately 7.5 days. Vancomycin is not removed by hemodialysis or peritoneal dialysis, unless F60 or F80 polysulfone filters are used (Volume 2, Chapter 43). In patients with normal renal function, vancomycin is dosed at 1 g IV every 12 hours, and levels are tested. Teicoplanin is dosed on an every 24-hour basis. In those patients with known or suspected renal impairment, an initial vancomycin dose of 15 mg/kg should be given, and the dosage interval increased. The appropriate dosage interval should be further determined using therapeutic drug level monitoring. When vancomycin is given with an aminoglycoside, increased incidence of nephrotoxicity is possible. For pseudomembranous colitis, a dosage of 125–500 mg orally every six hours for 7–10 days is appropriate.

### Antimicrobial Activity/Spectrum/Resistance

Vancomycin is bactericidal against essentially all staphylococci (both *S. aureus* and coagulase-negative Staphylococci), all *S. pneumoniae*, *S. pyogenes*, and *S. viridans*. It is bacteriostatic against most Enterococcus and most *Corynebacterium* spp. A few anaerobes are susceptible, but virtually no gram-negative organisms are susceptible to vancomycin. Vancomycin has achieved a prominent role in therapy of critically ill patients due to the large prevalence of MRSA in hospitals. To an increasing extent, critically ill patients have temporary or permanent foreign bodies implanted as pacemakers, vascular access, valves, or shunts. These devices are particularly predisposed to infection by Staphylococci, including *S. aureus* and coagulase-negative Staphylococci, an increasing fraction of which is methicillin-resistant.

Vancomycin intermediate-susceptible *S. aureus* (VISA) is used to describe decreased susceptibility of *S. aureus* to vancomycin (79,80). In 1997, the first strain of *S. aureus* with reduced susceptibility to vancomycin was reported from Japan (81). The Clinical and Laboratory Standards Institute (CLSI) defines Staphylococci requiring concentrations of vancomycin of ≤4 mcg/mL for growth inhibition as susceptible, those requiring 8 to 16 mcg/mL as intermediate (VISA) (79,80), and those requiring concentrations of >32 mcg/mL as resistant (VRSA) (82). Implications of multi-drug resistant organisms make therapeutic choices much more difficult and reinforce the need to control the use of vancomycin and other antibiotics (16). Infections with these vancomycin resistant microorganisms are usually sensitive to linezolid, daptomycin, or dalfopristin/quinupristin.

The proportion of Enterococci isolated from ICUs that were resistant to vancomycin increased from 0.3% in 1989 to almost 24% in 1998. Enterococci are able to build cell walls in the presence of glycopeptide antibiotics because they can bypass an intermediate molecule to which the glycopeptide binds (83). Risk factors for the emergence of VRE include exposure to broad spectrum cephalosporins, vancomycin, or antibiotics with significant anaerobic activity; and prolonged hospital and/or ICU stay. The empiric use of vancomycin should be limited to life threatening infections in order to reduce the emergence of VRE.

### Adverse Effects and Drug Interactions

Vancomycin is now considered approximately 95% free of impurities; therefore the incidence of adverse effects has declined (84). However, phlebitis still occurs with

peripherally administered vancomycin in approximately 13% of patients. Hypotension, flushing, tingling, and erythema affecting upper trunk, face, and arms (red person syndrome) are associated with rapid infusion in 3% to 11% of patients, especially if 1-g doses are used. Treatments with fluid administration, antihistamines, and corticosteroids have been suggested, as well as slowing the infusion. Rash unrelated to “red person syndrome” is also seen in about 2% to 5% of patients. The rash is often described as maculopapular, but rare cases of Stevens-Johnson have been reported. Neutropenia occurs in approximately 2% of patients (84), the onset typically being delayed up to 30 days after commencing the drug. Nephrotoxicity and ototoxicity are uncommon if peak serum levels are maintained <50 mcg/mL, but more likely to occur if vancomycin is administered with other nephro- or ototoxic compounds, and more common in critically ill patients.

Drugs that increase the risk of nephrotoxicity when co-administered with vancomycin include: amphotericin B, aminoglycosides, parenteral bacitracin, capreomycin, cidofovir, cisplatin, cyclosporine, foscarnet, ganciclovir, IV pentamidine, polymyxin B, streptozocin, and tacrolimus. The combined use of vancomycin and cidofovir is contraindicated. Vancomycin should be discontinued seven days prior to beginning cidofovir.

Orally administered vancomycin should not be used with cholestyramine or colestipol. These anion-exchange resins can bind vancomycin and reduce its effectiveness. Since these drugs are sometimes used to treat *C. difficile* colitis by binding the toxin in the intestinal lumen, patients may be taking vancomycin and one of the resins simultaneously. If patients must take both drugs, doses should be administered several hours apart.

Vancomycin should be used cautiously with other ototoxic drugs such as aminoglycosides, aspirin or other salicylates, capreomycin, ethacrynic acid, furosemide, or paromomycin. Vancomycin may potentiate the neuromuscular effects of nondepolarizing neuromuscular blockers (Volume 2, Chapter 6). Vancomycin, when used concomitantly with metformin, may increase the risk of lactic acidosis. Vancomycin can decrease metformin elimination by competing for common renal tubular transport systems, necessitating careful monitoring while on concurrent therapy.

### Therapeutic Drug Level Monitoring

The ideal vancomycin-dosing regimen is one that results in peak vancomycin concentrations that are less than 30 to 50 mg/L and trough concentrations that are in the range of 5 to 15 mg/L. Therapeutic drug monitoring of vancomycin remains controversial (85). Vancomycin exhibits concentration-dependent killing, requiring a serum concentration >1 mg/L. Therefore, higher concentrations are not necessarily associated with improved bactericidal effects (especially in the lung)! For MRSA pneumonia vancomycin troughs should be >15 to 20 mg/L. Most clinicians believe patients at high risk for therapeutic failure or potential toxicity should have both peak and trough values monitored. These patients include the elderly, those with poor renal function, or patients with suspected alteration in their volume of distribution; this includes the critically ill.

### Therapeutic/Clinical Uses

The primary indication for vancomycin is for MRSA infections, and empiric administration in critically ill patients with significant infections or sepsis until culture results

return. Other indications for vancomycin include Staphylococcal and Streptococcal infections in patients allergic to penicillins, and as an alternative to penicillin for the prophylaxis of bacterial endocarditis. Vancomycin is being used in conjunction with ceftriaxone in locales with high prevalence rates of highly penicillin-resistant pneumococcal meningitis. For organisms susceptible to beta-lactams, clinical experience has demonstrated improved patient outcome with the use of beta-lactams rather than with vancomycin. Vancomycin is also useful in oral therapy against *C. difficile* colitis.

## DAPTOMYCIN

### History/Description

Daptomycin is the first antibacterial agent from a novel class of drugs, the cyclic lipopeptides (derived from *Streptomyces roseosporus*). Discovered more than 20 years ago, its clinical research was halted due to concerns of skeletal muscle toxicity. However, development resumed in response to the increasing demand for bactericidal antibiotics effective against VRE and VRSA (86). Daptomycin is now approved for the treatment of complicated skin and skin structure infections caused by gram-positive bacteria. It recently received FDA approval for use in the treatment of bacteria and endocarditis (87). Because of inactivation by alveolar surfactant, daptomycin is not effective in the treatment of pneumonia. However, it has excellent concentrations in all other tissues (88–90).

### Mechanism of Action, Pharmacology, Administration, and Dosage

Daptomycin works by binding to and interfering with the integrity of cell wall structure in gram-positive bacteria but does not penetrate the bacterial cytoplasm. Upon binding, transmembrane channels are formed, causing rapid depolarization of membrane potential and inhibition of protein, DNA, and RNA synthesis, resulting in bacterial cell death. It has a concentration-dependent bactericidal activity.

Daptomycin is poorly absorbed orally and should be administered intravenously only. Direct toxicity to muscles prohibits intramuscular injection. Daptomycin is highly bound to human plasma protein (92%), primarily to serum albumin. The serum half-life is eight to nine hours in normal subjects, allowing once daily administration. Approximately 80% of the administered drug is excreted unchanged by the kidney with a smaller portion (6%) excreted in the feces. Dosage adjustment is required for creatinine clearance below 30 mL/min. Daptomycin is removed by hemodialysis and the dose should be administered immediately following dialysis.

### Antimicrobial Activity/Spectrum/Resistance

Daptomycin is unable to permeate the outer membrane of gram-negative bacteria, thus its spectrum of activity is limited to gram-positive organisms only. Daptomycin is active in vitro against both antibiotic-susceptible and resistant gram-positive bacteria, including Staphylococci (MSSA, MRSA, VISA, and VRSA), *S. pyogenes*, *Streptococcus agalactiae*, *Streptococcus dysgalactiae* subspecies *equismilis*, and Enterococci (both *E. faecalis*, and *E. faecium* including (VRE), and *S. pneumoniae* (including penicillin-resistant).

In an in vitro comparative study with vancomycin, linezolid, and quinupristin/dalfopristin, daptomycin was found to have the most rapid bactericidal activity and

approximately 8- to 30-fold greater activity against MSSA and MRSA than the other products (90,91). Against VISA, quinupristin/dalfopristin was the most active agent, followed by daptomycin, linezolid, and vancomycin (92). The activity of daptomycin against both VRE vancomycin-sensitive *E. faecalis* was greater than all the other agents tested (92,93).

Bacteria in the stationary growth phase (as occurs in endocarditis and foreign body infections) are killed faster with daptomycin than with vancomycin or nafcillin. To date, no mechanism of resistance to daptomycin or cross-resistance with other antimicrobials has been reported.

### Adverse Effects and Drug Interactions

The most frequently reported side effects with daptomycin use are headache, constipation, and rash. Initial development of daptomycin was suspended in the early 1980s due to concerns of skeletal muscle toxicity. With less frequent administration (98 hour vs. daily), clinical toxicity has not been seen. Elevations in serum creatine phosphokinase (CPK) have been reported in patients receiving daptomycin. Accordingly, weekly CPK levels should be monitored, and patients should be examined for muscle pain or weakness throughout therapy. Daptomycin should be used cautiously in patients with a history of myopathy or peripheral neuropathy. Although no drug-drug interactions have been identified, patients receiving medications that have the potential to cause rhabdomyolysis, such as HMG-CoA reductase inhibitors, should be closely monitored during daptomycin use. Daptomycin does not inhibit or induce the C-P450 enzymes.

### Therapeutic/Clinical Uses

Daptomycin is indicated for treatment of complicated skin and skin structure infections caused by MSSA and MRSA, VISA, and VRSA strains, hemolytic streptococci, and vancomycin-susceptible enterococci and VRE. A recent clinical trial demonstrated that daptomycin is noninferior to comparator agents (vancomycin and semi-synthetic penicillins) for the treatment of bacteremia and right-sided endocarditis due to *Staphylococcus aureus*; The drug recently received FDA approval for these indications. Daptomycin is uniquely ineffective for the treatment of pneumonia due to its inactivation by surfactant, and is not appropriate for this infection.

## SULFONAMIDES AND TRIMETHOPRIM

### History/Description

Sulfonamides are derived from sulfonic acid, and were discovered in 1932. Sulfamethoxazole (SMX) and Sulfadiazine remain the most useful members of this class of antibiotics. Trimethoprim (TMP) was first used for the treatment of infections in humans in 1962, and it was registered for clinical use in combination with SMX in 1968 (94,95).

### Mechanism of Action, Pharmacology, Administration, and Dosage

TMP and SMX in combination have synergistic effects. The optimal ratio of serum concentrations of TMP to SMX against most bacteria is 1:20. Both drugs inhibit bacterial folic acid synthesis at different steps in the pathway. SMX inhibits dihydropteroate synthetase, which catalyzes the formation of dihydrofolate from para-aminobenzoic acid. In the subsequent step of the pathway, TMP inhibits

dihydrofolate reductase, which catalyzes the formation of tetrahydrofolate from dihydrofolate.

TMP is 45% and SMX is 66% bound to plasma proteins. In patients with normal renal function, the half-lives of TMP and SMX are approximately 11 and 9 hours, respectively. When the creatinine clearance decreases to less than 30 mL/min, the dosage of TMP/SMX should be adjusted.

TMP/SMX (trade names Bactrim® or Septra®) is available in a single strength tablet, containing 80 mg TMP and 400 mg of sulfamethoxazole; a double strength tablet, containing 160 mg TMP and 800 mg of sulfamethoxazole; as an oral suspension; and intravenous solution. Dosing equivalents for TMP/SMX are one DS tablet equivalent to 10 mL intravenous solution, equivalent to 20 mL oral suspension. For most indications, one double-strength tablet is administered twice daily for 7 to 14 days depending on the type and severity of the infection. For the treatment of *Pneumocystis carinii* pneumonia (PCP) the administration of dosages of 15 mg/kg of TMP daily, is recommended typically divided into three doses for 21 days. PCP prophylaxis may be achieved with 1 double-strength tablet daily or every other day.

### Antimicrobial Activity/Spectrum/Resistance

Many aerobic gram-positive and gram-negative bacteria, *Pneumocystis carinii*, and several protozoa are inhibited or killed by clinically achievable concentrations of TMP/SMX. Certain nosocomial pathogens, such as *Burkholderia cepacia*, *Stenotrophomonas maltophilia*, and *Serratia* spp. are frequently susceptible to SMZ-TMP. In immunosuppressed individuals, some microorganisms of particular concern such as *Nocardia asteroides* and *Listeria monocytogenes* are also usually inhibited by TMP/SMX.

Important pathogens that are usually resistant to TMP/SMX are *P. aeruginosa*, *B. fragilis*, and most other obligatory anaerobic bacteria. Additionally, *M. tuberculosis*, *Campylobacter* spp., *Treponema pallidum*, and *Rickettsiae* are resistant to SMZ-TMP. MRSA is variably susceptible, and most penicillin-resistant pneumococci are resistant. The clinical use of TMP/SMX has gradually declined during recent decades as a result of growing resistance to this agent among most major bacterial pathogens (96).

### Adverse Effects and Drug Interactions

SMX can cause blood dyscrasias. Hypersensitivity reactions may also occur with this medication, most commonly manifested as rashes, but may include erythema multiforme major (Stevens-Johnson syndrome). TMP has fewer life-threatening side effects than do the sulfonamides. However, TMP has been shown to cause drug-induced aseptic meningitis. TMP/SMX is contraindicated in pregnancy. TMP/SMX may potentiate the effects of warfarin, phenytoin, tolbutamide, and chlorpromamide.

### Therapeutic/Clinical Uses

Growing resistance and potential toxicity has led to the decreased use of TMP/SMX. However, this agent is still used in the treatment and prophylaxis of urinary tract infections, treatment and prevention of PCP, shigellosis, and otitis media. Of note, TMP/SMX is being used more frequently in the treatment of severe Staphylococcal infections (97).  
**✦ TMP/SMX may be extremely useful in severe infections caused by susceptible organisms in the critically ill patient, especially those infections caused by *Enterobacter***

*sp.*, and other gram-negative rods that may be multi-resistant to beta-lactam drugs. ⚡

## QUINOLONES

### History/Description

Nalidixic acid, the first quinolone, was developed in 1962 as a byproduct of chloroquine synthesis, and was only useful in urinary tract infections. Its poor pharmacokinetic profile and its toxicity led to the development of the 6-fluorine-substituted quinolones in the 1980s. The fluoroquinolones are reviewed in references (98–100).

### Mechanism of Action, Pharmacology, Administration, and Dosage

The quinolones have a novel mechanism of action. These compounds target bacterial topoisomerases II and IV. Topoisomerase II (also known as DNA gyrase) is responsible for nicking and sealing DNA, as well as regulating supercoiling. Topoisomerase IV separates the DNA daughter molecules after DNA replication.

The quinolones have excellent oral bioavailability (approximately 90–99%), which allows for early conversion from intravenous to oral formulations. All are available as tablets or capsules. Parenteral formulations of ciprofloxacin, gatifloxacin, ofloxacin, levofloxacin, moxifloxacin, and trovafloxacin (as the pro-drug alatrofloxacin) are also available. Administering the fluoroquinolones with food delays the absorption, but does not alter its extent. However, concomitant administration of divalent ions such as aluminum, magnesium, zinc, iron, and/or calcium may block absorption.

The quinolones have a post-antibiotic effect of approximately one to two hours, similar to the aminoglycosides, but greater than that with the beta-lactam antibiotics (101). Gemifloxacin and trovafloxacin have a greater tendency to bind to proteins than the other quinolones

(approximately 70% vs. less than 50% for the other quinolones), but are not likely to displace other protein-bound drugs.

Routes of metabolism vary greatly between the different quinolones. Moxifloxacin and trovafloxacin undergo extensive hepatic metabolism; however, the metabolites are less active than the parent compounds. Ciprofloxacin, gatifloxacin, gemifloxacin, levofloxacin, lomefloxacin, and ofloxacin are renally eliminated. The fluoroquinolones have elimination half-lives of approximately 3 to 20 hours. Please refer to Table 10 for dosing of the commercially available quinolones.

### Antimicrobial Activity/Spectrum/Resistance

⚡ Quinolone antibiotics, similar to the cephalosporins, are traditionally categorized into first to fourth generations based upon spectrum of activity. In general, the second, third, and fourth generations have enhanced gram-positive cocci activity (except ciprofloxacin) and gram-negative rod activity. Excellent anaerobic activity is seen with trovafloxacin and moxifloxacin. ⚡

In 1995, an alarming trend toward increased resistance to ciprofloxacin was noted in *S. aureus*, *E. coli*, *Citrobacter freundii*, *S. marcescens*, and *P. aeruginosa*. The activity of the fluoroquinolones against gram-positive bacteria has been reviewed (102). Approximately 28% of the fluoroquinolone-resistant enteric bacilli also demonstrated aminoglycoside and B-lactam resistance. Multiple mechanisms, many of which are bacteria-specific have been identified in fluoroquinolone resistance, and different bacteria may acquire more than one mutation to confer resistance. Because mutations in the genes that code for the subunits of topoisomerase II and IV vary between bacteria, patterns of quinolone resistance will vary.

### Adverse Effects, Drug Interactions

About 5% of patients experience GI side effects with the fluoroquinolones (100). CNS effects (headache, dizziness, insomnia, and nervousness) are also noted with some of

**Table 10** Quinolones: Dosing

Quinolone	Dosage form	Dose (mg)	Dosing interval (hours)	Adjust dose (for renal impairment)	Dosage adjustment
<i>First generation</i>					
Nalidixic acid	PO	250, 500, 1000	6	None	None
<i>Second generation</i>					
Ciprofloxacin	PO	250, 500, 750	8, 12	CrCl < 30 mL/min, HD <sup>a</sup>	250–500 mg q18 hr 250–500 mg q24 hr, after HD <sup>a</sup>
	IV	200, 400	8, 12	CrCl < 30 mL/min	200–400 mg q18–24 hr
<i>Third generation</i>					
Levofloxacin	PO	500, 750	24	CrCl 20–50 mL/min	500–750 mg LD, then 250–500 mg q24 hr
	IV	500, 750	24	CrCl < 20 mL/min	500–750 mg LD, then 250–500 mg q48 hr
<i>Fourth generation</i>					
Trovafloxacin <sup>a</sup>	PO	200	24	Hepatic	Avoid if possible, if not, half-dose
	IV	300	24	Impairment	
Moxifloxacin	PO	400	24	Hepatic	Not studied
	IV	400	24	Impairment	
Gemifloxacin	PO	320	24	CrCl < 40 mL/min	320 mg LD, then 160 mg qd

<sup>a</sup>Trovafloxacin should only be used in hospitalized patients when the potential benefits are greater than the risks. See text.

Abbreviations: HD, hemodialysis; IV, intravenously; LD, loading dose; PO, per OS.

the quinolones, primarily at higher dosages. Allergic reactions occur in 1% to 2% of patients. Phototoxicity is a possible side effect with fluoroquinolone therapy. Although taking the medication at bedtime can reduce this effect, patients should remain indoors and away from ambient light while on this drug.

Maintaining adequate hydration and urine acidity will prevent crystalluria, an infrequent effect of the fluoroquinolones. Laboratory test abnormalities, including hematologic, hepatic, and renal function markers, occur at a rate of approximately 11.6%. Both hypoglycemia and hyperglycemia have been reported with all the quinolones.

Animal studies have shown that the fluoroquinolones have a propensity to cause toxicity to chondrocytes (103). Tendon rupture has also been described with many of the fluoroquinolones (104–116). Recent research indicates that oxidative stress is involved (103). There is an increased risk in the elderly, those on steroids, and those with renal failure (105). For this reason, fluoroquinolones should be avoided in the elderly when other options exist; and those who must take a fluoroquinolone should be advised to avoid heavy exercise. If a patient complains of tendon pain, fluoroquinolones should be discontinued unless there are very compelling indications for their use. Additionally, fluoroquinolones should not be prescribed for pregnant and breast-feeding women, and only used for specific indications for children. Trovafloxacin has also been found to cause rare but fatal cases of liver toxicity. Therefore the FDA has asked that it be reserved for short-term intravenous use for life-threatening infections in hospitalized patients.

In contrast to ciprofloxacin, the third- and fourth-generation quinolones do not seem to inhibit theophylline or caffeine metabolism. Although a modest increase in digoxin concentrations was noted in studies with gatifloxacin, no change in the renal elimination of digoxin was noted, therefore no dosage adjustments appear necessary for either drug (117).

QT<sub>c</sub> prolongation has been reported at a rate of less than 1% for nearly all the quinolones, but the manufacturer reports an incidence 1.3% for sparfloxacin. Torsades de pointes have been reported with all quinolones but seem to occur more frequently with levofloxacin, gatifloxacin, sparfloxacin, and moxifloxacin. The potential for QT<sub>c</sub> prolongation with sparfloxacin and moxifloxacin suggests concomitant Class IA and Class III anti-dysrhythmic drugs should be avoided (Volume 2, Chapter 20). Case reports with ciprofloxacin had noted increased levels of cyclosporine and decreased levels of phenytoin. Levels of these medications should be carefully monitored with ciprofloxacin administration.

### Therapeutic/Clinical Uses

All of the newer quinolones offer lower MICs against various streptococcal species, particularly *S. pneumoniae* although there are reports of *S. pneumococcus* resistance to levofloxacin (118). Compared with the newer entities, ciprofloxacin retains equal or better activity against enteric gram-negative rods (especially *P. aeruginosa*). As a result of their anaerobic activity, several of the fluoroquinolones may be useful in the treatment of both community-acquired and hospital-acquired aspiration pneumonia (119), although older agents of different classes still remain useful with more clinical experience. Trovafloxacin, gatifloxacin, and moxifloxacin have enhanced in vitro activity against anaerobes, a property not demonstrated by previous fluoroquinolones. Resistance

in anaerobic bacteria, most importantly of the *B. fragilis* group, is increasingly common. The newer agents appear to also have activity against atypical bacteria, such as *Legionella* spp. and *Mycoplasma pneumoniae*. The fluoroquinolones, especially moxifloxacin, gatifloxacin, and levofloxacin (in this order) are sometimes useful in the treatment of mycobacterial infections (120).

## TOPICAL ANTIMICROBIALS FOR BURN WOUNDS

### General Considerations

Burns impair the skin integrity, allowing infectious organisms to invade deeper tissues. Within hours of sustaining a burn, gram-positive organisms populate the wound. After several days, more virulent gram-negative organisms replace the gram-positive ones. The most commonly isolated gram-negative organisms include *P. aeruginosa*, *Proteus* spp., and *Klebsiella* spp (121). The gram-negative organisms have greater morbidity, possess many antibiotic resistance mechanisms, and have the ability to secrete collagenases, proteases, lipases, and elastases, enabling them to proliferate and penetrate into the subeschar space (122). If host defenses are inadequate, invasion of viable tissue occurs. Please refer to Volume 1, Chapter 34 and the following references for additional information about topical antimicrobials and burns (123–127).

Topical antimicrobials are applied after injury to limit bacterial colonization. Established infection requires use of topical agents that can penetrate the eschar to reduce microbial counts and to prevent systemic dissemination. Systemic agents are instituted for cellulitic wound infections, gram-positive suppurative infections, extensive fungal invasion, or systemic spread.

### Mafenide (Sulfamylon)

Mafenide was discovered by German scientists just before World War II but was not used clinically until the early 1960s after Robert Lindberg demonstrated its ability to control *P. aeruginosa* infections in a rat-burn model.

Mafenide is a topical sulfonamide formulated as an 11.1% suspension in a water-soluble cream base. It diffuses rapidly and freely into the eschar, and is detected in the systemic circulation. Mafenide is renally metabolized to an inactive salt. The salt itself constitutes a large osmotic load, promoting an osmotic diuresis. Mafenide is also metabolized to a carbonic anhydrase inhibitor that may result in a clinically significant metabolic acidosis.

Mafenide should be avoided in patients with renal impairment. Occlusive dressings should not be used, as the drug is usually applied every 12 hours, but it dissipates from the wound surface after approximately three hours (due to its excellent absorption), leaving up to nine hours of bacterial proliferation time on the wound surface. However, tissue levels remain adequate for 9 to 10 hours after application.

Mafenide has excellent bacteriostatic activity against most gram-positive species, including clostridia, but has limited activity against some *S. aureus*, particularly methicillin resistant strains. Mafenide is highly effective against gram-negative organisms, including *Pseudomonas* spp., but has minimal antifungal activity.

Pain or burning frequently occurs upon application to partial thickness burns. The pain is hypothesized to result from the hyperosmotic properties of the preparation, as well as some irritating quality of the drug itself. Hypersensitivity reactions may also occur in up to 50% of patients

treated with this agent (124), and rashes may mimic cellulitis (127).

Mafenide may still be the most useful agent for the treatment of invasive burns because of its superior eschar penetration, but careful monitoring of pulmonary function and acid-base status is critical.

### Silver Nitrate

Silver nitrate solutions had been used for centuries as an incompletely understood antiseptic. In 1965, Moyer (128) reintroduced topical use of silver nitrate to burn wound management where it is typically employed as a 0.5% solution. The precise mechanism of action is unknown, but ionic silver is known to exert bacteriostatic activity via several potential mechanisms.

Silver nitrate does not penetrate the burn eschar because silver chloride and other silver salts are highly insoluble and precipitate on the wound surface. Application with silver nitrate is relatively painless, but requires frequent nursing attention, as the dressing cannot be allowed to dry. The dressing must be rewetted every two to three hours with fresh 0.5% silver nitrate solution, otherwise the concentration of silver nitrate rises to caustic levels.

Silver nitrate is effective against most strains of *S. aureus* and coagulase-negative Staphylococci, and it also has activity against *P. aeruginosa*. It has less activity against other gram-negative species such as *Enterobacter* spp. and *Klebsiella* spp. An advantage of this compound is the infrequent emergence of silver-resistant bacteria.

Silver nitrate's insolubility requires it be prepared with distilled water. This results in a hypotonic compound. This hypotonicity causes electrolyte abnormalities as the silver removes electrolytes from the wound. Hyponatremia is the most common electrolyte disturbance. Hyponatremia can become significant, even fatal, when children with large burns are treated for long periods with silver nitrate and do not have their serum sodium monitored or replaced. Silver nitrate also stains everything it comes into contact with brown-black. Methemoglobinemia can occur with silver nitrate but is a rare complication, related to bacterial oxidation of nitrate to nitrite. The organism most often involved when patients have developed methemoglobinemia is, *Enterobacter cloacae*, as this organism efficiently metabolizes nitrate ( $\text{NO}_3^-$ ) to nitrite ( $\text{NO}_2^-$ ) and in so doing oxidizes the iron heme moiety hemoglobin from ferrous ( $\text{Fe}^{++}$ ) to ferric ( $\text{Fe}^{+++}$ ).

The vigilant nursing attention required with this compound, coupled with the fact that silver nitrate does not penetrate the eschar, means this compound should be avoided in very deep burns or in wounds where topical care has been delayed and the wounds are already heavily colonized. However, silver nitrate is attended with rapid debridement of the eschar, and less hypertrophic scar is seen than with other compounds.

### Silver Sulfadiazine (Silvadene)

Silver sulfadiazine (SSD) was formulated in 1967 by mixing the weakly acidic sulfadiazine with silver nitrate. It was initially thought that both the silver ion and sulfadiazine had antimicrobial properties; however more recent work suggests sulfadiazine is simply an effective means of delivering silver to the wound. Penetration of SSD into the wound is intermediate between the readily absorbed mafenide and minimally absorbed silver nitrate. Unlike mafenide, the application of SSD is painless. Its antibacterial activity

lasts up to 24 hours, but like most burn agents, it is often applied every 12 hours coupled with daily wound debridement.

SSD has bactericidal activity against many gram-positive and gram-negative bacteria, as well as yeast. SSD has excellent activity against *P. aeruginosa* and *S. aureus*. Generally, more organisms are resistant to SSD than mafenide. And although SSD-resistant strains of *P. aeruginosa* and enteric gram-negative rods have been reported, the incidence of infection with these resistant organisms is not increasing.

SSD is contraindicated for pregnant or breast feeding women because of the possibility of kernicterus in the infant. SSD should also be used with caution in patients with G6PD deficiency and renal insufficiency. This compound may induce leukopenia as a result of direct bone marrow suppression, but this generally resolves over 72 to 96 hours without discontinuing the medication with no concomitant increase in morbidity or mortality in studies. Hypersensitivity reactions are relatively uncommon with cutaneous reactions occurring in fewer than 5% of patients (124). SSD may cause sulfa crystal formation in the urine, but this is less of a problem when patients are adequately hydrated. Absorption of propylene glycol (the vehicle) has also been reported to cause problems in evaluating the patient's serum osmolality, as this causes an osmolar load. The effect of proteolytic enzymes (collagenase, papain, suti-lains) is reduced when used concomitantly with SSD. ⚡  
**SSD represents a compromise between the high efficacy of mafenide and the high maintenance of silver nitrate. It is therefore the most commonly employed topical antimicrobial agent in the burn patient, and frequently used as combination treatment (often alternating every 12 hours) with mafenide.** ⚡

## ANTI-MYCOBACTERIAL AGENTS

### General

⚡ Although many anti-TB agents are available, the most important drugs for therapy of critically ill patients are commonly known as "RIPE" which stands for: rifampin, isoniazid, pyrazinamide, and ethambutol (49,50). ⚡ Certain other antituberculosis agents also have an important role and include streptomycin and certain fluoroquinolone antibiotics (129,130). Linezolid also has antimycobacterial activity, but its expense precludes its frequent use. The first two agents of RIPE, namely, rifampin and isoniazid, a few of the fluoroquinolone antibiotics, and numerous aminoglycoside agents are available for parenteral administration. With the recent epidemic spread of TB in the United States and worldwide (131) and the fear of multi-drug resistant TB, critical care clinicians are likely to use these drugs with increasing frequency. The "gold standard" recommendations for the treatment of TB infections emanate from the American Thoracic Society and the Centers for Disease Control and Prevention (132–134).

### Treatment Recommendations

Treatment recommendations typically include isoniazid (INH), rifampin, pyrazinamide, and ethambutol (Table 11).

INH is the hydrazine of isonicotinic acid, and is bactericidal against replicating mycobacteria (including *M. tuberculosis*, and some atypical mycobacteria). It appears to work by inhibiting mycolic acid formation in the cell wall.

**Table 11** First-Line Anti-TB Medications, Dosage, and Adjustment for Renal and Hepatic Insufficiency

Anti-TB drug name	Dosage form	Standard dose	Dosing interval	Requires dose adjustment for renal insufficiency (CrCl <30 mL/min)	Requires dose adjustment for hepatic failure
INH	PO or IM	300 mg (5 mg/kg)	Every 24 hr	No	Yes
RIF	PO or IV	600 mg (10 mg/kg)	Every 24 hr	No	Yes
RFB	PO	300 mg (5 mg/kg)	Every 24 hr	No	Yes
PZA	PO	2000 mg (25 mg/kg)	Every 24 hr	Yes	Yes
EMB	PO	1000 mg (15–25 mg/kg)	Every 24 hr	Yes	No
SM	IM or IV	1000 mg (12–15 mg/kg)	Every 24 hr	Yes	No

*Abbreviations:* EMB, ethambutol; IM, intramuscular; INH, isoniazid; IV, intravenously; PO, per OS; PZA, pyrazinamide; RIF, rifampin; RFB, rifabutin; SM, streptomycin.

Approximately one in 10<sup>5</sup> TB organisms is genetically resistant (intrinsic resistance) to INH.

INH is well absorbed enterally, and therapeutic levels are obtained in all body tissues, including the CSF. The drug is acetylated and hydrolyzed and then excreted in the urine. Acetylation is genetically determined, and INH serum concentration is 50% to 80% lower in rapid acetylators than in slow acetylators.

INH-induced side effects develop in approximately 5% of patients and may include rash, peripheral neuritis, fever, hypersensitivity reactions (including an SLE-type reaction), and jaundice arthritis. Peripheral neuritis can be prevented with concurrent administration of pyridoxine (vitamin B<sub>6</sub>). Hepatic injury due to INH is the most common concern with its use. A mild increase in hepatic transaminases (ALT and AST two to three times the upper limit of normal) is common and does not predict more serious hepatic injury. The drug need not be stopped in these patients as long as they are monitored. In contrast, the drug should be discontinued immediately in patients with symptoms of hepatitis (nausea, malaise, anorexia, and jaundice) including those whose transaminases are above five times normal. The risk of hepatitis is increased in people who drink large quantities of alcohol and in patients with chronic hepatitis from other causes. Older patients are also at higher risk for both neuritis and hepatic damage, but isoniazid should not be withheld in the elderly if they have recent skin test conversion or active TB despite the hepatitis risk.

Rifampin is just as potent as isoniazid for TB. Rifampin is also active against many gram-positive and gram-negative organisms in addition to *M. tuberculosis* by inhibiting the bacterial DNA-dependent RNA polymerase, which suppresses the initiation of RNA chain synthesis. A single point mutation in the target enzyme is sufficient to confer resistance, and resistance occurs quickly when it is used as a single agent, therefore, the drug must be combined with other antibiotics.

Rifampin is well absorbed orally and distributes widely in body tissues, including the CSF. Rifampin is metabolized in the liver by active deacetylation and is ultimately excreted via the bile in the gastrointestinal tract. Adverse effects due to rifampin occur in about 4% of patients and include fever, rash, jaundice, GI upset, and hypersensitivity reactions.

Rifampin increases the metabolism of numerous drugs, including some B-blockers, corticosteroids, oral contraceptives, warfarin, some oral hypoglycemics, some antiarrhythmics, various immunosuppressants (cyclosporine,

tacrolimus, sirolimus), clarithromycin, triazole antifungals, protease inhibitors, methadone, theophylline, and phenytoin (135). Reduced drug levels may cause serious problems unless the affected drug dose is appropriately adjusted. Conversely, caution must be exercised when discontinuing rifampin therapy to avoid supratherapeutic and/or toxic effects. Rifabutin can be used as an alternative to rifampin. It can be given less frequently and has fewer drug interactions than rifampin.

Rifaximin, an analog of rifampin, was recently approved by the FDA for traveler's diarrhea. Of note, it is devoid of *M. tuberculosis* activity. In the ICU, rifaximin (400 mg orally three times daily) has been used enterally in place of neomycin for hepatic encephalopathy (134). Both neomycin and rifaximin are minimally absorbed enterally, and both inhibit the urease-producing bacteria responsible for intestinal ammonia production. Neomycin can cause ototoxic and nephrotoxic effects, especially if used over several months. Rifaximin is not approved in the US for this indication; however, it is increasingly employed to protect against hepatic encephalopathy because it is not associated with either renal toxicity or ototoxicity (136).

Pyrazinamide is an analog of nicotinamide and is well absorbed orally, and penetrates tissues throughout the body (129). Pyrazinamide is a pro-drug and is metabolized to pyranizic acid, which is bactericidal against intracellular replicating organisms. The exact mechanism of action is unknown; pyrazinamide is hydrolyzed by the liver and is excreted primarily by renal glomerular filtration. Hepatotoxicity is the most common side effect and has been reported in approximately 15% of patients who received 40 to 50 mg/kg/day, a regimen used previously. With current dosages of 15 to 30 mg/kg/day, pyrazinamide toxicity is substantially lessened. The drug can also cause hepatitis, arthralgias, and nausea.

Ethambutol is an orally active compound with excellent tuberculostatic activity. The drug widely distributes throughout the body, including the CSF. Approximately 50% of the dose is excreted unchanged in the urine. Optic neuritis occurs rarely with the standard dose of 15 mg/kg/day. Patients should be tested for visual acuity and green color perception before and periodically during ethambutol therapy. If a dosage of more than 15 mg/kg/day adjusted for renal function is used, tests should be conducted monthly. Other adverse effects are rare.

Streptomycin is an aminoglycoside antibiotic long used to treat tuberculosis, and is tuberculocidal. Vestibular toxicity, auditory toxicity, and to a lesser degree than the

**Table 12** Clinically Significant Fungi and Their Antimicrobial Drugs of Choice

Microorganism	Drug of choice <sup>a</sup>	Alternative agents

<sup>a</sup>Amphotericin lipid formulations are less toxic.

<sup>b</sup>An echinocandin = anidulafungin, caspofungin, micafungin.

other aminoglycosides, nephrotoxicity has been reported with streptomycin use. Amikacin is sometimes used in place of streptomycin to treat tuberculosis.

Various fluoroquinolones, namely, moxifloxacin, gatifloxacin, and levofloxacin, have been used as second line therapy in the treatment of tuberculosis in combination with other antituberculosis agents, but their efficacy for the treatment of tuberculosis is not entirely clear (101).

## ANTIFUNGALS

### History/Description

Introduced in 1960. Amphotericin B was the first clinically useful anti-fungal agent for the treatment of systemic fungal infections. Subsequently, lipid-based preparations of amphotericin B (with diminished toxicities) has made therapy safer. Additionally, the introduction of agents with different mechanisms of action (i.e., 5-flucytosine, miconazole, voriconazole, and the echinocandins), have increased the ability to treat serious fungal infections (137–140). The major fungi responsible for human disease and their antifungal drugs are summarized in Table 12.

### Mechanism of Action, Pharmacology, Administration, and Dosage

Amphotericin B and all of the lipid-based preparations bind to ergosterol, an essential component of the fungal cell wall, with the resultant membrane permeability leading to cell death. Nystatin is in the same class of antifungal drugs as amphotericin but is not given systemically and is used

primarily topically (e.g., swish and swallow) and for oral and esophageal candidiasis. Table 13 shows the characteristics of various amphotericin B formulations. Liposomal amphotericin B is better tolerated than other formulations of amphotericin B (141). The azoles, including the triazoles, inhibit the fungal cytochrome P450 enzymes responsible for the conversion of lanosterol to ergosterol, an essential compound for fungal replication and the target upon which amphotericin acts. Table 14 compares the various azole agents. Refer to Tables 13 and 14 for dosing guidelines of the various preparations of amphotericin and the azoles, respectively.

Caspofungin, the first licensed drug in the class of echinocandins, inhibits cell wall synthesis by acting upon the beta-1,3 glucan synthase (142). Some fungi have cell wall glucans, which are glucose polymers akin to cellulose in plant cell walls; other fungi have chitin, which is a polymer of glucosamine. Echinocandins are not active against fungi that have chitin in the cell wall; this property restricts the range of fungi that can be targets for this class of drug.

Caspofungin, only available in a parenteral formulation, is given as a loading dose of 70 mg/kg, followed by 50 mg per day with dose adjustment for hepatic insufficiency. Caspofungin can cause some hepatic toxicity with elevation of liver enzymes and bilirubin. There is no dosage adjustment for renal insufficiency; safety data shows that it can be used in patients with mild to moderate hepatic disease (Child-Pugh class B), but its safety in patients with severe liver disease is untested (143). The FDA approved a second echinocandin drug, micafungin, for the

**Table 13** Characteristics of Various Amphotericin Formulation Preparations

Characteristic	Amphotericin B deoxycholate	Amphotericin B cholesteryl sulfate	Amphotericin B lipid complex	Liposomal Amphotericin B
Brand name	Fungizone <sup>®</sup>	Amphotec <sup>®</sup>	Abelcet <sup>®</sup>	AmBisome <sup>®</sup>

<sup>a</sup>Penetration into CSF does not always correlate with clinical efficacy in meningitis.

Abbreviations: CSF, cerebrospinal fluid; IV, intravenously; PO, per OS.

use in treating esophageal candidiasis and febrile neutropenia in recipients of hematologic stem cell transplants. It has not received approval yet for invasive candidiasis or invasive aspergillosis. However, its mechanism of action and its in vitro spectrum of activity are identical to those of caspofungin, so it will probably be used for these purposes (144). Another echinocandin, anidulafungin, anidulafungin, the third FDA approved echinocandin; it has the same spectrum of activity and mechanism of action as caspofungin (145). Neither micafungin or anidulafungin requires dose adjustments for end stage renal disease or end stage liver disease, including Child-Pugh “Class C” disease.

Flucytosine inhibits the formation of fungal RNA and DNA. Inside fungal cells, 5-FC is converted to 5-fluorouracil, which interferes with pyrimidine metabolism and decreases the pool of precursors for incorporation into DNA and RNA, thereby inhibiting DNA replication and fungal cell multiplication. 5-FC is readily bioavailable when given orally. It distributes widely to body tissues, including the central nervous system. It is not metabolized by humans and is excreted unchanged in the urine, so it must be used cautiously in patients with renal insufficiency. Levels must be monitored so that steady state levels are from 25 to 100 mcg/mL to avoid toxicity.

### Antimicrobial Activity/Spectrum/Resistance

Amphotericin B remains the reference standard by which all anti-fungal agents are measured because it has the broadest spectrum, and has been available for the longest period of time. Amphotericin B has activity against most fungi and yeasts; however, several organisms that are not usually pathogens in the ICU display intrinsic resistance, including *Cladosporium* spp. and *Fonsecaea* spp., and it has variable activity against *Fusarium* spp., *Scedosporium* spp. and *Sporothrix schenckii*. Alternative anti-fungals for these organisms include voriconazole in most cases, or sometimes flucytosine (which should not be used as a single agent). Because of these resistance patterns in these relatively unusual molds, it is increasingly important that complete identification of clinically important fungi and yeasts be performed. Some *Candida albicans* have developed resistance to fluconazole, some have unpredictable resistance patterns (*C. glabrata*), and certain non-albicans *Candida* are intrinsically resistant to the fluconazole (such as *C. krusei*).

Itraconazole is effective against *Candida* spp. Additionally, it has activity against *Aspergillus* spp. and some of the organisms that cause endemic mycoses, such as *Coccidioides immitis* and *Histoplasma capsulatum*. Its major drawback is poor bioavailability; the capsules do not dissolve in the

absence of gastric acid, and the drug is poorly absorbed. The suspension is well-absorbed, but it is unpalatable.

Voriconazole is effective against most strains of fluconazole-resistant *C. albicans* and *C. glabrata*. In contrast to the other azoles, it is fungicidal for *Aspergillus*, *Scedosporium*, and *Fusarium*, although it has poor activity against *Zygomycetes* (which includes mucor), where amphotericin B remains the drug of choice (146). The efficacy and safety of voriconazole in the treatment of acute invasive aspergillosis was recently reviewed by Denning et al. (147) Voriconazole was recently shown to have better responses and improved survival against invasive aspergillosis, and have fewer severe side effects than the standard therapy of amphotericin B (148). In addition, an oral formulation of voriconazole is available with excellent oral bioavailability, making itraconazole and voriconazole the only oral agents with activity against *Aspergillus* sp.

Posaconazole is a new triazole drug that has received FDA approval for treatment of candida infections and for prophylaxis of invasive fungal infections, specifically in the setting of cancer chemotherapy and transplantation (149). Posaconazole is promising because it has activity against the *zygomycetes*, which are the cause of invasive mucormycosis (150). One potential disadvantage to the use of posaconazole is that there is no intravenous formulation. It does come as a suspension and may be given orally or down a nasogastric tube. Ravuconazole is another triazole in phase III testing (151). It also has activity against *Candida* and *Aspergillus*; it is not as active against *zygomycetes* as posaconazole. They both may be useful for treating fungi that are resistant to some of the older azole drugs.

Caspofungin is only clinically effective for infections due to *Aspergillus* spp. and *Candida* spp. Caspofungin has been shown to be at least as effective as amphotericin B for the treatment of invasive candidiasis, and candidemia (152). It is also as effective as liposomal amphotericin in the treatment of aspergillosis and has fewer side effects. Caspofungin is not active against *Cryptococcus* spp. (142,143), despite the fact that this organism has a polyglucan cell wall; the large capsule that surrounds the *Cryptococcus* sterically prevents the drug from reaching its site of action.

### Adverse Effects and Drug Interactions

#### Amphotericin

Amphotericin B has immediate (infusion-related toxicities) and delayed nephrotoxic effects. Infusion-related toxicities include fever, chills, rigors, myalgia, malaise, nausea, and vomiting. Pre-medication with acetaminophen, diphenhydramine, and low-dose meperidine (for rigors) may mitigate

these responses. Hypotension, bradycardia, and ventricular dysrhythmias may also occur and are related to the infusion rate of amphotericin. All of the amphotericin preparations can cause these infusion-related adverse effects; however, they tend to be less frequent and less severe with the lipid preparations than with the deoxycholate formulation (140). The major delayed adverse effects of amphotericin B involve the kidney, and these can become permanent. These effects include nephrotoxicity, electrolyte abnormalities (especially hypokalemia and hypomagnesemia), and renal tubular acidosis. Amphotericin B deoxycholate is more nephrotoxic than the other lipid-based preparations of amphotericin B; however, these other agents still exhibit dose and time-dependent nephrotoxicity. Co-administration of corticosteroids or ACTH can exacerbate hypokalemia. Anemia is sometimes seen, and bone marrow toxicity of ganciclovir is exacerbated by amphotericin B. Finally, probenecid may increase the plasma levels of amphotericin B.

### Azoles

The most common side effects for all of the azoles include anorexia, nausea, and vomiting. Other side effects include rash, headache, and potential hepatotoxicity (especially with ketoconazole). The azoles should be used with caution, in patients on medications metabolized via the CP450 system, due to their numerous clinically significant interactions (153). Unique adverse effects from specific azoles include: diminished testosterone and cortisol levels with ketoconazole; mineralocorticoid excess with itraconazole (less so with ketoconazole); cardiac dysrhythmias with itraconazole; and transient, reversible visual changes (seen only with voriconazole).

### Echinocandins

Caspofungin is generally well tolerated with minimal side effects. Caspofungin interacts with cyclosporine (increasing the risk of liver toxicity), and tacrolimus (increasing clearance, thereby decreasing available tacrolimus). Minor dosage adjustments are necessary with these drugs and are outlined in the package insert. Micafungin and anidulafungin have none of the above listed drug interactions. Anidulafungin must be reconstituted in alcohol for infusion and, therefore, risks inducing a disulfiram-like reaction if given to a patient also receiving metronidazole; administration of anidulafungin also required a larger volume (up to 500mL) for infusion, which may present a problem for fluid management in an ICU patient.

### Therapeutic/Clinical Uses

The choice of anti-fungal therapy may be complex due to the numerous anti-fungal agents with different mechanisms of action, spectrum of activity, various adverse effects, and the paucity of comparative studies. ⚡ **Amphotericin B remains the reference standard by which all anti-fungals are measured. For fungi known to be resistant, other agents including the azoles and echinocandins may be considered in the treatment of systemic infections (154).** ⚡ The option of treating with enteral antifungals has also been recently recognized with agents that have excellent oral bioavailability (fluconazole, itraconazole suspension, and voriconazole).

The newer liposomal preparations of amphotericin B are significantly more expensive than amphotericin B deoxycholate but are also less toxic. Caspofungin and micafungin are similar in expense to liposomal amphotericin B. The

**Table 15** Antimicrobial Drugs of Choice Against Selected Viruses (Tables 16–18)

Microorganisms	Drug of Choice	Alternative agents
Cytomegalovirus	Ganciclovir	Foscarnet, cidofovir, valganciclovir
Herpes simplex	Acyclovir	Ganciclovir, foscarnet, valganciclovir, famciclovir
Herpes zoster	Acyclovir	Foscarnet, penciclovir, famciclovir, valganciclovir
Influenza	Oseltamavir, rimantidine	Zanamavir, amantadine

enterally effective azoles are much less expensive alternatives via that route. Therefore, the choice of antifungal agent(s) must take into account the specific mold or yeast suspected or proven, local epidemiologic patterns (especially non-albicans *Candida* spp. infection), severity of illness, ability to take oral medication, toxicities, allergies, drug–drug interactions, and cost.

Guidelines for the treatment of *Aspergillus* infections have recently been reviewed (155,156), and practice guidelines for the treatment of *Candida* infections have also been published (157,158).

There are no prospective RCTs available that describe the use of putatively synergistic combinations of antifungals although these treatment strategies appear reasonable based upon the respective mechanisms of action. For instance, the combination of an azole, like voriconazole, with caspofungin make intuitive sense since the azoles inhibit ergosterol synthesis and caspofungin works on the cell wall, which are separate biochemical pathways. In a similar vein, the combination of caspofungin and amphotericin formulations would appear to be a useful combination. The use of multiple anti-fungal agents has been used anecdotally in case reports and case series (159,160). However, azoles should not be used together with amphotericin B because they are antagonistic.

## ANTIVIRALS

Antiviral agents will be discussed in terms of viral infections that are commonly seen in the critical care unit (Table 15). Antiretroviral agents, used for patients infected with the human immunodeficiency virus (HIV), will not be discussed, but the interested reader may refer to recently published treatment guidelines (161–163). Antimicrobials useful for the prophylaxis of opportunistic infections in patients with HIV infection were recently reviewed (164).

⚡ **Currently there are more than a dozen antiviral drugs commercially available in the US for the treatment and/or prophylaxis of viral infections. Most of these drugs function as nucleoside analogs and can be conveniently divided into drugs useful for herpes virus infections, influenza infection (165), hepatitis viruses (166), and miscellaneous viral infections.** ⚡ Several recent reviews of antiviral drugs are noted (167–169).

### Herpes Virus Antivirals

The most common viral infections seen in the ICU are due to one or more of the herpes viruses that include herpes simplex virus (HSV) (Table 16), Varicella-zoster virus

**Table 16** Antiviral Agents for Herpes Simplex Virus Infections

Viral infection	Drug	Route	Usual dosage
Genital herpes <sup>a</sup>	Acyclovir	PO or IV	400 mg tid for 5–10 days
	Famciclovir	PO	250 mg tid for 7–10 days
	Valacyclovir	PO	1 g bid for 10 days
Herpes encephalitis	Acyclovir	IV	10 mg/kg every 8 hr in 1-h infusion for 14–21 days
Mucocutaneous disease in immunocompromised hosts	Acyclovir	IV	5 mg/kg every 8 hr for 7–14 days
		PO	400 mg five times daily for 7–14 days
	Ganciclovir	IV	5 mg/kg every 8–12 hr for 7 days
	Famciclovir	PO	500 mg bid for 7 days
Orolabial herpes	Penciclovir 1%	Topical	q2 hr while awake for 4 days
Keratoconjunctivitis <sup>b</sup>	Trifluridine 1%	Topical—solution	One drop, every 2 hr up to 9 drops/day
	Vidarabine 3%	Topical—ointment	1/2 inch ribbon five times daily

<sup>a</sup>In acyclovir-resistant in HSV or VZV infections, IV foscarnet 40 mg/kg every 8 hr appears beneficial.

<sup>b</sup>Treatment of HSV ocular infections should be supervised by an ophthalmologist.

Abbreviations: HSV, herpes simplex virus; IV, intravenously; PO, per OS; VZV, varicella–zoster virus.

**Table 17** Antiviral Agents for Varicella–Zoster Virus Infections<sup>a</sup>

Viral infection	Drug	Route	Usual dosage
Varicella in normal adults	Acyclovir	PO	20 mg/kg up to 800 mg qid for 5 days
Varicella in immunocompromised hosts	Acyclovir	IV	500 mg every 8 hr for 7–10 days
Zoster in normal hosts	Acyclovir	PO	800 mg five times daily for 7–10 days
	Valacyclovir	PO	1 g tid for 7 days
	Famciclovir	PO	500 mg tid for 7 days
Zoster in immunocompromised hosts	Acyclovir	IV	10 mg/kg every 8 hr in 1-hr infusion for 7 days

<sup>a</sup>In acyclovir-resistant in HSV or VZV infections, IV foscarnet 40 mg/kg every 8 hr appears beneficial.

Abbreviations: HSV, herpes simplex virus; IV, intravenously; PO, per OS; VZV, varicella–zoster virus.

(VZV) (Table 17), (reviewed in Gnann) (170) and cytomegalovirus (CMV) (Table 18). There are a variety of antivirals available for the treatment and/or prophylaxis of the various herpes virus infections.

Acyclovir, the first orally available anti-herpes drug, is a nucleoside analog and is available in both enteral and parenteral forms. Because of its poor oral bioavailability, a unique pro-drug, a covalent conjugate of valine and acyclovir, has been developed into the pro-drug valacyclovir (the pro-drug). Valacyclovir is converted to acyclovir by a host enzyme in the intestinal mucosa, leading to improved bioavailability of acyclovir. Similarly, famciclovir, which is available only in an oral preparation, is a pro-drug of penciclovir.

Famciclovir has essentially the same spectrum of activity as acyclovir but with improved oral bioavailability.

Ganciclovir differs only slightly from acyclovir structurally and, in addition to the herpes virus spectrum of acyclovir, also is active against CMV. An oral preparation of ganciclovir is available; however, its poor oral bioavailability recently led to the development of valganciclovir, an orally available pro-drug of ganciclovir, which is metabolized in the same manner as valacyclovir.

Foscarnet is an analog of inorganic pyrophosphate and complexes with DNA polymerase, thereby inhibiting viral DNA synthesis. This agent is useful against all of the herpes viruses, including CMV. Its clinical use is not

**Table 18** Antiviral Agents for CMV Infections

Viral infection	Drug	Route	Usual starting dosage
CMV retinitis	Ganciclovir	IV	5 mg/kg every 12 hr in 1-hr infusion for 14–21 days
	Ganciclovir	Oral	1000 mg every 8 hr for 21 days
	Valganciclovir	Oral	900 mg every 12 hr for 21 days
	Cidofovir	IV	5 mg/kg weekly for two doses
	Formivirsen	Intravitreal	330 µg every 2 weeks
	Foscarnet	IV	60 mg/kg every 8 hr in 1–2 hr infusion for 14–21 days
CMV pneumonia	Ganciclovir	IV	5 mg/kg every 12 hr in 1-hr infusion + IV immunoglobulin for 14–21 days (in BMT patients)

Abbreviations: BMT, bone marrow transplant; CMV, cytomegalovirus; IV, intravenously.

**Table 19** Antiviral Agents for Hepatitis B and C Infections

Viral infection	Drug	Route	Usual dosage
Chronic hepatitis B	Interferon- $\alpha$	SC	10 MU three times weekly or 5 MU daily
	Lamivudine	PO	100 mg/day
	Adefovir	PO	10 mg/day
	Entecavir	PO	0.5–1 mg/day
Chronic hepatitis C	Peginterferon alfa-2a $\pm$ Ribavirin	SC PO	180 mcg weekly 800–1200 mg/day depending on weight and genotype
	Pegylated interferon alfa-2b $\pm$ Ribavirin	SC PO	1.0–1.5 mcg/kg weekly 800–1200 mg/day depending on weight and genotype
	Interferon alfa-2a	SC/IM	3 MU three times weekly
	Interferon alfa-2b	SC/IM	3 MU three times weekly
	Interferon alfacon-1	SC	9 mcg three times weekly

Abbreviations: IM, intramuscular; PO, per OS; SC, subcutaneously.

popular, however, because of its toxicities (nephrotoxicity and electrolyte abnormalities), and it is generally reserved for mainly for acyclovir-resistant HSV and CMV infections.

Cidofovir is a phosphonate nucleotide analog that is available intravenously for the treatment of cytomegalovirus infection. It is only useful intravenously. Its use is complicated by nephrotoxicity and renal tubular acidosis, and it is generally reserved for patients who have failed or have a contraindication to ganciclovir. Dosing guidelines for drugs used to treat HSV and CMV infections are shown in Tables 16 to 18.

### Hepatitis B and C Antivirals

Hepatitis B and C are notable causes of chronic hepatitis and cirrhosis. Treatment for acute hepatitis is generally supportive in nature. Many patients in an ICU setting having liver disease and antiviral treatment for hepatitis B and C are discussed in this context. Ribavirin is a guanosine analog that inhibits ribonucleoprotein synthesis, is active against many RNA viruses, including infections caused by hepatitis C virus (especially in combination with interferon), and hemorrhagic fever viruses. Its major toxicity is anemia that can be clinically quite significant. Lamivudine (3TC) is a nucleoside that is useful for both HIV infection and hepatitis B virus infection. Adefovir, which was originally used for HIV but taken off the market due to nephrotoxicity at higher doses, can be used in much lower doses to treat hepatitis B. Tenofovir, a congener of adefovir, can also be used for

**Table 20** Antiviral Agents for Treatment of Influenza Virus Infections<sup>a</sup>

Viral infection	Drug	Route	Usual dosage
Influenza A or B virus	Oseltamivir	PO	75 mg bid for 5 days
	Zanamivir	Aerosol	10 mg bid by inhaler for 5 days
Influenza A virus	Amantadine	PO	100 mg bid for 5 days for treatment
	Rimantadine	PO	200 mg/day for 5 days for treatment

<sup>a</sup>Different doses used for prophylaxis.

Abbreviation: PO, per OS.

both hepatitis B and HIV. Interferon-alpha and polyethylene glycol-conjugated forms of interferon are also used as antivirals for infections caused by hepatitis B and hepatitis C infections. They are generally poorly tolerated, must be given parenterally (subcutaneously), must be taken over a long period of time, and frequently cause a flu-like syndrome. Treatment of hepatitis B and C are reviewed elsewhere (171–174). Refer to Table 19 for antiviral drug useful in the treatment of Hepatitis B and Hepatitis C infections.

### Influenza Antivirals

Influenza, (and its sequelae) is the major cause of respiratory failure in and outside of the US. Influenza vaccines, which are manufactured annually, according to which subtypes are judged to be the most likely epidemic strains, can prevent a large majority of the cases of severe illness. There are also several drugs that are available for the prophylaxis and treatment of influenza virus infections. Two of the older drugs, amantadine and rimantadine are oral agents that inhibit the replication of only influenza A virus but not influenza B virus. Two newer agents inhibit the replication of both influenza A and B viruses: oral oseltamivir (Tamiflu<sup>®</sup>) and inhaled zanamivir (Relenza<sup>®</sup>). Please refer to Table 20 for dosing guidelines recommendations.

### IMMUNOMODULATORS: ACTIVATED PROTEIN C History/Description

Despite advances in critical care, the rate of death from severe sepsis still ranges from 30% to 50%. Though all the mechanisms of sepsis have yet to be elucidated, our understanding of this complex condition has greatly increased in the past decade (Volume 2, Chapter 47). This has led to the development of compounds that interrupt the detrimental inflammatory and coagulation process involved in sepsis. One such development is drotrecogin alfa (Xigris<sup>®</sup>), a recombinant version of natural human plasma-derived activated protein C (APC). Several studies have reviewed this agent (175–177). Kox (178) recently reviewed other immunomodulator agents for sepsis and two reviews of the treatment of sepsis were recently published by Wheeler (179) and Healy (180) and will not be discussed further. Refer also to Volume 2, Chapter 47 for a discussion on sepsis and Volume 2, Chapter 63 for a review of SIRS.

## Mechanism of Action, Pharmacology, Administration, and Dosage

The antithrombotic effects of APC are mediated by inactivation of clotting factors Va and VIIIa. APC also increases fibrinolytic activity by inhibiting plasminogen-activator inhibitor 1 (PAI-1), which increases endogenous tissue-plasminogen activator (t-PA). In vitro data suggests that APC exerts anti-inflammatory effects by inhibiting the production of the inflammatory cytokines TNF- $\alpha$ , interleukin-1 (IL-1), and interleukin-6 (IL-6) by monocytes and by limiting the rolling of monocytes and neutrophils along injured endothelium.

The average half-life after a 24 mcg/kg/hour infusion of APC is 1.2 hours. This is five times longer than the average half-life of native APC. APC is metabolized and inactivated by endogenous plasma protease inhibitors. There is a linear relationship between APC concentrations and activated partial thromboplastin time (aPTT) response in healthy patients. To date, no patients with sepsis have been re-administered APC. Antibodies to the recombinant APC (drotrecogin alfa) have been detected in two patients during phase II and III trials. One of the patients with neutralizing antibodies developed superficial and deep vein thrombi and died of multi-organ failure.

The dosage of APC is 24 mcg/kg/hour infused intravenously for 96 hours. The drug must be infused within 24 hours from the time of reconstitution or preparation. Patients with end-stage renal disease were excluded from phase III studies. However, in six non-septic ESRD patients, APC was not cleared by dialysis, and patients had clearance rate similar to patients without ESRD.

## Adverse Effects and Drug Interactions

The most common adverse event associated with APC is bleeding, which is consistent with the drug's antithrombotic activity. Bleeding occurred in 25% of treated patients and 18% of placebo-treated patients in the Efficacy and Safety of Recombinant Human Activated Protein C for Severe Sepsis (PROWESS) trial. However, the frequency of serious bleeding with APC was only 3.5%, compared to 2.0% in the placebo-treated patients, but this difference was not clinically or statistically ( $P = 0.06$ ) significant (177). Serious bleeding tended to occur mostly during the infusion period and in patients with predisposing conditions such as gastrointestinal ulceration, traumatic injury to a blood vessel, highly vascular organ injury, or markedly abnormal coagulation values. Relatively uncommon side effects found in phase I trials included headache, ecchymoses, diarrhea, and pain at the site of injection.

Because the major adverse effect of APC is bleeding, concomitant administrations of medications that also increase the risk of bleeding are relatively contraindicated. These medications include the use of unfractionated heparin at  $>15,000$  units/day within eight hours of drug infusion; LMWH at any dose higher or more frequent than recommended by their package inserts within 12 hours of drug administration; warfarin if used within seven days of APC infusion or warfarin-type medications within  $<5$  half-lives at the time of drug administration and the PT  $>13.3$  seconds, and/or INR  $> 3.0$ ; antiplatelet drugs (ticlopidine or clopidogrel) or ASA  $>650$  mg/day or compounds that contain ASA  $>650$  mg/day within seven days prior to drug administration; thrombolytic therapy (unless used to treat an intra-catheter thrombosis) within three days of drug administration (e.g., streptokinase, tPA, rPA, and

urokinase); glycoprotein IIb/IIIa antagonists (abciximab, eptifibatid, tirofiban) within seven days of drug administration; antithrombin infusion of  $>10,000$  units received within 12 hours of drug administration; and protein C concentrate infusion within 24 hours of drug administration.

## Therapeutic/Clinical Uses

♣ The PROWESS study demonstrated a statistically significant decrease in 30-day mortality in septic patients treated with APC. ♣ However, safety and economic concerns have led to the development of strict usage criteria for APC at most institutions. There are absolute and relative contraindications to the use of APC. Absolute contraindications are active bleeding, epidural anesthesia, intracranial hemorrhage, retroperitoneal bleeding, and recent major surgery. Relative contraindications include those patient populations excluded from the PROWESS trial and for which no data exist. These relative contraindications include pregnant or breastfeeding mothers, platelet count  $<30,000/\text{mm}^3$ , and age  $<18$  years. The cost of a complete course of APC therapy is approximately \$7,000 to \$10,000.

## EYE TO THE FUTURE

Microbes are developing resistance to a number of previously efficacious antimicrobials. Accordingly, new modalities are being explored and developed to combat microbial pathogens. New vaccines targeted at nosocomial pathogens are being assessed that may lead to infection prevention in this patient population (181,182). Antibiotics specifically designed with activity against emerging resistant organisms are currently under investigation (183). Antibacterial agents in development showing clinical promise include fluoroquinolones (184–186), ketolides (187,188), oxazolidinones (189–193), everninomycins (194), carbapenems (195–198), glycopeptides (199–201), and glycylicylines (202–203). Likewise, many new and novel antifungal (204–208) and antiviral (209–213) agents are in clinical development.

A potentially helpful addition to preventing staphylococcal infections has emerged recently with the use of a vaccine (StaphVAX<sup>®</sup>) for the prevention of *S. aureus* infections in chronic dialysis patients, a group of patients who are susceptible to repeated line associated infections (214). The vaccine consists of a mixture of type 5 and type 8 capsular polysaccharides conjugated to a carrier protein, and immunization of dialysis patients decreased *S. aureus* infections by 64% at 32 weeks post immunization as compared to controls. Unfortunately, immunity wanes within a year, so annual vaccinations are necessary. Future vaccines might contain more serotypes. Further, it remains an open question as to whether the protection seen in patients with chronic renal failure can be extended to other sets of patients.

Better insight into the understanding of septic shock will bring us additional agents targeted to alter the natural history of this most feared complication of infection (215–219). In addition, many immunomodulatory therapies are being investigated for severe sepsis and septic shock (220,221). To date, more than 70 phase II and phase III RCTs have been performed evaluating the potential role of adjuvant mediator-targeted therapy in patients with sepsis. A great deal has been learned from these investigations and the future of sepsis research holds not only the prospect of fundamental new insights into the interaction of the host, the environment, and medical intervention in disease

pathogenesis, but also the possibility that a major cause of global morbidity and mortality can be successfully confronted (222).

Adjunctive immune therapy using immunomodulatory therapies and combination antifungal therapy are being explored to help combat the ever-increasing spectra of encountered fungal infections (223–229). Resolution of invasive fungal infections is dependant on host defenses. Clinical trials utilizing granulocyte colony-stimulating factor and interferon products are currently underway that will hopefully establish whether immunotherapy is of clinical value in the treatment of invasive fungal infections (229).

Newly discovered antimicrobial peptides (AMPs) are being studied to help overcome bacterial resistance that

currently hampers our ability to treat many hospital-acquired infections (230–232). AMPs have a broad antimicrobial spectrum and lyse microbial cells by interaction with biomembranes. They also have multiple roles as mediators of inflammation that can influence diverse processes such as cell proliferation, immune induction, wound healing, cytokine release, chemotaxis, and protease-antiprotease relationship. Studies are currently ongoing investigating the biology of AMPs that will hopefully determine their place in therapeutics for infectious and inflammatory diseases (231).

In addition, exciting research is currently underway investigating the newly discovered Type III secretion systems common to several important bacteria and may prove to be a beneficial new target for combating these

**Table 21** Antibiotic Guidelines for Trauma Patients

Site/diagnosis	Potential organisms	Primary therapy	Alternative therapy
Aspiration pneumonia during traumatic event	Oral flora	Clindamycin or third-generation cephalosporin <sup>a</sup>	Fluoroquinolone + clindamycin or metronidazole
Closed head injury with ventriculostomy	<i>Staphylococcus aureus</i> , coagulase-negative staphylococci	Need for prophylaxis controversial	Oxacillin <sup>b</sup> or cefazolin or vancomycin
Open head injury	<i>S. aureus</i> , GNR	Ceftriaxone + oxacillin <sup>b</sup>	Vancomycin
Post-brain injury abscess	<i>S. aureus</i> , GNR (including <i>Pseudomonas</i> ), anaerobes	Ceftazidime + metronidazole + oxacillin <sup>b</sup>	Meropenem + vancomycin
Blunt chest trauma	n/a	Antibiotics not recommended	n/a
Chest tube prophylaxis	n/a	Antibiotics not recommended	n/a
Blunt abdominal trauma			
Without visceral penetration	n/a	Antibiotics not recommended	n/a
With visceral penetration	Enteric GNR, enterococcus	Ampicillin + third-generation cephalosporin <sup>a</sup> + metronidazole	Vancomycin + fluorquinolone or aminoglycoside <sup>c</sup> + metronidazole or carbapenem or piperacillin/tazobactam
If gastric rupture involvement	<i>Candida albicans</i>	Fluconazole	Voriconazole or caspofungin or amphotericin B
Gunshot wound abdomen	GNR, anaerobes, enterococcus	Ampicillin + third-generation cephalosporin or fluoroquinolone + metronidazole	Vancomycin or piperacillin/tazobactam or carbapenem ± aminoglycoside <sup>c</sup> + metronidazole
Biliary trauma	GNR, enterococci, anaerobes (less often)	Ampicillin or piperacillin + an aminoglycoside <sup>c</sup>	Add metronidazole if initial therapy is unsuccessful
Renal trauma			
Nicked ureter	n/a	Antibiotics not recommended	n/a
Nicked kidney	Follow urine cultures and treat accordingly	n/a	n/a
Orthopedic			
Grade I	<i>S. aureus</i>	Cephalosporin <sup>b,d</sup>	Oxacillin or vancomycin
Grade II	<i>S. aureus</i>	Cephalosporin <sup>b,d</sup> + aminoglycoside <sup>c</sup>	Oxacillin or vancomycin + an aminoglycoside <sup>c</sup>
Grade III	<i>S. aureus</i> ; GNR; possible anaerobes	Cephalosporin <sup>b,d</sup> + an aminoglycoside <sup>c</sup> ± metronidazole or clindamycin	Vancomycin + an aminoglycoside <sup>c</sup> ± metronidazole or clindamycin
Acute burns			
Topical	<i>S. aureus</i>	Topical sulfadiazine or sulfamylon	Nitrofurazone
Inhalational	n/a	Antibiotics not recommended	n/a

<sup>a</sup>Cefotaxime, ceftriaxone, ceftazidime.

<sup>b</sup>Vancomycin if methicillin-resistant *S. aureus* is common.

<sup>c</sup>Gentamicin, tobramycin, amikacin.

<sup>d</sup>First-generation cephalosporin (cefazolin, cephalothin).

Abbreviation: GNR, gram-negative rods.

pathogenic bacteria. In the 1980s and 1990s researchers studying *Yersinia* (the causative agent of bubonic plague) discovered that these organisms utilized a syringe-like injection system to deliver virulence factors inside the mammalian host cell (233). These have since been called Type III secretion systems, and significant homology exists across several species of pathogenic gram-negative organisms (including *Yersinia*, *E. coli*, *P. aeruginosa*, *B. pertussis*, *Salmonella*, *Shigella*, as well as *Chlamydia* spp, and various plant and fish pathogens) (234). Further study of these flagella-like structures likely be a source of anti-infective therapy in the not so distant future (235).

Finally, the field of pharmacogenomics is a rapidly emerging discipline of interest in medicine and pharmaceutical research and development. Pharmacogenomics may have considerable and significant impact on infectious disease therapy, including antibiotic therapy. The last few

years have witnessed an enormous increase in genomic-related technologies as they apply to antibacterial therapies (237). Pharmacogenomics has the potential to revolutionize the prevention, diagnosis, and treatment of infectious diseases (238–245).

## SUMMARY

Many patients with severe illness or conditions like multiple trauma and severe burns are susceptible to infection due to their depressed immune function. The goal of antimicrobial therapy is to prevent an infection from developing or to treat an existing infection. In this chapter we have reviewed a multitude of antimicrobials, including antibacterials, antifungals, and antivirals, that are currently available to the clinician for utilization in preventing or treating infections

**Table 22** Empiric Antibiotic Therapy for the Critically Ill Intensive Care Unit Patient

Anatomic site/ diagnosis	Potential organism	Primary therapy	Alternative therapy
Blood/bacteremia — line associated— endocarditis	<i>Staphylococcus aureus</i> coagulase-negative- staphylococci GNR	Oxacillin <sup>a</sup> or nafcillin <sup>a</sup> + an aminoglycoside <sup>b</sup> (if enterococcus is suspected, add ampicillin)	Vancomycin or cephalosporin <sup>d</sup> + an aminoglycoside <sup>b</sup>
		A third-generation cephalo- sporin <sup>c</sup> + aminoglycoside <sup>b</sup>	Imipenem or meropenem or piperacillin/tazobactam or azteonam or fluorquinolone + aminoglycoside <sup>b</sup>
CNS/meningitis	<i>Streptococcus</i> <i>pneumoniae</i> <i>Neisseria meningitidis</i> GNR, <i>S. aureus</i>	Ceftriaxone + vancomycin <sup>e</sup>	Imipenem or meropenem
		Penicillin Oxacillin <sup>a</sup> or nafcillin <sup>a</sup> + ceftriaxone + an aminoglycoside <sup>b</sup> or use ceftazidime in place of ceftriaxone if <i>Pseudomonas</i> suspected	Ceftriaxone or imipenem Vancomycin + ceftriaxone + an aminoglycoside <sup>b</sup>
Intracranial/acute abscess	<i>S. aureus</i>	Oxacillin <sup>a</sup> or nafcillin <sup>a</sup> + an aminoglycoside <sup>b</sup>	Vancomycin
	Anaerobes (commonly subacute)	Add metronidazole	Chloramphenicol
Lungs/pneumonia	<i>S. aureus</i>	Oxacillin <sup>a</sup> or nafcillin <sup>a</sup>	Cephalosporin <sup>d</sup> or vancomycin or linezolid
	GNR, oral anaerobes	Third-generation cephalosporin <sup>c</sup> + metronidazole	Fluoroquinolone or imipenem or piperacillin (+clindamycin) or piperacillin/tazobactam + an aminoglycoside <sup>b</sup>
Abdomen/peritonitis, abscess	GNR, anaerobes, enterococci	Ampicillin or piperacillin + metronidazole + an aminoglycoside <sup>b</sup> (if <i>Pseudomonas</i> )	Vancomycin in place of penicillin + metronidazole + an aminoglycoside <sup>b</sup> or third-generation cephalosporin <sup>c</sup> ; imipenem or piperacillin/tazobactam
Abdomen/biliary tract	GNR, enterococci, anaerobes (occur late and in the elderly)	Ampicillin or piperacillin + an aminoglycoside <sup>b</sup>	Add metronidazole if initial therapy is unsuccessful
Pelvis/PID	GNR/anaerobes	Gentamicin and clindamycin	Cefoxitin and doxycycline
Urinary tract/ pyelonephritis	GNR, enterococci	Ampicillin or vancomycin + an aminoglycoside <sup>b</sup>	Third-generation cephalosporin (with ampicillin or vancomycin if entero- coccus suspected)

<sup>a</sup>Vancomycin if methicillin-resistant *S. aureus* common.

<sup>b</sup>Gentamicin, tobramycin, amikacin.

<sup>c</sup>Cefotaxime, ceftriaxone, ceftazidime.

<sup>d</sup>First-generation cephalosporin (cefazolin, cephalothin).

<sup>e</sup>In areas with high incidence of penicillin-resistant *S. pneumoniae*, vancomycin should be added.

Abbreviations: GNR, gram-negative rods; PID, pelvic inflammatory disease.

in critically ill patients. In addition, we have highlighted many areas currently being investigated with the quest of identifying additional agents to assist in the control of antibiotic-resistant bacteria and opportunistic infections.

Antibiotic use should be planned deliberately from the time of admission in hospitalized patients. Prophylactic antibiotic use should be restricted to a specific diagnosis and exceptional conditions. The antibiotic choice should be determined based on prevailing, institution-specific bacterial resistance patterns. Only through judicious antimicrobial use can prevention of the development of multi-resistant pathogens be realized. The choice of antimicrobial agent must be influenced by a clinician's familiarity with the available drugs. Empiric guidelines for Trauma patients are provided in Table 21, and those for critically ill patients of trauma, surgical, or medical origin are shown in Table 22.

## ACKNOWLEDGMENTS

The authors wish to dedicate this chapter to their colleague, Lee Rickman, who tragically died during the preparation of this manuscript. We also wish to recognize his immense contributions to patient care in San Diego, infectious disease education around the world, and to his insightful and enthusiastic assistance with this chapter prior to his passing.

## KEY POINTS

- ✎ Antimicrobial selection for trauma and critical care is based on the following seven considerations: (i) whether the antibiotics are planned for prophylaxis or treatment of an established infection; (ii) the anatomic site of infection; (iii) whether the infection is community-acquired or nosocomial; (iv) best guess of the most probable causative microorganism (based upon geographical and institutional isolate profiles); (v) the patient's innate immunological status; (vi) the severity of the infection and general condition of the patient; and (vii) financial cost.
- ✎ A primary tenet of antimicrobial therapy is to use the narrowest spectrum antibiotic possible, rather than a broad-spectrum agent.
- ✎ As Ignaz Phillip Semmelweis discovered 150 years ago, the most important means of preventing the transmission of micro-organisms from one patient (via the doctor or nurse) to another patient is strict hand washing (and now, the use of clean disposable gloves).
- ✎ At present, the majority of infections in hospitalized trauma patients are due to gram-positive organisms (19) for example, MRSA and VRE and to a lesser extent, multi-resistant gram-negative rods (20).
- ✎ Penetrating intra-abdominal injury, perforated abdominal viscera, and open fractures, all warrant antibiotic prophylaxis (22–25).
- ✎ The addition of a beta-lactamase inhibitor to beta-lactam antibiotics produces efficacy against beta-lactamase producing organisms, such as *S. aureus*, *E. coli* and most anaerobic bacteria. However, these combo products add no additional activity against *Pseudomonas aeruginosa* and have no activity against MRSA.
- ✎ In general, as one selects a second, third or fourth generation cephalosporin, there is increased activity against aerobic gram-negative bacteria and less activity against gram-positive organisms.
- ✎ The cephamams, specifically cefoxitin and cefotetan, have unique broad-spectrum activity against most anaerobic organisms (except there are increasing resistant forms of *B. fragilis*).
- ✎ Aztreonam is devoid of antibacterial activity against gram-positive and anaerobic bacteria.
- ✎ Carbapenems are the class of antibiotics with the greatest spectrum activity of any class of antibiotics for systemic use in humans. They are active against gram-positive (except MRSA), gram-negative, and anaerobic bacteria. These agents (except ertapenem) are particularly useful for hospital-acquired infections where bacterial resistance (other than MRSA and VRE) may be a concern.
- ✎ Patients with a history of penicillin allergy due to rash or pruritus only occurring more than three days after administration are no more likely to have any allergic reaction to a cephalosporin than patients without a history of penicillin allergy, and can safely receive cephalosporins.
- ✎ There is up to a 50% chance of developing a rash to carbapenems in patients with a history of rash to penicillins.
- ✎ Aztreonam is considered a safe alternative in patients allergic to penicillins or cephalosporins requiring gram-negative coverage, and vancomycin is the recommended choice for those patients requiring gram-positive coverage.
- ✎ All aminoglycosides are nephrotoxic and ototoxic and can prolong the duration of neuromuscular blockade drugs.
- ✎ Tetracycline has a broad spectrum of antimicrobial activity including gram-positive, gram-negative, and anaerobic bacteria, as well as rickettsias, mycoplasma, chlamydias, protozoa, actinomycetes, and certain viruses.
- ✎ Azithromycin has an extremely long intracellular dwell time, permitting once daily (or less often) dosing.
- ✎ Because of its gram-positive and anaerobic coverage, clindamycin is useful (with combination gram-negative therapy) for necrotizing fasciitis, most oral and vaginal anaerobic infections, and diabetic foot infections, which tend to be polymicrobial and virulent.
- ✎ Metronidazole is indicated for the treatment of serious polymicrobial infections involving anaerobes (e.g., necrotizing fasciitis and infections involving contamination from the GI tract). Importantly, other agents with aerobic gram-positive and gram-negative coverage must be coadministered.
- ✎ *Bacteroides fragilis* is probably the most frequently encountered clinically significant anaerobe and metronidazole should be considered the drug of choice, especially in intra-abdominal infections (57).
- ✎ The greatest utility of quinupristin/dalfopristin, daptomycin, and linezolid is in the management of patients with VRE or MRSA infections for which limited alternatives exist.
- ✎ Vancomycin is most often used parenterally to treat MRSA, empirically in life-threatening infections, and orally for *C. difficile* colitis.
- ✎ TMP/SMX may be extremely useful in severe infections caused by susceptible organisms in the critically ill patient, especially those infections caused by *Enterobacter* sp., and other gram-negative rods that may be multi-resistant to beta-lactam drugs.
- ✎ Quinolone antibiotics, similar to the cephalosporins, are traditionally categorized into first to fourth generations based upon spectrum of activity. In general, the second, third, and fourth generations have enhanced

gram-positive cocci activity (except ciprofloxacin) and gram-negative rod activity. Excellent anaerobic activity is seen with trovafloxacin and moxifloxacin.

✂ SSD represents a compromise between the high efficacy of mafenide and the high maintenance of silver nitrate. It is therefore the most commonly employed topical antimicrobial agent in the burn patient, and frequently used as combination treatment (often alternating every 12 hours) with mafenide.

✂ Although many anti-TB agents are available, the most important drugs for therapy of critically ill patients are commonly known as "RIPE" which stands for: rifampin, isoniazid, pyrazinamide, and ethambutol (49,50).

✂ Amphotericin B remains the reference standard by which all anti-fungals are measured. For fungi known to be resistant, other agents including the azoles and echinocandins may be considered in the treatment of systemic infections (151).

✂ Currently there are more than a dozen antiviral drugs commercially available in the United States for the treatment and/or prophylaxis of viral infections. Most of these drugs function as nucleoside analogs and can be conveniently divided into drugs useful for herpesvirus infections, influenza infection (162) hepatitis viruses (163), and miscellaneous viral infections.

✂ The PROWESS study demonstrated a statistically significant decrease in 30-day mortality in septic patients treated with APC.

### INTRODUCTION

✎ **Anemia is common in the intensive care unit (ICU), and blood transfusions are often used to treat anemia in critical care.** ✎ Anemia in the critically ill can result from trauma, surgical intervention, occult gastrointestinal (GI) bleeding, repeated phlebotomy for diagnostic testing, and chronic diseases. Critically ill patients often have impaired erythropoiesis due to blunted endogenous erythropoietin (EPO) production, direct inhibition from inflammatory cytokines and certain drugs, or nutritional deficiencies (iron, folate, vitamin B<sub>12</sub>). Shortened red cell life span can result from consumptive problems, such as disseminated intravascular coagulation (DIC).

This chapter reviews the definition and diagnosis as well as the classification of anemia in specific patient populations (including trauma and critical illness). In addition, the normal physiologic adaptation to anemia and its impact on patient outcome is reviewed. Finally, strategies for preventing and treating anemia are discussed.

### DEFINITION OF ANEMIA

Anemia can be defined technically as a hemoglobin (Hb) concentration below the normal laboratory range. The World Health Organization (WHO) defines anemia as a Hb concentration <12 g/dL (women) and <13 g/dL (men). Hemoglobin concentration is determined by hemoglobin mass and plasma volume (1). ✎ **Low Hb concentration typically accompanies a decreased red blood cell (RBC) count and a decrease in packed cell volume, although these indices may be normal in an anemic patient with low Hb levels alone.** ✎

Age influences “normal” Hb concentrations. An evaluation of 420,000 healthy Swedes found significant age-related decline in Hb from age 70 to 88, particularly among men (2). In addition, Hb levels considered “optimal” in a stable condition are not necessarily adequate or “normal” in pathologic conditions (e.g., heart failure), or in certain environments (i.e., high altitude).

### DIAGNOSIS OF ANEMIA

#### Clinical Signs and Symptoms

✎ **Symptoms are dictated by the etiology, severity, and chronicity of the anemia.** ✎ Weakness, fatigue, and lethargy

are common. Cardiac symptoms include palpitations, angina pectoris, or dyspnea. Patients may complain of headaches and visual disturbances.

Signs of anemia include pallor, tachypnea, dyspnea, tachycardia, a “thready” pulse, and confusion, perhaps indicating cardiac failure. Alternatively, bounding pulse and systolic flow murmur can signify chronic anemia. Signs of specific causes of anemia may be evidence, for example, koilonychia with iron (Fe) deficiency.

#### Laboratory Diagnosis

✎ **Evaluation of red cell indices is the most clinically relevant measurement tool.** ✎ Mean corpuscular volume (MCV) is a measure of the average size of the RBC. Mean corpuscular hemoglobin (MCH) is a measure of the amount of Hb per RBC. Both the MCV and the MCH are used to classify anemia as microcytic/hypochromic, normocytic/normochromic, or macrocytic. Concomitant leukopenia and thrombocytopenia indicates pancytopenia, suggesting bone marrow disease or cell sequestration (hypersplenism) or hemodilution. Granulocytosis and thrombocytosis often occur after significant hemorrhage (as occurs with trauma), and with hemolysis.

The reticulocyte count can assist in the diagnosis of anemia. The normal reticulocyte count is 0.5 to 2.5% with an absolute count of 25 to 125 × 10<sup>9</sup>/L. The reticulocyte count should rise in anemia due to EPO increase; the more severe the anemia, the greater the usual increase in a reticulocyte count. Thus, a relatively low reticulocyte count suggests bone marrow dysfunction and/or impaired EPO response.

The reticulocyte count directly reflects effective bone marrow erythrocyte production, while the proportion of circulating macroreticulocytes (red cells with high RNA content) reflects the intensity of EPO stimulation (3). This tool may differentiate between bone marrow erythrocyte production and intensity of EPO stimulation. In states of chronic hemolysis, the bone marrow demonstrates erythroid hyperplasia accounting for increased EPO and rapid increases in reticulocyte count. This is in contrast to the slower response that occurs after trauma and major hemorrhage. After significant hemorrhage, in a patient with no previous hematological disease, the marrow demonstrates an EPO response in approximately six hours. The reticulocyte count begins to increase in two to three days, maximizes in 6 to 10 days and remains elevated until the Hb level returns to normal.

Blood smear examination is helpful for the diagnosis of anemia. Besides assessing red cell morphology and presence of inclusions, white cell and platelet abnormalities also provide useful information.

Examination of the bone marrow aspirate can assess normoblastic versus megaloblastic erythropoiesis, and quantitate proportions of different cell lines (myeloid:erythroid ratio) and iron stores. Bone marrow biopsy reveals architecture, cellularity, and presence of fibrosis or malignant cells.

In ICU settings, measurement of Hb (g/dL) or hematocrit (Hct, %) are the red cell indices most utilized, with typical causes of anemia being acute hemorrhage (after trauma or surgery) or anemia of chronic illness (prolonged ICU stay). A reduction in plasma volume, as seen in dehydration or acute hemorrhage, can mask anemia until normal plasma volume is restored. Dehydration can even cause hemoconcentration (pseudo-polycythemia), with normal total red cell volume. This is particularly common following major burns, and differs from acute hemorrhage wherein proportional losses of blood volume and Hb occur.

✎ **Laboratory evaluation of nutritional deficiencies that cause anemia should also be considered.** ✎ A recent study of 184 ICU patients found 13% to have potential deficiencies, including iron (9%), vitamin B<sub>12</sub> (2%), and folate (2%) (4). However, as serum iron and total iron binding capacity (TIBC) levels were low, and serum ferritin levels high, iron deficiency was not necessarily present.

The laboratory diagnosis of iron deficiency can be made by multiple criteria: saturation of transferrin (TrfS) ≤15%, hypochromic erythrocytes ≥10%, and a serum ferritin concentration ≤50 µg/L. A high plasma transferrin receptor (sTfR) concentration is useful in distinguishing iron deficiency anemia from anemia of chronic disease (ACD) (5).

The ratio of sTfR to serum ferritin (R/F ratio) is used to estimate body Fe stores, and can be used to evaluate the degree to which Fe deficiency complicates the anemia of critical illness. High levels of sTfR, and R/F ratios above 500 are generally correlated with deficiency of tissue iron storage (6). The R/F ratio is not influenced by the use of recombinant human EPO (rHuEPO). However, inflammatory conditions and the use of parenteral Fe supplementation may interfere with this metabolic relationship (7). Recent studies have suggested that erythrocyte zinc protoporphyrin may be a superior test for assessment of iron deficiency in critically ill and injured patients (8). In iron deficiency, zinc protoporphyrin (ZPP) is produced instead of heme, and the ZPP concentration in erythrocytes is increased (normal ≤40 µmol/mol heme) (9).

✎ **The endogenous hormone erythropoietin is critical for the normal bone marrow response to anemia.** ✎ EPO synthesis is increased in states of anemia, when Hb is unable to release oxygen appropriately, when oxygen levels are low, or when there is low cardiac output. Increased severity of anemia typically results in higher plasma EPO concentrations (inverse correlation between plasma EPO and Hb concentrations). Plasma concentrations of EPO assess the individual response to anemia. Endogenous EPO deficiency is a fundamental factor in the pathophysiology of the anemia of critical illness (10).

## ANEMIA CLASSIFICATIONS

### Microcytic/Hypochromic

Microcytic/hypochromic anemia is characterized by a decrease in MCV, MCH, and mean corpuscular hemoglobin

concentration (MCHC). Red cells are small (microcytic) and pale (hypochromic) due to reduced Hb synthesis. The most common etiology world-wide is Fe deficiency, with chronic inflammation or malignancy ("chronic disease") and thalassemia also important causes.

Iron deficiency is caused by chronic blood loss, increased demand, malabsorption or poor diet. In developed countries, the most common cause is chronic blood loss, usually from the uterus or GI tract, whereas in developing countries, dietary deficiency predominates. Fe deficiency due to increased Fe demand usually occurs during times of growth (childhood and adolescence), pregnancy, lactation, or menses.

Critically ill patients can have microcytic/hypochromic anemia, but the platelet count is often increased, especially following hemorrhage (see Volume 2, Chapter 55). The blood film may demonstrate target cells and poikilocytes alongside the small, poorly-hemoglobinized red cells. In a patient with recent iron therapy or blood transfusion, macrocytic cells can coexist together with microcytic cells.

Serum ferritin levels reflect tissue Fe stores. Ferritin is low in Fe deficiency anemia, whereas elevated levels are seen in Fe overload, following excessive tissue damage, during the acute phase response, and in ACD. Low serum Fe and elevated TIBC are characteristic of Fe deficiency anemia, whereas both are low in ACD.

### Normocytic/Normochromic

Normocytic/normochromic anemia is characterized by an MCV 80 to 95 fl, and MCH >26 pg/cell. Causes include acute hemorrhage, renal disease, hemolysis, and bone marrow failure (e.g., hypoplasia, post-chemotherapy, infiltration by carcinoma).

### Macrocytic

Macrocytic anemias are so named because of the large RBC size, that is, an MCV >95 fl. These anemias are further classified as megaloblastic or non-megaloblastic.

Megaloblastic anemias are characterized by abnormal erythroblasts ("megaloblasts") in the bone marrow. Nuclear chromatin appears open and "lace-like." Normal Hb formation progresses in the cytoplasm, whereas nuclear maturation is delayed due to abnormal DNA synthesis. The macrocytes are oval and the bone marrow is hypercellular. Giant megamyelocytes ("giant bands") are also characteristic. Increased unconjugated bilirubin and lactate dehydrogenase reflect increased turnover of RBCs and Hb within the marrow. Megaloblastic anemia is most often caused by vitamin B<sub>12</sub> or folate deficiency, with rare explanations including congenital abnormalities of vitamin B<sub>12</sub> or folate metabolism.

Vitamin B<sub>12</sub> deficiency can occur in adults due to pernicious anemia (most common), GI bacterial overgrowth, or loss of ileal function. Pernicious anemia is impaired vitamin B<sub>12</sub> absorption due to loss of intrinsic factor activity. Intrinsic factor is a glycoprotein secreted by the gastric parietal cells. It then binds dietary vitamin B<sub>12</sub>, facilitating its uptake by cells located in the terminal ileum. Common causes of pernicious anemia in surgical or critically ill patients include partial or total gastrectomy, intestinal blind loop syndrome, ileal resection, and Crohn's disease. Dietary deficiency of vitamin B<sub>12</sub> is rare; it typically takes two years to deplete body stores in the absence of dietary intake.

Elevated homocysteine levels (potential vascular risk factor) are associated with low folate, vitamin B<sub>12</sub>, and

vitamin B<sub>6</sub> levels. Prophylactic vitamin administration should be considered in hyperhomocysteinemic patients, although benefits remain to be established.

Non-megaloblastic macrocytic anemias can be caused by liver disease, excess alcohol ingestion (even in the absence of liver disease), myxoedema, primary marrow disorders (aplasia, myelodysplasia, myeloproliferative disorders), pregnancy, and ingestion of certain drugs, notably phenytoin and azathioprine.

## EPIDEMIOLOGY OF ANEMIA IN TRAUMA AND CRITICAL CARE

Anemia is a common diagnosis following trauma and during critical illness and results in a large burden of patients requiring blood transfusion. **It is important to understand the epidemiology of anemia in trauma and critical care in order to appreciate the large number of patients that require treatment for anemia.**

Two recent large multicenter prospective observational studies have examined the prevalence of anemia in the ICU: the Anemia and Blood Transfusion in Critical Care (ABC) trial (11) (Europe) and the CRIT study (12) (U.S.A.). The ABC trial included 3534 patients from 146 ICUs. The mean Hb concentration at ICU admission was  $11.3 \pm 2.3$  g/dL (29% of patients had level  $<10$  g/dL). Overall, 37.0% were transfused, with differences among specific subgroups, for example, emergency surgery (57.5%), trauma (48%), elective surgery (42.1%), and medical (32%). Older patients and those with longer length of stay (LOS) were more often transfused. Of patients with ICU stays beyond seven days, 73% were transfused. The overall mean pretransfusion Hb was  $8.4 \pm 1.3$  g/dL.

The CRIT study enrolled 4892 patients from 284 ICUs (12). Its goal was to quantify the incidence of anemia and RBC transfusion in critically ill patients and to examine the relationship of anemia and RBC transfusion to clinical outcomes. Mean baseline Hb concentration on admission to the ICU was  $11.0 \pm 2.4$  g/dL, and mean Hb decreased to  $9.8 \pm 1.4$  g/dL by the end of the study ( $P < 0.0045$ ). Of patients evaluated, 44% were transfused (mean  $4.6 \pm 4.9$  units) during their ICU stay. Patients with an ICU LOS stay

of seven days or longer were more commonly transfused (63.0%) than patients with shorter stays (33.4%;  $P < 0.0001$ ). Mean pretransfusion Hb was  $8.6 \pm 1.7$  g/dL.

A Canadian multicenter cohort study examined RBC transfusion in 5298 consecutive patients admitted to six tertiary level ICUs (13). One-quarter of the patients received red cell transfusions, with the number of transfusions per patient-day averaging  $0.95 \pm 1.39$  (range  $0.82 \pm 1.69$  to  $1.08 \pm 1.27$  between institutions;  $P < 0.001$ ). Independent predictors of pre-transfusion Hb thresholds included patient age, admission Acute Physiology and Chronic Health Evaluation (APACHE) II score, and the institution ( $P < 0.0001$ ). The most frequent reasons for administering red cells were acute bleeding (35%) and to augment oxygen delivery (25%). This study documented significant institutional variation in ICU transfusion practice, with many intensivists adhering to a 10 g/dL threshold despite contrary published guidelines.

Another prospective observational study assessing transfusion practice in critically ill patients in the UK found that 53% of 1247 consecutive patients received RBC transfusions (14). Transfused patients had higher mortality but they also had higher APACHE II scores and longer durations of stay. The average pre-transfusion Hb concentration was below 9 g/dL in 75% of transfusion episodes. The common indications for transfusion were low Hb (72%) and hemorrhage (25%).

Table 1 reveals common features of these studies examining anemia and transfusion practice in the ICU among different countries. First, the most critically ill patients have anemia at ICU admission. Second, the transfusion trigger is a Hb of approximately 8.5 g/dL. Third, RBC transfusion rates increase with greater LOS stay and increased patient age. Finally, the most common indication for RBC transfusion was the treatment of anemia.

## ANEMIA IN SPECIFIC TRAUMA AND CRITICALLY ILL POPULATIONS

### Anemia Due to Acute Hemorrhage

Anemia is common in critically injured trauma patients. A post hoc analysis of a subset of trauma patients ( $n = 576$ ) from the CRIT study documented a high incidence of

**Table 1** Results of Epidemiologic Studies on Anemia and Blood Transfusions in Critical Care

	ABC Trial [2] (western Europe)	CRIT Study [3] (U.S.A.)	TRICC Investigators [9] (Canada)	North Thames Blood Interest Group [5] (U.K.)
<i>n</i>	3534	4892	5298	1247
Mean admission hemoglobin (g/dL)	$11.3 \pm 2.3$	$11.0 \pm 2.4$	$9.9 \pm 2.2$	—
Percentage of patients transfused in ICU	37%	44.1%	25%	53.4%
Mean transfusions per patient (units)	$4.8 \pm 5.2$	$4.6 \pm 4.9$	$4.6 \pm 6.7$	$5.7 \pm 5.2$
Mean pretransfusion hemoglobin (g/dL)	$8.4 \pm 1.3$	$8.6 \pm 1.7$	$8.6 \pm 1.3$	$8.5 \pm 1.4$
Mean ICU length of stay (days)	4.5	$7.4 \pm 7.3$	$4.8 \pm 12.6$	—

anemia (15). Mean baseline Hb was  $11.1 \pm 2.4$  g/dL and patients remained anemic throughout the study, with or without transfusion (Fig. 1). Transfusions (mean,  $5.8 \pm 5.5$  units) were given to 55.4% of patients (43.8% had an ICU LOS  $\geq 7$  days). Mean pre-transfusion Hb was  $8.9 \pm 1.8$  g/dL. However, blood transfusion was also common in patients with a Hb greater than 10 g/dL (Fig. 2). Compared with the full study population, trauma patients were more likely to be transfused (55.4% vs. 44%) and received an average of one additional unit of blood.

Severe trauma is associated with major blood loss leading to progressive anemia during fluid resuscitation.

**Figure 2** Intensive care unit transfusion rates by baseline hemoglobin levels in trauma patients ( $n = 576$ ). Note that a large number of transfusions (in over 50% of trauma patients) were administered when the hemoglobin concentration was  $> 10$  g/dL. \*The difference is significant at  $P < 0.01$  (Bonferroni adjustment) compared with the first baseline hemoglobin group. †The difference is significant at  $P < 0.01$  (Bonferroni adjustment) compared with the previous baseline hemoglobin group. ♂ An acute normocytic, normochromic anemia is associated with systemic blood loss. ♂ The degree of anemia correlates directly with the volume of blood lost. Besides their anemia resulting from early blood loss, trauma victims regularly exhibit persisting low red cell counts and low Hb levels during their ICU stay, without necessarily having ongoing bleeding.

♂ In trauma, hemorrhagic shock and tissue injury also result in an acute inflammatory response, and the anemia associated with inflammation (or critical illness) rapidly ensues. ♂ This was shown in a study of 23 patients with severe trauma (injury severity score  $\geq 30$ ) (16). Hb levels were low on admission (mean, 10.0 g/dL; range, 6.8–12.9 g/dL) and did not increase to day 9. Serum EPO levels were low (mean 49.8 U/L) on post-injury day 1 and did not show significant increase thereafter. In contrast, acute blood loss in healthy individuals and in animal models leads within minutes to an increase in serum EPO; these increased levels persist for at least one to two days, stimulating erythropoiesis.

The normal inverse correlation between EPO and Hb concentrations was missing in these trauma patients (Fig. 3). Possible explanations for the inadequate EPO response in trauma includes inflammatory mediators that inhibit EPO (17), such as the cytokines IL-1 $\alpha$ , IL-1 $\beta$ , and TNF- $\alpha$ , which suppress EPO gene expression and production. Table 2 shows the time course of proinflammatory cytokines following severe trauma. IL-6 levels are high at admission, and do not decrease thereafter. Neopterin, a marker for the activation of the cellular immune system known to suppress EPO production, increased 4.3-fold. Furthermore, neopterin stimulates the release of nitric oxide (suppressor of EPO production) by the activation of inducible nitric oxide synthase. Thus, the inadequate EPO response to anemia in severe trauma may result from the systemic inflammatory response resulting from trauma and its effects on inhibiting EPO production.

Anemia in trauma patients is also characterized by disturbed iron homeostasis (Table 3). During the

**Figure 3** Semilogarithmic presentation of the exponential increase in serum erythropoietin with the degree of anemia as shown by the hemoglobin concentration in 63 subjects (normal persons and patients with primary hemopoietic disorders; triangles) and the missing correlation in the 23 multiple traumatized patients (black dots; pooled data for all collection times). Abbreviations: EPO, erythropoietin; hb, hemoglobin. Source: From Ref. 17.

**Figure 4** Reduced erythropoietin concentrations in critically ill patients. Box and whisker plot of erythropoietin (EPO) concentrations against time for all patients. Hollow circles indicate outliers (cases with values of the variable between 1.5 and 3 times the length of the corresponding box for that day and group); filled circles indicate extreme values (cases with values greater than three times the corresponding box for that day and group). *Abbreviation:* ARF, acute renal failure. *Source:* From Ref. 10.

inflammatory response, iron is incorporated into the storage protein, ferritin, resulting in low serum Fe concentrations. Serum Fe decreases on day two post-trauma, and remains low, as do transferrin levels (17). Serum ferritin is already elevated on admission and remains so until at least day nine. Proinflammatory cytokines enhance iron uptake by the reticuloendothelial system via enhanced transferrin-receptor expression and stimulate the transcription of ferritin, thus causing hypoferrremia. Thus, this study shows that anemia in severe trauma results from the interplay of bleeding, blunted EPO response to low Hb levels, proinflammatory mediators, and a resulting hypoferrremic state. Anemia in trauma patients thus shares a common pathophysiology with anemia of chronic inflammatory disease.

A recent study examined bone marrow and hematopoietic function in trauma patients (18). The mean Hb concentration and reticulocyte counts of the trauma patients were  $8.6 \pm 1.0$  g/dL and  $2.75 \pm 0.7\%$ , respectively. Bone marrow aspirates and peripheral blood were obtained between day 1 and 7 following injury from 45 multiple trauma patients. Normal volunteers served as controls. Peripheral blood and bone marrow were cultured for various types of hematopoietic progenitor cells. Bone marrow progenitor cells were reduced, whereas peripheral blood progenitor cells were increased in the trauma patients, compared with controls. Bone marrow stroma failed to grow to confluence by day 14 in  $>90\%$  of trauma patients (confluent growth was always observed in controls). This study thus identified profound changes in bone marrow function after traumatic injury.

### Anemia of Critical Illness

Several factors contribute to anemia in the ICU, including pre-existing anemia, blood loss (e.g., GI bleeding), repeated phlebotomy for diagnostic tests, reduced RBC life span, impaired Fe/vitamin B<sub>12</sub>/folate availability, organ dysfunction (renal,

**Table 2** Time Course of Proinflammatory Cytokines, Cytokine Receptor Antagonists, and Neopterin After Severe Trauma

	Day 1	Day 2	Day 4	Day 6	Day 9	P Value
TNF- $\alpha$ , pg/mL [ $<10$ ]	18 (2–59)	17 (0–40)	18 (0–64)	29 (3–172)	25 (6–86)	NS
sTNF-rI, pg/mL [750–2000]	2979 (260–6000)	3201 (710–6700)	4518 (247–29,000)	6564 (589–51,000)	6882 (1496–5100)	0.003
IL-1-ra, pg/mL [106–1550]	3825 (355–10000)	3023 (233–9500)	2534 (329–9400)	3275 (633–9100)	3250 (267–9100)	NS
IL-6, pg/mL [ $<6$ ]	913 (34–3500)	969 (22–3200)	390 (10–2400)	452 (65–2300)	344 (67–2310)	NS
Neopterin, nmol/L [ $<10$ ]	6.0 (2.2–20.9)	10.1 (3.8–24.5)	12.7 (4.7–33)	22.2 (5–119)	25.5 (5.7–120)	$<0.001$

Data are given as mean values and range, respectively. Normal values are shown in square brackets. The P value indicates the time dependence of the measured parameters as analyzed by means of an analysis of variance for repeated measures. A P value  $< 0.05$  was considered statistically significant. Blood was collected within 12 hours after trauma and in the morning on days 2, 4, 6, and 9 after admission to the intensive care unit. Changes in TNF- $\alpha$ , sTNF-rI, IL-1-ra, and IL-6 are presented in *Table 2*. TNF  $\alpha$  was detectable in all trauma patients at admission, but it did not show significant alterations. In contrast to TNF  $\alpha$ , its soluble receptor sTNF-rI increased significantly 2.3-fold until day 9. On day 1, IL-1-ra was above normal and did not change further. IL-6 was very high at admission and remained high thereafter. Serum neopterin was low after admission, but it increased significantly until day 9.

*Abbreviations:* TNF- $\alpha$ , tumor necrosis factor- $\alpha$ ; sTNF-rI, soluble tumor necrosis factor receptor I; IL-1-ra, interleukin 1-receptor antagonist; IL-6, interleukin 6. *Source:* From Ref. 17.

**Table 3** Variables of Iron Status During the First Nine Days After Severe Trauma

	Day 1	Day 2	Day 4	Day 6	Day 9	P Value
s-Fe, $\mu\text{mol/L}$ [9.5–30]	9.5 (1.6–22.9)	3.9 (0.5–18.1)	3.4 (1.1–16.9)	4.0 (1.4–16.8)	5.0 (2.3–16)	0.0043
Transferrin, mg/dL [200–360]	166 (87–268)	166 (114–242)	155 (102–245)	162 (110–243)	161 (96–219)	NS
Ferritin, $\mu\text{g/L}$ [20–300]	832 (76–3137)	547 (143–2035)	466 (251–1054)	530 (368–1261)	842 (406–2931)	NS

Data are given as mean values and range, respectively. Normal values are shown in square brackets. The P value indicates the time dependence of the measured parameters as analyzed by means of an analysis of variance for repeated measures. A P value <0.05 was considered statistically significant. Blood was collected within 12 hours after trauma and in the morning on days 2, 4, 6, and 9 after admission to the intensive care unit.

Serum iron was significantly decreased on day 2 post-trauma and remained low during the study. In contrast, no change in serum transferrin was observed. Ferritin values were already elevated at admission and remained above the normal range for healthy subjects.

Abbreviation: s-Fe, serum iron.

Source: From Ref. 17.

hepatic), and direct inhibition of erythropoiesis by inflammatory cytokines (19,20). Biochemical and clinical markers of systemic inflammation include proinflammatory cytokines and multiple organ dysfunction syndrome (MODS), respectively. The pathogenesis of anemia in nontraumatized critically ill patients is complex, and generally is a mix of ACD and continued blood loss from GI sources and phlebotomy.

☞ **Phlebotomy is a significant contributor to ICU-acquired anemia.** ☞ A recent prospective observational study of 1136 patients from 145 European ICUs demonstrated that the average total volume of blood drawn per patient was 41.1 mL during a 24-hour period (mean volume per blood draw, 10.3 mL) (21). A positive correlation between organ dysfunction and the number of blood draws (and total volume drawn) was shown. An earlier study (22) documenting an even greater daily blood draw (61–70 mL) found that phlebotomy accounted for half the variation in amount of RBCs transfused.

A blunted EPO response was observed in 36 critically ill, non-hypoxic patients who stayed more than seven days in an ICU (though not in the non-septic subgroup with preserved renal function) (23). Thus, EPO deficiency can contribute to ICU-acquired anemia.

☞ **A blunted EPO response is commonly seen in critically ill or injured patients.** ☞ This blunted EPO response is not age-dependent, as it is also seen in pediatric ICU patients (24). Serum EPO concentrations in the acutely anemic group were significantly lower than in the chronically anemic group, and were similar to levels in the critically ill control and acutely hypoxemic groups.

Similar to the findings in trauma patients, the blunted endogenous EPO response in critically ill patients is due to the inflammatory response. Abnormal cytokine elaboration has been associated with diseases associated with hematopoietic insufficiency and anemia (25,26). ACD, commonly observed in patients with chronic infections, malignancy, trauma, and inflammatory disorders, is a well-known clinical entity. Recent evidence shows that the inflammatory cytokine IL-6 induces production of hepcidin, an iron-regulatory hormone that may account for some features of this disorder (27).

Recent evidence suggests an association between the activation of the immune system and the development of anemia in critically ill patients. Similar to events that occur in trauma, immune activation induces oxidative stress and leads to a shift of Fe from the circulation into storage sites, thus decreasing bioavailability of free Fe for erythropoiesis. Moreover, released proinflammatory cytokines inhibit erythroid precursor cells and reduce the formation of EPO. The combination of low EPO values (for the degree of anemia), increased production of proinflammatory cytokines, and low serum Fe despite adequate stores that is characteristic of ACD has been identified in patients with the anemia of critical illness.

### Anemia of Chronic Disease

☞ **ACD is encountered frequently in surgery and critical care, and may exacerbate acute anemia associated with trauma and hemorrhage.** ☞ This condition is common, and is most often associated with inflammatory processes (infectious and non-infectious), renal failure, and malignancy. Laboratory and histological features include normocytic and normochromic (or slightly hypochromic) indices and RBC morphology; reduced serum Hb, Fe and TIBC; and normal or increased serum ferritin (reflecting normal or increased Fe stores).

Repletion of serum Fe does not improve ACD, whereas rHuEPO may benefit. The best treatment is to cure or control the underlying disease.

The pathogenesis of ACD involves decreased RBC life span, inadequate erythropoiesis due to inflammatory mediator release, and decreased release of Fe from macrophages. Hepcidin is an acute-phase reactant that could be a key mediator of ACD. It is an antibacterial protein produced in the liver that can be found in blood or urine, and that participates in host defense. Recent studies demonstrate that hepcidin is a key regulator of Fe balance in the intestinal mucosa, and that abnormalities in hepcidin gene expression are associated with clinical abnormalities in Fe parameters and, in some cases, with anemia (28).

### Anemia Associated with Renal Disease

Most patients with renal failure have associated normochromic anemia (approximate 2 g/dL Hb decrease for a 10 mmol/L increase in blood urea). Reduced EPO production by the kidneys is the major explanation for decreased RBC production. Uremia also shortens RBC life span, perhaps related to abnormal RBC morphology (spur and burr cells). RBC levels of 2,3-diphosphoglycerate (2,3-DPG) and uremic acidosis shift the Hb dissociation curve to the right, accounting for only mild symptoms in relation to the degree of anemia. Exacerbation of anemia due to Fe deficiency (e.g., blood losses during hemodialysis or bleeding secondary to platelet dysfunction), folate deficiency, and/or aluminum excess (inhibitor of erythropoiesis) are all contributory. Treatment with rHuEPO after repletion of Fe and folate can correct the anemia.

Increased cardiac output induced by anemia is associated with left ventricular hypertrophy and cardiac disease in renal patients (29). Impaired endothelium-induced vasodilation, impaired angiogenesis, and atherosclerosis can result.

### Anemia Associated with Cardiac Disease

Anemia occurs in 10% to 20% of patients with chronic heart failure (30), compromising oxygen-carrying capacity and contributing independently to increased mortality. Causes of anemia include ACD, decreased EPO production (renal insufficiency), and perhaps other poorly defined mechanisms. Treatment with rHuEPO and Fe improves symptoms and exercise capacity (31). rHuEPO supplementation also improves the functional capacity of the failing myocardium, and potentially reverses detrimental myocardial remodeling, thereby reducing mortality and morbidity among patients receiving maximal pharmacologic therapy for heart failure.

### Anemia Associated with Liver Disease

Mild macrocytic anemia is associated with chronic liver disease. Contributing factors include blood loss (increased bleeding tendency) and deficiency of vitamin K, Fe, and/or folate. Hemolytic anemia can be seen in end-stage liver disease, Wilson's disease, or due to (autoimmune hemolysis) in some patients with chronic hepatitis. Aplastic anemia rarely complicates acute viral hepatitis.

### Anemia Associated with Thyroid Disease

Thyroxine augments EPO and thus thyroid disease associated with decreased thyroxine can result in a macrocytic anemia. Thyroxine therapy benefits the anemia and often reduces the MCV. In addition autoimmune thyroiditis is associated with anemia (see Volume 2, Chapter 52).

## ADAPTATION AND RESPONSE TO ANEMIA

✎ **The physiological response to anemia is dictated by the etiology and rapidity of onset of the anemia and the age and general state of health of the patient.**

✎ The cardiovascular compensation for anemia involves tachycardia and increased stroke volume, coordinated with vascular changes serving to boost preload. Peripheral resistance may be decreased and oxygen extraction from Hb increased to augment tissue oxygen delivery (29). Immunological compensation includes cytokine and neuroendocrine changes. Hypoxia inducible factors are associated with the transcriptional activation of genes involved in these adaptive mechanisms (29). At the red cell level, anemia is associated with an increase in 2,3-DPG and a shift of the O<sub>2</sub> dissociation curve to the right so that oxygen is delivered to tissues expeditiously.

Inducing acute severe isovolemic anemia (Hb about 5 g/dL) in 95 healthy, unmedicated volunteers (32) reveals an inverse linear relationship between heart rate and Hb concentration that exhibits greater slope among females. The relationship between anemia and heart rate resembles that found in conscious dogs, but differs from the pattern reported in anesthetized humans, in which either no change or a decreased heart rate is seen.

A study (33) compared 41 elderly patients (mean age 70 years) with chronic severe anemia (mean Hb 6.3 g/dL) and no history of cardiac disease with 63 healthy age- and sex-matched controls. Although heart rates were similar between patients and controls, mean arterial blood pressures were significantly lower in the anemic patients (92.7 vs. 102.1 mmHg,  $P < 0.001$ ). No patient had congestive heart failure (CHF). Thus, in the absence of cardiac disease, chronic severe anemia is well tolerated by the aging heart.

In general, more rapid onset of anemia causes more symptoms, as the compensatory physiological processes have less time to adapt. Although symptoms are uncommon until the Hb falls below 9 to 10 g/dL, older patients may be quite symptomatic at these levels. In contrast, gradual onset of anemia in a young, otherwise healthy patient may not produce symptoms and signs even with a Hb of 6.0 g/dL.

Anesthesia reduces the typical cardiac output response to anemia (34). Anesthetized patients have significantly smaller increases in cardiac index (resulting from increased stroke volume), whereas awake patients have increases both in heart rate and in stroke volume (34).

The normal physiologic response to anemia is to increase erythropoiesis, a complex process regulated by EPO, an erythropoietic hormone primarily produced (90%) in the peritubular interstitial cells of the kidney in response to low tissue oxygen tension. EPO stimulates erythropoiesis by shifting hematologic progenitor cells towards greater production of erythrocytes, resulting in expansion of marrow erythroid cells, which in extreme states of chronic anemia can lead to erythropoiesis even within extramedullary sites.

✎ **Adaptation to anemia and hypoxia results in the induction and regulation of a number of physiologically relevant genes in response to changes in intracellular oxygen tension.**

✎ These include genes encoding EPO, vascular endothelial growth factor, and tyrosine hydroxylase. Studies on the regulation of the EPO gene have provided insights into the common mechanism of oxygen sensing and signal transduction, leading to activation of the hypoxia-inducible transcription factor 1 (HIF-1) (35).

## ANEMIA AND PATIENT OUTCOME

✦ **Anemia adversely affects patient mortality and morbidity.** ✦ However, in many critically ill populations, transfusions are associated with worse outcomes than occurs in anemic patients who are not transfused (see later). Patient outcomes will be reviewed by specific patient group.

### TRAUMA

A study of over 15,000 trauma patients found that anemia (Hct < 36%) was an independent risk factor for blood transfusion, mortality, ICU admission and LOS, hospital LOS after controlling for indices of shock and blood product transfusion (36).

A prospective observational cohort study of 550 hip fracture surgery patients found anemia (Hb < 12.0 g/dL) in 40.4% of patients on admission, in 45.6% at the presurgery nadir, rising to 93.0% at the postsurgery nadir, and in 84.6% near discharge (37). In multivariate analyses, higher Hb levels on admission were associated with shorter LOS and lower odds of death and readmission. Previous studies in hip fracture patients revealed similar findings (38).

### Critical Care

Anemia is associated with adverse outcome in critically ill patients, but it remains uncertain whether adverse outcomes are related to anemia alone, or to the resulting use of blood transfusions.

The CRIT study evaluated the association of anemia to outcome in critically ill patients (12). Baseline Hb in ICU patients was related to the number of RBC transfusions but was not an independent predictor of LOS or mortality. However, a nadir Hb concentration of < 9 g/dL was a predictor of increased LOS and mortality.

In the ABC trial, anemia was associated with adverse outcome. The 28-day survival curves differed significantly by admitting Hb category in transfused patients (Kaplan–Meier log rank = 30.3,  $P < 0.001$ ), but not in nontransfused patients (11). Moreover, mortality rates were higher in transfused than in nontransfused patients at every Hb category.

### Surgery

In the largest study of surgical patients, prospective data from the National Veterans Administration Surgical Quality Improvement Program identified a high rate of perioperative anemia in 6301 noncardiac surgical patients over a five-year period (39). Preoperative anemia (Hct < 36%) was found in 33.9% and postoperative anemia was found in 84.1% of the study cohort. Multiple logistic regression analysis documented that low preoperative Hct, low postoperative Hct, and increased blood transfusion rates were associated with increased mortality ( $P < 0.01$ ), increased postoperative pneumonia ( $P < 0.05$ ), and increased LOS ( $P < 0.05$ ).

Prior studies in surgical patients documented similar findings. A retrospective cohort study in surgical patients ( $n = 1958$ ) who declined blood transfusion for religious reasons documented a higher mortality associated with preoperative anemia (40). The overall 30-day mortality was 3.2% (95% CI 2.4–4.0); however, the mortality was only 1.3% (0.8–2.0) in patients with preoperative Hb 12 g/dL or greater, but 33.3% (18.6–51.0) in patients with preoperative

Hb less than 6 g/dL. The increase in risk of death with anemia was more pronounced in patients with cardiovascular disease. The effect of blood loss on mortality was greater in patients with low preoperative Hb. Thus, decisions about blood transfusion in the perioperative period should consider cardiovascular status in addition to Hb levels and operative blood loss.

### Geriatrics

The appropriateness of using WHO criteria for anemia (Hb < 12 g/dL for women; < 13 g/dL for men) in older populations is debatable, as the incidence of anemia rises with age (41). Additionally, anemia is more often symptomatic in the elderly, and is associated with increased mortality in people more than 85 years of age (42). A retrospective review of 900 long-term residents in skilled-nursing facilities (median age 82 years) that applied the WHO criteria for anemia found a prevalence of 48%, with a higher hospitalization rate among those with more severe anemia (43).

### Chronic Heart Failure

Anemia is also common in chronic forms of CHF, and is more frequent in patients with more severe CHF (44). Patients with both CHF and anemia have a poorer quality of life, reduced exercise tolerance, higher hospital admission rates, and other adverse outcomes. Although treatment of anemia can result in improved symptoms, it may also provoke hypertension or thrombosis in this patient population.

A recent prospective study of 912 patients, the Randomized Etanercept North American Strategy to Study Antagonism of Cytokines (RENAISSANCE) trial, investigated the relationship between anemia, CHF severity, and clinical outcomes (45). Anemia (Hb  $\leq$  12.0 g/dL) was present in 12% of subjects. Regression analysis indicated that for every 1 g/dL-higher baseline Hb, the risk of mortality was 15.8% lower ( $P = 0.0009$ ) and the risk of mortality or hospitalization for CHF was 14.2% lower ( $P < 0.0001$ ). Greater CHF severity was associated with lower Hb concentrations. Investigations of a 69 patient subgroup who underwent cardiac MRI (at randomization and 24 weeks later) showed an increase in Hb over time associated with a decrease in left ventricular mass and lower mortality, whereas a decrease in Hb over time associated with an increase in left ventricular mass and higher mortality. In multivariate analysis, anemia remained a significant, independent predictor of death or hospitalization for CHF.

### Acute Ischemic Cardiac Disease

The impact of anemia in patients with acute myocardial infarction (MI) undergoing percutaneous coronary intervention (PCI) was recently evaluated (46). In the Controlled Abciximab and Device Investigation to Lower Late Angioplasty Complications (CADILLAC) trial, 2082 patients with MI undergoing primary PCI were randomized to balloon angioplasty versus stenting, each with or without abciximab. Outcomes were stratified by presence of anemia at baseline (WHO criteria). Anemia was present in 12.8% of randomized patients. Patients with baseline anemia more frequently developed in-hospital hemorrhagic complications (6.2% vs. 2.4%,  $P = 0.002$ ), had higher rates of blood transfusions (13.1% vs. 3.1%,  $P < 0.0001$ ), and had prolonged (median 4.1 vs. 3.5 days,  $P < 0.0001$ ) index hospitalization. Anemic patients also had higher mortality during hospitalization

(4.6% vs. 1.1%,  $P = 0.0003$ ), at 30 days (5.8% vs. 1.5%,  $P < 0.0001$ ), and at one year (9.4% vs. 3.5%,  $P < 0.0001$ ), as well as higher rates of disabling stroke at 30 days (0.8% vs. 0.1%,  $P = 0.005$ ) and at one year (2.1% vs. 0.4%,  $P = 0.0007$ ). Anemia independently predicted in-hospital (hazard ratio, 3.26;  $P = 0.048$ ) and one-year mortality (hazard ratio, 2.38;  $P = 0.016$ ).

Anemia is also an independent risk factor for mortality in patients requiring PCI, based on a study (47) examining outcomes of 6116 patients in relation to the pre-procedural Hb value. Anemia was associated with higher 30-day major adverse cardiac events, greater post-PCI peak troponin and creatine kinase-MB fraction, and longer LOS. The adverse impact of anemia on survival was observed irrespective of whether patients presented with stable or unstable angina, or with MI.

A recent study (48) examining the relation between blood transfusion and mortality among patients with acute coronary syndrome (ACS) raises concerns about possible adverse consequences of transfusion. The post hoc analysis included 24,112 enrollees in three large international clinical trials of ACS patients, of whom 2401 (10.0%) received at least one blood transfusion. Patients who underwent transfusion were older and had more comorbid illness at presentation. They also had a significantly higher unadjusted 30-day mortality rate (8.0% vs. 3.1%;  $P < 0.001$ ) and MI rate (25.2% vs. 8.2%;  $P < 0.001$ ), compared with patients who did not undergo transfusion. The relationship between blood transfusion and increased mortality persisted after adjustment for other predictive factors. Given the limitations of post hoc analysis, a randomized controlled trial (RCT) of transfusion strategies is warranted. However, routine use of blood to maintain an arbitrary Hct level in a stable patient with ischemic heart disease probably should be avoided.

### Chronic Renal Disease

Anemia is strongly associated with morbidity and mortality in hemodialysis patients, as documented in the Dialysis Outcomes and Practice Patterns Study (DOPPS) (49). The DOPPS study also documented inconsistencies in anemia management practices, despite availability of consensus guidelines. Greater efforts to attain the recommended Hb concentrations may improve patient outcomes, as with rHuEPO therapy. For example, a RCT of early versus deferred initiation of rHuEPO in non-diabetic patients with chronic renal insufficiency and anemia (50) found that early treatment (50 U/kg/wk of rHuEPO alpha aiming for Hb  $\geq 13$  g/dL) significantly slowed the progression of renal disease compared with later therapy (initiated only when the Hb fell to  $< 9$  g/dL).

### Malignancy

Anemia is highly prevalent in patients with cancer, in part because of anti-cancer therapy. The resulting decrease in oxygen carrying capacity of blood manifests as fatigue, dyspnea, palpitations, anorexia, cold hypersensitivity, and general weakness (51).

✎ **Anemia in cancer patients correlates with poor clinical outcome, including reduced tumor response to anti-cancer therapy and mortality.** ✎ Since anemia compromises both quality of life and survival, effective and well-tolerated treatment strategies are needed (52). A Cochrane meta-analysis of 19 RCTs of rHuEPO involving 2865 cancer patients showed improved survival with rHuEPO. A more recent meta-analysis of nine RCTs of epoetin beta

( $n = 1413$ ) suggested that this therapy may reduce tumor progression, but had no favorable survival effect (52). Unlike the potential survival benefit of rHuEPO, blood transfusion has not been shown to improve patient survival.

## PREVENTION OF ANEMIA

### Control of Hemorrhage

✎ **Cessation of active bleeding is a key component in the prevention of anemia due to acute hemorrhage.** ✎ Maneuvers associated with control of active hemorrhage can be life-saving. Most often, hemorrhage is controlled by direct digital or hand compression of bleeding soft tissue and/or control of a distinct bleeding vessel. Definitive control often requires more advanced procedural or surgical intervention. Recently there has been increased interest in other methods of hemorrhage control, including pharmacological approaches.

### Tourniquets

The most widely used mechanical systems incorporate use of a tourniquet. The use of tourniquets in the prehospital setting is primarily associated with the military, rather than the civilian, emergency medical system, primarily due to the longer medical evacuation times in the military (particularly during battle), and the increased frequency of life-threatening extremity wounds in recent armed conflicts.

A four-year retrospective analysis of tourniquet applications by Israeli Defense Force soldiers demonstrated that a total of 78% of applications were effective, with higher success rates for medical staff compared with soldiers (53). These researchers concluded that tourniquet application is an effective method for preventing exsanguination in the military prehospital setting. One-handed tourniquets have recently been developed.

Recent experience with elastic adhesive dressings for the treatment of bleeding wounds in trauma patients has demonstrated efficacy in emergency situations (54). A similar elastic bandage was used to avoid fasciotomy in treating upper extremity compartment syndrome (55). Tourniquets are also used for elective surgery when limited blood flow to an extremity is needed.

### Damage Control and Packing

Damage control surgery, such as packing liver injuries, limits bleeding and permits resuscitation “catch-up,” and helps to protect against anemia (56). ✎ **Damage control concepts, including early control of hemorrhage and delay of definitive treatment or reconstruction, have now been applied to areas of trauma care beyond abdominal injuries, including treatment of thoracic injuries where hemorrhage control is quickly established (57,58)** ✎ (Volume 1, Chapter 21 reviews the concepts and application of damage control).

### Angiographic Embolization

Angiographic embolization is an adjunctive strategy to treat hemorrhage from injured organs (e.g., liver, spleen) and pelvic fractures (59–61). It is safe and effective for controlling bleeding after blunt and penetrating intra- and retroperitoneal injuries.

### Pharmacological Interventions

Pharmacologic agents that inhibit fibrinolysis (aprotinin,  $\epsilon$ -aminocaproic acid, tranexamic acid) or increase von Willebrand factor release (desmopressin) are used to

decrease bleeding and blood product use in selected clinical settings. For example, aprotinin is well-established in reducing bleeding with cardiac surgery (62). Tranexamic acid was shown to reduce blood loss by 30% and drainage volume by 50%, with reduced transfusion requirements, in a study of knee arthroplasty (63). However, particularly in settings of acute trauma, interest in recent years has focused on recombinant factor VIIa (rFVIIa).

rFVIIa is approved for treatment of bleeding in hemophilia patients with inhibitors to factors VIII and IX. It is also used during surgery in these patients to control hemorrhage (64–66). Hemostasis is initiated by formation of a complex between tissue factor (TF), exposed by blood vessel wall injury, and activated FVII (FVIIa), normally present in circulating blood (66). TF-FVIIa complexes then convert FX to FXa on TF-bearing cells; FXa then activates prothrombin to thrombin, with thrombin clotting fibrinogen, activating several coagulation factors (VIII, V, XI), and activating platelets. The activated platelets undergo a conformational change, and form a template for coagulation factor assembly and full thrombin generation, which is needed to produce the fibrin component of the hemostatic plug. If thrombin generation is impaired, the fibrin plugs are loose and permeable, and readily dissolved by normal fibrinolytic activity. The addition of rFVIIa normalizes fibrin clot permeability in vitro and tightens the fibrin structure (66,67).

Recently, rFVIIa was found to be efficacious in both surgical and trauma patients with profuse bleeding (68–73). It has also been used to correct warfarin-related coagulopathy in preparation for emergency surgery (74,75). Based upon its mechanism of action, it is expected that its hemostatic effects are mainly limited to the site of injury, without systemic activation of coagulation (76). rFVIIa also appears to be efficacious in moderate hypothermia, but not in severe acidosis (72,77).

rFVIIa demonstrated a significant reduction of perioperative blood loss in patients undergoing radical retropubic prostatectomy (78). Median perioperative blood loss was 1235 mL and 1089 mL in groups given rFVIIa 20 and 40  $\mu\text{g}/\text{kg}$ , respectively, compared with 2688 mL in placebo controls ( $P = 0.001$ ). Seven of twelve placebo-treated patients were transfused, whereas none who received 40 mg/kg rFVIIa needed blood.

Trauma-associated bleeding can be reduced by rFVIIa (68,69). Seven massively bleeding, coagulopathic, multi-transfused trauma patients treated with rFVIIa (median, 120  $\mu\text{g}/\text{kg}$ ) achieved cessation of diffuse bleeding, reduction in blood requirements, and shortening of prothrombin and activated partial thromboplastin times (68). Similar results were seen in 19 critically-ill, multi-transfused trauma patients (70), as well as in a series of 21 Australian patients with life-threatening hemorrhage due to trauma or surgery (79). Few thrombotic events directly attributable to rFVIIa have occurred. rFVIIa also has been shown to correct the coagulopathy associated with traumatic brain injury more effectively than plasma infusion, allowing for earlier placement of invasive monitors (80). Animal models of hemorrhagic shock indicate that early rFVIIa administration decreases bleeding and improves survival without producing thrombosis in vital organs (65,81,82).

Recently, results of an international multicenter, double-blind, placebo-controlled RCT of rFVIIa in trauma ( $n = 301$ ) were reported (83). Patients with blunt or penetrating trauma requiring transfusion of eight units RBC were randomized to three infusions of rFVIIa (200, 100, and 100  $\mu\text{g}/\text{kg}$ ) or placebo at entry, one hour and three hours.

In blunt trauma, after excluding early deaths, rFVIIa resulted in a significant decrease in the number of RBC transfusions within 48 hours, and a trend to reduced MOF and ARDS.

### Topical Fibrin Sealant

Fibrin sealant (FS) is a prohemostatic agent initially created by combining human fibrinogen concentrate with thrombin solutions containing calcium (84). More recent products also contain factor XIII and aprotinin. The components are combined and applied to tissue with instantaneous formation of a coagulum. The fibrinogen is obtained from single donor plasma. FS can be applied topically or injected into organ parenchyma.

FS has been used to control bleeding in trauma and surgery patients for many years (85). Animal studies demonstrate effective hemostasis of superficial and deep hepatic injuries (86–90), control of arterial injuries without compromising blood flow (91), and control of renal bleeding (92). Dry FS dressings provide rapid hemorrhage control and improved survival in swine with grade V liver injuries (93). Clinical studies suggest efficacy in trauma as well (84,94,95). FS use in thermally-injured patients led to reduced need for blood transfusion (96). A multicenter trial of FS for topical hemostasis in skin grafting demonstrated its safety and suggested it may have contributed to accelerated scar maturation (97).

FS has demonstrated efficacy in a multitude of surgical procedures. It has been used to seal esophageal, gastric, colonic, or rectal anastomoses, and provided a 41% reduction in incidence of air leakage when added to suture lines in patients undergoing pulmonary resection (98). It has been utilized to seal cerebrospinal fluid leaks in neurosurgery, and has attenuated bleeding after dental extraction (98). Endoscopic injection of FS was superior to sclerotherapy in a RCT of 805 patients with bleeding peptic ulcer (98). FS was found to be a safe, simple and efficacious endoscopic treatment option in patients with gastric variceal bleeding (99). FS also has been shown to decrease blood loss and transfusion requirements in major joint replacement surgery (100–102). FS was more effective than bipolar or needle point coagulation for hemostasis in tonsillectomy and adenoidectomy (103).

### Reduction of Blood Loss Due to Phlebotomy

Multiple studies have documented that ICU patients are phlebotomized about 40 to 70 mL/day (11,104). **Repeated phlebotomy for diagnostic laboratory testing contributes significantly to blood loss in critically ill patients.** Simple strategies to reduce such blood loss include the use of blood conservation devices, low-volume adult (or pediatric) sampling tubes, and minimizing diagnostic testing.

A RCT in 100 medical ICU patients found that a blood conservation device incorporated into the arterial pressure monitoring system reduced the total volume of discarded blood from  $103.5 \pm 99.9$  mL to  $19.4 \pm 47.4$  mL ( $P < 0.0001$ ) (105). Discarded blood volume proved to be an independent predictor of Hb concentration decline.

A survey of 280 ICUs throughout England and Wales found that few measures were taken to reduce diagnostic blood loss from arterial blood sampling (106). The average volume of blood withdrawn to clear the arterial line before sampling was 3.2 mL, which was subsequently returned to the patient in only 18.4% of ICUs. Specific measures to reduce the blood sample size by the routine use of pediatric sample tubes occurred in only 9.3% of adult ICUs. In

pediatric ICUs, the average volume withdrawn was 1.9 mL, which was routinely returned in 67% of units.

Strategies to reduce blood loss related to diagnostic phlebotomy, including use of pediatric tubes, low-volume adult tubes, and blood conservation devices, should be implemented in all ICUs, thereby reducing the incidence of anemia and need for blood transfusion (107).

### Prophylaxis for Stress-Related Mucosal Damage

GI bleeding in ICU patients, both occult and overt, is commonly related to stress-related mucosal disease (SRMD), representing a continuum ranging from stress-related injury (superficial mucosal damage) to stress ulcers (focal deep mucosal damage) (108,109). Pharmacologic prophylaxis to prevent SRMD includes histamine-2-receptor antagonists, proton pump inhibitors, sucrilate, misoprostol, enteral nutrition, and antacids, though few modern ICUs still use antacid titration approaches.

Patients with coagulopathy and respiratory failure are at highest risk for SRMD. Other risk factors include head and spinal cord injury, multiple trauma, sepsis, and steroid therapy. All high-risk patients should be started on enteral nutrition as soon as possible and receive concomitant pharmacologic prophylaxis (see Volume 2, Chapter 30).

## TREATMENT OF ANEMIA

### Correction of Nutritional Deficiencies

When present, correction of nutritional deficiency (Fe, folate, or B<sub>12</sub>) is imperative to correct the anemia.

### Erythropoietin

♣ **Recombinant human erythropoietin (rHuEPO) rapidly produces erythropoiesis, and is used for treatment of anemia and to reduce the need for RBC transfusions.** ♣

The use of rHuEPO is approved by the FDA for treatment of anemia in many patients, including those with renal disease, cancer, HIV, and before surgery. Treatment with rHuEPO should be supplemented with Fe and vitamin C for optimal efficacy. The first prospective study evaluating rHuEPO in critically ill patients was conducted in trauma patients with MODS (110). Patients received either 600 IU/kg intravenous rHuEPO three times weekly ( $n = 9$ ) or saline control ( $n = 10$ ). Whereas serum EPO concentrations in controls remained low, the active treatment group achieved pharmacologic EPO blood levels, and showed significantly increased reticulocyte counts compared with controls and baseline. Subsequently, several RCTs have evaluated rHuEPO for treating anemia in critically ill patients. The studies vary with respect to rHuEPO (and concurrent Fe) dosing, patient characteristics, and transfusion thresholds.

In 1999, the first large-scale RCT ( $n = 160$ ) of rHuEPO for preventing anemia in critically ill patients was published (111). Study drug (300 units/kg of rHuEPO or placebo) was given by subcutaneous injection beginning ICU day three and continuing daily for five days; subsequently, dosing was every-other-day (target Hct >38%), with study drug given a minimum of two weeks (or until ICU discharge) up to six weeks post-randomization. This study demonstrated that rHuEPO decreased by 50% the number of packed red blood cells (PRBCs) transfused (166 vs. 305 units) and increased the HCT compared to placebo, without increase in adverse events.

The response to rHuEPO was carefully evaluated in a study of 36 anemic ICU patients in a single-center,

open-label trial (112). The patients were divided into three groups: one group received rHuEPO (epoetin alfa, 300 IU/kg subcutaneously) plus intravenous Fe on days 1, 3, 5, 7, and 9, another group received intravenous Fe alone, and the third group (controls) received no additional therapy (all patients received folate). Serum EPO concentrations were inappropriately low for the degree of anemia at baseline irrespective of renal status. EPO concentrations increased among rHuEPO-treated patients from  $23 \pm 13$  to a maximum of  $166 \pm 98$  IU/L on day 10 ( $P < 0.05$ ). The reticulocyte count increased exclusively in the rHuEPO group from  $56 \pm 33 \times 10^9/L$  to a maximum of  $189 \pm 97$  on day 13 ( $P < 0.05$ ). Serum transferrin receptor levels rose only in the rHuEPO group, indicating increased erythropoiesis. Interestingly, this study identified an increased zinc protoporphyrin concentration in the rHuEPO group, suggesting iron deficiency, despite the concurrent Fe supplementation.

The efficacy of weekly rHuEPO administration to decrease RBC transfusion was examined in a large multicenter RCT (113). ICU patients ( $n = 130$ ) expected to be in the ICU for at least two days were randomized to receive either 40,000 IU of rHuEPO or placebo. rHuEPO was started on day 3 and doses continued weekly for a total of three doses (patients remaining in the ICU on day 21 received a fourth dose). Patients treated with rHuEPO were less likely to undergo transfusion compared with placebo (50.5% vs. 60.4%;  $P < 0.001$ ), with an overall 19% reduction in total units of RBCs transfused (1590 vs. 1963 units) and reduction in RBC units transfused per day alive (ratio of transfusion rates, 0.81). Increase in Hb from baseline to study end was greater in the rHuEPO group (1.32 vs. 0.94 g/dL;  $P < 0.001$ ). Mortality (14% for rHuEPO and 15% for placebo) and adverse clinical event rates did not differ, however. The lower efficacy of rHuEPO in reducing blood transfusion in this study (113) [19% vs. 50% reduction (111)] could be due to the shorter study duration (28 vs. 42 days), lower rHuEPO dose (40,000 IU weekly), and inclusion of a transfusion protocol.

rHuEPO treatment can cause hypertension, particularly in uremic patients (29). Potential explanations include increased blood viscosity, reversal of hypoxic vasodilation, increased blood volume, and impaired nitric oxide synthesis. Antibody-associated pure red-cell aplasia (PRCA) has also been reported as a rare but serious adverse event (114). Between January 1998 and April 2004, 175 cases of rHuEPO-associated PRCA were reported for Eprex, 11 cases for Neorecormon (a formulation of epoetin beta), and five cases for Epogen. Over half occurred in France, Canada, the United Kingdom, and Spain. After adoption of procedures to ensure appropriate storage, handling, and administration of Eprex, the exposure-adjusted incidence decreased by 83% worldwide.

### Blood Transfusion

The transfusion of ABO/Rhesus-matched PRBCs is the mainstay of therapy for many anemic patients.

### Transfusion Triggers

In the late 1990s, research trials were undertaken to determine the optimal Hb/Hct level at which transfusion of blood products should occur. Too often, ICU patients received blood transfusions based on an arbitrary transfusion trigger or simply a "below normal" Hb level rather than a physiological need for blood (104).

One of the earliest studies evaluating physician response to various Hb levels divided the patient population into three groups based on the following Hb levels: 7.5 to 7.9, 7.0 to 7.4, and <7.0 g/dL (115). Approximately the same number of patients was transfused in each group. Patients in the progressively more anemic groups received slightly more transfused units and the post-transfusion Hb increase was higher in more anemic patients. The physicians surveyed indicated that the Hb critical limit could be lowered without adverse consequence. These investigators concluded that the transfusion trigger and low critical limit for Hb are distinct entities (115).

In 1999, the Canadian Critical Care Trials Group published the results of the only RCT, named the Transfusion Requirements in Critical Care (TRICC) trial (117), which compared two transfusion “triggers” with the primary outcomes of mortality and severity of organ dysfunction. Critically ill patients ( $n = 838$ ) with euvolemia after initial treatment for Hb concentrations less than 9 g/dL within 72 hours following ICU admission were enrolled. Patients were randomized to a *restrictive strategy* of transfusion, in which PRBCs were transfused if the Hb concentration dropped below 7 g/dL, with Hb maintained at 7 to 9 g/dL, or to a *liberal strategy*, in which transfusions were given when the Hb fell below 10 g/dL, and Hb concentrations maintained at 10 to 12 g/dL. Overall, there was a trend to lower 30-day mortality in the restrictive transfusion strategy group (18.7% vs. 23.3%,  $P = 0.11$ ). Moreover, mortality was significantly lower with the restrictive strategy among less acutely ill patients (APACHE II score of  $\leq 20$ ; 8.7% vs. 16.1%,  $P = 0.03$ ) and in patients less than 55 years of age (5.7% vs. 13.0%;  $P = 0.02$ ), but not among patients with clinically significant cardiac disease (20.5% vs. 22.9%;  $P = 0.69$ ). The in-hospital mortality rate was significantly lower in the restrictive strategy group (22.3% vs. 28.1%,  $P = 0.05$ ). In a post hoc analysis of 257 patients with severe ischemic heart disease, there were no statistically significant differences in any survival measures; the restrictive group had a lower, but nonsignificant, absolute survival rate compared with patients in the liberal group (117). **✎ A restrictive strategy of red cell transfusion is at least as effective as and probably superior to a liberal transfusion strategy in critically ill patients, with the possible exception of patients with acute MI or unstable angina. ✎**

Subsequent analysis of the TRICC trial patient cohort requiring mechanical ventilation ( $n = 713$ ) found no evidence that a liberal PRBC transfusion strategy for treating anemia decreased the duration of mechanical ventilation (118). Similarly, analysis of the cohort of trauma patients in the TRICC trial showed no significant differences in mortality, MODS severity or change, or in ICU or hospital LOS (119). Nevertheless, the number of PRBCs transfused per patient was significantly less in the restrictive transfusion group ( $2.3 \pm 4.4$  vs.  $5.4 \pm 4.3$ ;  $P < 0.0001$ ), indicating that a restrictive PRBC transfusion strategy appears safe for critically ill trauma patients.

A meta-analysis (120) of 10 trials with 1780 patients demonstrated that restrictive transfusion strategies reduced PRBC transfusion by 42% (mean, 0.93 units per patient). Mortality, cardiac events, and hospital LOS were unaffected. The authors conclude that the use of restrictive transfusion triggers is appropriate in patients free of serious cardiac disease, although they cautioned that most of the data were generated by one trial.

Most stable critically ill patients can probably be managed using a restrictive transfusion strategy (121).

Indeed, abnormally high Hb levels may be detrimental in the critically ill patient. High Hb levels upon entry into the ICU were associated with increased mortality, increased incidence of MI, and with more severe left ventricular dysfunction in 2202 cardiac patients who underwent coronary artery bypass graft surgery (CABG) (122). In contrast, low intraoperative HCT ( $<0.22$ ) was associated with stroke, MI, sepsis, and MODS in another study (123), indicating the need for further studies of optimal transfusion thresholds (124). Despite studies supporting a transfusion threshold between 7 and 8 g/dL for most patients, actual clinical practice continues to vary widely (125).

Correcting decreased oxygen delivery by transfusing an anemic patient has been hypothesized to help in weaning from mechanical ventilation. However, Hebert et al. (118) found that a liberal transfusion strategy did not decrease the duration of mechanical ventilation.

### **Nontraditional Transfusion Triggers**

The concept of a viscosity trigger has been evaluated. Theoretically, hemodilution to a Hb level of 7 to 8 g/dL might not compromise oxygen delivery and consumption; however, the corresponding reduced blood viscosity might not transmit adequate pressure to the capillaries, causing functional capillary density (FCD) to decrease and jeopardizing organ function through the inadequate extraction of products of metabolism from the tissue by the capillaries (126). Previous studies in hemorrhagic shock have demonstrated that survival is primarily determined by maintenance of FCD and secondarily by tissue oxygenation; thus, increasing plasma viscosity may extend the transfusion trigger and reduce the use of blood transfusions.

The use of an oxygen extraction ratio of 50% as a transfusion trigger has been shown to lead to a reduction in allogeneic blood transfusion in postoperative CABG patients (127). Oxygen saturation may also be used as a transfusion trigger. A recent study using near-infrared spectroscopy measured regional Hb oxygen concentration from the cerebral cortex and gastrocnemius muscle, as well as arterial oxygen saturation, end-tidal carbon dioxide tension, mean arterial pressure, and Hb concentration, in patients undergoing acute normovolemic hemodilution (128). Hb concentration and blood loss volume correlated with both cerebral cortex and gastrocnemius oxygen saturation.

### **Complications Associated with Utilization of Blood Products**

**✎ The transfusion of blood products has been associated with worse clinical outcome in numerous studies (36,129,130). ✎** One explanation could be transfusion-induced immunomodulation (131), such as decreased T-cell-mediated immunity (132) observed with both autologous and allogeneic blood (133). Blood transfusion is associated with an increase in serum and soft tissue tumor necrosis factor $\alpha$  (TNF- $\alpha$ ), interleukin (IL)-1 $\beta$ , IL-6, IL-8, and other cytokines and their soluble receptors (134–138). Blood transfusion enhances inflammatory mediator release from normal neutrophils incubated with plasma from stored blood (139). Cardiac surgery patients demonstrated increased levels of IL-6 and bactericidal permeability increasing protein in relation to the number of PRBCs transfused (135). Release of IL-8, IL-1 $\beta$ , and TNF- $\alpha$  and secretory phospholipase is amplified by older ( $>14$  days) blood (140).

Transfusion of blood products in the perioperative period has also been associated with cancer recurrence, as demonstrated in patients undergoing hepatic resection for hepatocellular carcinoma (141), and those undergoing colon cancer resection. In this latter group, perioperative blood transfusion was associated with a significant decrease in overall survival (3 years vs. 4.6 years for non-transfused patients) (142).

♣ **Blood transfusion is associated with increased risk for death, perioperative infection, MODS, and ICU admission in the trauma patient population (129,143–146).** ♣ Blood transfusion within the first 24 hours of admission was a significant independent risk factor for SIRS, mortality, and ICU admission and LOS in 9569 acute trauma patients (147). Age (>15 days storage) of blood was also an independent predictor of increased ICU admission and LOS and hospital LOS in a study evaluating >15,000 acute trauma patients (148).

♣ **Blood product age correlates with mortality in patients admitted to the ICU with severe sepsis.** ♣ In one study (149), the median age of blood was 17 days for survivors versus 25 days for non-survivors. Age of blood was also associated with worse outcome in a study of 416 patients (269 transfused) who underwent CABG (150). The risk of postoperative pneumonia increased 1% per day of increase in mean storage time of PRBCs and increased 5% per unit of PRBCs or platelets transfused.

Blood transfusion is associated with increased risk for infection. In a study of trauma patients, transfusion of PRBCs within the first 48 hours of admission was associated with an increase in infection rate (33.0% for patients receiving at least one blood transfusion vs. 7.6% in patients not transfused) (146). Transfusion was associated with a 1.35-fold increased risk for bacterial infection and a 1.52-fold increased risk for pneumonia in a retrospective cohort study of 9598 consecutive hip fracture patients who underwent surgical repair (144). A dose–response relationship between blood transfusion, bacterial infection, and pneumonia was also observed. Allogeneic blood transfusion was a dose-dependent, independent predictor of postoperative bacterial infection and mortality in a prospective analysis of 1349 patients (282 transfused) who underwent colorectal surgery (151). Transfused medical-surgical ICU patients had a significantly higher rate of nosocomial infections when 1717 patients were stratified for severity of illness, age, and gender (145). A dose–response relationship was established between number of units of PRBCs transfused and risk for nosocomial infection. The odds of infection were increased by a factor of 1.5 for each unit of blood transfused. In another cohort study of 738 surgical patients, transfusion of four or more units led to an increased risk for severe postoperative infection and nosocomial pneumonia (152). Preoperative anemia and intraoperative blood transfusion were independent predictors of postoperative pneumonia in 6301 non-cardiac surgical patients in a prospective observational trial (153).

### Leukodepletion

Leukocytes present in RBC and platelet concentrates have been implicated in several immunological and infective complications of blood transfusion (154). Transfusion can result in persistent survival of donor leukocyte subpopulations in the recipient (microchimerism), a phenomenon that likely reflects engraftment within the recipient of donor hematopoietic stem cells. Microchimerism is very uncommon following transfusion for elective surgery,

sickle cell anemia, thalassemia, and HIV, but occurs significantly more often in trauma patients. A recent prospective study of 45 transfused trauma patients found that 53% had evidence of microchimerism by polymerase chain reaction (155). The long-term sequelae of microchimerism in trauma patients are unknown.

Leukodepletion is a process whereby filtration is used to remove the vast majority of white blood cells from blood products, typically resulting in less than  $5 \times 10^6$  residual leukocytes per transfused unit. This is typically accomplished soon after collection (prestorage leukodepletion), although it can be done at the bedside. However, bedside leukofiltration can be associated with bradykinin-induced hypotension (156) that results when platelets are exposed to negatively charged leukocyte filters.

In a recent study evaluating leukodepletion filters, IL-8 levels were lower on storage days 1 and 35 in filtered concentrates compared with control (unfiltered) counterparts (157). In another study, leukodepletion during CABG led to reduced need for blood transfusion and crystalloid infusion in the postoperative period compared to controls (158).

Whether or not *universal* leukoreduction of blood products should be performed is controversial. The largest RCT of universal leukodepletion failed to establish efficacy (159). Patients ( $n = 2780$ ) received either unmodified blood components or stored leukocyte-reduced RBCs and platelets. Three prespecified primary outcome measures did not differ between the leukodepletion and control groups (respectively), namely in-hospital mortality (9.0 vs. 8.5% control;  $P = 0.64$ ), hospital LOS post-transfusion (median days, 6.3 vs. 6.4;  $P = 0.21$ ), and total hospital costs (median, \$19,200 vs. \$19,500;  $P = 0.24$ ). Secondary outcomes (ICU LOS, postoperative LOS, antibiotic usage, and readmission rate) also did not differ. Subgroup analysis based on patient age, gender, amount of blood transfused, or type of surgery showed no effect. However, patients receiving leukodepleted blood had a lower incidence of febrile reactions ( $P = 0.06$ ).

### Saline Washing

Saline washing refers to rinsing of donor RBCs in isotonic sodium chloride, thereby depleting the PRBCs of leukocytes, microaggregates and nearly all of the plasma (160). The optimal number of washings needed is controversial. One study that measured total protein, immunoglobulin levels, and complement factor C3 content, along with RBC osmotic fragility in whole blood washed anywhere from one to six times (161) found that protein, immunoglobulin, and C3 levels decreased precipitously after the first two washing procedures, without significant effect from subsequent washes. Interestingly, more washes were needed when storage time was greater. RBC osmotic fragility increased with each wash and with greater storage time. These researchers concluded that optimal results were obtained when a one to two week old unit of whole blood was washed two to three times. As the immunomodulatory effects of RBC transfusion include neutrophil priming for cytotoxicity (an effect exacerbated by longer storage times), post-storage saline washing abrogates neutrophil priming (162).

### Hemoglobin-Based Oxygen Carriers

♣ **Increasing demand for blood products and safety concerns have stimulated the search for alternative erythrocyte transfusion strategies such as the development of hemoglobin-based oxygen carriers (HBOCs) (163,164).** ♣

Several unforeseen adverse effects have kept blood substitutes “out of reach” (165). Agents under investigation are pathogen-free, have acceptable side effect profiles, and long shelf lives. Two HBOCs include polymerized bovine Hb (HBOC-201, Hemopure, Biopure Corporation, Cambridge, MA) and human polymerized Hb (PolyHeme, Northfield Laboratories, Evanston, IL).

### **Hemopure—Polymerized Bovine Hemoglobin (Hemoglobin-Based Oxygen Carriers-201)**

Phase III trials with polymerized bovine Hb demonstrate that allogeneic blood transfusions can be reduced in certain perioperative settings (166,167). This product has also been used to enhance oxygen delivery in a severely anemic Jehovah’s Witness pending response to high-dose rHuEPO (168). HBOC can reach post-stenotic or other poorly perfused tissues where erythrocytes cannot pass, thus enhancing tissue oxygenation (163). Compared with PRBC transfusion, low doses of HBOC-201 maintained enhanced oxygen extraction after extended hemodilution, and provided a faster and higher increase in muscular tissue PO<sub>2</sub> in animal studies (169).

### **PolyHeme—Polymerized Human Hemoglobin**

PolyHeme is a chemically-modified Hb solution derived from outdated human blood developed as an alternative to transfused blood (170). As single Hb molecules are toxic to the kidneys and cause vasoconstriction, the Hb molecules are polymerized to create small chains of linked tetramers.

Initial studies of PolyHeme demonstrated that it was safe when used in patients with acute blood loss, reducing the use of allogeneic blood (171). In a recent RCT, PolyHeme given in lieu of PRBCs to trauma patients requiring urgent transfusion avoided the neutrophil priming seen in other patients who had received PRBCs (172). Utilization of PolyHeme could therefore decrease risk for MODS in this patient population.

Another recent study comparing survival in 171 trauma or urgent surgical patients with life-threatening anemia given PolyHeme to historical controls (300 similarly anemic patients refusing transfusion) found increased survival with Polyheme (173). Johnson et al. (174) measured serial pro- and anti-inflammatory cytokine levels in critically injured patients resuscitated either with PRBCs or with PolyHeme, and found higher cytokine levels among patients who received PRBCs, with exaggerated levels of these cytokines associated with adverse outcomes.

## **EYE TO THE FUTURE**

Continued advances are being made in the pathogenesis, diagnosis, and treatment of anemia associated with trauma and critical illness, including the development of nontransfusional therapies.

### **Hepcidin**

Hepcidin is a recently discovered hepatic peptide that regulates intestinal absorption and placental transport of Fe. It probably also affects release of Fe from hepatic stores and from macrophages involved in the recycling of Fe from Hb. Hepcidin is a key mediator of hypoferrremia of inflammation, contributing to pathogenesis of ACD (175). The inflammatory cytokine IL-6 induces production of hepcidin

(Fig. 5). Studies of human liver cell cultures, mice, and human volunteers indicate that IL-6 is the necessary and sufficient cytokine for the induction of hepcidin during inflammation, indicating that the IL-6-hepcidin axis is responsible for the hypoferrremia of inflammation (176).

Decreased hepcidin leads to tissue Fe overload, while hepcidin overproduction causes hypoferrremia and ACD. Ferroportin is an Fe exporter present on the surface of absorptive enterocytes, macrophages, hepatocytes, and placental cells. A recent study determined that hepcidin is bound to ferroportin in tissue culture cells (177). Following binding, ferroportin was internalized and degraded, leading to decreased export of cellular Fe. The post-translational regulation of ferroportin by hepcidin may thus complete a homeostatic loop whereby Fe regulates secretion of hepcidin, which in turn controls the concentration of ferroportin on the cell surface.

If inflammatory induction of hepcidin causes hypoferrremia, it is logical to predict that inhibition of hepcidin expression or activity would ameliorate the anemia of inflammation. Would that be advantageous? We know that patients and mice lacking hepcidin have increased intestinal Fe absorption and increased serum Fe, and this is unlikely to be harmful in the short term. However, there may be cause for concern in patients with infections or malignancy, as decreased serum Fe contributes to host defense against invading pathogens and tumor cells, while hepcidin itself has antimicrobial properties (178).

### **“Old” Blood and Free Hemoglobin**

Increased blood storage time leads to increased hemolysis, producing free Hb within the unit of PRBC. Stroma-free plasma Hb rapidly destroys nitric oxide by oxidation to met-Hb and nitrate ions (Fig. 6). Cell-free Hb, due to its low molecular weight, may also diffuse into extravascular spaces where it can bind nitric oxide as well. Limited nitric oxide bioavailability under these conditions promotes systemic vasoconstriction and organ dysfunction.

Similarly, first-generation HBOCs were associated with adverse events, including severe hypertension and renal failure as a result of severe vasoconstriction due to nitric oxide binding by cell-free Hb monomers and dimers.

Under normal circumstances, confinement of Hb within RBCs reduces the rate of reaction of Hb with nitric oxide by a factor of 1000 or greater, because the RBC membrane creates a barrier to the diffusion of nitric oxide. Furthermore, in rapidly flowing arterial blood, the streaming of plasma along the endothelium separates nitric oxide from

**Figure 5** Hepcidin and the anemia of critical illness.

Regulation of hepcidin production in inflammation. Inflammation leads to macrophage elaboration of IL-6, which acts on hepatocytes to induce hepcidin production. Hepcidin inhibits macrophage iron release and intestinal iron absorption, leading to hypoferrremia.

Source: From Ref. 178.

**Figure 6** A model of the interactions of nitric oxide with erythrocytes (RBCs) and cell-free hemoglobin in an arterial blood vessel. The diagram illustrates the major processes regulating nitric oxide (NO) levels in blood vessels during pharmacologic NO delivery (left), under normal conditions (center), and under pathologic conditions, such as acute or chronic hemolysis (right). The overall blood-vessel NO concentration is depicted by the width of the blue band above the vessel. Within the vessel, smooth-muscle cells and a layer of endothelial cells are shown. Under normal conditions (*center*), NO produced by endothelial NO synthase with arginine as a substrate (and also producing citrulline) diffuses into smooth muscle to activate soluble guanylyl cyclase (sGC) to form cyclic guanosine monophosphate and thus maintain basal vascular tone. Intravascular destruction of NO by intraerythrocytic hemoglobin is limited by diffusional barriers in the red-cell-free layer adjacent to the endothelium and factors in and around the erythrocyte membrane that slow nitric oxide transit. Note shading around the RBCs and endothelium. However, sufficient NO is consumed to limit its activity to the local environment. When NO is administered by inhalation or infusion (left), high intravascular nitric oxide concentrations promote nitric oxide reactions, with erythrocyte hemoglobin and plasma proteins that can either protect it, thereby promoting systemic vasodilatation, or destroy it. Possible mechanisms of protection and delivery of nitric oxide from iron-nitrosyl hemoglobin ( $\text{Fe}^{\text{II}}\text{-NO}$ ) and S-nitrosohemoglobin ( $\beta\text{-cys93-SNO}$ ) within erythrocytes and from plasma nitric oxide species (including nitric oxide gas [ $\text{NO}^-$ ], plasma SNO, and nitrite ions [ $\text{NO}_2^-$ ]) are shown, as are conditions that may promote these reactions, including low oxygen tension ( $\downarrow \text{PO}_2$ ) and low pH ( $\downarrow \text{pH}$ ). Of considerable recent interest is the possible bioactivity of nitrite ions, since they can be converted to nitric oxide by enzymatic reactions (including by xanthine oxidoreductase or heme proteins) or nonenzymatic reactions. The extent to which these processes occur in normal physiology is not yet clear. During hemolysis (right) or the infusion of hemoglobin-based blood substitutes, cell-free ferrous hemoglobin (shown as a protein tetramer with one  $\text{Fe}^{\text{II}}\text{-O}_2$  molecule) in the plasma rapidly destroys nitric oxide by being oxidized to methemoglobin ( $\text{Fe}^{\text{III}}$ ) and nitrate ions. Owing to its low molecular weight, cell-free hemoglobin (especially as a dimer subunit) may diffuse into extravascular spaces. Limited nitric oxide bioavailability under these conditions promotes systemic vasoconstriction and organ dysfunction.

much of the red cell mass, thereby reducing its contact with oxy-Hb. Further study is needed to optimize methods to reduce storage-associated hemolysis, or to remove free Hb.

### Prehospital Trials of Hemoglobin-Based Oxygen Carriers

The management of uncontrolled bleeding in trauma patients is difficult in the prehospital setting. Current prehospital therapies (low volume resuscitation, compression of external bleeding sites, mobilization of fractures to reduce bleeding) do not include blood transfusion due to logistics and storage. HBOCs exhibit many desirable characteristics that make them potential therapeutic agents in this setting. These compounds do not need cross-matching, have favorable oxygen dissociation characteristics, long half-lives, do not transmit infectious disease, appear less immunoreactive than blood, and do not require refrigeration. An RCT in the prehospital setting has been initiated, entitled "A Phase III, Randomized, Controlled, Open-Label Multicenter, Parallel Group Study Using Provisions for Exception from Informed Consent Requirements Designed to Evaluate the Safety and Efficacy of Poly SFH-P Injection [Polymerized Human Hemoglobin (Pyridoxylated) PolyHeme<sup>®</sup>] When Used to Treat Patients in Hemorrhagic Shock Following Traumatic Injuries Beginning in the Prehospital Setting."

In this study, patients in hemorrhagic shock will begin to receive either the standard of care with crystalloid fluid resuscitation (control) or PolyHeme. Treatment would begin before arrival at the hospital, and continue during a 12-hour post-injury period. In the hospital, patients in the control group will receive crystalloid for resuscitation and blood transfusion if necessary, as required. Patients in the treatment group will receive crystalloid for resuscitation and PolyHeme<sup>®</sup> instead of blood transfusion. The maximum dose of PolyHeme will be six units during the first 12 hours. Blood will be used thereafter, if oxygen delivery levels need to be increased. Information regarding this trial is available at [http://www.northfieldlabs.com/amb\\_trial.html](http://www.northfieldlabs.com/amb_trial.html).

Similarly, plans are underway to conduct an RCT of Hemopure for out-of-hospital resuscitation of patients with severe hemorrhagic shock. Entitled "Restore Effective Survival in Shock" (RESUS), the trial is intended to support an indication for out-of-hospital military and civilian trauma applications. The scientific advisory committee for this protocol includes Navy, Army, and Air Force medical researchers and academic experts in trauma, emergency medicine, critical care, and statistics. Because the proposed RESUS protocol involves waiver of patient informed consent (WIC), regulations require the submission of a separate investigational new drug application (IND). Once a new IND is assigned and the final protocol is agreed upon with the FDA, the participating hospitals' internal review boards must approve the protocol. This process may require obtaining separate approvals at each trial site for the WIC community notification program, which begins prior to patient enrollment, and for the actual initiation of patient enrollment. Further information regarding this study is at <http://www.biopure.com/shared/home.cfm?CDID=2&CPgID=19>.

### Recombinant Human Hemoglobin

A considerable problem with human or bovine HBOCs is procuring an adequate supply, since human HBOC derives from outdated human blood, and bovine HBOC is made

from a U.S. cattle source. The recent development of a recombinant human Hb (rHb 2.0) that has reduced reactivity with nitric oxide is exciting, since it would potentially provide limitless HBOC supply.

A recent study evaluated the efficacy of this second-generation HBOC for resuscitation in a swine model of uncontrolled perioperative hemorrhage (179). After instrumentation, animals underwent splenectomy and rapid hemorrhage to a systolic blood pressure of 35 mmHg and isoelectric electroencephalography; 15 minutes of shock was followed by resuscitation over 30 minutes. rHb2.0 for injection performed as well as heterologous blood, did not cause sustained pulmonary hypertension, maintained adequate cardiac output and oxygen delivery, and was superior to either LR or the first-generation HBOC, diaspirin-cross-linked Hb. No human studies of rHb2.0 have yet been undertaken.

### Perfluorocarbons

Significant efforts have been made over the past 70 years to find an oxygen-carrying solution that could substitute for blood (180). During this time, the focus has shifted to developing a solution capable of delivering oxygen to the tissues. Perfluorocarbons (PFCs) are highly inert solutions with a high solubility for all gases, making them a prime candidate to become such an oxygen delivery agent. Although research efforts with these agents continue, the rapid disappearance of emulsified PFCs from the vascular space, and their accumulation in the liver and spleen, limit their usefulness as transfusion substitutes.

Because of their ability to dissolve significant quantities of oxygen and carbon dioxide, these agents may be more attractive as oxygen delivery agents during periods of local or global organ ischemia, including preservation of organs for transplantation. PFCs have also been tested in animal models of cardiopulmonary bypass, and may be efficacious in adsorbing the gases present in air emboli.

Recently a second class of oxygen therapeutics (allosteric modifiers) has been developed, and these agents enhance oxygen delivery by shifting the oxygen dissociation curve to the right, thus increasing tissue  $PO_2$ . Allosteric modifiers have been shown to shift the  $p50$  of Hb 10 mmHg at clinically relevant dosages, reduce (in animal models) cerebral infarct size following carotid ligation, and improve myocardial performance following myocardial ischemia. Despite significant research efforts, however, none of the solutions under development are currently approved for clinical use, with the exception of myocardial contrast imaging agents.

The oxygen transport capacity of PFCs was recently investigated in the hamster chamber window model microcirculation to determine the rate at which oxygen is delivered to the tissue in conditions of extreme hemodilution (Hct = 11%) (181). It was found that systemic and microvascular oxygen delivery was 25% and 400% higher in the PFC animals compared with Hydroxyethylstarch (HES) control animals, respectively, showing that PFCs deliver oxygen to the tissue when combined with hyperoxic ventilation in the present experiments, with no evidence of vasoconstriction or impaired microvascular function. Oxygen ventilation (100%) led to a positive base excess for the PFC group ( $5.5 \pm 2.5$  mmol/L) versus a negative balance ( $-0.8 \pm 1.4$  mmol/L) for the HES group, suggesting that microvascular findings corresponded to systemic events.

### Liposome-Encapsulated Hemoglobin and Hemoglobin Vesicles

Besides HBOCs and PFCs, liposome-encapsulated Hb, Hb with low oxygen affinity ( $P50 = 40-50$  mmHg), and Hb vesicles (phospholipid vesicles encapsulating concentrated human Hb) are candidate blood substitutes (182).

Animal studies have documented that hemodilution with liposome-encapsulated low-oxygen-affinity Hb facilitates rapid recovery from incomplete forebrain ischemia in the rat (183). On the basis of circulation kinetics, the half-life of  $99mTc$ -LEH in blood was determined to be 30 and 39.8 hours in rats and rabbits, respectively (184). Most recently, the effect of hemodilution with NeoRedCell (NRC, liposome-encapsulated Hb) on myocardial perfusion was evaluated in rat hearts under 300 bpm pacing and 100 mmHg perfusion pressure (185). The results suggested that NRC is superior to erythrocytes in terms of the homogenization of oxygen delivery, indicating its potential therapeutic value in myocardial microcirculatory failure.

Hb vesicles are produced from outdated human blood, and are stable in long-term storage, with a Hb concentration of 8.6 g/dL. Hb vesicles are similar to RBCs, since both have lipid bilayer membranes that prevent direct contact of Hb with endothelium and scavenging of nitric oxide. The oxygen transport capacity of phospholipid vesicles encapsulating purified Hb produced with a  $P50$  of 8 mmHg and 29 mmHg were investigated in the hamster chamber window model using microvascular measurements to determine oxygen delivery during extreme hemodilution (186). This study documented that improved tissue  $PO_2$  was obtained when red blood cells deliver oxygen in combination with an oxygen carrier with high rather than low oxygen affinity.

In a recent study using a rat hemorrhagic shock model, resuscitation with Hb-vesicle suspended in recombinant human serum albumin (HbV/rHSA) at an Hb concentration of 8.6 g/dL was compared with shed autologous blood (187). HbV suspended in rHSA provided restoration from hemorrhagic shock comparable with that using shed autologous blood.

### SUMMARY

Anemia is a common problem in trauma and critical care, and has significant consequences, including the high prevalence of blood transfusion and associated adverse outcomes. In trauma and critical care, multiple strategies for preventing anemia, including reduction in diagnostic phlebotomy, pharmacologic prophylaxis for stress-related mucosal damage and GI bleeding, and efforts to reduce blood loss in renal replacement therapy should be initiated. Furthermore, the use of blood transfusion for treatment of anemia should be considered only for manifestations of physiologic intolerance of anemia. Alternatives to blood transfusion are undergoing active investigation, including rHuEPO and HBOCs.

### KEY POINTS

- ✦ Anemia is common in the intensive care unit (ICU), and blood transfusions are often used to treat anemia in critical care.
- ✦ Low Hb concentration typically accompanies a decreased red blood cell (RBC) count and a decrease

in packed cell volume, although these indices may be normal in an anemic patient with low Hb levels alone.

9 Symptoms are dictated by the etiology, severity, and chronicity of the anemia.

9 Evaluation of red cell indices is the most clinically relevant measurement tool.

9 Laboratory evaluation of nutritional deficiencies that cause anemia should also be considered.

9 The endogenous hormone erythropoietin is critical for the normal blood marrow response to anemia.

9 It is important to understand the epidemiology of anemia in trauma and critical care in order to appreciate the large numbers of patients that require treatment for anemia.

9 An acute normocytic, normochromic anemia is associated with systemic blood loss.

9 In trauma, hemorrhagic shock and tissue injury also result in an acute inflammatory response, and the anemia associated with inflammation (or critical illness) rapidly ensues.

9 Phlebotomy is a significant contributor to ICU-acquired anemia.

9 A blunted erythropoietin response is commonly seen in critically ill or injured patients.

9 Anemia from chronic disease is encountered frequently in surgery and critical care, and may exacerbate acute anemia associated with trauma and hemorrhage.

9 The physiological response to anemia is dictated by the etiology and rapidity of onset of the anemia and the age and general state of health of the patient.

9 Adaptation to anemia and hypoxia results in the induction and regulation of a number of physiologically relevant genes in response to changes in intracellular oxygen tension.

9 Anemia adversely affects patient mortality and morbidity. Anemia in cancer patients correlates with poor clinical outcome, including reduced tumor response to anticancer therapy and mortality.

9 Cessation of active bleeding is a key component in the prevention of anemia due to acute hemorrhage.

9 Damage control concepts, including early control of hemorrhage and delay of definitive treatment or reconstruction, have now been applied to many areas of trauma care other than laparotomy and solid organ injuries, including treatment of thoracic injuries where hemorrhage control is quickly established.

9 Repeated phlebotomy for diagnostic laboratory testing contributes significantly to blood loss in critically ill patients.

9 Recombinant human erythropoietin (rHuEPO) rapidly produces erythropoiesis, and is used for treatment of anemia and to reduce the need for red blood cell transfusions.

9 A restrictive strategy of red cell transfusion is at least as effective as and probably superior to a liberal transfusion strategy in critically ill patients, with the possible exception of patients with acute MI or unstable angina.

9 The transfusion of blood products has been associated with worse clinical outcome in numerous studies.

9 Blood transfusion is associated with increased risk for death, perioperative infection, MODS, and ICU admission in the trauma patient population.

9 Blood product age correlates with mortality in patients admitted to the ICU with severe sepsis.

9 Increasing demand for blood products and safety concerns have stimulated the search for alternative

erythrocyte transfusion strategies such as the development of hemoglobin-based oxygen carriers (HBOCs).

### PLATELET PHYSIOLOGY

#### Platelet Production

##### Normal Platelet Count Range

✎ The normal platelet count is generally between 150 and  $400 \times 10^9/L$ . Although this is a wide normal range, the platelet count tends to remain fairly constant during the lifetime of an individual (1). ✎ However, as will be discussed later, the normal platelet count range is much higher (about  $250\text{--}1000 \times 10^9/L$ ) during the second week following an acute, reversible thrombocytopenia (2), because of transient platelet overproduction (“post-thrombocytopenia thrombocytosis”; discussed below).

#### The Megakaryocyte

Platelets originate from megakaryocytes, the largest cells resident within the bone marrow. Although platelets constitute about 5% of circulating blood cells, megakaryocytes are relatively infrequent, making up only 0.05% of nucleated marrow cells (3). However, each of the 40 million megakaryocytes can make 2000 to 3000 platelets (4). As the average human has about one trillion circulating platelets, and another one-half trillion platelets exchangeably sequestered within the spleen, the normal 10-day platelet survival indicates that about 150 billion platelets are manufactured daily. ✎ Normal platelet survival is approximately 10 days. ✎

Megakaryocytes develop in stages (5): the earliest committed megakaryocyte precursor in adult marrow is the burst-forming unit-megakaryocyte, followed by the colony-forming unit-megakaryocyte. These progenitor cells, which cannot be recognized morphologically, represent intermediate stages between the multipotential stem cell and megakaryocytes. Subsequent intermediate stages (megakaryoblast, basophilic megakaryocyte) can be identified morphologically.

Megakaryocytes are large multilobed cells that average  $35 \mu\text{m}$  in diameter (6). They exhibit a unique biologic process known as *endomitosis*, that is, repeated nuclear replication in the absence of cytoplasmic division, leading to polyploidy. Although present in largest numbers within the marrow, megakaryocytes are also found in extravascular sites, such as the spleen and lungs.

Complex cytoplasmic changes occur during megakaryocyte development. The most unique and dramatic is

the formation of extensive tubular, membrane-like organelles (the demarcating membrane system), which are involved in platelet formation (7). Microtubule bundles form within the megakaryocyte to create organelle-containing extensions called proplatelets. The demarcation membranes act as a reservoir, continuously providing membrane for the growing cytoplasmic proplatelet projections, which ultimately form both the internal (open canalicular system) and external platelet membranes (8). Specific platelet granules that contain adhesive and other platelet proteins are also formed.

Megakaryocytes are located in the extravascular marrow space. To what extent platelets are released from megakaryocytes directly into the marrow sinuses, versus release of intact proplatelets that subsequently fragment into platelets, and to what extent such fragmentation might occur in the circulation outside the marrow—or even within the pulmonary capillary bed (9)—remain uncertain.

#### Platelet Heterogeneity

Platelets exhibit remarkable size heterogeneity (10). The normal platelet size histogram is right-skewed, that is, there is a prominent “tail” of large-sized platelets. This size distribution can be normalized statistically by converting the platelet volume determinations to log values (“log-normal distribution”) (10). Platelet size can change somewhat under different situations: for example, animal models of acute thrombocytopenia demonstrate rapid increase in mean platelet volume (MPV) that indicates the capacity to modify platelet production rapidly (11). Platelets are also heterogeneous with respect to activation response to chemical agonists (12,13).

#### Platelet Distribution

Although the spleen normally receives only 5% of the cardiac output, at any one time about one-third of the circulating platelets are present within the spleen (splenic “sequestration” or “pooling”) (14,15). This relationship is explained by the relatively long splenic transit time (about 10 minutes) (16) compared with the average time a platelet takes to traverse other organs during the average circulatory pass (only about 1 minute) (Fig. 1).

**Figure 1** Physiologic and pathologic platelet splenic sequestration. Normally, about 5% of cardiac output is to the spleen; however, a platelet that enters the spleen spends about 10 minutes there (splenic transit time  $\sim 10$  minutes). In contrast, it usually takes only about one minute for a platelet to make a circulatory pass elsewhere. Thus, about one-third of the platelets at any one time are located within the spleen:  $(5\% \times 10 \text{ minutes}) : (95\% \times 1 \text{ minutes})$ , or a  $\sim 1:2$  ratio. In hypersplenism, the splenic blood flow can increase by a factor of 5, that is, from 5% to 25% of total blood flow per minute. Thus, even without increase in splenic transit time, up to 70% or more of the platelets can be exchangeably sequestered within the spleen.

☞ **Normally, about one-third of the circulating platelets are exchangeably sequestered within the spleen; increased spleen size leads to greater splenic pooling and thus thrombocytopenia (“hypersplenism”).** ☞

In pathologic states associated with splenomegaly, the splenic pool contains up to 70% or more of the platelet mass (hypersplenism). Two factors determine the extent of splenic pooling (17): splenic blood flow and splenic transit time. The most important determinant of splenic blood flow is the spleen size, and the most important determinant of splenic transit time is splenic perfusion (spleen blood flow/spleen volume) (16–18). However, as disorders that alter splenic transit time (e.g., congestive heart failure, rheumatologic disorders) usually have counterbalancing effects on splenic blood flow (17), in practical terms, spleen size correlates well with splenic platelet pooling. Thus, radiologic imaging of spleen size is indicated when assessing whether thrombocytopenia is caused by hypersplenism. A more recent concept is that reduced hepatic production of thrombopoietin (TPO) also contributes to the thrombocytopenia of hypersplenism secondary to liver disease (19).

## Thrombopoietin

### Thrombopoietin Structure, Regulation, and Function

Cytokines such as granulocyte-macrophage colony-stimulating factor and interleukin-3 (IL-3), and hormones, notably TPO (20), maintain the platelet count under tight regulatory control. TPO, which was cloned in 1994, consists of a 353-amino acid polypeptide, including a 21-amino acid secretory leader sequence, a 155-amino acid amino (N)-terminal domain, and a 177-amino acid carboxyl (C)-terminal domain. The N-terminal region has extensive homology with erythropoietin, and is responsible for binding of TPO to its cellular receptor. The C-terminal region, which has no homology with any known protein, is responsible for the long elimination half-life (30 hours), which exceeds that of any other hematopoietic factor.

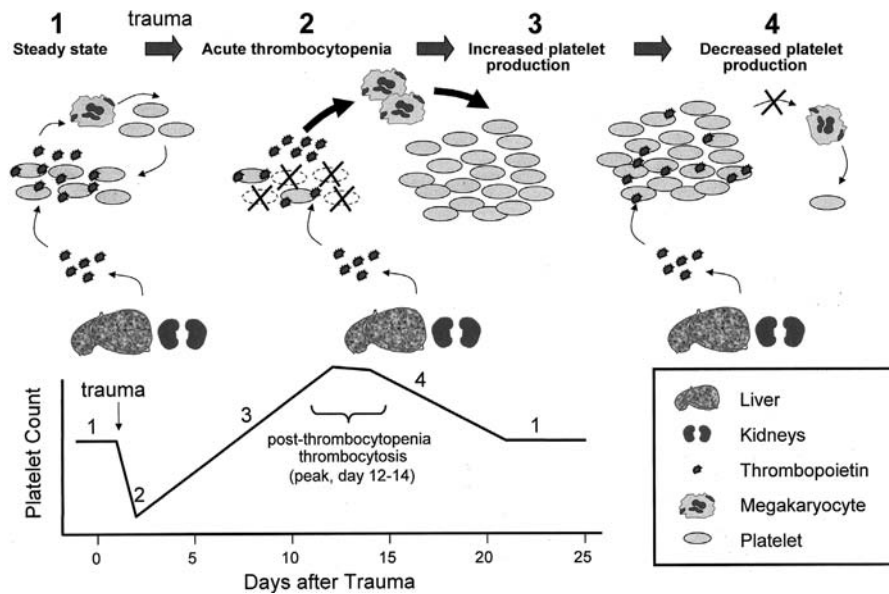

TPO exhibits relative specificity for the megakaryocyte lineage of hematopoietic stem cells. TPO binds a specific receptor (c-Mpl) on megakaryocytes and platelets (20). TPO binding to megakaryocyte receptors leads to megakaryocyte differentiation and proliferation. In contrast, binding of TPO to platelet receptors results in the degradation of TPO and its removal from circulation. Basal levels of TPO are produced constitutively by the liver (major source) and kidneys, which results in a constant level of TPO under steady-state conditions (Fig. 2) (21,22). During thrombocytopenia, the decreased platelet mass results in higher levels of free TPO, stimulating megakaryocytes to proliferate, differentiate, and shed new platelets. In thrombocytosis, the increased platelet mass acts as a “sink” for TPO and blood levels of the hormone decline. Thus, TPO concentrations are inversely related to platelet and megakaryocyte mass, forming a primitive feedback loop.

During thrombocytopenic “stress,” TPO can also be produced to a minor extent by the bone marrow and spleen (23). Thus, both constitutive and inducible TPO production elements contribute to platelet count regulation. TPO also “primes” platelets, making them more sensitive to platelet agonists (24).

Perhaps surprisingly, TPO levels are decreased in chronic platelet destructive disorders, such as chronic immune thrombocytopenic purpura (ITP), even when the platelet count is very low (25). It appears that the high platelet turnover in these disorders, which are characterized by increased megakaryocyte mass and increased platelet production, leads to considerable removal of TPO from the circulation, despite the chronic thrombocytopenia. In contrast, TPO levels are high in thrombocytopenic patients with megakaryocyte hypoplasia, for example, aplastic anemia, postchemotherapy, or postradiation therapy.

### Post-thrombocytopenia Thrombocytosis

The primitive TPO feedback loop (Fig. 2) ensures that acute thrombocytopenia associated with trauma, whether caused

**Figure 2** Thrombopoietin (TPO) physiology and post-thrombocytopenia thrombocytosis. TPO binds to platelets and megakaryocytes via a specific receptor (c-Mpl, not shown). The receptor-bound TPO is removed from circulation and degraded. The level of circulating TPO is thus inversely related to the mass of platelets and megakaryocytes. In thrombocytopenia, fewer binding sites are available, and free TPO levels are high, stimulating megakaryocyte proliferation and differentiation and leading to increased platelet production. In thrombocytosis, the high platelet mass acts as a “sink” for removing TPO, with decreased stimulus for platelet production. Thus, following acute thrombocytopenia, TPO levels rise about two-fold, leading to increased platelet production that begins on days 2 to 4, with resulting thrombocytosis that generally peaks about days 12–14 (post-thrombocytopenia thrombocytosis), and returns to baseline by about day 21.

by fluid resuscitation (hemodilution) and/or effects of the injury itself (DIC), leads to transient increase in blood TPO levels (about two-fold) (26). Because of the prolonged biological effects of TPO—due to its long elimination half-life (~30 hours) and its stimulation of both primitive and mature thrombopoietic cells—this acute thrombocytopenia will generally be followed by increased platelet count production that is first evident three to four days post-trauma, when the platelet count is first observed to begin to increase from the post-trauma nadir usually seen on day 2 or 3. Subsequently, thrombocytosis results, with the peak platelet count observed about 12 to 14 days post-trauma. At this point, the elevated platelet numbers lead to decreased TPO levels, reduced platelet production, and the platelet count returns to the normal baseline by about 3 weeks post-trauma (Fig. 2). If the platelet count fails to follow this normal recovery pattern, it often indicates complications of trauma, e.g., septicemia or SIRS.

♣ **Acute decrease in the platelet count in trauma leads to increase in TPO levels. The long half-life of TPO (30 hours) and its effects on early megakaryocyte progenitors mean that this trauma-associated thrombocytopenia is invariably followed by thrombocytosis from day 7 to 21 (peak, days 12–14), unless clinical complications lead to ongoing platelet consumption.** ♣

### Therapy with Thrombopoietin

Two forms of TPO have undergone clinical investigation: (a) TPO (full-length polypeptide) and (b) a truncated form consisting only of the receptor-binding moiety chemically modified by addition of polyethylene glycol (PEG). Unfortunately, commercial development of the latter preparation (PEG-conjugated recombinant human megakaryocyte

growth and development factor) was abandoned because of the occurrence of cross-reactive anti-TPO antibodies that caused long-term thrombocytopenia in some human volunteers (27). Unlike the experience with erythropoietin, clinical benefit of TPO even in patients with severe cancer-associated thrombocytopenia remains to be established. Ironically, platelet transfusions given to severely thrombocytopenic patients binds the TPO administered, thus negating its therapeutic effects.

## Platelet Function

### Platelet Adhesion (Primary Hemostasis)

Platelets provide the initial hemostatic response to vessel injury by adhering to subendothelial molecules (*primary hemostasis*). Adhesion is mediated by a platelet surface glycoprotein (GP) complex (GP Ib–IX–V) and the multimeric adhesion protein, von Willebrand factor (vWF) (28). Once tethered to the subvessel tissues, irreversible adhesion contacts form between platelet integrins and specific subendothelial matrix proteins, leading to platelet activation and aggregation. Besides normal quantities of platelets and vWF, a normal hematocrit is also important for maintaining primary hemostasis (Fig. 3).

♣ **Three components are required for normal primary hemostasis: (i) platelets, (ii) vWF, and (iii) normal hematocrit. In trauma, acquired thrombocytopenia and anemia lead to impaired primary hemostasis.** ♣

In trauma patients, acquired anemia and thrombocytopenia lead to impaired primary hemostasis. The common congenital bleeding disorder—type 1 von Willebrand disease (vWD-1), which occurs to a mild extent in 1% to 2% of the population, is not a common cause of bleeding

**Figure 3** Three determinants of primary hemostasis. In the microcirculation, the central location of the red blood cell column maintains platelets near the vessel wall, contributing to increased platelet–subendothelial interaction during vessel injury. Thus, a low hematocrit is one factor that leads to impaired primary hemostasis, for example, prolonged bleeding time, increased microvascular bleeding. Other factors include thrombocytopenia and deficiency in von Willebrand factor (vWF). Very rarely, congenital absence of the platelet surface glycoprotein complex (GP Ib–IX–V)—a disorder known as Bernard–Soulier syndrome (not shown)—explains inability of the platelets to bind to vWF, and thus impaired primary hemostasis. *Abbreviations:* RBC, red blood cell; vWF, von Willebrand factor.

post-trauma, because the physiologic response to injury includes release of endothelial stores of vWF (29).

### **Platelet Aggregations and Platelet Procoagulant Activity (Secondary Hemostasis)**

Following adhesion, platelets undergo aggregation and various “procoagulant” membrane changes (secondary hemostasis). A recent cell-based hemostasis model views three overlapping phases of coagulation, beginning when injury results in blood coming into contact with cells such as fibroblasts that are rich in tissue factor (TF) (Fig. 4) (30,31). The initiation phase of coagulation occurs when zymogen (proenzyme) factor VII binds to TF, leading to formation of activated factor VII (VIIa). The amplification phase results when small amounts of thrombin first generated on TF-bearing cells now activate cofactors (V to Va and VIII to VIIIa) and XI (to XIa) on the platelet surface. In the final propagation phase, the active serine proteases (Xa and IXa) combine with their cofactors (Va and VIIIa, respectively) to generate the “tenase” and “prothrombinase” complexes on platelet surfaces, producing the “thrombin burst” that leads to fibrin polymerization.

### **The Fixed Platelet Requirement**

The ongoing physiologic role of platelets in maintenance of hemostasis is illustrated by the concept of the “fixed platelet requirement,” that is, the constant homeostatic platelet losses needed to maintain vascular integrity. For example, radiolabeled platelet lifespan studies demonstrate an apparent reduction in platelet survival in all severely thrombocytopenic patients, including patients with impaired platelet production. To explain this, it has been proposed that a minimal, fixed number of platelets ( $7 \times 10^9/L$ , or about 20% of normal platelet turnover) is removed from the circulation each day independent of the platelet count (32). Although such platelet losses,

which are believed to contribute to maintaining vascular integrity via platelet–endothelial interactions, represent only a small part of normal platelet turnover, they constitute a relatively large component of platelet loss in patients with severely impaired platelet production.

This physiologic role of platelets in maintaining vascular integrity means that profound thrombocytopenia is incompatible with life. For example, a >99% decline to “only” 10 billion circulating platelets (i.e., a platelet count of  $1-2 \times 10^9/L$  or less) presents a major risk of fatal hemorrhage. Usually, such severe thrombocytopenia occurs only in patients with primary hematologic disorders, for example, severe ITP. However, in the context of a trauma patient, thrombocytopenia of even a moderate degree can contribute to bleeding because of the impairment in hemostasis that additionally results from injury to vessels, coagulopathy, and reduced hematocrit.

## **THROMBOCYTOPENIA**

Thrombocytopenia indicates reduced numbers of blood platelets. The term is derived from three Greek roots: *thrombo* = clot, *cyto* = hollow vessel (i.e., cell), and *penia* = poverty or need. Thus, the rough literal meaning—“need for a clotting cell”—is apropos to the context of thrombocytopenia complicating trauma, where platelet transfusions may be needed to prevent or treat bleeding.

Trauma often occurs to young and otherwise healthy individuals. Thus, pre-existing, chronic thrombocytopenia is uncommon in this patient population. Rather, thrombocytopenia in trauma is generally acute, either from direct effects of tissue injury leading to accelerated platelet consumption [e.g., disseminated intravascular coagulation (DIC)] or indirect effects of resuscitation (i.e., hemodilution). Besides initial thrombocytopenia, trauma patients are also at

**Figure 4** Cell-based model of hemostasis. Hemostasis is usually initiated when zymogen VII in blood contacts a TF-bearing cell, such as a fibroblast. Ultimately, small amounts of thrombin (IIa) are formed from prothrombin (II), leading to thrombin-induced platelet activation. The surface of activated platelets binds several active coagulation factors (Va, VIIIa, XIa), leading to propagation of coagulation, culminating in the “thrombin burst” that clots fibrinogen. During therapy with rVIIa, direct binding of VIIa to activated platelet surfaces may lead directly to thrombin generation on platelet surfaces (not shown). *Abbreviation:* TFPI, tissue factor pathway inhibitor.

risk for delayed onset of thrombocytopenia, in which later platelet count declines can indicate common complications such as septicemia or systemic inflammatory response syndrome (SIRS), or rare events such as drug-induced immune thrombocytopenia.

✎ **Four general mechanisms for thrombocytopenia exist: (i) decreased platelet production, (ii) increased platelet consumption (or destruction), (iii) hemodilution, and (iv) hypersplenism. Only two mechanisms—increased platelet consumption and hemodilution—are common in acute trauma. However, decreased production can develop following critical illness, or (along with hypersplenism) can be present as a pre-existing condition.** ✎

## APPROACH TO THROMBOCYTOPENIA

### Platelet Count Measurements (via Automated Particle Counters)

Blood count determinations are generally made using electronic particle counters, which provide the hemoglobin count, white blood count, and platelet count. In addition, various cell indices are provided, such as red cell volume (mean corpuscular volume) and platelet size (MPV). There is no single normal range for the MPV because this parameter varies with the platelet count: The normal MPV for a platelet count of  $150 \times 10^9/L$  is 9 to 12 femtoliters (fL), whereas for a platelet count of  $400 \times 10^9/L$ , it is 7.5–10 fL (33).

The MPV may assist the clinician in classifying the thrombocytopenic disorder (33). For example, thrombocytopenia caused by increased platelet destruction with a normal megakaryocyte response is characterized by a higher MPV (and more hemostatically effective platelets) than disorders of impaired platelet production or hypersplenism. However, the practical significance of these observations remains uncertain, and we believe that the MPV is only modestly helpful in classifying thrombocytopenia.

Occasionally, electronic particle counters will falsely under- or overestimate the true platelet count. Whenever this is suspected, a hematologist should review the peripheral blood smear, to evaluate platelet morphology and perform a manual platelet count. This is discussed further

below in the section on “Pseudothrombocytopenia and Pseudothrombocytosis.”

## History and Physical Examination

### Platelet Count History

As platelet counts are generally stable over an individual’s lifetime, one can usually obtain a patient’s “baseline” platelet count from their family physician’s office, or from records of prior hospitalizations. This can help in determining whether the patient has pre-existing chronic thrombocytopenia (see the section on “Pre-existing Thrombocytopenia”) or a prior episode of acute thrombocytopenia. Information about any previous bleeding, transfusion, or thrombotic events should be sought.

### Physical Examination

The clinical impact of thrombocytopenia usually is apparent from the physical examination. ✎ **The hallmark of severe thrombocytopenia is mucocutaneous bleeding, particularly pin-point intradermal hemorrhages known as petechiae.** ✎ These are non-raised, non-blanching, and represent capillary hemorrhages. Petechiae are most common in dependent areas, for example, the legs and feet in outpatients, and the back and posterior thighs in bedridden patients, because hydrostatic pressure contributes to the microvascular bleeding.

Oozing at intravascular catheter sites, or hemorrhage from the nose, genito-urinary tract, or other mucosal sites, can indicate severe thrombocytopenia. For example, “blood blisters” (hemorrhagic vesicles of the oral mucosa or tongue) are sometimes seen when the platelet count is  $10 \times 10^9/L$  or less, particularly if caused by autoimmune or drug-induced immune thrombocytopenia.

*Echymosis* denotes intradermal hemorrhage greater than 2 mm (larger than petechiae). However, ecchymoses are less specific for thrombocytopenic bleeding than are petechiae.

## Examining the Blood Film

### Pseudothrombocytopenia and Pseudothrombocytosis

Review of the blood film occasionally reveals spurious thrombocytopenia or thrombocytosis. For example, “pseudothrombocytopenia,” which occurs in about 0.1%

of complete blood counts, is caused by naturally occurring antibodies that lead to platelet clumping or (more rarely) to platelet “rosetting” around white blood cells. This phenomenon occurs under the low-calcium conditions of anticoagulated blood, for example, ethylene-diaminetetraacetic acid (EDTA)-induced pseudothrombocytopenia (34,35). Thus, the electronic particle counter underestimates the true platelet count. The major clinical significance is the risk for falsely diagnosing thrombocytopenia that is not present, or in causing difficulty in determining the true platelet count in a patient who also has true thrombocytopenia. Usually, collecting the blood into one of several alternative anticoagulants (heparin, sodium citrate, acid-citrate dextrose) and maintaining the temperature of the blood at 37°C until testing yield an accurate count. Additionally, the platelet count can be estimated by review of the blood film.

☞ **“Pseudothrombocytosis” occurs in patients with severe burns (36): Thermal injury to red cells produces microspherocytes that can be falsely identified as platelets by the electronic particle counter, and thus suggest apparent thrombocytosis when the patient may actually suffer acute burn-induced thrombocytopenia and DIC.** ☞

### Morphologic Clues to Diagnosis

Examining the peripheral blood film can provide important diagnostic clues in evaluating thrombocytopenia. Paradoxically, inspection of the red and white cells is usually more helpful than looking at the platelets. In a trauma patient, the presence of red blood cell (RBC) fragments suggests DIC, as the red cells are “scissored” by intravascular fibrin strands (37,38). Nucleated RBCs (normoblasts) and “left-shift” of leukocytes (“bands,” myelocytes, etc.) indicate a “leukoerythroblastic” picture that can be seen in severe shock or hemolysis. Granulocytes that contain “toxic” granules, cytoplasmic vacuolation, and pale blue cytoplasmic inclusions (Döhle bodies) strongly suggest septicemia. Pre-morbid hematologic disorders might also be suggested by the blood film, for example, macrocytic red cells suggestive of alcohol consumption or megaloblastic anemia, “tear drop” cells consistent with marrow fibrosis, red cell spherocytes indicating hereditary spherocytosis or immune hemolysis, dysplastic white cells suggesting myelodysplasia, etc.

## Hemostasis Testing

### Screening Assays

In a trauma patient, acute thrombocytopenia can indicate DIC, hemodilution secondary to fluid resuscitation, or both. Table 1 lists coagulation assays helpful for evaluating the presence of DIC, such as the prothrombin time (PT)—usually expressed as the international normalized ratio (INR)—the activated partial thromboplastin time (aPTT), fibrinogen, thrombin clotting time (TCT), and cross-linked fibrin degradation products (fibrin D-dimer). Generally, an increase in fibrin D-dimers or a positive “paracoagulation” assay (e.g., protamine sulfate test) suggests DIC (although both hemodilution and DIC cause abnormalities in routine coagulation assays, such as the INR, aPTT, TCT, and fibrinogen levels, hemodilution does not result in increased fibrin D-dimer or a positive protamine sulfate test). Nowadays, however, few hospital laboratories perform paracoagulation tests (38,39). DIC is more fully discussed in Volume 2, Chapter 58.

☞ **Coagulation testing is needed to distinguish whether thrombocytopenia is caused by hemodilution or acute DIC in a patient with trauma. Generally, increase in**

**fibrin D-dimers or a positive paracoagulation assay (e.g., protamine sulfate test) is confirmatory of DIC. Both hemodilution and DIC can cause abnormalities in routine coagulation assays, such as the INR, aPTT, TCT, and fibrinogen levels.** ☞

### Specialized Assays

The bleeding time is sometimes used to estimate the clinical significance of thrombocytopenia, although it is doubtful whether this provides information beyond that gleaned from the magnitude of the patient’s thrombocytopenia and

**Table 1** Hemostasis Testing Appropriate in a Trauma Patient

Test	Comments
CBC	Hemoglobin/hematocrit and platelet counts are important for assessing primary hemostasis
PT (often expressed as the INR <sup>a</sup> )	Assesses function of the “extrinsic” pathway factor (VII) and subsequent common pathway factors (X, V, II)
aPTT	Assesses function of the “intrinsic” pathway factors, including the contact factors <sup>b</sup> , VIII, and IX, as well as the subsequent common pathway factors (X, V, II)
Fibrinogen	Direct measurement of fibrinogen is useful because the INR and aPTT do not increase in hypofibrinogenemia unless the fibrinogen is severely reduced
TCT	Assesses fibrinogen levels and/or presence of heparin (which has antithrombin activity)
Fibrin D-dimer	Detects cross-linked fibrin degradation products which are formed when thrombin and plasmin have acted sequentially upon fibrinogen
Protamine sulfate or ethanol gel “paracoagulation” test	Semi-quantitative assay in which incubation of plasma with protamine sulfate (positively charged protein) leads to gelling of plasma in presence of clinically significant concentrations of fibrin monomer and fibrin degradation products (thus, the assay is fairly specific assay for DIC)
Bleeding time	Assesses “primary hemostasis” (Fig. 3); infrequently performed in a trauma patient

<sup>a</sup>The INR is determined by the patient’s prothrombin time (PT), the control PT, and a constant International Sensitivity Index (ISI) that is determined for the thromboplastin reagent and the coagulation analyzer used, as follows:  $INR = (PT_{patient}/PT_{control})^{ISI}$ .

<sup>b</sup>There are four contact factors: XI, XII, prekallikrein, and high-molecular-weight kininogen; only deficiency of factor XI is associated with bleeding. *Abbreviations:* CBC, complete blood count; DIC, disseminated intravascular coagulation; PT, prothrombin time; INR, international normalized ratio; aPTT, activated partial thromboplastin time; TCT, thrombin clotting time.

signs of hemostatic impairment on physical examination. Occasionally, other specialized coagulation tests provide useful information. For example, severe depletion in natural anticoagulants such as antithrombin or protein C can explain microvascular thrombosis and acral limb ischemia in a patient with DIC (38).

### **Pre-existing Thrombocytopenia** **Immune Thrombocytopenic Purpura**

Acute and chronic thrombocytopenia is often caused by autoantibodies that bind to platelet membrane GPs, leading to premature platelet destruction by the macrophages of the reticuloendothelial system (40–42). Treatment is generally avoided unless the patient has symptomatic thrombocytopenia, which usually occurs only when the platelet count is  $30 \times 10^9/L$  or less. Thus, there is the potential for marked thrombocytopenia in a trauma patient who has pre-existing chronic ITP. Although platelet transfusions are rarely indicated in chronic ITP (because antiplatelet antibodies limit their survival and clinical efficacy), their use is appropriate in emergency situations such as trauma. Adjunctive medical therapies that raise the platelet count within 24 to 48 hours include high-dose corticosteroids and high-dose intravenous gammaglobulin (IVIgG; 1 g/kg given over 6 to 8 hours intravenously on two consecutive days). Although Rh immune globulin administered to an Rh(D)-positive individual also raises the platelet count, this effect is generally slower than with IVIgG, and so anti-D is usually not given in emergency situations such as post-trauma. Also, anti-D is ineffective in patients who have previously undergone splenectomy for chronic ITP. Splenectomy is a relatively common therapy for chronic ITP, as it has a 75% probability of effecting long-term “cure” or amelioration of chronic thrombocytopenia.

### **Hereditary Thrombocytopenia**

These are relatively rare disorders that sometimes exhibit characteristic syndromes, e.g., thrombocytopenia-absent radii syndrome (marked reduction in megakaryocytes, deformed forearms and hands secondary to absent radii) and Wiskott-Aldrich syndrome (very small platelets, eczema, immunodeficiency, X-linked inheritance). Most often, patients with hereditary thrombocytopenia have very large platelets (“macrothrombocytopenia”), normal numbers of marrow megakaryocytes, and autosomal-dominant inheritance (43). In some families with macrothrombocytopenia, white cell inclusions are evident on microscopy, either without other somatic abnormalities (Sebastian syndrome) or with clinical features such as glomerulonephritis and deafness (Fechtner’s syndrome). No specific therapy is available for these disorders, and platelet transfusions should be reserved for life-threatening bleeding.

### **Hypersplenism**

Any cause of splenomegaly can cause chronic pancytopenia secondary to splenic sequestration of blood cells (see the section on “Platelet Distribution” and Fig. 1). Usually, mild-to-moderate thrombocytopenia and leukopenia are observed that parallel each other in severity; the reduction in hemoglobin is usually less marked. In western societies, the most common cause of hypersplenism is alcohol-induced cirrhosis, and so coagulopathy secondary to hepatic cellular dysfunction can coexist. Platelet transfusion response is often suboptimal in hypersplenism, because the transfused platelets become sequestered in the spleen to the same extent as

the patient’s own platelets. Patients with splenomegaly and particularly severe thrombocytopenia ( $20\text{--}50 \times 10^9/L$ ) probably also have impaired platelet production secondary to decreased hepatic TPO production (19).

### **Alcohol-Induced Thrombocytopenia**

Very heavy alcohol consumption has the potential to cause severe, isolated thrombocytopenia due to a direct toxic effect on megakaryocytes (44). Upon ceasing alcohol, the platelet count begins to increase after two to three days, typically leading to thrombocytosis by 10 to 17 days.

### **Clonal Marrow Disorders**

Demographics trends—particularly the “graying” of the population—suggest that increasing numbers of elderly patients will become victims of trauma. The elderly are at particular risk for one or more chronic cytopenias—often including thrombocytopenia—caused by clonal marrow disorders, for example, myelodysplasia (“preleukemia”) (45) or chronic lymphoid leukemia. In contrast, clonal myeloproliferative disorders often produce thrombocytosis (see the section on “Physiologic vs. Pathologic”). Platelet dysfunction in some patients with myelodysplasia may cause greater bleeding than expected for the degree of thrombocytopenia. Even in the absence of later transformation to acute leukemia, patients with myelodysplasia are at increased risk for death from infection, bleeding, or transfusional iron overload.

### **Platelet Dysfunction**

♂ **Platelet dysfunction in trauma patients is often the result of renal failure (uremia) or drug effects (e.g., aspirin, clopidogrel).** ♂ Less often, marrow disorders, gammopathy, cirrhosis, and post-cardiopulmonary bypass (CPB) status are possible explanations.

### **Uremia**

Acute or chronic renal failure causes bleeding diathesis characterized by prolonged bleeding time and various platelet function abnormalities (46). Defective primary hemostasis is partly explained by a low hematocrit, particularly in chronic renal failure (low erythropoietin levels), which explains why transfusing red cells can dramatically lower the bleeding time (47–49). Table 2 lists various strategies to reduce the uremic bleeding defect (46–62).

### **Drugs**

Antiplatelet agents, such as aspirin [acetyl-salicylic acid (ASA)] and clopidogrel, are increasingly used to prevent vascular thrombosis. Both can prolong the bleeding time and increase surgical bleeding (63,64). Although ASA and clopidogrel inhibit different aspects of platelet physiology [cyclooxygenase-1 (COX-1) and the adenosine diphosphate receptor, respectively], their effects are irreversible for the duration of the platelet lifespan; accordingly, platelet dysfunction lasts for up to 10 days even after stopping either drug (65). This contrasts with reversible COX inhibitors (e.g., nonsteroidal antiinflammatory agents, such as indomethacin, ibuprofen, and naproxen), in which platelet function recovers within hours after stopping the drug. Selective COX-2 inhibitors (e.g., celecoxib, rofecoxib) do not affect platelet function (66).

Platelet transfusions are indicated for life-threatening bleeding if clinical suspicion for significant drug-induced

**Table 2** Treatment of Abnormal Hemostasis Complicating Acute or Chronic Renal Failure

Treatment	Comment
Red cell transfusions (47–49) and/or erythropoietin (50) (target hematocrit >0.30)	Raised hematocrit improves hemostasis via enhanced platelet–subendothelial interaction (Fig. 3)
Increased intensity of hemodialysis	Removal of uremic “toxins” that impair platelet function
Desmopressin (L-deamino-8-D-arginine vasopressin), 0.3 µg/kg (maximum, 20 µg) in 50 mL normal saline over 30 min IV (51); may repeat once 8–12 hr later	Induces release of vWF <sup>a</sup> from endothelial stores; thus, less effective with repeated doses (tachyphylaxis) (52); hemostatic effect begins 30–60 min post-infusion and lasts for 8–12 hr
Conjugated estrogens, for example, Emopremarin, 0.6 mg/kg OD IV for 5 days (53–55); or Premarin, 50 mg po OD until bleeding time corrects (up to 9 days) (56)	Mechanism unknown, but possibly by reducing endothelial nitric oxide (physiologic platelet inhibitor) [57]; effect of 5-day course begins 6 hr after first dose, peaks at 5–7 days, and lasts for 14 days
Cryoprecipitate, 10 units (52,58)	Provides vWF <sup>a</sup> and fibrinogen; variable benefit (59); usually used only if patient does not respond to desmopressin and estrogens (60)
Platelet transfusions (for bleeding or shortly before invasive procedure)	Usually used only if patient does not respond to desmopressin and conjugated estrogens
rVIIa, 90 µg/kg IV once (30,61)	May enhance coagulation reactions on platelet surfaces in the absence of TF; anecdotal experience only; very expensive

<sup>a</sup>Abnormal vWF multimer distribution in uremic platelets and plasma has been reported (62).

Abbreviations: rVIIa, recombinant factor VIIa; TF, tissue factor; vWF, von Willebrand factor.

platelet dysfunction exists. Indeed, transfusing 5 to 10 units of platelets largely corrects ASA-induced platelet dysfunction, because the transfused platelets can provide thromboxane A<sub>2</sub> to the patient's aspirin-treated platelets via transcellular metabolic pathways.

### Miscellaneous Disorders

Platelet dysfunction is a common feature of certain acquired bone marrow disorders, such as myelodysplasia and myeloproliferative disorders. Marked elevations in monoclonal or polyclonal immunoglobulin levels (gammopathy) also can lead to impaired platelet function. Cirrhosis is another explanation for platelet dysfunction that can be transiently benefited by desmopressin (67); however, most patients with advanced liver disease also have thrombocytopenia, deficient coagulation factors, and hyperfibrinolysis. Heart surgery utilizing CPB leads to impaired hemostasis via transient platelet dysfunction, hyperfibrinolysis, and thrombocytopenia. Antifibrinolytic agents, especially when given during CPB, ameliorate bleeding.

Rare congenital disorders with abnormal platelet structure [e.g., Bernard–Soulier syndrome (absent platelet GP Ib–IX–V receptor complexes), Glanzmann's thrombasthenia (absent platelet GP IIb/IIIa receptors)] can be associated with severe abnormalities in platelet function. More common are poorly characterized platelet function disorders that may prompt consideration for platelet transfusions and/or desmopressin following trauma, particularly if one obtains a history of chronic mucocutaneous bleeding in the patient or family members.

## ABRUPT ONSET OF THROMBOCYTOPENIA AFTER TRAUMA

### Hemodilution

#### General Principles

A platelet count decline that is roughly proportional to the amount of crystalloid, colloid, or red cell concentrates administered is known as dilutional thrombocytopenia. Even in the absence of ongoing platelet losses, thrombocytopenia

persists for two to four days, prior to platelet count increase and subsequent thrombocytosis resulting from increased platelet production (Fig. 2). Dilutional coagulopathy generally accompanies thrombocytopenia. However, acute DIC frequently coexists, and thus frequent CBC and coagulation testing is important for assessment of hemostatic compromise (Table 3).

**Table 3** Interpretation of Platelet Count and Coagulation Test Results

Test	Approximate normal range	Patient #1	Patient #2
Platelet count	150–400 × 10 <sup>9</sup> /L	50	50
INR	0.9–1.2	1.6	1.6
aPTT	26–38 sec	50	50
TCT <sup>a</sup>			
10 unit	7–11 sec	15	15
2 unit	20–30 sec	40	40
Fibrinogen (clottable)	1.6–4.2 g/L	0.8	0.8
Fibrin D-dimer <sup>b</sup>	<500 µg/L	500	>2000
Protamine sulfate test <sup>b</sup>			
15 min	Negative	Negative	2+
30 min	Negative	Negative	3+
Interpretation		Hemodilution	DIC (± hemodilution)

<sup>a</sup>Different concentrations of thrombin can be used to perform the thrombin clotting time (TCT). The lower the thrombin concentration, the more sensitive the assay is to the presence of heparin in the blood sample.

<sup>b</sup>Generally, an increase in fibrin D-dimers or a positive paracoagulation assay (e.g., protamine sulfate test) is needed to diagnose DIC, as hemodilution can lead to abnormalities in routine coagulation assays, such as the INR, aPTT, TCT, and fibrinogen levels.

Abbreviations: aPTT, activated partial thromboplastin time; DIC, disseminated intravascular coagulation; INR, international normalized ratio; TCT, thrombin clotting time.

✎ **Dilutional thrombocytopenia related to fluid resuscitation is the most common cause of thrombocytopenia in a trauma patient. Repeated CBC and coagulation testing is important to assess the presence and severity of coexisting DIC.** ✎

### Massive Transfusion

Massive transfusion is generally defined as replacement of a patient's blood volume within 24 hours, that is, about 3000 mL or 10 units of red cell concentrates in an average-size individual (68,69). Trauma accounts for at least one-third of massive transfusion situations (68,69). At one time, "formulaic" approaches to massive transfusion were advocated, that is, the automatic transfusion of platelets and fresh frozen plasma (FFP) after every 'nth' unit of red cells or whole blood. However, a randomized trial of prophylactic platelet transfusion and FFP during massive transfusion did not show improved outcomes using this approach (70). Further, diffuse microvascular bleeding is relatively uncommon even when serious derangements in platelet count and coagulation tests result (70,71), and the correlation between units of red cells transfused and laboratory abnormalities observed is poor (68). Thus, "automatic" platelet transfusions are not generally advised. However, aggressive correction of platelet and coagulation abnormalities was associated with improved survival in one retrospective study (72). ✎ **When diffuse bleeding is evident or relatively severe thrombocytopenia is documented (generally, less than  $50 \times 10^9/L$ ), platelet transfusion support is appropriate (73–75). A higher platelet count threshold (i.e.,  $100 \times 10^9/L$ ) is a more appropriate transfusion trigger for certain conditions (e.g., traumatic brain injury).** ✎

### Acute Disseminated Intravascular Coagulation

DIC is a clinicopathologic disorder in which systemic generation of intravascular thrombin leads to a generalized derangement of the hemostatic mechanism via consumption of coagulation factors and platelets, and generation of intravascular fibrin and fibrinogen/fibrin degradation products (76–79). Bleeding can result from depletion of procoagulant factors and platelets, and from parallel generation of plasmin (the enzyme that degrades the fibrin clot). Formation of intravascular fibrin is one mechanism to account for multiple-organ dysfunction syndrome (MODS). Occasionally, depletion of natural anticoagulant factors (e.g., antithrombin, protein C) leads to dramatic syndromes of micro- or macrovascular thrombosis. The clinical spectrum of DIC is wide, ranging from laboratory abnormalities without clinical sequelae, to severe bleeding caused by depletion of coagulation factors and platelets and/or hyperfibrinolysis, to organ dysfunction and skin necrosis resulting from microvascular thrombosis.

Thrombocytopenia in DIC probably results at least in part from platelet activation and consumption caused by thrombin, the major physiologic platelet agonist. Indeed, thrombin concentrations as low as 0.15 nmol/L can activate platelets without any effect on fibrin generation (80). Thrombin-induced platelet activation also leads to formation of procoagulant platelet-derived microparticles, suggesting that platelet activation directly promotes the consumption of the coagulation factors in acute DIC.

DIC in trauma is usually multifactorial. For example, an early event in many trauma patients is vascular disruption, which causes blood to become exposed to extravascular TF (81). This leads directly to activation of coagulation via the

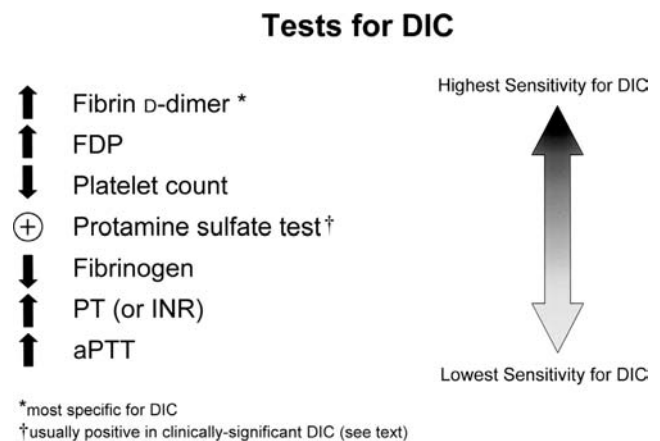

"extrinsic" system: TF:VII(a) complexes directly activate factor X to Xa on TF-bearing cells (Fig. 4). In some patients, procoagulant substances are liberated through massive red cell membrane disruption, for example, burn-associated hemolysis. Subsequent events such as shock and acidosis lead to further procoagulant changes on endothelium. Finally, generation of cytokines and other proinflammatory mediators characteristic of SIRS occurs, often with concomitant MODS and adult respiratory distress syndrome (ARDS) (82,83).

Figure 5 lists various coagulation assays that can be used for rapid laboratory assessment of DIC. An important tenet of viewing DIC as a clinicopathologic disorder is that no single laboratory profile is diagnostic of DIC. For example, a routine postcardiac surgery patient will have laboratory abnormalities that resemble that for DIC, so interpretation of test results in the clinical context is paramount. Similarly, fluid resuscitation will cause a trauma patient to have prolonged INR and aPTT assays, reduced fibrinogen, thrombocytopenia, and so on. However, greatly increased fibrin D-dimer levels and a strongly positive ethanol gel or protamine sulfate paracoagulation assay (38,39) suggest intravascular fibrin formation and hence have greater specificity for indicating the presence of DIC (Table 3).

Management of DIC includes treating the cause (where possible) and any potentiating factors. Thus, treating hypovolemia, acidosis, hypoxemia, infection, and so on are mandatory. In addition, red cell, plasma, and platelet transfusions for patients with coagulopathic bleeding or severe derangement in laboratory parameters may also improve outcomes. Diagnosis and management of DIC are discussed further in Volume 2, Chapter 58.

### Systemic Inflammatory Response Syndrome

Severe trauma complicated by DIC often leads to early death from MODS. In less serious trauma, systemic inflammation

**Figure 5** Sensitivity and specificity of routine coagulation assays for DIC. In the authors' opinion, the protamine sulfate paracoagulation assay for fibrin monomer has a relatively high sensitivity and specificity for clinically significant DIC, that is, DIC complicated by thrombosis or bleeding. However, this assay is no longer widely performed. *Abbreviations:* DIC, disseminated intravascular coagulation; FDP, fibrin(ogen) degradation products; INR, international normalized ratio; PT, prothrombin time; aPTT, activated partial thromboplastin time; ↑, increased, ↓, decreased; +, positive.

associated with activation of coagulation and fibrinolysis is self-limited, and initially abnormal hemostasis parameters, including the platelet count, normalize. However, there remain a sizeable group of trauma patients who develop SIRS (83). In these patients, laboratory abnormalities consistent with DIC persist. Microvascular thrombosis secondary to DIC is associated with MODS and ARDS. Associated hemostasis abnormalities include persisting thrombocytopenia, elevated fibrin D-dimers, elevated plasminogen activator inhibitor-1 (PAI-1) levels, and decrease in natural coagulation inhibitors (antithrombin, protein C). These abnormalities appear to be related to proinflammatory cytokines such as tumor necrosis factor- $\alpha$ , interleukin-6, and interleukin-8, that promote TF-mediated DIC and increased PAI-1 levels. The strong association between thrombocytopenia and SIRS is one reason why persisting thrombocytopenia is a simple, but strong, risk factor associated with increased mortality following trauma (82,83).

### Mechanical Assist Devices

Platelet consumption from intravascular devices such as the intra-aortic balloon pump or left (or right) ventricular assist devices may contribute to thrombocytopenia (84,85). However, the extent to which the mechanical device directly contributes to platelet consumption vis-a-vis platelet activation related to shock, ARDS, and so on, is difficult to ascertain. Heparin is generally given with these devices, and so an important issue is whether the thrombocytopenia may be caused by immune heparin-induced thrombocytopenia (HIT) (see the section on "Immune Heparin-induced").

### Hypothermia

Thrombocytopenia of mild-to-moderate severity that corrects with rewarming has been observed in humans undergoing planned or accidental hypothermia. Platelet kinetic studies in cooled dogs demonstrate reversible hepatic and splenic platelet sequestration (86,87). Indirect evidence suggests that decreased platelet production may contribute to this phenomenon as well (88).

## DELAYED ONSET OF THROMBOCYTOPENIA AFTER TRAUMA

### Septicemia

Infection is a relatively common cause of unexpected thrombocytopenia that occurs during the hospitalization of a trauma patient. Usually, thrombocytopenia in this setting indicates microbial invasion of the blood, that is, bacteremia, fungemia, and so on. Thus, blood cultures should be drawn in any patient with unexpected thrombocytopenia. Examination of the blood film often reveals other evidence for infection, that is, left-shift in the white blood cells, "toxic" changes such as vacuolation, and dark granules in neutrophils. These findings may be evident even when the total leukocyte count is not increased. Coagulation assays for DIC should also be ordered, although in many patients with septicemia-associated thrombocytopenia, evidence for DIC is limited to elevated fibrin D-dimer levels, with normal INR, aPTT, fibrinogen, and protamine sulfate para-coagulation test results.

🐉 **Late onset of thrombocytopenia in a trauma patient can indicate acute bacteremia, so blood cultures should always be drawn in this situation.** 🐉

The pathogenesis of thrombocytopenia is multifactorial, and includes platelet activation by thrombin (89),

increased platelet clearance by reticuloendothelial cells (90), decreased marrow platelet production, and direct and indirect effects of microbial toxins (91,92). Elevation in PAI-1 may contribute to hypofibrinolysis, with increased risk for MODS.

Aggressive treatment of the infection is crucial. Prophylactic platelet transfusions are usually given for severe thrombocytopenia (e.g., platelet count less than  $20 \times 10^9/L$ ), although a higher platelet count threshold (e.g.,  $50 \times 10^9/L$ ) is appropriate if the patient is bleeding or an invasive procedure is planned.

### Drug-Induced Thrombocytopenia

Table 4 lists various drug-induced thrombocytopenic syndromes. In general, drug-induced thrombocytopenia is rare, and is most unlikely to be the cause of thrombocytopenia in a trauma patient. The major exception to this rule is immune HIT, which can explain thrombocytopenia in about 1% to 3% of patients treated with unfractionated heparin (UFH) for more than one week (2,93).

### Immune Heparin-Induced Thrombocytopenia

🐉 **HIT is by far the most common drug-induced, immune-mediated thrombocytopenia. Paradoxically, HIT is associated with thrombosis rather than bleeding (2).** 🐉 Typical sequelae of HIT include: venous thromboembolism (deep-vein thrombosis, pulmonary embolism), thrombosis of large arteries (lower limb > cerebrovascular > coronary > other), and other complications such as skin lesions and acute inflammatory or cardiorespiratory reactions post-heparin bolus (Table 5) (94). Hypotension and/or abdominal pain suggests adrenal hemorrhagic infarction, which typically is bilateral and therefore results in acute and chronic adrenal insufficiency (Fig. 6) (94). By recognizing this syndrome, the clinician can prevent death from adrenal failure by administering corticosteroid replacement.

🐉 **Hypotension and/or abdominal pain in a thrombocytopenic patient treated with heparin suggests bilateral adrenal hemorrhagic infarction with acute adrenal failure: Corticosteroid replacement therapy can be life-saving.** 🐉

HIT can be difficult to diagnose in trauma patients, for several reasons. First, trauma patients often have multiple alternative explanations for thrombocytopenia (DIC, ARDS, septicemia, etc.). Second, thrombocytopenia is usually not very severe in HIT: The platelet count nadir falls between  $30$  and  $100 \times 10^9/L$  in about 60% of HIT patients, which is similar to that observed in DIC, ARDS, septicemia, and so on (Fig. 7) (94). Third, even when HIT antibodies are detected in the laboratory, these are not specific for HIT, as many patients who receive heparin develop subclinical seroconversion (generation of non-pathogenic antibodies) (2,93). Particularly in a trauma patient—where multiple alternative explanations for thrombocytopenia may exist—the lack of diagnostic specificity is problematic. An important clinical clue indicates that HIT is the onset of an unexpected fall in the platelet count beginning 5 to 10 days after beginning a course of heparin (94).

Pathogenesis (Fig. 8): The pathogenic HIT antibodies recognize a "self" protein, platelet factor 4 (PF4) (95,96). PF4 is a tetrameric, positively charged protein found within platelet  $\alpha$  granules. Neopeptides are formed when PF4 binds to heparin (negatively charged mucopolysaccharide) (97). When multimolecular complexes of heparin, PF4, and the pathogenic IgG antibodies form on platelet surfaces, the Fc "tails" of the HIT-IgG interact with a low-affinity class

**Table 4** Syndromes of Drug-Induced Thrombocytopenia

Syndrome	Implicated drugs	Comments
Immune HIT	UFH; LMWH; certain polyanion but non-heparin drugs (e.g., pentosan polysulfate)	Most common immune drug reaction; prothrombotic; typically causes mild-to-moderate thrombocytopenia
D-ITP	Quinine, quinidine, gold salts, vancomycin, rifampicin, sulfa drugs (e.g., sulfamethoxazole-trimethoprim), naproxen, pentamidine, acetaminophen, aspirin, carbamazepine, carbimazole, cefotetan, etc.	Very rare; severe thrombocytopenia with mucocutaneous bleeding (platelet count nadir typically less than $20 \times 10^9/L$ ); treatment may include platelet transfusions and high-dose IVIgG
Abrupt D-ITP caused by platelet GP IIb/IIIa inhibitors	Abciximab (Reopro <sup>®</sup> ), eptifibatid (Integrelin) tirofiban (Aggrastat <sup>®</sup> )	Moderate-to-severe thrombocytopenia that occurs abruptly in ~1–2% of patients
Drug-induced platelet agglutination	Protamine sulfate, porcine vWF, heparin, others	Mild platelet fall that is not clinically significant
Drug-induced microangiopathy (TTP or HUS)	Mitomycin C, cyclosporine, quinine, ticlopidine, clopidogrel	Antibodies against vWF-cleaving metalloproteinase have been reported in ticlopidine-associated TTP
Drug metabolite-dependent decrease in platelet production (?)	Valproic acid	Mild thrombocytopenia without clinical relevance; thrombocytopenia correlates with levels of valproate metabolite

*Abbreviations:* D-ITP, drug-induced immune thrombocytopenic purpura; HIT, heparin-induced thrombocytopenia; HUS, hemolytic uremic syndrome; LMWH, low-molecular-weight heparin; TTP, thrombotic thrombocytopenic purpura; UFH, unfractionated heparin; vWF, von Willebrand factor.

of platelet Fc receptors, causing the platelets to activate. Heparin chains that are at least 10 monosaccharide units in length bind to PF4 (98), perhaps explaining why UFH causes HIT antibody formation, and clinical HIT, more often than does low-molecular-weight heparin (2,93).

HIT is a hypercoagulability disorder, that is, there is increased thrombin generation in vivo (99). Activation of coagulation occurs by formation of procoagulant platelet-derived microparticles during platelet activation, as well as activation of endothelium and monocytes. Nevertheless,

“overt” DIC—manifesting either hypofibrinogenemia or elevated INRs—occurs in only 5% to 10% of HIT patients. Once triggered, the prothrombotic nature of HIT persists for a few weeks, even despite stopping heparin (100).

The systemic activation of coagulation explains the association between HIT and venous thrombosis, as well as the risk for progressive microvascular thrombosis during acute protein C depletion (warfarin-associated venous limb gangrene complicating HIT) (99). Thus, warfarin should be avoided during acute HIT, among other “treatment

**Table 5** Clinical Sequelae of Immune HIT

Venous thrombosis	Arterial thrombosis	Miscellaneous
DVT	Aorto-iliofemoral thrombosis	Heparin-induced skin lesions <sup>c</sup>
Lower-limb (often bilateral)	Limb ischemia/necrosis	Coumarin (warfarin)-induced skin necrosis <sup>b</sup>
Upper-limb DVT (usually at intravascular catheter site)	Paralysis	Acute systemic reaction post-intravenous heparin bolus
Phlegmasia cerulea dolens <sup>a</sup>	Thrombotic stroke	Inflammatory reaction: fever, chills, flushing
Coumarin (warfarin)-associated venous limb gangrene <sup>b</sup>	Myocardial infarction	Cardiorespiratory reaction, for example, cardiac or respiratory arrest
Pulmonary embolism	Intracardiac thrombosis (atrial, ventricular)	Gastrointestinal: vomiting, diarrhea
Cerebral dural sinus thrombosis	Miscellaneous thrombosis involving: mesenteric arteries, renal arteries, spinal arteries, brachial arteries and so on	Neurologic: transient global amnesia
Adrenal hemorrhagic infarction acute and/or chronic adrenal insufficiency		DIC (risk for microvascular thrombosis)

<sup>a</sup>Inflamed, blue, painful limb, that is, venous ischemia (prodrome to venous limb gangrene); in heparin-induced thrombocytopenia (HIT)-associated deep vein thrombosis, progression to venous limb gangrene has been linked to warfarin therapy causing depletion of the vitamin K-dependent natural anticoagulant, protein C (99).

<sup>b</sup>Warfarin-induced necrosis is more likely to manifest as venous limb gangrene (acral necrosis) than as “classic” skin necrosis (central sites, e.g., breast, abdomen, thigh) when it complicates a platelet activation disorder such as immune HIT.

<sup>c</sup>Occurs at heparin injection sites, and ranges from erythematous plaques to frank necrosis.

*Abbreviations:* DVT, deep-vein thrombosis; HIT, heparin-induced thrombocytopenia; DIC, disseminated intravascular coagulation.

**Figure 6** Bilateral adrenal hemorrhagic infarction complicating HIT and septicemia. Abdominal ultrasonography on day 16 showed massive bilateral adrenal hemorrhages that were not evident on imaging performed five days earlier. In such a patient, corticosteroid therapy can be life-saving. *Abbreviation:* HIT, heparin-induced thrombocytopenia.

paradoxes" (Table 6). Currently, treatment of HIT involves substitution of heparin with another anticoagulant that inhibits thrombin directly (lepirudin, argatroban) or that reduces thrombin generation by inhibition of factor Xa (danaparoid) (Fig. 9) (95,101). Lepirudin is renally excreted, and thus is relatively contraindicated in renal failure, which occurs commonly in ill post-trauma patients.

**Drug-Induced Immune Thrombocytopenic Purpura**

There are several drugs for which severe immune-mediated thrombocytopenia can occur, albeit rarely (Table 4). Typically, platelet count nadirs are less than  $20 \times 10^9/L$ . For example, sulfamethoxazole-trimethoprim causes D-ITP in about 1/15,000 to 1/25,000 patients, and quinidine in about 1/1,000 patients (102). For patients with life-threatening thrombocytopenia, platelet transfusions along with reticuloendothelial blockade with high-dose IVIgG is appropriate. The rarity of these reactions means that they will almost

**Figure 7** Severity of thrombocytopenia in drug-induced immune thrombocytopenia: comparison of D-ITP and immune HIT. Note that the relative risk of HIT-associated thrombosis increases as the platelet count nadir decreases. Note also that the median platelet count nadir in HIT (about  $60 \times 10^9/L$ ) resembles that seen in many other causes for thrombocytopenia in a patient with trauma, for example, DIC, ARDS, SIRS, and so on. *Abbreviations:* D-ITP, drug-induced immune thrombocytopenic purpura; HIT, heparin-induced thrombocytopenia.

never explain thrombocytopenia in a critically ill trauma patient.

**Miscellaneous Drug-Induced Thrombocytopenia**

Table 4 also lists other distinct drug-induced thrombocytopenic syndromes (102,103). In general, these syndromes are unlikely to cause significant thrombocytopenia in a trauma population.

**Nutritional Thrombocytopenia**

Acute folic acid deficiency is a possible explanation for acquired thrombocytopenia in a trauma patient who has increased metabolic demands following tissue injury and blood losses, and who may not be receiving adequate nutrition following the injury (104,105).

**Thrombocytopenia Following Blood Transfusion**

Paradoxically, blood transfusion therapy itself can result in severe thrombocytopenia. Three examples that are discussed later in this chapter (see the section on Contraindications to platelet transfusion") include (in decreasing order of frequency): transfusion-associated bacteremia, post-transfusion purpura (PTP), and passive alloimmune thrombocytopenia (PAT). A more common situation is that the clearance of transfused platelets over 24 to 48 hours after platelet transfusion mimics new-onset thrombocytopenia (Fig. 9).

**PLATELET TRANSFUSION THERAPY**

**Overview**

In general, life-threatening bleeding caused by thrombocytopenia is rare. Indeed, mortality usually results from the underlying cause of the thrombocytopenia, rather than from thrombocytopenic bleeding itself. This is evident in trauma patients, where severe injury that results in thrombocytopenia can cause death via any of a large number of mechanisms other than bleeding, particularly given the wide availability of platelet transfusions for preventing and treating thrombocytopenic bleeding of numerous etiologies. Indeed, some 8 million units of platelets are transfused each year in the United States (106).

The following section will outline aspects of the preparation of platelet products and safety issues. The expected therapeutic response to transfusion, important contraindications to platelet transfusions, and complications will also be reviewed.

**Platelet Preparation**

**Pooled Platelets vs. Single-Donor Plateletpheresis**

Platelets are usually prepared by separating the platelet component from random-donor whole blood donations. Each "unit" of platelet concentrate is stored for up to five days, and then (usually) five units of platelets, each from a different donor, are pooled shortly before use. After pooling, a standard 5-unit "dose" of platelets contains about  $300 \times 10^9$  platelets, that is, about one-fifth the normal number of circulating platelets in an average-size adult. This product also contains about 250 to 300 mL plasma (each platelet donor contributes about 50–60 mL plasma) and (if unfiltered) also contains about  $0.5 \times 10^9$  leukocytes.

Alternatively, platelets can be collected from a single donor using apheresis ("plateletpheresis"), whereby an efferent venous catheter channels whole blood from the donor into a blood separator where the platelet component is collected; the remaining (platelet-poor) blood flows back

**Figure 8** Pathogenesis of HIT: a central role for thrombin generation. The target antigen of HIT is a “self” protein, platelet factor 4, that expresses one or more neopeptides when bound to heparin. HIT-IgG antibodies lead to increased thrombin generation, by activating platelets via their Fc receptors (which results in formation of procoagulant, platelet-derived microparticles), as well as activating endothelium and monocytes. *Abbreviation:* HIT, heparin-induced thrombocytopenia.

**Table 6** Paradoxes in the Treatment of HIT

Treatment	Paradox	Comments
Stop heparin	Risk for thrombosis persists for days to weeks	Use alternative anticoagulant <sup>a</sup> even for “isolated HIT”
Warfarin	Warfarin-induced venous limb gangrene or skin necrosis	Avoid warfarin unless satisfactorily anticoagulated with alternative anticoagulant <sup>a</sup> and thrombocytopenia has substantially recovered (platelet count $>150 \times 10^9/L$ )
LMWH	Although less likely to cause HIT than UFH, LMWH is contraindicated to treat HIT	Approximately 50% risk of thrombocytopenia and/or thrombosis if LMWH is used to treat HIT caused by UFH
Platelet transfusions	May increase risk for thrombosis	Spontaneous bleeding rare and platelet transfusions theoretically confer risk
Dosing of alternative anticoagulant	“Therapeutic” dosing of anticoagulation is appropriate even when preventing thrombosis in acute HIT	Prophylactic-dose for danaparoid (750 Units bid s.c.) is suboptimal for preventing thrombosis in HIT; therapeutic doses are recommended (initial 2250 unit bolus for average-size adult, then 3600–4800 Unit 24 hr); argatroban and lepirudin are also generally prescribed in therapeutic doses
Repeat use of heparin	Re-exposure to heparin is appropriate under exceptional circumstances	Negligible risk of acute HIT once antibodies are no longer detectable

<sup>a</sup>Alternative anticoagulants include: lepirudin, bivalirudin, argatroban, and danaparoid (danaparoid has been withdrawn from the U.S. market, but is available in Canada, Europe, Japan, Australia, and New Zealand).

*Abbreviations:* HIT, heparin-induced thrombocytopenia; LMWH, low-molecular-weight heparin; UFH, unfractionated heparin.

## Typical-Onset HIT

**Figure 9** Typical-onset HIT in a trauma patient. The initial platelet count fluctuations are explained, in sequence, by: hemodilution  $\pm$  DIC, platelet transfusions, and clearance of the transfused platelets. The dotted line indicates the expected platelet count sequence in this patient. Thus, the unexpected platelet count fall on day 5 indicates immune HIT, which was confirmed by strong positive testing for HIT antibodies. The patient received prophylactic-dose danaparoid sodium, although therapeutic-dose anticoagulation would have been preferred in this situation (102). (Note: Danaparoid is no longer available in the United States, as it was withdrawn by the manufacturer in April 2002.) *Abbreviation:* HIT, heparin-induced thrombocytopenia.

to the donor via an afferent venous catheter. The volume of platelet concentrate can be predetermined prior to plateletpheresis, but in general, the equivalent of five units of random-donor platelets are collected from a single apheresis donor. Following collection, the platelets are also stored for up to five days prior to use.

Both types of platelet concentrate are equally effective in raising the platelet count (107,108), with an equivalent incidence of nonimmune refractoriness (109). However, febrile non-hemolytic transfusion reactions (FNHTR, "febrile reactions") occur less often with apheresis platelets (110), an effect that may have been due to differences in storage times in comparative studies (111). Obviously, the risk of infectious disease transmission with pooled platelets from multiple donors is greater (about five-fold). However, the current rates of viral disease transmission are so low that the absolute risk-reduction using single-donor apheresis platelets is negligible (112). The incidence of bacterial contamination appears to be lower with apheresis platelets as well (113), although fatal septicemia has occurred with both preparations.

Limiting exposure to multiple donors also has the advantage of decreasing the likelihood of HLA alloantibody formation by the blood recipient, thus potentially reducing subsequent immune-mediated platelet transfusion refractoriness. However, removing the white blood cells (which cause alloimmunization) by filters is also effective at preventing HLA alloimmunization, and much more cost-effective. Leukoreduction of platelet and red cell products is even standard in Canada, with filtration performed soon after blood collection ("universal pre-storage leukodepletion"). However, avoiding HLA alloimmunization is not a major issue in the trauma patient, in contrast to patients who require long-term platelet transfusion support (e.g., cancer patients).

Platelets collected by apheresis also have a place in specialized transfusion situations, for example, when a patient must receive HPA-1b homozygous platelets (only 2% of Caucasians) because of PTP.

### Platelet Storage

Platelets can be stored at room temperature for up to five days; if not transfused by that time, they are discarded. Prior to 1985, platelet storage up to seven days was permitted by the FDA. However, the risk of bacterial contamination in platelets rises with increasing storage time, especially since platelets—unlike other blood products—are stored at room temperature (114). Platelet viability is lost if they are cooled, and they are stored with constant agitation to inhibit clumping. Also, with prolonged storage, function and viability of platelets are adversely affected (115,116).

The plasma component within a platelet product is responsible for producing most febrile reactions, due to the presence of proinflammatory cytokines such as interleukin-1 $\beta$  and interleukin-6 produced during platelet storage by residual white cells (117). This explains why prestorage leukodepletion reduces the frequency of these reactions (118), whereas bed-side filtration does not (the cytokines pass through the filter). In special transfusion situations, platelets can be washed to remove the plasma.

Leukocytes are the vector for certain transmissible viruses, including cytomegalovirus, human T-cell leukemia/lymphoma virus I and II, and Epstein-Barr virus (119), and so leukofiltration theoretically reduces the risk of transmitting these diseases. White cells can also be killed by ultraviolet-B irradiation, which should be administered to blood products prior to their administration to severely immunocompromised patients, so as to avoid transfusion-related graft versus host

disease. Blood irradiation also reduces HLA alloimmunization, and associated alloimmune platelet transfusion refractoriness, to an equivalent extent as does leukodepletion by filtration (120).

### Therapeutic Effects

#### Expected Platelet Count Increments Post-transfusion

Although a normal platelet has a lifespan of about 8 to 10 days (16), routine collection and storage result in transfused platelets having a lower survival (about 2–3 days) compared with the expected survival (4–5 days). The rise in platelet count after a platelet transfusion can be expressed as the “percent platelet recovery” (PPR), defined as (120a):

PPR

$$\text{PPR} = \frac{\text{platelet increment} \times 10^9 \times \text{blood volume (as 75 mL/kg)} \times 100\%}{\text{number of platelets transfused} (\times 10^{11}) \times 0.67 \times 10^{-3}}$$

The expected PPR is about  $66 \pm 8\%$  (121). (The PPR is not 100%, reflecting exchangeable splenic sequestration of about one-third of the transfused platelets).

Another measure of the platelet count increment is the “corrected count increment” (CCI), which normalizes the platelet count response for the patient blood volume and platelet dose, as follows (120b):

$$\text{CCI} = \frac{\text{platelet count increment (per } \mu\text{L)} \times \text{body surface area (m}^2\text{)} \times 10^{11}}{\text{number of platelets transfused} (\times 10^{11})}$$

Thus, a 6-foot male trauma patient weighing 78 kg (body surface area =  $2.0 \text{ m}^2$ ) whose platelet count rose from 50,000 to 80,000 per  $\mu\text{L}$  ( $50$  to  $80 \times 10^9/\text{L}$ ) after receiving five random donor units (containing a total of about  $3.0 \times 10^{11}$  platelets) would have a PPR of 87% and a CCI of 20,000.

The expected CCI between 10 minutes and one hour post-transfusion is  $>7500$ . The CCI measured at 18 to 24 hours after transfusion should be  $>4500$  (122). However, both the PPR and CCI require measuring the platelet count in the platelet product itself (not routinely performed), and are seldom used outside of research purposes.

☞ **For an average-size adult, the usual platelet dose ( $300\text{--}400 \times 10^9$ ) within 5 units of pooled random-donor platelets, or one single-donor (plateletpheresis) product, is expected to raise the platelet count approximately  $50 \times 10^9/\text{L}$  immediately after transfusion. However, in an observational study (122a) of platelet transfusions in critically ill patients, the median post-transfusion platelet count rise was much lower at  $14 \times 10^9/\text{L}$ .** ☞ In a trauma setting, a suboptimal platelet count rise probably reflects ongoing platelet consumption or hemodilution, although in other patient settings (e.g., cancer patients) alloimmune refractoriness may be operative.

#### Platelet Transfusion Refractoriness

If the post-transfusion platelet count is less than expected (e.g.,  $\text{CCI} < 7500$  at 1 hour) on two consecutive transfusions, the patient is considered “refractory” to platelet transfusion. This is generally caused by shortened survival of transfused platelets (123). Reasons for refractoriness are often multifactorial, and can be classified by non-immune and immune causes (Table 7) (124–126). In the trauma patient, the most common explanation probably is accelerated platelet

**Table 7** Nonimmune and Immune Causes of Platelet Transfusion Refractoriness

Nonimmune	Immune
Platelet quality (storage lesion)	HLA alloimmunization
DIC <sup>a</sup>	ABO incompatibility <sup>a</sup>
Sepsis <sup>a</sup>	Allo- or isoantibodies against platelet-specific allo(iso)antigens <sup>b</sup>
Fever <sup>a</sup>	
Splenomegaly	
Amphotericin B	
Post-bone marrow transplantation	

<sup>a</sup>DIC, sepsis, and fever are common in trauma patients; however, it should be noted that these factors were identified in studies (124–126) of cancer patients, rather than trauma patients.

<sup>b</sup>allo- or isoantibodies are a rare form of immune-mediated platelet dysfunction.

Abbreviation: DIC, disseminated intravascular coagulation.

destruction associated with DIC, SIRS, and so on. In contrast, immune causes of refractoriness predominate in multiply transfused patients (e.g., cancer patients). However, a multiparous female trauma victim with multiple HLA alloantibodies (resulting from previous pregnancies) could have immune refractoriness. The standard practice of administering “incompatible” platelets (e.g., from a blood group A donor to a group O recipient) can also lead to a blunted platelet count response, particularly if the recipient has high-titer ( $>1:64$ ) anti-A antibodies (127).

#### Platelet Transfusion Triggers

Therapeutic platelet transfusion indicates when platelets are given to treat clinically important bleeding in the context of thrombocytopenia. Prophylactic platelet transfusion denotes their use in preventing bleeding in thrombocytopenic patients. Platelet count thresholds below which the potential risk of hemorrhage is judged to outweigh the risks associated with platelet transfusions (discussed later in the section on “Complications of Platelet Transfusions”) are known as “platelet triggers.” However, appropriate triggers vary broadly among various clinical situations (Table 8), and further require individualized assessment of patient risk (73–75,128–133).

Platelet transfusion triggers have been evaluated most extensively in cancer patients receiving myeloablative chemotherapy, particularly adults with acute leukemia. In this patient population, a platelet threshold of  $10 \times 10^9/\text{L}$  is believed to be safe, unless there is concomitant bleeding or fever, in which case a threshold of  $20 \times 10^9/\text{L}$  is used (128). In 2001, the American Society of Clinical Oncology (ASCO) published guidelines for platelet transfusion that included recommended platelet count thresholds for thrombocytopenic patients undergoing invasive procedures (129). These guidelines are largely based on retrospective reviews, as few (if any) randomized trials have been done. The ASCO guidelines state that, in the absence of other coagulopathies, a platelet count of at least  $40$  to  $50 \times 10^9/\text{L}$  is sufficient to perform major invasive procedures, including placement of central venous catheters, lumbar punctures, endoscopic transbronchial and esophageal biopsies, fiberoptic bronchoscopy and bronchial lavage, and even major surgery. Certain procedures are safe at even lower platelet counts, e.g., most hematologists do not transfuse

**Table 8** Platelet Transfusion Triggers

Clinical scenario	Platelet transfusion trigger ( $\times 10^9/L$ )
Neurosurgery/head trauma	$\leq 100$
Major surgery	$\leq 50$
Massive transfusion	$\leq 50$
Central venous catheter insertion	$\leq 50$
Transbronchial and gastrointestinal endoscopy with biopsy <sup>a</sup>	$\leq 50$
Liver biopsy	$\leq 50$
Lumbar puncture	$\leq 20$
Acute leukemia (with fever or bleeding)	$\leq 10$ ( $\leq 20$ )

Triggers are based on the authors' interpretation of various published studies and reviews (73–75,128–133).

<sup>a</sup>Prophylactic platelet transfusions may not be necessary for endoscopy even if the platelet count is  $< 20 \times 10^9/L$ , provided that biopsy is not performed (133).

platelets before performing a bone marrow aspirate and biopsy even when the platelet count is less than  $20 \times 10^9/L$  (129). Liver biopsy was judged to be relatively safe at a platelet count of at least  $50 \times 10^9/L$  (129), based upon a retrospective study in which patients with moderate thrombocytopenia ( $50$  to  $99 \times 10^9/L$ ) had a bleeding incidence similar to controls without thrombocytopenia (130).

Prophylactic platelet transfusion after massive transfusion did not show improved outcomes in a randomized control trial (70). However, aggressive correction of thrombocytopenia and coagulopathies was associated with improved survival in one retrospective study (72). In general, when bleeding is evident or severe thrombocytopenia is present (generally, less than  $50 \times 10^9/L$ ), platelet transfusion support is considered appropriate (73–75). An even higher platelet count threshold ( $100 \times 10^9/L$ ) is suggested prior to neurosurgical procedures (74,132), suggesting a similar trigger may be appropriate in trauma patients with serious head injury or evidence for intracranial bleed. Table 8 lists the platelet transfusion triggers for various clinical scenarios.

### Contraindications to Platelet Transfusions

For some thrombocytopenic patients, platelet transfusions are contraindicated (73,95). For example, immune HIT and thrombotic thrombocytopenic purpura (TTP) are characterized by *in vivo* platelet activation and vWF-dependent platelet agglutination, respectively. Theoretically, platelet transfusions could increase the risk for vessel occlusion in these patients. Platelet transfusions are also contraindicated when the patient has pseudothrombocytopenia, as the actual circulating platelet count is normal.

### Complications of Platelet Transfusion

#### Infection

##### Viral Infection

Continuing improvements in screening for transmissible infectious disease in the developed world have greatly reduced the risk for blood-borne infection (Table 9) (134). As most platelet transfusions are pooled from five or more different donors, they carry a greater relative risk of

**Table 9** Risk of Infection per Unit of Blood

Transmissible infectious disease	Approximate risk
HIV <sup>a</sup>	1/1,930,000 (134)
Human T-cell leukemia/lymphoma virus	Negligible (with leukodepletion)
Hepatitis A	Very rare
Hepatitis B	1/138,700 (134)
Hepatitis C <sup>a</sup>	$< 1/543,000$ (134)
Syphilis	Extremely rare
Septicemia	1/10,000 septic episodes per unit of platelets transfused (114)

<sup>a</sup>Blood screening includes NAT for viral genetic material and thus gives greater sensitivity for detecting HIV and hepatitis C than serology alone. *Abbreviations:* HIV, human immunodeficiency virus; NAT, nucleic acid testing.

viral contamination than individual red cells or plasma transfusions, but the difference in absolute risk remains negligible. Transfusion-transmitted Creutzfeld–Jacob disease (prion disease) has also been reported.

#### Bacterial Contamination

Currently, the most common cause of mortality directly attributable to a platelet transfusion is bacterial contamination leading to septicemia (114,135). This is because platelets—unlike red cells and plasma—are stored at room temperature, making a fertile culture medium for bacteria. The reported incidence of bacterial contamination of platelets is about 1/3000, but usually without clinical consequence as few organisms are actually transfused (114). Overt sepsis is estimated at about 1/50,000 per platelet unit transfused (114), with significant risk for morbidity and mortality. Besides fever and chills, clinical features that suggest bacterial contamination of a blood product include hypotension/shock, vomiting, and respiratory distress beginning within two hours of transfusion (114).

#### Non-infectious

##### Febrile Non-hemolytic Transfusion Reactions (FNHTR)

This is the most common complication of platelet transfusion, with an overall frequency of about 25% to 30% (117,136,137): The reaction is about five times more common following platelet than red cell transfusions. Typically, symptoms occur toward the end of the transfusion, and include a rise in temperature by at least  $1^\circ C$ , often accompanied by chills, rigors, feelings of discomfort, nausea and vomiting. Sometimes, these symptoms are present without a rise in temperature. The reaction is self-limiting, and responds to antipyretics. If the reaction is very severe or accompanied by hypotension or respiratory distress, bacterial contamination must be suspected, the transfusion immediately stopped, and the unit(s) returned for culture. FNHTR appears to be caused by leukocyte-derived proinflammatory cytokines (e.g., interleukin-6) (137), and thus occurs more often with older platelet units (136), and much less often when the blood product has undergone prestorage leukodepletion (118).

### Allergic and Anaphylactic Reactions

Allergic reactions after platelet (or other blood component) transfusions are due to plasma proteins within the blood product reacting with pre-existing IgE antibodies in the recipient. This results in a type I hypersensitivity reaction and the release of histamine and prostaglandins from mast cells. Symptoms and signs include cutaneous reactions (urticaria, pruritus, erythema, flushing), cardiorespiratory complications (laryngeal edema with the potential for upper airway obstruction, wheezing, chest tightness, chest pain), gastrointestinal complaints (nausea, vomiting, abdominal cramps), and hypotension. Urticaria (hives) occur in about 3% of blood transfusions (138), and usually respond to antihistamines. Other preventative measures for recipients that have experienced less severe anaphylactic reactions include washed blood products that are deplete of plasma proteins and premedication with antihistamines and/or steroids (138). For mild reactions, the transfusion can be resumed as the symptoms abate.

Anaphylactic reactions are characterized by intractable hypotension and shock, often with a component of airway obstruction; fever is usually not seen. This syndrome is caused by IgG anti-IgA antibodies that can occur in IgA-deficient patients (139), as small quantities of IgA are present in the blood product. The frequency is about 1/20,000 to 1/50,000 units of blood products transfused (140). Anaphylactic transfusion reactions usually begin very soon after initiating transfusion. Treatment involves immediate discontinuation of the transfusion, subcutaneous epinephrine, intravenous fluids, and other measures appropriate for shock. The patient's pretransfusion serum must be tested for the presence of anti-IgA antibody and if present, blood products from IgA-deficient blood donors, or washed blood products, can be given.

### Alloimmune Thrombocytopenia

There are two rare situations in which blood products—including platelets—can paradoxically cause thrombocytopenia: PTP and PAT (141). PTP typically begins about 1 week after blood transfusion, and is characterized by generally severe thrombocytopenia and mucocutaneous hemorrhage. Typically, affected patients are elderly parous women who are homozygous for the HPA-1b alloantigen on platelets, and they form strong anti-HPA-1a alloantibodies (also known as anti-Zw<sup>a</sup> and anti-PI<sup>A1</sup> alloantibodies), although other alloantigen systems have also been implicated. For uncertain reasons, these alloantibodies lead to transient destruction of the patient's own platelets. IVIgG with or without platelet transfusions (ideally, giving HPA-1a negative platelets) is used for treatment. The timeframe of PTP closely resembles immune HIT, with which it can be confused (142).

In contrast, PAT is characterized by abrupt onset of severe thrombocytopenia following a blood transfusion (141,143). It is caused by the passive administration of antiplatelet alloantibodies that were present in the plasma of the blood donor, for example, if the donor was sensitized to a platelet alloantigen such as HPA-1a during previous pregnancy, and the blood product recipient is HPA-1a positive. In contrast to PTP, this syndrome resolves within a few days.

### Transfusion-Related Acute Lung Injury

Transfusion-related Acute Lung Injury (TRALI) is a very rare but life-threatening acute lung injury caused by plasma-containing blood components. Clinically and radiologically,

TRALI resembles ARDS, with typical onset between one and six hours after transfusion. The mortality rate is about 5% to 10% (cf. ARDS: 40–50% mortality), with the survivors usually recovering within 48 to 96 hours (144–146). Passive transfer of complement-fixing alloantibodies against granulocyte-specific or HLA antigens present within donor plasma is believed to cause this syndrome. Other possible mechanisms of pulmonary injury include neutrophil-priming lipids which may develop during routine storage of blood components (147,148) and cytokine-mediated injury, e.g., tumor necrosis factor. Although very rare, TRALI is the third most common cause of transfusion-related death (after ABO hemolytic reaction and bacteremia). Aggressive supportive treatment, including mechanical ventilation, is often needed for this transient but life-threatening syndrome.

## THROMBOCYTOSIS

### Physiologic vs. Pathologic

♣ Thrombocytosis in the trauma patient typically represents an appropriate physiologic response to initial acute thrombocytopenia, and thus is normal and expected in the second or third week post-trauma (Fig. 2) (149–151). ♣ Indeed, lack of thrombocytosis during this time period may indicate ongoing complications (septicemia, SIRS, ARDS, etc). This is consistent with a retrospective study (152) that found thrombocytosis in critical care patients to be associated with lower mortality despite longer intensive care unit (ICU) stays, that is, the longer ICU stay provided sufficient time to observe the expected increase in platelet count in a recovering patient. Table 10 lists the differential diagnosis of thrombocytosis.

Two studies of platelet counts following orthopedic surgery indicate the magnitude of post-thrombocytopenia thrombocytosis that can be expected following trauma (2,151). The median peak platelet count in a post-orthopedic

**Table 10** Causes of Thrombocytosis

#### Physiologic

- Post-thrombocytopenia thrombocytosis (common during second and third week post-trauma)
- Post-splenectomy or congenital/acquired asplenia (the peak post-operative platelet count in a trauma patient who undergoes splenectomy typically reaches 500 to 1500 × 10<sup>9</sup>/L; subsequently, the platelet count declines to a normal range that is about one-third higher than in normal, non-splenectomized patients, reflecting absence of splenic pooling)
- Hereditary or familial thrombocytosis

#### Pathologic

- Inflammatory/infectious (polymyalgia rheumatica, rheumatoid arthritis, polyarteritis nodosa, inflammatory bowel disease, tuberculosis, chronic infection)
- Neoplastic (myeloproliferative disorders, e.g., polycythemia rubra vera, chronic myeloid leukemia; essential thrombocythemia, myeloid metaplasia; myelodysplasia, e.g., 5q- syndrome, refractory anemia with ringed sideroblasts; solid tumors, especially metastatic)
- Iron deficiency
- Hemolytic anemia
- Pseudothrombocytosis (e.g., burns)

patient population is about 400 to  $500 \times 10^9/L$ , with the upper 2 SD value approximately  $1000 \times 10^9/L$ .

### Post-splenectomy

Dramatic thrombocytosis is common following splenectomy performed following trauma, for example, for splenic rupture. This is because physiologic thrombocytosis that follows acute trauma-associated thrombocytopenia is exacerbated by the lack of splenic sequestration of platelets, which normally represents about one-third of the platelet distribution. Thus, platelet counts as high as  $1500 \times 10^9/L$  can occur, usually peaking about 12 to 14 days following trauma, occasionally later. It is unknown whether physiologic thrombocytosis imparts a greater risk for postoperative thrombosis compared with a similar patient who has a less marked platelet count rise. ⚡ **Long-term, the loss of platelet sequestration means that the platelet count of the post-splenectomy patient is about 30% higher than the preoperative platelet count, baseline (153).** ⚡

### EYE TO THE FUTURE

Platelets are extraordinarily complex “cells” that provide effective hemostasis in response to day-to-day tissue injury and in response to major trauma. Platelets serve as the major effectors of primary hemostasis by forming the platelet plug at the site of injury, and they are crucial for proper secondary hemostasis by providing the proper phospholipid membrane surface for coagulation reactions. At present, the only routine source of exogenous platelets are pooled concentrates from allogeneic donors or apheresis platelets, stored at room temperature for a maximum of five days. Despite advances in safety processing and storage of conventional platelet concentrates, there are still important shortcomings, including short supply. There is much interest in developing novel platelet products and platelet substitutes, and some of these products are entering phase III clinical trials.

Novel platelet products include frozen platelets, cold-liquid stored platelets, photochemically treated platelets (a strategy for pathogen inactivation), platelet-derived microparticles, lyophilized platelets, and platelets cultured from megakaryocytes in vitro (154). Frozen platelets are currently the only viable alternative to fresh platelets, but cryopreservation is cumbersome and expensive, and offers little advantage over standard platelet products.

Various platelet substitutes are under current investigation (154). “Thromboerythrocytes” are red cells with surface-bound fibrinogen or surface-bound arginine-glycine-aspartic acid (fibrinogen-mimicking) peptides. Fibrinogen-coated albumin microcapsules/microspheres are albumin-based microspheres coated with fibrinogen. These platelet substitutes promote hemostasis by enhancing platelet activation and aggregation at sites of vessel injury. Liposome-based hemostatic agents include plateletsomes, which are extracts of platelet membranes contained within a lipid vesicle, and vesicles that contain phospholipid with or without Factor Xa. These products have only undergone preclinical testing (animal models).

Finally, one possible alternative approach for otherwise uncontrollable bleeding in a trauma patient may become available: recombinant factor VIIa (rVIIa, NovoSeven, Novo Nordisk, Denmark). This agent is believed to promote hemostasis either by facilitating tissue

factor-mediated initiation of coagulation, or by binding directly to the surface of activated platelets, where it directly activates factor X in the absence of TF (30,31). The latter mechanism does not require coagulation factors VIII or IX, and may explain why rVIIa in high doses is effective for bleeding patients with hemophilia A or B (lacking factor VIII or IX, respectively) who have developed inhibitory antibodies against the factor they lack. Although rVIIa is currently approved only for hemophiliacs with inhibitors, its investigational and “off-label” use as a general procoagulant agent in a variety of challenging hemostatic crises—including patients with severe coagulopathy and bleeding secondary to trauma—is increasing (155–159).

Unfortunately, this agent is extremely expensive: the approximate per-patient cost for one regimen under study for bleeding following trauma (200  $\mu\text{g}/\text{kg}$  first dose, with two subsequent 100  $\mu\text{g}/\text{kg}$  doses one and three hr later) is about US \$20,000 (assumes an 80-kg recipient, and an approximate cost of CDN \$1/ $\mu\text{g}$  rVIIa) (160).

Recently, Dutton et al. showed that rFVIIa therapy led to an immediate clinical reduction of coagulopathic hemorrhages in a retrospectively reviewed series of trauma cases conducted at the Maryland Shock-Trauma Center (161). More recently, two prospective placebo-controlled, double-blind RCTs, one in blunt trauma ( $n = 143$ ) and the other in penetrating trauma ( $n = 134$ ) were completed (162). The studies suggest that rFVIIa may decrease transfusion requirements, particularly in patients with blunt trauma.

In another retrospective study, Dutton’s group showed that profound acidosis and severe shock may predict failure of rFVIIa therapy for trauma-related coagulopathy, and suggest that these variables should be considered as potential contraindications to the use of rFVIIa (163). Although earlier administration of rFVIIa, before the development of massive blood loss and severe shock, may increase the rate of clinical response, few would administer this very expensive drug unless some of these poor prognosticating signs were present.

Accordingly, further research is required to identify those bleeding trauma patients in whom this therapy is safe and effective; in addition, the optimum dose and duration of rFVIIa therapy requires further clarification.

### SUMMARY

Platelets are produced in the bone marrow by the megakaryocyte, and normally survive for about 10 days. In normal individuals, the platelet count is usually fairly constant within a broad normal range (about  $150\text{--}400 \times 10^9/L$ ). The megakaryocyte-stimulating hormone, TPO, contributes to platelet count regulation via a primitive feedback loop. Normally, about 30% of circulating platelets are exchangeably sequestered within the spleen (splenic pooling).

In trauma patients, initial thrombocytopenia is usually caused by increased platelet consumption (DIC) or hemodilution (fluid resuscitation). Thrombocytopenia that persists or that begins later during the hospitalization often indicates complications, such as septicemia, SIRS, ARDS, or drug reactions, particularly immune HIT. Blood levels of TPO increase after trauma-induced thrombocytopenia, which leads to transient thrombocytosis that peaks about 14 days post-trauma, before returning to baseline during the third week. If a trauma patient undergoes splenectomy, the platelet counts are about 30% greater than expected because of the absence of physiologic splenic platelet pooling.

Investigating thrombocytopenia in a trauma patient includes: assessing the temporal features of the thrombocytopenia (early thrombocytopenia: DIC and/or hemodilution; late thrombocytopenia: bacteremia, SIRS, ARDS, drug reaction, etc.); clinical evidence for impaired hemostasis (petechiae, ecchymoses, line-site oozing, etc); severity of the thrombocytopenia (e.g., prophylactic platelet transfusions often are appropriate for platelet count thresholds between 50 and  $100 \times 10^9/L$ , depending on the perceived bleeding risk); and coagulation assays, including testing for DIC (e.g., fibrin D-dimers). Impaired primary hemostasis results from thrombocytopenia and anemia, as adequate red cell numbers are required in the microcirculation to optimize platelet–subendothelial interactions. Even though mild von Willebrand disease is a common congenital bleeding disorder, it only rarely contributes to bleeding in these patients, as vWF levels can increase dramatically during the acute “stress” associated with trauma.

Blood cultures are appropriate in patients with unexpected “late” thrombocytopenia. Immune HIT is a prothrombotic adverse reaction of heparin that mandates cessation of heparin, and usually also requires substitution with an alternative anticoagulant. However, warfarin is contraindicated during acute HIT because it paradoxically increases the risk for thrombosis, particularly microvascular thrombosis associated with limb loss (syndrome of warfarin-associated venous limb gangrene complicating immune HIT).

## KEY POINTS

- ✎ The normal platelet count range is between 150 and  $400 \times 10^9/L$ . Although this is a wide normal range, the platelet count tends to remain fairly constant during the lifetime of an individual (1).
- ✎ Normal platelet survival is approximately 10 days.
- ✎ Normally, about one-third of the circulating platelets are exchangeably sequestered within the spleen; increased spleen size leads to greater splenic pooling and thus thrombocytopenia (“hypersplenism”).
- ✎ Acute decrease in the platelet count in trauma leads to increase in TPO levels. The long half-life of TPO (30 hours) and its effects on early megakaryocyte progenitors mean that this trauma-associated thrombocytopenia is invariably followed by thrombocytosis from day 7 to 21 (peak, days 12–14), unless clinical complications lead to ongoing platelet consumption.
- ✎ Three components are required for normal primary hemostasis: (i) platelets, (ii) vWF, and (iii) normal hematocrit. In trauma, acquired thrombocytopenia and anemia lead to impaired primary hemostasis.
- ✎ Four general mechanisms for thrombocytopenia exist: (i) decreased platelet production, (ii) increased platelet consumption (or destruction), (iii) hemodilution, and (iv) hypersplenism. Only two mechanisms—increased platelet consumption and hemodilution—are common in acute trauma. However, decreased production can develop following critical illness, or (along with hypersplenism) can be present as a pre-existing condition.
- ✎ The hallmark of severe thrombocytopenia is mucocutaneous bleeding, particularly pin-point intradermal hemorrhages known as *petechiae*.
- ✎ “Pseudothrombocytosis” occurs in patients with severe burns (36): Thermal injury to red cells produces microspherocytes that can be falsely identified as platelets by the electronic particle counter, and thus suggest apparent thrombocytosis when the patient may actually suffer acute burn-induced thrombocytopenia and DIC.
- ✎ Coagulation testing is needed to distinguish whether thrombocytopenia is caused by hemodilution or acute DIC in a patient with trauma. Generally, increase in fibrin D-dimers or a positive paracoagulation assay (e.g., protamine sulfate test) is confirmatory of DIC. Both hemodilution and DIC can cause abnormalities in routine coagulation assays, such as the INR, aPTT, TCT, and fibrinogen levels.
- ✎ Platelet dysfunction in trauma patients is often the result of renal failure (uremia) or drug effects (e.g., aspirin, clopidogrel).
- ✎ Dilutional thrombocytopenia related to fluid resuscitation is the most common cause of thrombocytopenia in a trauma patient. Repeated CBC and coagulation testing is important to assess the presence and severity of coexisting DIC.
- ✎ When diffuse bleeding is evident or relatively severe thrombocytopenia is documented (generally, less than  $50 \times 10^9/L$ ), platelet transfusion support is appropriate (73–75). A higher platelet count threshold (i.e.,  $100 \times 10^9/L$ ) is a more appropriate transfusion trigger for certain conditions (e.g., traumatic brain injury).
- ✎ Late onset of thrombocytopenia in a trauma patient can indicate acute bacteremia, so blood cultures should always be drawn in this situation.
- ✎ HIT is by far the most common drug-induced, immune-mediated thrombocytopenia. Paradoxically, HIT is associated with thrombosis rather than bleeding.
- ✎ Hypotension and/or abdominal pain in a thrombocytopenic patient treated with heparin suggests bilateral adrenal hemorrhagic infarction with acute adrenal failure: Corticosteroid replacement therapy can be life-saving.
- ✎ For an average-size adult, the usual platelet dose ( $300\text{--}400 \times 10^9$ ) within five units of pooled random-donor platelets, or one single-donor (plateletpheresis) product, is expected to raise the platelet count approximately  $50 \times 10^9/L$  immediately after transfusion.
- ✎ However, in an observational study (122a) of platelet transfusions in critically ill patients, the median post-transfusion platelet count rise was much lower at  $14 \times 10^9/L$ .
- ✎ Thrombocytosis in the trauma patient typically represents an appropriate physiologic response to initial acute thrombocytopenia, and thus is normal and expected in the second or third week post-trauma (Fig. 2) (149–151).
- ✎ Long-term, the loss of platelet sequestration means that the platelet count of the post-splenectomy patient is about 30% higher than the preoperative platelet count baseline.

### INTRODUCTION

Venous thromboembolism (VTE) is a term used to describe thromboses that may occur in any vein as well as the emboli that result when one of these thrombi breaks off and migrates to other areas in the systemic venous network, most notably the pulmonary circulation. When the veins involved are superficial, the resultant superficial phlebitis may be painful, but is of minor consequence. When the affected veins are located in the deep system, the phenomenon is termed deep venous thrombosis (DVT), which has more serious implications than its superficial counterpart.

The occurrence of VTE is of particular significance in patients following trauma or in those with critical illness for several reasons. First, these patients are at high risk for VTE, often due to hypercoagulability, intimal injury, or stasis, all of which predispose to formation of venous thrombosis and propagation of pre-existing thrombi. Secondly, the compromise of hemodynamics and organ perfusion caused by venous and/or pulmonary arterial obstruction is more deleterious in a patient whose cardiopulmonary function is already compromised. These facts help to explain why pulmonary embolus (PE) is the third major cause of death following trauma in those who survive longer than 24 hours after injury (1,2).

Since the lower extremities are the usual areas affected with thrombosis, the term DVT is often used in reference to lower extremity thromboses alone. However, following trauma and critical care, upper extremity DVTs may also have clinical significance. Accordingly, we will consider the pathophysiology of all DVTs in this chapter and also review the prophylaxis, diagnosis, and treatment of PE. Finally, recent guidelines from the Seventh American College of Chest Physicians (ACCP) Conference on Antithrombotic and Thrombolytic Therapy will be provided (3). These will be evaluated within the context of the previously published trauma VTE recommendations by the EAST Workgroup, (4) and more recent data summarized by Knudson et al. from the American College of Surgeons National Trauma Data Bank (ACS-NTDB) (5).

### PATHOGENESIS

☞ **The components of Virchow's triad (hypercoagulation, endothelial injury, and venous stasis) have long been**

**recognized as the etiological factors for VTE. When one or more of these factors are present, initiation of the coagulation cascade is increased, as is the risk of clot formation.** ☞

### Normal Clot Formation

When the integrity of the endothelial lining of the blood vessels is disrupted, platelets in the blood become exposed to the collagen of the vessel wall. Contact with the collagen causes the usually smooth-surfaced (resting) platelet (Fig. 1A) to become irregular and "sticky" (activated) (Fig. 1B) as it adheres to the area of the injury. The activated platelet secretes a number of factors including von Willebrand factor (vWF), which recruits more platelets to the area of injury and stimulates them to adhere. Other factors released by the platelets initiate the coagulation cascade.

Coagulation occurs via two main pathways, the intrinsic and extrinsic pathway (Fig. 2). The intrinsic pathway is primarily triggered by the disruption of vascular endothelial integrity exposing blood vessel collagen to circulating blood. The extrinsic pathway is more often activated in conditions such as sepsis, infection, and trauma, where tissue factor and factor VII initiate coagulation without necessarily exposing endothelial collagen. Regardless of which pathway initiates coagulation, the final common event is the conversion of prothrombin to thrombin (factor II), which catalyzes the conversion of soluble fibrinogen (factor I) to insoluble fibrin filaments. These filaments form a net, trapping additional blood cells and platelets and causing the clot to form, grow, and mature.

Like many other physiologic responses in the body, clotting has its own negative feedback controls. ☞ **As soon as clot formation begins, processes are initiated to turn off (or down-regulate) clotting [antithrombin III (AT III) and proteins C and S] or dissolve the already formed clots (plasmin and tissue plasminogen activator). Proper regulation of clotting and clot dissolution will minimize the risk of VTE.** ☞

These two interactive systems may be grouped together as the coagulofibrinolytic system (Fig. 3). The balance of the coagulation and fibrinolytic arms of this system is especially important for critically ill trauma patients because its homeostasis may be disturbed by injury, surgery, sepsis, the systemic inflammatory response syndrome, and multiple organ dysfunction syndrome. The recent PROWESS study demonstrated that treatment with activated protein C reduced

**Figure 1** Resting platelets (A) are smooth and travel through the blood vessels unimpeded. When platelets adhere to areas of endothelial injury, they become activated (B), undergo shape change, and form platelet aggregates.

thrombosis and conferred a survival advantage in septic patients (see Volume 2, Chapters 56 and 63) (6).

**Hypercoagulation**

The body forms a clot in response to an injury that causes loss of blood from the vascular system. The system is also programmed to dissolve that clot after it has served its purpose. It should not form unnecessary clots, such as

**Figure 2** The coagulation cascade is activated through the intrinsic or extrinsic pathways. Both pathways convert prothrombin to thrombin, which stimulates the polymerization of soluble fibrinogen to an insoluble fibrin clot.

**Figure 3** The coagulofibrinolytic system includes factors that stimulate clotting and fibrin formation and opposing factors that antagonize coagulation and stimulate fibrinolysis. *Abbreviation:* vWF, von Willebrand factor.

those that cause DVTs, and should be able to dissolve unwanted clots when they do occur. ⚡ **Overactivity of the procoagulant system or underactivity of the anticlotting or fibrinolytic systems results in a hypercoagulable state, also termed thrombophilia (Table 1).** ⚡

Examples of procoagulant overactivity include the presence of factor V Leiden, or very high levels of homocysteine; factors VIII, IX, or XI, thrombin activatable fibrinolysis inhibitor (TAFI); or fibrinogen (7). There are certain acquired conditions such as pregnancy, malignancy, trauma, surgery, heparin-induced thrombocytopenia (HIT), and ingestion of oral contraceptives that also result in overactivity of the coagulation cascade. Of note, many of these conditions are found in the critically ill patient.
