*This book is dedicated to the trauma victims, as well as the doctors, nurses, prehospital personnel, and other members of the trauma team who tirelessly strive to provide optimum care for their recovery.*

# Foreword

From my recent perspective as the 17th surgeon general of the United States, along with my prior experiences as a trauma surgeon, combat experienced U.S. Army Special Forces medical specialist, paramedic, police officer, and registered nurse, I have witnessed numerous developments over the last three decades in the fields of trauma and critical care. Despite these significant advances, trauma remains the chief cause of death and disability of individuals between 1 and 44 years of age; hence, much work remains to be done.

Trauma is a worldwide phenomenon with profound public health implications and numerous existent challenges, including the need for an increased emphasis on accident prevention; overcoming barriers to care for the indigent, the elderly, and rural populations; and streamlining and improving disaster response effectiveness.

This two-volume book provides comprehensive coverage of all realms of modern trauma management, including the important aforementioned areas of care, which continue to impact the outcomes for these vulnerable populations.

Volume 1 focuses on initial management and is divided into sections that mirror the continuum of care, including prehospital, resuscitation suite, and perioperative management. The prehospital section includes chapters on trauma mechanisms, epidemiology, scoring and triage, and transport. The authors acknowledge that optimal management algorithms for this early phase of care can differ based on the setting (urban/rural) and the prevailing geographical, political, and financial conditions. Hospital-based components of management (e.g., primary survey, secondary survey, etc.) are meticulously reviewed, including specific chapters on the critical elements of care (e.g., airway management, fluid therapy, etc.). The perioperative section details the anesthetic and surgical priorities, but surgical technical details are minimized in favor of global management guidelines, which are important to all members of the care team. Important trauma-related conditions are also fully reviewed.

Volume 2 encompasses the critical care management of trauma and other surgical conditions. These topics are

arranged in sections according to organ systems, with each chapter dedicated to a specific lesion or critical illness condition. Recent evidence-based principles are fully characterized, including the management of abdominal compartment syndrome, tight glucose control, adrenal suppression, and thromboembolism, etc. In addition, chapters covering post-traumatic stress disorder, family centered care, rehabilitation, and palliation at the end of life provide a breadth of coverage not present in other trauma books.

Chapters in both volumes are co-authored by experts from complimentary specialties, with surgeons, anesthesiologists, emergency medicine physicians, and pulmonologists involved throughout. Specialty sections are written by medical or surgical sub-specialists with extensive trauma and critical care experience. Interdisciplinary collaboration is further evident with chapters co-authored or edited by experienced nurses, pharmacists, and social workers, as well as occupational, physical, and respiratory therapists, among others.

The editors are eminently qualified and have succeeded in producing an authoritative and comprehensive book on trauma. Drs. Wilson, Grande, and Hoyt have each conducted important research and have published and lectured extensively on numerous trauma-related topics over the last two decades. They have assembled a superb table of contents and an expert array of contributors and associate editors. The editors have also insured that recommendations are evidence based where possible. Accordingly, the novice will learn in depth about the scientific basis of the guidelines provided here, and the expert will be updated on the latest thinking in trauma management.

In summary, this two-volume book is an extremely valuable contribution because of the importance of the subject, the fact that the topic has not been so comprehensively covered in one book until now, and because of the wisdom and insight of the editors.

*Vice Admiral Richard Henry Carmona, MD, MPH, FACS  
17th Surgeon General of the United States of America*

# Foreword

The modern-day management of trauma is multidisciplinary and requires teamwork. The specialists involved include emergency physicians, anesthesiologists, radiologists, surgeons, toxicologists, and critical care specialists along with paramedics, nurses, and technical staff.

Those involved in the management of trauma have a need for a comprehensive book that spans the entire spectrum of trauma management by all specialists, including prehospital, perioperative, and critical care. This two-volume book, edited by Wilson, Grande, and Hoyt, does precisely that. Along with a superbly designed table of contents, the editors have recruited a world-class group of contributors from all specialties to write the chapters. The editors are abundantly qualified to oversee a work of this magnitude in terms of academic and intellectual strength, as well as in terms of clinical expertise.

Volume 1 covers the areas of prehospital, emergency department, and perioperative management. Other important trauma-related conditions (e.g., alcohol and drug intoxication, burns, near drowning, environmental conditions) and management of unique populations of trauma patients (e.g., pediatric, geriatric, and obstetric) are also reviewed by experts in this volume. In addition to reviewing the key conditions, this volume contains clear guidelines for

medical and surgical decision making in the various stages of care.

In Volume 2, the critical care management of trauma is reviewed. This volume proceeds in a logical systems-based presentation of the conditions and complications commonly encountered in a modern trauma or surgical intensive care unit. All of the evidence-based measures recommended to improve outcomes in critically ill patients are included. In addition, emerging topics such as the remote evaluation and management of trauma and critical illness are introduced.

As the only book to cover the full spectrum of trauma management, this two-volume set is strongly recommended for all students and clinically active physicians engaged in the management of trauma and surgical critical care.

*Peter J. F. Baskett, BA, MB, BCh, BAO,  
FRCA, FRCP, FCEM  
Consultant Anaesthetist Emeritus, Frenchay Hospital  
and the Royal Infirmary, Bristol, U.K.  
Editor-in-Chief, Resuscitation  
Past President, International Trauma Anaesthesia  
and Critical Care Society*

# Foreword

Three decades ago, as an impressionable resident physician-in-training at the University of Washington in Seattle, I was asked to respond with the city's emergency medical services personnel on 9-1-1 emergency calls. Working out of the Harborview Emergency-Trauma Center, I soon began to recognize how the outcomes of those with severe injury are often determined, for better or for worse, in the first few minutes after injury. After accompanying hundreds of patients from the incident scene, in the back of ambulances, in the emergency centers, and in operating rooms and intensive care units, I soon learned that a continuity of optimized care must be stewarded by an integrated team of experts from many disciplines. In turn, I have always stressed that an interdependent "chain of survival/recovery" had to be created with each link being strong and solidly connected to each other. I have been fortunate to train, perform research, and provide care in all of those arenas, and thus appreciate the tremendous expertise and demands required of each team member at each and every link.

This two-volume book (edited by Wilson, Grande, and Hoyt) is, in many ways, the first book to examine that entire spectrum of trauma care. Accordingly, as an emergency medicine physician originally trained in surgical critical care and trauma fellowships to challenge sacred cows with clinical trials, and as a prehospital care trauma specialist who has since spent many a night responding to out-of-hospital 9-1-1 incidents, I am now honored to write a foreword for this book. For those of us who have come to understand the chain of care and the impact of early decision making on long-term outcomes, this book is a tremendous gift.

Volume 1 discusses many of the areas with which I am quite familiar, namely the initial treatment priorities in prehospital care, the resuscitation suite, and the perioperative period. These chapters are very current, including recent citations emphasizing the need for only a few assisted rescue breaths in conditions of severe circulatory impairment, while also minimizing initial intravascular fluid

infusion in the face of internal injuries resulting from penetrating trauma. Associated conditions known to confound initial trauma care are also expertly reviewed.

Volume 2 covers the critical care management of trauma and the other emergency surgical conditions commonly encountered in modern surgical intensive care units. Recent evidence-based principles of care are provided for virtually every condition for which such data exist. In addition, there are chapters focusing on the patient's transition to recovery following the critical care period, including physical, occupational, and psychological rehabilitation. For example, it addresses screening and treatment of posttraumatic stress disorder.

Complementing the breadth of material, the chapters are co-written by experts from all of the relevant pivotal specialties, ranging from resuscitologists, emergency medicine doctors, anesthesiologists, and orthopedists to the spectrum of surgeons, intensivists, psychiatrists, and rehabilitation experts. In addition, the co-authors hail from around the globe, emphasizing the international appeal, perspective, and orientation of this extremely inclusive, contemporary book.

Finally, I should also say that the editors are exceptionally well qualified for a book of this magnitude. They are all experienced investigators, authors, and international lecturers on the many topics covered. In summary, this two-volume book should be considered as mandatory reading for every clinician actively involved in the care and management of trauma patients.

*Paul E. Pepe, MD, MPH, FACEP, FCCM  
Professor of Surgery, Medicine, Public Health  
and Riggs Family Chair in Emergency Medicine,  
University of Texas Southwestern Medical Center  
and the Parkland Emergency Trauma Center  
Director, City of Dallas Medical Emergency Services  
for Public Safety, Public Health, and Homeland Security  
Dallas, Texas, U.S.A.*

# Foreword

Physicians involved in the care of injured patients come from many different disciplines and are sometimes called “traumatologists.” Emergency medical services personnel, emergency physicians, anesthesiologists, surgeons, intensivists, and hospital administrators are all concerned with a broad spectrum of trauma management. This two-volume book, edited by Wilson, Grande, and Hoyt, joins relatively few such comprehensive books on this subject and describes management of the trauma patient from a multidisciplinary standpoint, and emphasizes the anesthesiologist’s physiologic perspective.

Internationally, the anesthesiologist is often the resuscitation or reanimation physician, with major responsibilities in the ambulance and in the evaluation area of hospitals, often without a specific trauma service. The table of contents reflects an international group of contributors assembled by the editors to author the chapters. The editors have ensured academic and intellectual strength and clinical expertise. They are to be commended for achieving such attention to detail in the first edition.

Dr. William C. Wilson, a trauma anesthesiologist and intensivist, is internationally recognized in the areas of trauma airway management, respiratory gas exchange, thoracic anesthesia, and monitoring. As editor-in-chief, Dr. Wilson’s editorial leadership is evident in the clear organization of the book, fluency of the writing, and balance of coverage.

Dr. Christopher Grande, a clinically active trauma anesthesiologist and intensivist, is the executive director of International Trauma Care (ITACCS). He has published extensively in the area of trauma anesthesia and critical care for decades. Doctor Grande’s editorial influence is evidenced by the expert international coverage of many topics.

Dr. Hoyt is a world-renowned trauma surgeon and surgical intensivist. He has been an active leader of numerous prestigious surgical trauma organizations, including past president of the American Association for the Surgery of Trauma and the Shock Society, as well as chairman of the American College of Surgeons Committee on Trauma.

He is the current president of the Pan American Trauma Society. Dr. Hoyt’s experience and wisdom are reflected in his careful editorial oversight of this comprehensive two-volume treatise on trauma care.

Volume 1 covers the areas of prehospital care, resuscitation, perioperative management, and associated trauma conditions. It is logically organized, covering the key conditions, and provides clear guidelines for medical and surgical decision making, including global operative considerations. However, by design, esoteric technical details of surgical procedures are omitted in favor of general management concepts and principles supported by recent literature. Other important trauma-related conditions (e.g., alcohol and drug intoxication, burns, near drowning, etc.) and management of unique populations (e.g., pediatric, geriatric, and obstetric) are also reviewed in Volume 1.

Volume 2 covers the critical care management of trauma and is a logical, systems-based presentation of the problems commonly encountered in a modern intensive care unit. This volume reviews medical conditions, the role of psychological factors, the family, rehabilitation, and ethics. In addition, emerging topics such as remote evaluation and management are introduced.

Because of the fundamental importance of the subject matter along with the editorial review, this two-volume set represents a compelling resource in the management of trauma and is highly recommended for all clinicians with primary responsibility for resuscitation and management of trauma patients.

# Preface

## OVERVIEW OF BOTH VOLUMES

Trauma is the leading cause of death in the young (ages 1-44) in the United States and the chief reason for lost years of productive life among citizens living in industrialized countries. Despite the enormous importance of the subject matter, no single text has yet been published that fully covers all phases of trauma management.

The purpose of this book is to bring together in one source a description of modern clinical management principles for the care of the trauma patient. This two-volume set, *Trauma, Volume 1: Emergency Resuscitation, Perioperative Anesthesia, Surgical Management and Trauma, Volume 2: Critical Care*, thoroughly encompasses the entire spectrum of trauma management from the prehospital phase through critical care and rehabilitation.

A comprehensive table of contents, at the front of each volume, encapsulates the organization of the entire book (providing a macroscopic view), and also details the sections and sub-headings within each chapter (providing a microscopic view). The extensive index at the back of the book is organized to provide expeditious referral to specific pages that cover the subject matter of interest. The reader is encouraged to utilize both the very detailed table of contents and the index as needed to quickly locate topics.

Each chapter in this work incorporates important features that greatly enhance information communication and learning. The chapters are generously illustrated with figures and tables to facilitate synthesis of important concepts. In addition, key points are highlighted within the text and are summarized at the end of each chapter for quick review. Care has been taken to minimize redundancy by maximizing appropriate cross-referencing throughout. Another useful aspect of each chapter is the Eye to the Future section, which reviews emerging concepts and new research findings likely to impact clinical management.

The contributors to these volumes are both authoritative (having performed original research and authored numerous publications on their subject matter) and have extensive clinical experience. The authorship considered as a whole is truly international, with contributors from all continents. Furthermore, both civilian and military considerations are reviewed whenever relevant. The majority of chapters have multi-specialty co-authorship by experts in trauma surgery, trauma anesthesiology, emergency medicine, and numerous other medical and surgical specialties. In addition, chapters have multidisciplinary involvement by experts in physical medicine, rehabilitation, nursing, and pharmacy, among other disciplines. The scientific

soundness is further insured by the multiple layers of editorial oversight; every chapter has been reviewed by at least three experts in the field (principal, associate and section editors). The high level of scientific accuracy and the reader-friendly nature of these two volumes are expected to facilitate learning in order to improve the care provided to trauma patients around the globe.

## VOLUME 2

Volume 2 is comprised of 74 chapters that are organized into sections beginning with a basic science review emphasizing the concepts most relevant to the practice of critical care. A section on analgesia, sedation, and neuromuscular blockade begins the clinical management portion of the volume. A review of the important monitoring principles of relevance to trauma critical care is provided next. The core of this volume is comprised of sections covering management considerations for surgical and trauma critical care conditions. These sections and chapters are grouped according to the systems affected, including neurological, cardiovascular, pulmonary, gastrointestinal, renal, infectious diseases, hematological, as well as endocrinological disorders and the systemic inflammatory response syndrome (SIRS). Sections are also provided covering physical and psychological rehabilitation, ethical concerns, and other topics, including techniques for conducting rounds, remote management, the economics of trauma, and severity of illness scoring.

Woven throughout this text are current diagnostic, monitoring, and organ support strategies recognized to improve outcomes in critically ill trauma patients. These concepts include: early enteral nutrition; aggressive monitoring and treatment of pain, agitation, and delirium; and prophylaxis against such complications as thromboembolism, stress ulcers, pressure sores, and ventilator-associated pneumonia. Newly emphasized guidelines such as tight glucose control with intensive insulin therapy, lung protective strategies of mechanical ventilation, early goal-directed therapy for sepsis, and other evidence-based recommendations are also provided where such data exist. The recognition that rehabilitation begins upon admission and that the consequences of early management decisions can impact long-term outcomes are also emphasized.

*William C. Wilson, MD, MA  
Christopher M. Grande, MD, MPH  
David B. Hoyt, MD, FACS*

# Acknowledgments

The editors would like to express gratitude to our families and loved ones for their unwavering support during the many years of planning and production of this book. Without their sacrifices, encouragement, and love, this two-volume book could not have been completed.

The associate editors and numerous section editors have likewise sacrificed time from their families and other professional responsibilities during their dedicated work on this important project. We cannot over express our gratitude for their contributions, or for our delight in the superb job accomplished by these gifted experts. Due to their diligence, this book has achieved a level of editorial oversight seldom found in multi-authored books.

Essential to the production of this work was the superb administrative assistance provided by Paul Hobson and Bertha Englund. Paul, in particular, must be acknowledged for his dedicated support, working weekends and late into many evenings throughout the process of chapter formatting and editing. In addition, the contributions made by Linda Kesselring, Jan Bailey, and Sereyrathana Keng during the early stages of this project were critical to the ultimate success of the book. The excellent administrative support of Linda Collins throughout the project was likewise essential.

Also vital to the development of this book has been the assistance of ITACCS (International TraumaCare), whose

membership has contributed numerous chapters, and whose leadership has supported this project throughout its development.

Finally, we would like to acknowledge the expert assistance provided by our publishers at Informa Healthcare. The professionalism of this organization has been superb, starting at the top with Sandra Beberman, and throughout the publication process with the able assistance of Vanessa Sanchez and Joe Stubenrauch. The professionals at the Egerton Group (Joanne Jay and Paula Garber) were likewise essential to the production of this book. In particular, Mrs. Garber, editorial supervisor, must be commended for providing excellent attention to detail, a strong work ethic, and calm, kind leadership throughout the typesetting and final editing. Geoffrey Greenwood must also be acknowledged for helping us initiate this project many years ago. Each of these individuals has served to kindly and expertly assist our navigation through the ardors of the publication process, and we are grateful to them all.

Charles D. Deakin

Department of Anesthesia, Southampton University Hospitals NHS Trust, Southampton, U.K.

### INTRODUCTION

Pathophysiological principles underpin the modern management of trauma and head injury. It is vital that healthcare professionals have a good understanding of neurophysiology and pathophysiology and are able to interpret the many monitoring parameters now available in order to offer best management.

In this chapter, the most important physiological principles relevant to the management of trauma patients, in general, and to head injury, in particular, will be discussed. Some important anatomy will be included. The pathophysiological response to injury of the central nervous system (CNS) will be outlined, which continues to be an area of intense research. Some pharmacological and therapeutic interventions will be discussed where relevant, and some monitoring techniques will be briefly considered.

### APPLIED ANATOMY

The nervous system may be divided anatomically into the CNS, the peripheral nervous system (PNS), and the autonomic nervous system (ANS). The CNS is further divided into brain, brainstem, and spinal cord. The cerebrospinal fluid (CSF) system provides a buffer against movement for the CNS, and the blood-brain barrier provides for some separation of the CNS from the systemic environment.

#### Brain

The brain has a mass of approximately 1500 g and is contained within a noncompliant bony vault: the skull. It is formed of the four major lobes (frontal, parietal, temporal, and occipital), the thalamus, the hypothalamus, the basal ganglia, brainstem, and the cerebellum (Fig. 1). A relatively thin stratum of neurons on the surface of the cerebrum and cerebellum comprise the portions known as the cerebral and cerebellar cortex. Each geographical region of the brain, and its associated structures, serve specific neurological functions. Accordingly, destructive lesions to discrete regions will result in characteristic clinical findings (Table 1).

#### **Four Major Lobes (Frontal, Parietal, Temporal, and Occipital)**

The frontal lobes are responsible for motor and various elements of intellectual and emotive function. The precentral gyrus, the primary motor cortex, is located immediately anterior to the central sulcus. The motor complex is somatotopically organized (Fig. 2) so that stimulation of the medial portion causes muscle contraction in the lower limb and trunk, stimulation of the middle portion causes muscle contraction in the upper limb, and stimulation of the most lateral portion causes muscle contraction in the head and neck. Immediately anterior to the primary motor cortex is the premotor cortex that is also somatotopically organized, but here stimulation at various points results in patterns of movement rather than individual muscle or muscle group contraction (1,2). Destructive lesions of the frontal lobe cause intellectual impairment, personality change, and contralateral motor dysfunction (3). An important speech region known as Broca's area is found within the frontal lobe (see subsequently).

The parietal lobes are located above the temporal lobes between the frontal and occipital lobes. The primary sensory cortex is located in the postcentral gyrus and like the primary motor cortex is somatotopically represented (Fig. 3) (4). Destructive lesions of the parietal lobes result in contralateral sensory dysfunction, apraxia, a failure to recognize faces or surroundings, and homonymous visual field defects (3).

The temporal lobes are situated inferior to the parietal lobes. Destructive lesions result in acalculia, confusional states, and homonymous visual field defects (3). Alexia and agraphia may result from either temporal or parietal lobe injuries. Also, auditory associations may be impaired when Wernicke's area is injured (see subsequently).

The occipital lobes contain the primary visual cortex. Destructive lesions result in visual field and visuo-spatial defects and disturbances in visual recognition (3).

#### **Cerebral Cortex**

The cerebral cortex forms a 2- to 5-mm surface layer of the brain, which is organized into six horizontal layers. The neurons of layers I, II, and III form connections with other parts of the ipsilateral or contralateral cerebral cortex. The neurons in layer IV receive sensory input from the thalamus. Projections to the brainstem and spinal cord take origin from cell bodies located in layer V, and corticothalamic fibers arise from layer VI (5,6).

**Figure 1** Major anatomical brain regions illustrated in the lateral view of the left hemisphere.

**Thalamus, Hypothalamus, and the Basal Ganglia**

The thalamus forms a relay station between the periphery and cerebral cortex. The hypothalamus provides a link between the nervous and endocrine systems. Together with a portion of the basal ganglia, these pathways form the limbic system, which controls emotion and physiologic drives (7,8).

**Table 1** Regions of the Brain, Their Primary Functions, and the Result of Destructive Lesions

Brain region	Primary function	Result of destructive lesion
Frontal lobe	Motor Intellect Personality Motor aspects of speech (Broca's area)	Contralateral hemiparesis Intellectual impairment Personality change Expressive dysphasia
Parietal lobe	Primary sensory	Contralateral sensory dysfunction Apraxia Homonymous visual field defects
Temporal lobe	Hearing Language Perception	Acalculia Alexia Agraphia Homonymous visual field defects
Temporal-parietal	Speech comprehension (Wernicke's area)	Receptive dysphasia
Occipital lobe	Primary visual	Visual field defects Disturbances of visual recognition
Thalamus	Relay station Memory	Signal disruption Disruption of long-term memory
Limbic system	Emotion and drives	Emotional instability/dysfunction
Cerebellum	Motor coordination	Ipsilateral loss of motor coordination

**Figure 2** The motor homunculus showing somatotopical representation of the primary motor cortex.

**Cerebellum and Cerebellar Cortex**

The cerebellum consists of a three-layered cortex and four paired nuclei. The vermis divides the cerebellum in the sagittal plane and is organized in a somatotopical fashion. The cerebellum and a portion of the basal ganglia are vital for the control and co-ordination of movement (9,10).

**Figure 3** The sensory homunculus showing somatotopical representation of the primary sensory cortex.

**Figure 4** Cross-section of the spinal cord showing the main ascending (*dark gray*) and descending (*stippled*) pathways. The ventral portion of the cord is shown on the bottom of the figure, and the dorsal portion is shown on the top of the figure.

**Brainstem**

The brainstem consists of the midbrain, pons, and medulla oblongata. It contains vital centers for respiratory and cardiovascular control, the reticular activating system, and the cranial nerve nuclei. It maintains consciousness, the sleep–wake cycle, and spontaneous ventilation. Descending and ascending pathways pass through the brainstem.

**Spinal Cord**

The spinal cord is approximately 45 cm long in the adult, terminating inferiorly in the conus medularis at approximately L1/L2; although there is considerable variation. The lumbar and sacral roots have a progressively longer course from the spinal cord to reach their corresponding intervertebral foramina and collectively form the cauda equine (11).

In transverse section, the cord consists of a central canal, a pericentral zone of gray matter, and an outer zone

of white matter. In the white matter, definite ascending and descending tracts are formed (Fig. 4). The function of the individual tracts is outlined in Table 2.

**Arterial Supply and Venous Drainage of the Central Nervous System**

**Brain and Brainstem**

♣ The blood supply of the brain derives from the Circle of Willis. ♣ The paired internal carotid arteries (ICAs) divide into anterior cerebral arteries (ACAs) and middle cerebral arteries (MCAs) and provide 70% of cerebral blood supply. The basilar artery is formed by the union of the paired vertebral arteries, dividing into the two posterior cerebral arteries (PCAs) to provide the remaining 30% of cerebral blood flow (CBF). The anterior communicating artery joins the two ACAs, and the posterior communicating artery joins the ICA with the PCA. This anastomosis forms the Circle of Willis (Fig. 5) (12). The ACA supplies the medial portions of the cerebral hemispheres, the MCA supplies the lateral portions, and the PCA supplies the occipital and inferior portions of the temporal lobe (13). The brainstem derives its blood supply from the vertebo-basilar system.

Venous blood drains from the brain cortex and subcortical medullary substance into superficial cerebral veins, and subsequently into the dural venous sinus network. The veins of the brain, as well as the dural sinus system, are entirely devoid of valves. The venous dural sinuses collect blood from the superficial and deep cerebral veins, as well as the skull, and represent the major drainage pathway of the cranial cavity. The venous dural sinuses drain into the jugular bulb and internal jugular vein, which empties into the superior vena cava on the right side, and the innominate vein on the left (13). In most individuals, one of the two internal jugular veins is dominant (receiving most of the dural sinus flow), usually the right one, hence the best site for jugular venous saturation monitoring.

**Spinal Cord**

The spinal cord blood supply emanates from the larger and more important anterior spinal artery (formed by the union

**Figure 5** Circle of Willis—the major blood supply to the brain.

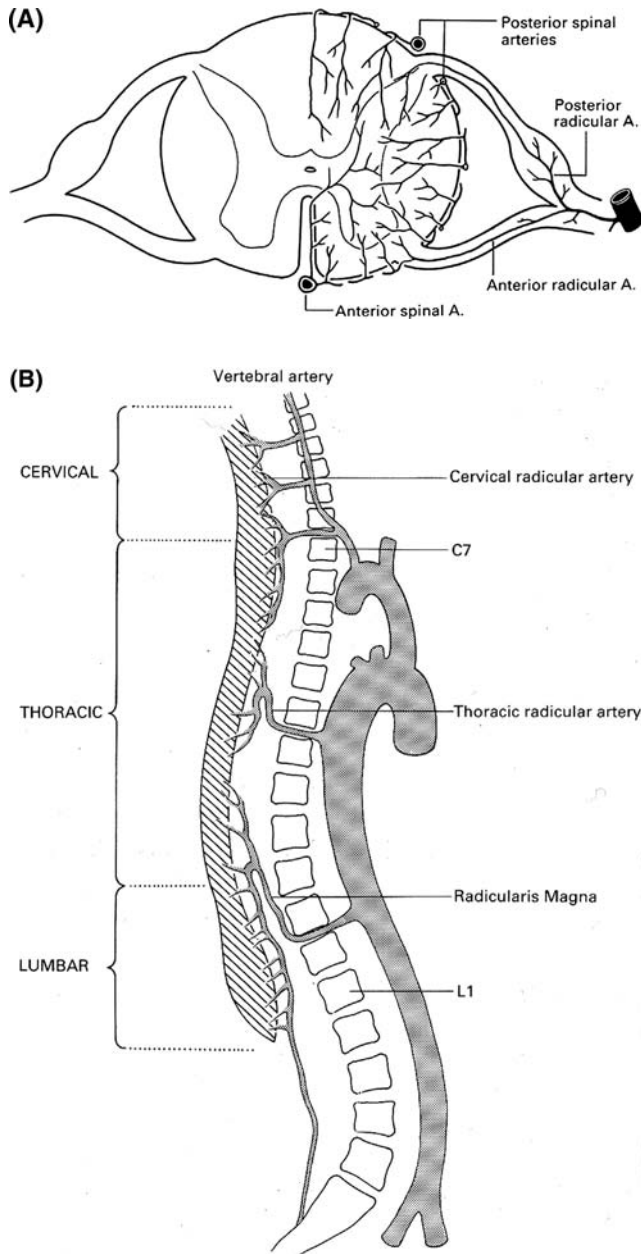

**Table 2** Name and Function of Major Spinal Cord Tracts

Tracts	Name	Function
Ascending (sensory)	Fasciculus gracilis	Contralateral touch, vibration, and proprioception of lower limb
	Fasciculus cuneatus	Contralateral touch, vibration, and proprioception of upper limb
	Spinothalamic	Contralateral pain and temperature
	Spinocerebellar	Transmit ipsilateral proprioceptive information to the cerebellum
Descending (motor)	Lateral corticospinal	Primary motor (75–90%)—crossed
	Ventral corticospinal	Primary motor (10–25%)—uncrossed
	Vestibulospinal	Transmit vestibular information to the motor system

of a branch from each vertebral artery) and the posterior spinal arteries (bilateral vessels which take origin from the inferior cerebellar arteries). The anterior blood supply is supplemented by a series of radicular branches most of which are small but some offer significant flow, particularly the radicularis magna, also known as the "artery of Adamkiewicz" (Fig. 6) (14).

Venous drainage of the spinal cord and vertebral column is complex, with numerous free anastomoses between two primary networks of veins (internal and external). The internal veins drain the spinal cord, and correspond to the arteries in their distribution, forming a

**Figure 6** Blood supply to the spinal cord. (A) Transverse section demonstrating contributions from the anterior, posterior, and radicular spinal arteries. (B) Lateral schematic view illustrating the contribution of the radicular branches. The thoracic radicular artery, and especially the radicularis magna ("artery of Adamkiewicz") are particularly important.

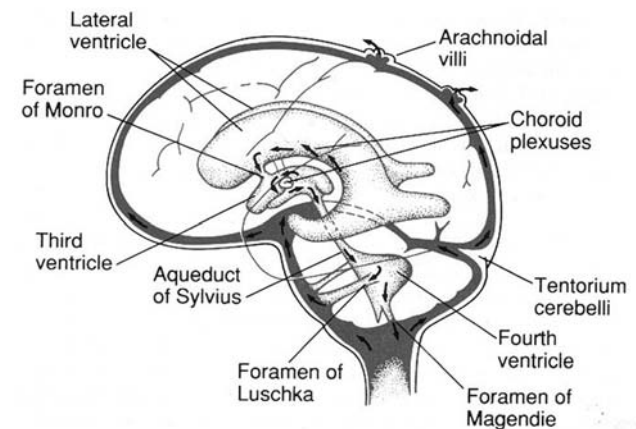

tortuous pattern in the pia matter surrounding the spinal cord. The venules empty into the anterior and posterior spinal veins, which drain above and below as well as segmentally into anterior and posterior radicular veins (adjacent to each nerve route as it exits the foramen). The external venous plexus drains the vertebral bodies (anterior) and laminae (posterior) and empties segmentally into the intervertebral veins. Here, there is anastomosis with the segmental drainage from the spinal cord. Therefore, changes in intrathoracic pressure or cerebral spinal fluid pressure may produce variations in cord blood volume and flow characteristics. Under various conditions, including surgery, placement of epidural fluids, pregnancy, and spinal trauma, the venous flow may become congested or alter its characteristics, making the cord more vulnerable to ischemia.

### Cerebrospinal Fluid System

The CSF system is comprised of the interconnecting ventricles, cisterns, and the subarachnoid space (Fig. 7). The two lateral ventricles communicate with the third ventricle via the interventricular foramina of Monro, and the third ventricle communicates with the fourth via the cerebral aqueduct of Sylvius. The fourth ventricle communicates with the basal cisterns via the bilateral foramina of Luschka and via the foramen of Magendie to the subarachnoid space. The intracranial ventricular system contains approximately 150 mL of CSF that, having the same specific gravity as CNS tissue, provides a buffer against movement and trauma (i.e., the brain essentially floats). Also, by changing the volume of CSF, it provides a pressure buffer against any expanding lesion within the cranium (14,15).

The bulk of CSF production occurs in the choroid plexuses of the four ventricles at a constant rate of approximately 500 mL/day, which allows for approximately four turnovers in 24 hours. The CSF circulates through the system to be eventually absorbed into the sagittal venous sinus via multiple arachnoid villi. The absorption rate determines both CSF volume and pressure (16). The normal intracranial pressure (ICP) ranges from 1 to 15 mmHg (i.e., 1–20 cm H<sub>2</sub>O).

When compared to plasma, the CSF contains lower glucose, potassium, and protein and greater sodium, chloride, and hydrogen ion concentrations (Table 3). There are no red blood cells and few white blood cells. The CSF

**Figure 7** The cerebral ventricular system.

**Table 3** Comparison of Plasma and Cerebrospinal Fluid Constituents

	Plasma	CSF
Na <sup>+</sup> (mmol/L)	134–146	146–148
K <sup>+</sup> (mmol/L)	3.4–5.0	2.8–3.1
HCO <sub>3</sub> <sup>-</sup> (mmol/L)	22–32	23–24
Cl <sup>-</sup> (mmol/L)	98–104	120–28
pH (pH units)	7.35–7.45	7.30–7.35
Glucose (mmol/L)	3.9–6.2	2.7–4.2
WBC (mm <sup>3</sup> )	5–10 <sup>3</sup> /mm <sup>3</sup>	<5/mm <sup>3</sup>
Protein (g/L)	63–78	0.15–0.45
IgG (g/L)	5.4–16.1	<0.05

*Abbreviations:* CSF, cerebrospinal fluid; WBC, white blood cell count; Ig, immunoglobulin.

is in direct communication with the CNS extracellular fluid, and hence their compositions are the same (3).

### Blood–Brain Barrier

The blood–brain barrier is formed by tight junctions between endothelial cells of CNS capillaries and, to a lesser extent, by astrocyte function. The movement of substances into the brain is restricted, and hence the composition of CSF and CNS extracellular fluid (CNS ECF) is not the same as ECF, elsewhere in the body. It is virtually impermeable to plasma proteins and large nonlipid-soluble molecules. It is slightly permeable to electrolytes and highly permeable to lipid-soluble substances, water, oxygen, and carbon dioxide (16,17).

### Cellular Elements

The key cellular elements of the CNS are neurons and their supporting glial cells. The adult human CNS is estimated to contain more than 100 billion neurons.

Despite considerable variability in neuronal morphology they all consist of three basic elements: the cell body, dendrites, and a single axon. Generally speaking, they are organized into two systems: afferent and efferent. The afferent neurons bring impulses inward for processing. For example, the sensory system is responsible for information reception regarding touch, temperature, pain, position, taste, smell, hearing, and sight. The efferent system includes all of the out going impulses (e.g., the motor system, which controls and co-ordinates movement). Neuronal function is dependent on rapid communication between neurons. This occurs via synapses. The synapses are junctions that may be chemical or electrical, the former comprising the vast majority. Presynaptic neuronal depolarization causes calcium-dependent synaptic vesicle/synaptic terminal membrane interaction and the subsequent release of neurotransmitter into the synaptic cleft (a 10–30 μ space between the synaptic terminal and postsynaptic neuron). Electrical synapses consist of low resistance gap junctions between neurons. Electrical communication occurs, allowing rapid signal transfer (18).

Glial cells outnumber neurons approximately ten to one. They have a supporting role and consist of several different types. The star-shaped astrocytes function to maintain the local environment within the CNS and secrete various regulatory factors. Oligodendrocytes ensheath neuronal processes, and are hence responsible for CNS myelination. Microglia have a predominantly phagocytic role. Ependymal cells separate neurons from the ventricular system (17,19).

### Autonomic Nervous System

The ANS has efferents to visceral organs, blood vessels, and secretory glands. ⚡ **Although influenced by higher brain centers, such as the limbic cortex, the ANS operates to control the homeostatic environment in a purely reflex fashion.** ⚡ Cardiac output (Q̇), arterial blood pressure, bronchiolar tone, gastrointestinal motility, urinary bladder function, sexual function, sweating and body temperature, and many other systems are influenced. It is conventionally divided into two systems: the sympathetic and the parasympathetic (Fig. 8), which differ anatomically, physiologically, and pharmacologically. Each has pre- and postganglionic neurons. Preganglionic neurons have cell bodies located in either the brainstem or spinal cord and synapse with postganglionic neurons located in ganglia via thinly myelinated axons. Postganglionic neurons send unmyelinated fibers to visceral effector cells (20–22).

#### Sympathetic (Thoraco-Lumbar)

The sympathetic chain is a ganglionated nerve trunk, extending from the base of the skull to the coccyx in close approximation to the spinal cord. Postganglionic branches from the sympathetic chain are unmyelinated, tend to run a long course, and may be divided into somatic and visceral groups. Somatic fibers, distributed by spinal nerves, supply the skin and sweat glands. Visceral fibers to the head and neck ascend with the internal carotid and vertebral arteries. Thoracic organs are supplied from local plexuses, and abdominal organs are supplied from the celiac, hypogastric and pelvic plexuses.

The cell bodies of preganglionic neurons are located in the intermediolateral horn of the spinal cord from segments T1–L2. The small segmental myelinated axons leave the spinal cord in the anterior primary rami and pass into the sympathetic chain at the same level via the white rami communicans. The axons then take one of three paths: (i) terminate in the sympathetic chain, at its level of origin; (ii) ascend or descend in the sympathetic chain, before synapsing at a different level; or (iii) exit the sympathetic chain without synapsing and terminate in paravertebral ganglion via splanchnic nerves. Sympathetic preganglionic neurons are generally short (23). Sympathetic innervation follows a segmental pattern. The spinal segments responsible are approximately as follows: head and neck, T1–2; upper limb, T2–7; thorax, T1–4; abdomen, T4–L2; lower limb, T11–L2 (24).

The adrenal medulla forms an important part of the sympathetic nervous system. It is supplied with a rich plexus of preganglionic fibers that pass directly through the celiac plexus. These fibers terminate in contact with medullary cells and stimulate the release of epinephrine and norepinephrine into the bloodstream from where they act at effector sites in a hormonal fashion (21,22). Sympathetic stimulation generally increases cardiovascular activity and arousal while reducing other visceral activity. This forms the “fight or flight” response.

#### Parasympathetic (Cranio-Sacral)

The parasympathetic system is less widely distributed. The bulk of innervation is to the body cavity viscera. There is no supply to skeletal muscle or skin. Preganglionic fibers are long and myelinated, whereas postganglionic fibers are short and are unmyelinated. Preganglionic fibers arise from a cranial and a sacral component.

**Figure 8** The efferent pathways of the autonomic nervous system. The sympathetic pathways are shown in bold lines, and the parasympathetic pathways are shown in thin lines.

Cell bodies of the cranial outflow are located in brainstem nuclei of the cranial nerves III, VII, IX, and X. Fibers are then distributed with these nerves. Fibers from III, VII, and IX are relayed via four ganglia close to the effector sites: III, the ciliary ganglion; VII, the pterygopalatine and submandibular ganglia; IX, the otic ganglion. The vagal outflow (X) has the most widespread and most important distribution. Fibers terminate in tiny ganglia that lie in visceral walls.

Cell bodies of the sacral outflow are located at sacral segments S2-4 from where their fibers leave in the anterior primary rami. Fibers from the anterior primary rami join to form the pelvic splanchnic nerves that pass through the pelvic plexus to synapse on tiny ganglia in the walls of the pelvic viscera (24). Postganglionic fibers synapse with effector organ cells. Parasympathetic stimulation is generally inhibitory to the heart and lungs and stimulatory to the gastrointestinal system. It also provides a "mechanism for emptying" (21,22).

**Neurotransmission (Cholinergic vs. Adrenergic) and Receptor Subtypes**

All preganglionic neurons and postganglionic parasympathetic neurons secrete acetylcholine as a neurotransmitter. Cholinergic receptors are subdivided into muscarinic and nicotinic. At both sympathetic and parasympathetic ganglia, postsynaptic membranes have nicotinic acetylcholine receptors. In addition, the neuromuscular junction (NMJ) of skeletal muscle is nicotinic (see Volume 2, Chapter 6). Nicotinic receptors are so named because nicotine is agonist and curare antagonist. Muscarinic receptors are located on all effector cells stimulated by postganglionic parasympathetic neurons. Muscarine has agonist and atropine antagonist actions at these receptors.

Sympathetic postganglionic neurons secrete norepinephrine as a neurotransmitter and are referred to as adrenergic, in all cases except for three (piloerector muscles, sweat glands, and some blood vessels) which secrete acetylcholine and are muscarinic.

Adrenergic receptors are subdivided into  $\alpha$ - and  $\beta$ -receptors. Norepinephrine has greater action at alpha receptors. Epinephrine has approximately equal action at both types. Effector tissue response to catecholamines is determined by the type and density of the receptors expressed by that tissue.

Receptors are further subdivided into pre- ( $\alpha_2$ ) and post- ( $\alpha_1$ ) junctional receptors. The  $\alpha_1$  stimulation causes vasoconstriction, contraction of gut and bladder sphincters, and dilation of the iris. The  $\alpha_2$  stimulation results in vasodilation, and centrally located receptors are important in the perception of pain.

$\beta$ -receptors are also subdivided into two types:  $\beta_1$  and  $\beta_2$ . The  $\beta_1$ -receptors are located on the heart and have positive inotropic and chronotropic effects. The  $\beta_2$ -receptors mediate bronchodilation, skeletal muscle vasodilation, uterine relaxation, and glycogenolysis (24).

### Autonomic Tone

It is appropriate to view the often-opposing actions of the sympathetic and parasympathetic nervous systems as a means of co-ordinating visceral activity. The basal rate of activity of the ANS allows a single division to exert a change in the function of an effector organ. For example, baseline sympathetic tone constricts systemic arterioles to approximately half of their maximum diameter. A decrease in sympathetic tone will result in vasodilation, and an increase in sympathetic tone in vasoconstriction (22).

## Location of Higher Intellectual Brain Functions

### Speech and Language

✎ **Almost all right-handed people and 70% of left-handed individuals have speech and language centers located in the left cerebral hemisphere.** ✎ The location of the speech and language centers designate hemisphere dominance. Two centers for speech are classically described: Broca's area located in the dominant frontal lobe and Wernicke's area located in the dominant temporoparietal zone. A lesion in Broca's area causes expressive dysphasia or aphasia; comprehension is preserved, but fluency is compromised. A lesion in Wernicke's area causes receptive dysphasia or aphasia; comprehension is compromised, but fluency of speech is preserved. However, the spoken words are often incorrect, and the affected patient speaks in muddled jargon (2,25).

### Memory

Memory formation is incompletely understood. It may result from changes in synapse structure or in altered pathways. Lesions in the hippocampus cause anterograde amnesia and disrupt short-term memory, whereas those in the thalamus and cortex disrupt long-term memory (2).

## PHYSIOLOGY

### Impulse Generation

#### Membrane Structure

Membranes form a permeability barrier to most water-soluble molecules, separate cells from one another, and divide compartments within cells. All cell membranes are composed of a lipid bilayer, approximately 10 nm in depth, with phospholipids and proteins being their major constituents. Phospholipid molecules have polar, usually

choline- containing, hydrophilic heads and hydrophobic fatty acid chains as tails. Membrane proteins are either intrinsic, which traverse the lipid bilayer, or extrinsic, which are located on the membrane surface. Membrane proteins form ion channels and receptors and also function as enzymes. A small amount of glycolipid exists on the outer surface of cell membranes that has important receptor function and constitutes antigens (26).

### Transport Across Membranes

The transfer of molecules across membranes is either passive (energy independent) or active (energy dependent). Active transport requires more oxygen ( $O_2$ ) and glucose utilization.

#### Passive Transfer (Diffusion and Osmosis)

Passive transfer of solutes occurs across cell membranes principally by diffusion (simple or facilitated), as molecules travel from an area of high concentration to an area of lower concentration. Diffusion results from the continuous random movement of molecules in the fluid state, resulting from the normal kinetic motion of matter.

Simple diffusion occurs without binding to specific proteins. Water-soluble molecules cross via membrane channels or junctions within the lipid bilayer. Lipid-soluble substances are able to pass directly through. In general terms, the rate of diffusion of a substance across a plasma membrane is directly proportional to its lipid solubility (27). The rate of diffusion may be described in the terms of Graham's law (i.e., "The rate of diffusion of a substance is inversely proportional to the square root of its molecular weight") (28), and by Fick's law (Equation 1), which states that the rate of diffusion is proportional to the surface area of the membrane and the concentration difference across a membrane and inversely proportional to the thickness of the membrane (26,28).

$$\text{Diffusion} = DA_{\text{surface}} \Delta C / T_{\text{membrane}} - 1 \quad (1)$$

where D is the diffusion coefficient of a substance through a particular membrane;  $A_{\text{surface}}$ , the surface area;  $\Delta C$ , the concentration difference; and  $T_{\text{membrane}}$ , the membrane thickness.

Facilitated diffusion requires binding to a specific carrier protein within the membrane. Conformational change occurs within the carrier protein, and both substance and protein move through the membrane in a nonenergy-dependent process. The substance is released on the other side of the membrane. The rate of diffusion is limited by the rate of conformational change of the carrier protein. Movement is only possible down a concentration gradient. An important example is the transport of glucose into cells (26,27,29).

Osmosis is the movement of water across a semi-permeable membrane from a higher to a lower concentration (of water). The osmotic pressure of a solution is the pressure that must be applied in order to prevent the movement of water into that solution. Osmotic pressure is described in terms of the number of particles per unit volume of fluid. Changes in the osmotic pressure gradient across cell membranes cause them to swell or shrink (26,27).

#### Active Transfer (Energy Dependent)

Active transport is an energy-dependent process that moves a substance against its electrochemical gradient. It relies on

the presence of a transmembrane carrier protein and can be primary or secondary.

Primary active transport is linked directly to the cellular breakdown of a high-energy phosphate compound, usually adenosine triphosphate (ATP). An important example is the sodium–potassium pump. Three sodium ions are moved out of the cell for every two potassium ions moved in. Binding of the ions to the carrier protein activates ATPase that cleaves a molecule of ATP to release the required energy. The pump is vital to maintain the normal resting negative electrical potential inside cells and for regulating cell volume (30). A further example is calcium ATPase found on cell plasma membranes and on those of intracellular vesicles in which calcium is concentrated. Calcium is a key second messenger, and the maintenance of a low baseline intracellular calcium concentration and the facility for its rapid control are vital to normal cellular function (26,27).

Secondary active transport utilizes the energy derived from the electrochemical gradient of a substance transported by primary active transport. It may be cotransport, the secondary substance moving in the same direction as the primary substance, or countertransport, the secondary substance moving in the opposite direction to the primary substance. Glucose and amino acids may be cotransported with sodium, whereas calcium and hydrogen ions may be countertransported with sodium (26,27,31).

### Resting Membrane Potential

The cytoplasm of all cells is electronegative, relative to extracellular fluid, and hence a potential difference exists across plasma membranes. This is termed the resting potential. Neurons and myocytes have the capability of electrical impulse generation. They are termed excitable tissues.

The resting potential is dependent upon ionic equilibria and the selective permeability of the plasma membrane. Ionic equilibrium exists when the two “forces” acting on charged particles (i.e., the concentration gradient and the electrical potential difference) balance. This is described mathematically for a single univalent ion  $X^+$  (such as potassium) by the Nernst equation (Equation 2).

$$EMF(\text{millivolts})_{X^+} = -61 \log \frac{[X^+]_i}{[X^+]_o} \quad (2)$$

where  $EMF_{X^+}$  is the electromotive force acting on  $X^+$ ;  $[X^+]_i$ , the concentration of  $X^+$  inside the cell; and  $[X^+]_o$ , the concentration of  $X^+$  outside the cell.

Plasma membranes are essentially impermeable to anionic protein molecules and selectively permeable to ions. At rest, the membrane is approximately one hundred times more permeable to potassium than to sodium. Therefore, at rest, potassium makes the most significant contribution to the resting potential. The Nernst equation represents the potential due to a single ion (the Nernst potential for potassium is  $-90$  mV), but in reality, other ions contribute to the resting potential, which approximates to  $-70$  mV. The overall membrane potential (which reflects the inside compared to outside concentrations for all of the clinically significant ions) is represented mathematically by the Goldman equation (which provides a value close to  $-70$  mV when normal intracellular and extracellular ion concentrations are present) (32,33).

### Action Potential

The action potential can be considered in three stages: depolarization, repolarization, and propagation. In nervous

**Figure 9** The action potential, showing the resting potential ( $-70$  mV), depolarization and repolarization.

tissue, it occurs extremely rapidly ( $<1$  msec) in an “all or nothing” fashion (Fig. 9).

#### Depolarization

An initial stimulus, for example, the action of a neurotransmitter on a postsynaptic membrane, causes the membrane potential to increase towards zero. If sufficiently large, the threshold potential is reached (approximately  $-55$  mV), and voltage-gated sodium channels open. Sodium conductance increases by a factor of about 5000, sodium moves inward down both electrical and concentration gradients, and the membrane potential reaches  $+35$  mV (34).

#### Repolarization

Voltage-gated sodium channels are inactivated (a process initiated simultaneously with channel opening, but at a slower rate), which halts the influx of sodium. Voltage-gated potassium channels open fractionally after sodium channel opening, allowing the efflux of intracellular potassium, and the membrane potential returns toward its normal resting potential. The sodium–potassium pump then restores intracellular resting sodium and potassium concentrations in an energy-dependent process (35).

#### Propagation

Depolarization at a single point of a neuronal membrane causes a change in potential in adjacent membrane of sufficient magnitude to open voltage-gated sodium channels, therefore creating a “wave” of depolarization. The electrical impulse travels unidirectionally because the previously depolarized section remains refractory to further stimulation until its resting state has been at least partially restored (32,35).

#### Metabolism

☞ The brain is one of the most metabolically active organs in the body and requires a constant supply of  $O_2$  and glucose. ☞ It has a mass of 1500 g (2% body weight), and receives 15%  $\dot{Q}$ , yet accounts for more than 20% of the total body  $O_2$  consumption ( $\dot{V}O_2$ ), and 25% of the total body glucose utilization. The extraction ratio for oxygen is

approximately 50% and that of glucose approximately 10%. Although glial cells comprise approximately 50% of the brain, they consume less than 10% of cerebral energy (36).

### **Aerobic and Anaerobic Metabolism**

Glycolysis and subsequent oxidative phosphorylation of glucose (60 mg/100 g/min) to water and carbon dioxide is by far the most important energy pathway in the brain (37). Thirty-eight molecules of ATP are formed per molecule of glucose. The ATP is vital for normal neuronal function, and having no significant energy store, the brain is extremely sensitive to any derangement in the supply of oxygen or metabolic substrate (38).

In the absence of  $O_2$ , the metabolism of glucose via the glycolytic pathway is very inefficient: only two molecules of ATP are formed per molecule of glucose (39).

### **SjO<sub>2</sub>, AVDO<sub>2</sub>, and CMRO<sub>2</sub>**

The SjO<sub>2</sub> is the percentage oxygen saturation of jugular venous blood. It normally varies between 55% to 65% (40,41). The AVDO<sub>2</sub> is the arterio-venous oxygen difference. It is calculated as the measured difference between the  $O_2$  content of arterial and jugular bulb venous blood. It represents a ratio of metabolism to blood and  $\dot{D}O_2$ . The normal value is 6.3 vol% (42). The CMRO<sub>2</sub> is the cerebral metabolic rate for oxygen. It is normally 3.5 mL/100 g/min (43). It decreases by 6% per degree Celsius fall in brain temperature.

There is coupling between CBF and  $\dot{V}O_2$ . This represents metabolic autoregulation. Normal aerobic metabolism, glucose consumption, and  $\dot{V}O_2$  lead to normal  $CO_2$  production ( $\dot{V}CO_2$ ) that mediates normal cerebral microcirculatory diameter, and hence blood flow. If CMRO<sub>2</sub> decreases,  $\dot{V}CO_2$  decreases, and hence CBF and oxygen delivery ( $\dot{D}O_2$ ) decrease. The converse is true. If CBF falls and the CMRO<sub>2</sub> remains unchanged, then the oxygen extraction and AVDO<sub>2</sub> will increase, and be reflected in a decreased SjO<sub>2</sub> (44). The AVDO<sub>2</sub> can increase to a maximum of double the normal value (39).

### **Brain Parenchymal Gas Tensions**

The determination of brain tissue  $O_2$  (Brain- $P_{ti}O_2$ ) and  $CO_2$  partial pressures is problematic. Human studies in normal brain do not exist. Normal values inferred from animal studies have estimated brain tissue oxygen at 25–30 mmHg with a  $PaO_2$  of 102–104 mmHg (39), and that for carbon dioxide at 55 mmHg (45). A change in  $CO_2$  tension results in a change in extracellular pH that profoundly affects neuronal function, and is tightly controlled.

Brain capillary  $O_2$  tension decreases from arterial to venous ends, as a result of oxygen extraction. Most models assume that each capillary supplies a cylindrical volume of tissue and that  $O_2$  freely diffuses into the tissues along the radial axis. The available  $O_2$  is less than the arterial supply and depends on the diffusion pressure of  $O_2$ , being the difference in oxygen tension between capillary and mitochondria. Similarly, the Brain- $P_{ti}O_2$  levels are lowest at the venous ends, hence forming more vulnerable regions. During normal resting conditions, some tissue  $O_2$  diffuses back into the capillary. This  $O_2$  surplus helps initially to meet any increase in tissue demand without the need for increasing CBF (46,47).

In models of global cerebral ischemia, Brain- $P_{ti}O_2$  changes with cerebral perfusion pressure (CPP) and is almost linearly coupled to local CBF. During systemic hypoxia, Brain- $P_{ti}O_2$  falls with  $SaO_2$  accompanied by a

compensatory increase in CBF. CMRO<sub>2</sub> falls steadily with Brain- $P_{ti}O_2$  until the ischemic threshold is reached, at which point CMRO<sub>2</sub> falls steeply, indicating exhausted compensatory increases in oxygen extraction during ischemia or CBF during systemic hypoxia (48).

Patients undergoing craniotomy for mass lesions and aneurysm surgery (ventilated with  $FIO_2 = 0.4$ ) had a Brain- $P_{ti}O_2$  value of  $48 \pm 13$  mmHg measured (49). The Brain- $P_{ti}O_2$  falls in parallel with other parameters of brain oxygenation (50), and may increase to  $> 130$  mmHg in patients ventilated with 100% oxygen (45). Although Brain- $P_{ti}O_2 < 25$  to 30 mmHg probably indicates impaired brain oxygenation, the anaerobic threshold for Brain- $P_{ti}O_2$  is in the order of 20 mmHg (39) (providing an intracellular  $pO_2$  somewhat greater than 1 mmHg) (47).

Following traumatic brain injury (TBI), both depth and duration of tissue hypoxia are independent predictors of poor prognosis (51,52). Following severe stroke in humans, therapeutic measures which decrease ICP and increase CPP have been associated with an increase in Brain- $P_{ti}O_2$  (53). Also, pattern changes in Brain- $P_{ti}O_2$  graphical plots may predict imminent herniation syndrome in this patient population (53). Before Brain- $P_{ti}O_2$  can be used clinically as targeted treatment, significant additional research needs to be conducted in normal and abnormal neurological states.

## **Intracranial Pressure**

### **The Monro-Kellie Doctrine**

The volume of the adult cranial cavity remains constant: the skull is a noncompliant bony vault of fixed dimensions. ⚡ **For ICP to remain constant (normal = 1–15 mmHg), the sum of the volumes of the intracerebral components must remain constant (54).** ⚡ The main intracerebral components are brain parenchyma (intracellular volume and interstitial volume), CSF, and cerebral blood volume (CBV). Therefore, if the volume of one component increases, the volume of another must decrease, otherwise ICP will increase (39). This forms the central idea of the Monro-Kellie doctrine (55,56).

The first line of compensation for increasing ICP is usually a decrease in CSF volume. As discussed earlier, the rate of CSF formation remains constant, and in order to decrease CSF volume, the rate of absorption must increase.

Approximately 5% of intracerebral volume is occupied by blood (roughly 60 mL), most of which is contained within the venules whose diameter remains fairly constant despite changes in other physiological variables. Arterial diameter does vary (80–160% baseline), which results in a corresponding change in CBV, ICP, and CPP (57). If CBF autoregulation is intact (see subsequently) an increase in CPP will result in cerebral vasoconstriction to keep CBF constant and a decrease in CBV and ICP.

### **Measurement of Intracranial Pressure**

The measurement of ICP is an important and now routine part of the management of severe head injury. The “gold standard” measuring device is the fluid-filled intraventricular catheter called a ventriculostomy (see Volume 2, Chapter 7). It is reliable, cost-effective, allows for periodic rezeroing and the withdrawal of CSF (for ICP control and CSF analysis). The catheter can sometimes block or leak. Alternatives include solid-state (pressure-sensitive resistors) and fiberoptic transducers that are usually placed within the parenchyma. Values correlate well with fluid-filled systems.

The major drawback is drift in ICP reading over time. Overall, indwelling ICP monitoring devices have an infection rate in the order of 7% and a hemorrhage rate of approximately 3% (58).

### Cerebral Perfusion Pressure and Intracranial Pressure

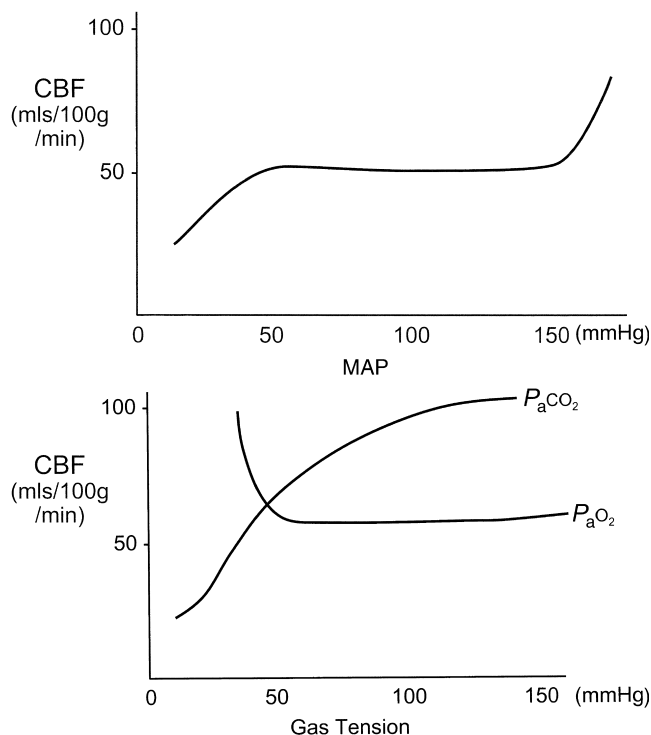

A true measure of CPP would naturally be mean arterial pressure (MAP)—cerebral venous pressure. However, cerebral venous pressure is not easily measured. ICP is the closest measurable variable to cerebral venous pressure, and thus the surrogate, used clinically. The CPP is therefore best represented by  $MAP - ICP$  (13). ICP is profoundly linked to CBF: as ICP increases, CPP must fall for any given MAP (39).

### Cerebral Blood Flow

It is vital to understand the physiological control of CBF, since its therapeutic manipulation is a key feature in neuro-trauma management. Normal CBF is 50 mL/100 g/min (4,20,1). Reversible loss of electrical activity occurs with flows less than 23 mL/100 g/min (ischemic threshold), and sodium–potassium ATPase pump failure occurs at flows less than 18 mL/100 g/min. Prolonged hypoperfusion results in infarction (39).

### Autoregulation

Autoregulation is the intrinsic ability of an organ to maintain a constant blood flow in the face of changing perfusion pressure, and is particularly well developed in the brain. As outlined earlier,  $CPP = MAP - ICP$ . **A normal value for CPP is approximately 70 mmHg.** Autoregulation

**Figure 10** Regulation of cerebral blood flow with mean arterial blood pressure (MAP) (*upper graph*) and gas tensions for carbon dioxide ( $PaCO_2$ ) and oxygen ( $PaO_2$ ) (*lower graph*).

operates between MAPs 50 and 150 mmHg (Fig. 10) (13,37,39,59). As MAP increases, cerebral arteriolar diameter decreases, cerebrovascular resistance (CVR) increases, and CBF is maintained. The brain is protected against ischemia during hypotension and from cerebral edema during hypertension. Outside the normal operating range, CBF varies more directly with CPP (13,37). Below the lower limit of autoregulation, oxygen extraction is initially increased but once maximal, further decreases in CPP result in cerebral hypoxia. The CVR reaches a minimum below the lower limit of autoregulation. If CPP reduces still further, there is a sharp rise in CVR subsequent upon cerebral vessel collapse and consequent severe ischemia. At CPP above the upper limit of autoregulation, forceful vasodilation may occur, resulting in a marked fall in CVR, blood–brain barrier damage, and cerebral edema (21).

The mechanism for autoregulation is likely to be a combination of myogenic, metabolic, and neurogenic factors. The myogenic process involves an inverse variation in arteriolar diameter in response to a changing transmural pressure gradient (13). The response occurs within seconds and is most effective at high CPP (39). Metabolic mechanisms involve increasing concentrations of by-products ( $CO_2$ ,  $H^+$ , and  $K^+$ ), as CBF fails to meet metabolic demands and is most effective at low CPP (13,59). The limits of autoregulation are under the dynamic control of the ANS (sympathetic discharge shifts the autoregulation curve to the right) and are affected by the renin–angiotensin system and some disease states. Chronic hypertension shifts the autoregulation curve to the right. Accordingly, hypotension and the associated fall in CPP is less well tolerated in the hypertensive population (21).

### Effect of Carbon Dioxide Tension

$PaCO_2$  is one of the most powerful factors affecting CBF (Fig. 10) (59,60). **Within the range  $PaCO_2$  25–60 mmHg, vasodilation and hence CBF increases linearly with  $PaCO_2$  (13,28).** Outside the quoted range, maximal vasoconstriction/vasodilation occurs and no further decrease/increase in CBF is possible.

The vasodilation caused by hypercapnia blunts the response of vasoconstriction seen as CPP increases. The autoregulatory plateau is narrowed, shifted upwards, and rendered more pressure passive (59).

### Effect of Oxygen Tension

Arterial oxygen tension has little effect on CBF within the normal  $PaO_2$  range (37). Very high  $PaO_2$  (>300 mmHg) can cause cerebral vasoconstriction. Breathing 100% oxygen causes a 10% reduction in CBF (13). At approximately  $PaO_2$  of 60 mmHg, cerebral vasodilation begins to occur, and CBF increases rapidly as  $PaO_2$  falls below this value (Fig. 10) (13,37).

### Neurogenic Control

Cerebral blood vessels are richly innervated, and it seems likely that neurogenic mechanisms provide a means of rapid CBF control (13,59). Sympathetic vasoconstrictor fibres arise from the superior cervical and stellate ganglia. Nerve endings secrete norepinephrine, serotonin, and neuropeptide Y and provide a means of protecting the brain from high CPP during systemic hypertension caused by sympathetic stimulation. Cholinergic parasympathetic fibers take origin from the sphenopalatine, internal carotid, and otic ganglia (13). Sensory innervation via the first

division of the trigeminal nerve and innervation from an intrinsic nerve supply also have a role (59). Cerebral blood vessels also express opiate receptors that may be important in the control of CBF during stress (13).

### Measurement of Cerebral Blood Flow

The Kety-Schmit method, based on the Fick principle, uses nitrous oxide or radio isotope as a tracer and is a cumbersome procedure. It does, however, directly measure flow. Single-photon emission computed tomography (SPECT), positron emission tomography (PET), angiography with magnetic resonance imaging, and stable xenon-enhanced computed tomography (sXe-CT) are other measures of CBF, which are research tools and not suitable for bedside use (60). Transcranial Doppler, jugular bulb oximetry (SjO<sub>2</sub>), and near-infrared cerebral spectroscopy (NIRS) measure variables related to CBF, but not flow itself (61–63). Jugular continuous thermodilution provides a direct measure of CBF and has been used successfully at the bedside (60).

### States of Brain Activity

#### Consciousness and Unconsciousness

Consciousness depends upon interaction between the cerebral hemispheres and the brainstem reticular activating system. It is defined as awareness of self and environment. Unconsciousness is therefore unawareness of self and environment and may be seen as a continuum from confusion (reduced awareness and disorientation) to coma (unrousable unresponsiveness). Although the Glasgow Coma Scale (GCS) was designed to grade the severity and prognosis of traumatic head injury, it is now used almost universally to grade the depth of unconsciousness from all causes (64).

#### Sleep

Sleep is defined as a recurrent state of unconsciousness from which one can be readily aroused by sensory stimuli. There are two components: slow wave sleep and rapid eye movement (REM) sleep.

Slow wave sleep is usually deep, with progressive slowing and an increase in amplitude on electroencephalogram (EEG). There is slowing of heart and respiratory rates, decreased peripheral vascular resistance, decreased muscle tone, and decreased metabolic rate.

REM sleep is characterized by a rapid, low-voltage EEG, with bursts of large phasic potentials associated with increases in heart rate, respiratory rate, and body temperature. Cerebral metabolic rate may increase by 20% and CBF also increases. There is marked muscular relaxation. Dreams occur during REM sleep and are often remembered. REM sleep occurs in a cyclical fashion every one to two hours and lasts up to one hour. There is considerable variation between individuals (65).

#### Seizures

A seizure is uncontrolled, excessive neuronal discharge, the motor consequences of which are termed convulsions. Epilepsy is a continuing tendency to have seizures and is classified according to the pattern of seizure activity. ⚡ **The cerebral metabolic rate is markedly increased during seizure activity (13).** ⚡ Increased metabolic activity in injured brain can cause cell injury and death. Accordingly, seizures should be promptly treated (benzodiazepines are often used first line). Seizure prophylaxis is widely

employed in the first couple of weeks following severe TBI (phenytoin is the most common first line drug) (66). However, the duration of prophylaxis, the relative need in the setting of concomitant sedation, and the most efficacious agents are all subjects of controversy (67).

#### Anesthesia

Anesthesia may be defined as a drug-induced, reversible loss of awareness and pain sensation. With increasing depth of anesthesia, there is slowing of EEG activity and a progressive increase in amplitude. Periods of isoelectricity interspersed with bursts of activity occur (burst suppression), and finally isoelectricity remains constant (68).

#### Brainstem Death

Brainstem death is a state of irreversible apneic coma. The diagnosis must be made with certainty. Rigid criteria must be fulfilled, which in most countries are based on U.K. or U.S. guidelines (69). Brainstem death is always followed by asystole within days, which almost always is preceded by an isoelectric EEG (70).

## PATHOPHYSIOLOGY

### Gross Pathology

The major mechanisms of TBI are positive pressure, negative pressure, brain laceration, and shear caused by direct impact or acceleration/deceleration (71).

TBI may be classified as primary or secondary and focal or diffuse. Primary injury is that which occurs at the time of impact and includes fracture, contusion, and hemorrhage. It is influenced only by prevention. Secondary brain injury is that which develops after the time of impact and includes ischemia, hypoxia, and the consequences of raised ICP. Its severity can be limited by prompt and appropriate medical and/or surgical intervention.

Focal brain injury is limited to a specific location and includes contusion and hematoma, whereas diffuse injury is more uniform throughout the brain, for example, diffuse axonal injury (DAI) and diffuse subarachnoid hemorrhage.

#### Contusion

A contusion is essentially a traumatic intracerebral hemorrhage resulting from mechanical injury to small-caliber vessels, that may, if severe, progress to necrosis. It typically occurs at the site of impact (coup) or at a point opposite the site of impact (contra coup) caused by brain movement within the skull.

#### Hemorrhage

⚡ **Hemorrhage usually presents as a space-occupying lesion, with increased ICP, and when severe, as brain or brainstem herniation.** ⚡ Extradural hematomas are caused by tearing of meningeal arterial vessels and separate the dura from the skull. The classic “lucid interval” may be seen. Subdural hematomas are usually caused by rupture of the veins that bridge the subdural space. Subarachnoid hemorrhage is the most common form of vascular injury seen following TBI and although usually minor, it may be life threatening.

Intracerebral hemorrhage is caused by rupture of vessels within brain parenchyma (72). When numerous small hemorrhages are scattered throughout the brain, the

term “diffuse vascular injury” is applied. It is uncommon, seen in only the most severe TBI (73).

### **Diffuse Axonal Injury**

DAI is a direct consequence of physical injury to the brain axons, caused by rotational acceleration/deceleration of the brain (71,74). It is characterized by axonal damage scattered throughout the brain that produces a clinical spectrum from mild-to-severe neurological impairment. The distribution of damaged axons is not uniform, but occurs predominantly throughout the corpus callosum, fornix, internal capsule, midline grey, cerebellar follicles and brainstem (75). Using conventional microscopy, axonal swellings are demonstrable at approximately 15 hours post injury (72). Evidence of axonal injury may be demonstrated much earlier, however, by more sophisticated techniques (76). DAI is really a pathological diagnosis. However, certain magnetic resonance imaging (MRI) findings (e.g., petechia along axon tracts) correlate with the pathologic findings.

Only with severe injury are axons sheared at the moment of impact. This is termed “primary axonotomy.” More commonly, axons undergo a series of changes, resulting in axonal disruption after the moment of injury, a process termed “secondary axonotomy.” Secondary axonotomy follows a sequence of events. At impact, there is transient depolarization, abnormal ionic flux, and abnormal axonal permeability. There is subsequent interruption of axoplasmic transport with the accumulation of cytoskeletal components and organelles (three to six hours). Axons and mitochondria then swell, secondary to calcium accumulation. Finally, the proximal axonal segment separates and the distal segment undergoes Wallerian degeneration (usually by 24 hours) (72,73,75).

### **Cell Death**

Cell death is conventionally divided into two main types: necrosis and apoptosis, which differ both morphologically and biochemically. Hybrid forms of cell death with features of both are also seen (77).

### **Necrosis**

Necrosis is triggered by abnormal physiology or extrinsic insults, for example, hypoxia, ischemia, trauma, and toxins. In normothermic patients, three to five minutes of arrest can cause necrosis of certain brain cells. The hippocampal region of the brain is one of the least tolerant to ischemia. Necrosis results from defective ion transport, ATP depletion, swelling and degeneration of organelles, loss of membrane integrity, cellular dissolution, and an accompanying acute inflammatory response. The process is usually complete within 24 hours and is more rapid with more severe insults (77). The mechanisms of necrotic death will be considered subsequently.

### **Apoptosis**

Apoptosis is a process of programmed cell death that has a vital role in normal development, and is just now becoming understood. Approximately 50% developing sensory and spinal motor neurons die by apoptosis. The earliest changes occur in the nucleus. The chromatin condenses followed by nucleolar disintegration. The cytoplasm then condenses, the cell shrinks and the plasma membrane remains intact. The cell then fragments into membrane bound “apoptotic bodies,” which are phagocytosed by neighboring cells.

An inflammatory response does not occur (77,78). The time course is similar to that seen in necrosis.

The mechanisms of apoptosis may be divided into intrinsic (arising from mitochondria) and extrinsic (initiated by the binding of “death factors”), both converging on the caspase pathway. The caspases are a family of proteases that are fundamental to the process of apoptosis. Activation of the caspase pathway causes amplification of the apoptic signal, amplification of the caspase cascade, altered cellular morphology, disables repair processes, inactivates survival signals, and produces a signal for phagocytosis. However, caspase-independent apoptosis is recognized, and caspase activation is not an absolute requirement (78). The bcl-2 proto-oncogene family have a regulatory role (77). Excitatory amino acids, changes in intracellular calcium, and free radicals can induce apoptosis. In fact, all of the mechanisms traditionally considered to be triggers of necrosis can trigger apoptosis if the correct conditions apply.

### **Hybrid Necrosis–Apoptosis/Necrosis–Apoptosis Spectrum**

☞ **Neuronal apoptosis and necrosis may be occurring simultaneously in the injured brain.** ☞ For example, although the features of ischemia and trauma are typically necrotic, apoptosis does occur in some neuronal groups and glial cells following ischemic injury, especially in the developing nervous system (77). Apoptosis also occurs alongside necrosis, following TBI, and can form a significant portion of neuronal loss (79). Apoptotic neurons have been identified at the site of injury, remote from the site of injury, and in contusions. Morphological features of both necrosis and apoptosis can occur in the same neuron. It is likely that the nature and intensity of an insult defines whether injured neurons undergo necrosis or apoptosis (80). Intracellular ATP concentrations may be a determinant of cell death route. If sufficient ATP is present, an injured neuron will have the metabolic capability to initiate the apoptotic cascade, whereas if deplete, necrosis will occur (81). Calcium influx during excitotoxicity may influence apoptosis and necrosis in opposing ways. The development of apoptosis may be inversely related to the intracellular calcium concentration at a critical point in the injury process. This forms the “calcium set point” hypothesis (79,82,83). Apoptosis may provide a protective mechanism, following TBI; since an inflammatory response is not initiated, surrounding cells are not damaged and therefore neuronal loss may be limited (79).

### **Mechanisms of Cell Death**

The mechanisms of cell death are complex, diverse, and interdependent, but will be considered under specific headings.

### **Excitotoxicity**

☞ **Excitotoxicity is the uncontrolled release of excitatory amino acids, causing massive sodium and calcium influx, further amino acid release, and ATP depletion culminating in cell death.** ☞ Glutamate is by far the most important and most studied excitatory amino acid. Normally, extracellular concentrations of glutamate are extremely low, subsequent upon reuptake by neurons and glia and intact cellular metabolic function that maintains a concentration gradient of glutamate between the intracellular (millimolar) and extracellular (micromolar) compartments (84).

The broad triggers of excitotoxicity include hypoxia, hypoperfusion, and TBI. Following TBI, the initial release of glutamate may occur secondary to neuronal depolarization on impact, direct membrane disruption, reverse function of glutamate pumps in neurons and glia, and the reversal of ionic gradients (85). Both CSF and extracellular levels of glutamate quickly reach toxic levels (85–87). Glutamate acts at three main sites: G-protein coupled receptors,  $\alpha$ -amino-3-hydroxy-5-methyl-4-isoxazole propionic acid (AMPA) receptors, and *N*-methyl-D-aspartate (NMDA) receptors. The G-protein, coupled receptor activation causes intracellular calcium release. The AMPA receptor activation mediates fast excitation mainly via sodium entry. The NMDA receptor activation causes calcium influx. Membrane depolarization results, allowing further calcium entry, via voltage-gated calcium channels, sodium entry and excessive activation of  $\text{Na}^+$ ,  $\text{K}^+$  ATPase causing cellular ATP depletion. Elevated intracellular calcium levels result in further glutamate release, activates calcium-dependent enzyme systems, and increase oxidative stress. A vicious spiral results in cellular swelling, cytotoxic edema, and cell death (88). Calcium accumulation lasts approximately four days postinjury, the duration showing some proportionality to injury severity (89). There is also evidence that nitric oxide mediates at least some of the neurotoxicity of glutamate (90,91).

NMDA receptor activation not only affects calcium flux, but also that of potassium. Changes in potassium flux influence metabolic pathways in favor of hyperglycolysis, resulting in lactate accumulation. This may represent an attempt to re-establish normal homeostasis and ionic gradients. Glycolysis continues for approximately one hour postinjury, after which injured brain enters a state of metabolic depression with an accompanying decrease in CBF. Excitotoxicity may therefore be seen in terms of a neurochemical and metabolic cascade (89).

### Oxidative Stress

During TBI, hypoxia, hypoperfusion and reperfusion, free radicals, and other strong oxidants are formed to which the brain is particularly vulnerable. Free radicals include superoxide, the hydroxyl radical, and the nitric oxide radical. Other strong oxidants include singlet oxygen and hydrogen peroxide. They affect the brain by causing NADH depletion, lipid peroxidation, interfering with mitochondrial ATP production, and activating neutrophil-mediated inflammation (88). The free-radical scavenging effects of mannitol may benefit patients with traumatic brain injuries; these and other effects of this antioxidant osmotic diuretic are further delineated later.

### Calcium-Sensitive Enzyme Activation

Intracellular calcium accumulation, following TBI, results in the activation of several calcium-sensitive enzyme systems: lipases, kinases, phosphatases, and proteases. Calpain (a family of calcium-activated intracellular proteases) activation appears to be a particularly important step in the pathogenesis of cellular injury. Calpains have some selectivity for the lysis of cytoskeletal proteins, calmodulin-binding protein, signal transduction enzymes, membrane proteins, and transcription factors. Unchecked pathological activation has profound effects on both neuronal structure and function (92,93).

### The Role of Mitochondria

Mitochondria are pivotal in calcium homeostasis and may be a source of reactive oxygen species. The exact mechanisms by which mitochondria participate in apoptosis and necrosis remains to be fully elucidated. Mitochondria actively accumulate calcium in response to excitotoxicity; subsequent mitochondrial swelling and lysis may be the primary cause of cell death. Inflammation and mechanical stress may also result in mitochondrial damage. Cell death proteins are released from mitochondria following TBI and induce apoptosis (94).

### Inflammation

There is increasing evidence that inflammation contributes to the pathogenesis of TBI. Following TBI, both tumor necrosis factor alpha ( $\text{TNF}\alpha$ ) and interleukin  $1\beta$  ( $\text{IL-1}\beta$ ) are expressed in the brain. Both are important in the initiation and propagation of the acute inflammatory response. The principal adhesion molecules necessary for leukocyte recruitment (ICAM 1 and VCAM) are rapidly upregulated following TBI. Neutrophils appear first, followed by macrophages. The resulting inflammatory response causes bystander cell damage and death and promotes edema formation (95).

### Gene Expression

Apolipoprotein E (APOE) is a lipoprotein produced by glial cells that may have a role in transporting lipids to injured neurons. There are three human isoforms:  $\epsilon 2$ ,  $\epsilon 3$ , and  $\epsilon 4$ . TBI may trigger  $\beta$  amyloid precursor protein ( $\beta\text{APP}$ ) deposition that forms part of the acute phase response. It appears that  $\beta\text{APP}$  deposition is more marked in those who express APOE  $\epsilon 4$ , leading to a worse outcome and an increased risk of developing Alzheimer's disease following TBI (96).

Chaperones (a group of proteins involved in the folding and intracellular transport of damaged proteins), immediate early genes (e.g., *c-fos*, *c-jun* and *jun-B*), and growth factors (e.g., nerve growth factor and insulin-like growth factor) are expressed following TBI and probably influence repair (93).

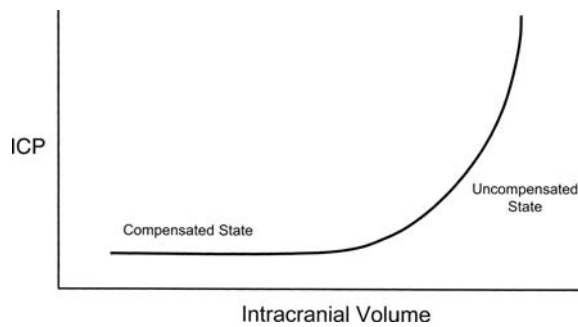

### Raised Intracranial Pressure

♣ **A sustained rise in ICP above 20 mmHg, following severe head injury, is a highly significant predictor of poor outcome (97).** ♣ Although CPP is generally held as the critical parameter, the direct effects of raised ICP remain detrimental even when CPP is maintained at normal levels. The causes of raised ICP include intracranial mass (tumor or hematoma), hydrocephalus, increased intravascular volume (arterial or venous), and cerebral edema (cytogenic or vasogenic).

Initially, as intracerebral volume rises, CSF and blood are displaced to maintain ICP at normal levels in a "compensated state." As intracranial volume rises further, an "uncompensated state" is reached where a small rise in volume causes a disproportionate rise in pressure (Fig. 11) (39). The CNS ischemic reflex and/or herniation syndromes may then occur.

The CNS ischemic reflex is an intense sympathetic discharge activated by low CPP probably secondary to increasing  $\text{CO}_2$  tension at the vasomotor center. The Cushing reflex is a special form of the former, triggered by raised ICP.

Herniation syndromes are shifts in brain tissue through rigid skull openings caused by raised ICP.

**Figure 11** Relation between intracranial pressure (ICP) and volume (elastance curve).

Other CNS components are compressed. The most common herniation syndromes are central, uncal, cingulate, upward cerebellar, and tonsillar.

*Uncal:* The medial uncus and hippocampal gyrus are forced over the edge of the tentorium, compressing the ipsilateral oculomotor nerve (unilateral dilating pupil) and brainstem (causing unconsciousness and contralateral hemiparesis). *Tonsillar:* The cerebellar tonsils descend through the foramen magnum, compressing the brainstem and causing respiratory arrest (98).

### Changes in Cerebral Circulation Following Traumatic Brain Injury

Changes in CBF, autoregulation, and vasoreactivity are critical factors in the development of secondary injury following brain trauma. Alterations occur at both macro- and microvascular level.

#### Cerebral Blood Flow

☞ **Most severely head-injured patients show a trimodal pattern of change in CBF: an initial decline, a period of relative hyperemia (high CBF relative to cerebral metabolism), flow again decreases (37).** ☞ CBF decreases early after TBI, often to extremely low levels; the degree of impairment in CBF increases with injury severity (41,99). In fact, there is postmortem evidence of cerebral ischemia in most patients who die from TBI (41). Vasospasm occurs in up to 40% of severe head injuries, causes a marked decrease in CBF, and is a predictor of poor outcome (37,100). In the region of contusions or hematomas, CBF is decreased even further than globally (101). Hyperemia can result in vasogenic cerebral edema with raised ICP; both extremely high as well as extremely low CBF results in poor prognosis (102).

#### Autoregulation and Vasoreactivity

Autoregulation is often disrupted or abolished following severe TBI not only in injured areas, but also in areas remote from the injury; changes in CPP are paralleled by changes in CBF (103,59). Therefore, at low CPP, compensatory vasodilation does not occur and ischemia may result. At high CPP, compensatory vasoconstriction does not occur and vasogenic cerebral edema and vascular injury may result. Furthermore, CBF may become uncoupled from cerebral metabolism (41). Impaired autoregulation is not only limited to severe head injury; it has been described in patients at six days, following mild head injury (104).

The cerebrovascular response to carbon dioxide is usually but not always preserved (105,106). A state of “dissociated vasoparalysis” therefore, frequently occurs.

### Mechanisms

Changes in the equilibrium of endothelin-1 (vasoconstriction) and nitric oxide (vasodilation) both acting at a microvascular level are thought to account, at least in part, for the alterations seen in CBF and autoregulation. It is probable that other vasoactive substances (acetylcholine, serotonin, vasopressin, angiotensin, and cytokines) also have a significant role (107). Vasospasm, which occurs at a macrovascular level, is probably related to the release of hemoglobin breakdown products into the CSF (41).

### Physiological Basis of Treatment Models

Increased morbidity and mortality, following TBI, are strongly related to hypotension (systolic BP <80 mmHg) and low CPP postinjury (107,108). The minimum CPP and the benefits of increasing it above this threshold remain controversial. Head injury management can be considered under three headings: traditional management, CPP management, and Lund therapy.

The traditional and well-established management of severe head injury involves avoiding hypoxia and hypotension with early ICU and neurosurgical intervention. ICP is monitored and controlled in a stepwise fashion, and secondary brain injury is limited (41).

Autoregulation may be altered but not lost, and this is the basic pathophysiological requirement in CPP management (109). The CPP management strategy, now incorporated into head injury guidelines, is based on the central theme of a “vasodilatory cascade” (110,111). A decrease in MAP or increase in ICP causes a fall in CPP, followed by cerebral vasodilation. Cerebral vasodilation causes an increase in CBV that, in the poorly compliant brain, further increases ICP and decreases CBF in a vicious circle. The aim of management is to increase MAP and break the cycle (108).

Lund therapy is a more controversial approach (108,112,113). The aim is to reduce microvascular pressure gradients and hence minimize edema formation. Colloid osmotic pressure is maintained and systemic blood pressure reduced.

### Metabolic and Neuroendocrine Complications of Traumatic Brain Injury

#### Cerebral Metabolism

Immediately following TBI, there is a short-lived but intense period of hyperglycolysis, as neurons attempt to normalize membrane gradients. This is followed by a profound state of metabolic depression (sometimes to half normal) that may be longstanding. This phase may be secondary to hypoxia, hypoperfusion, and mitochondrial dysfunction (114).

#### Basal Metabolic Rate

☞ **Following TBI, a hypermetabolic and hypercatabolic state ensues.** ☞ This persists for at least two weeks. There is a marked increase in calorific requirement (to approximately 140% baseline) and nitrogen wasting (triple normal fasting levels) (115,116). Glucose stores are rapidly depleted, and amino acids become the major substrate for gluconeogenesis. A patient can lose approximately 1 kg/day muscle mass if the situation goes unchecked, resulting in severe protein/energy malnutrition. The process is driven by massive stress hormone and cytokine release (117). Calorific requirement may be decreased to 100% expected if the patient is paralyzed and sedated. Current guidelines

recommend the provision of 140% resting metabolic expenditure in nonparalyzed and 100% resting metabolic expenditure in paralyzed patients (118). The mode of nutritional support has no effect on neurological outcome.

### **Syndrome of Inappropriate ADH Secretion**

TBI stimulates excessive anti diuretic hormone (ADH) release, which when prolonged, produces the syndrome of inappropriate ADH (SIADH) secretion. This is characterized by hyponatremia and decreased plasma osmolality with urine osmolality greater than serum osmolality. The free water retained promotes cerebral edema formation.

### **Diabetes Insipidus**

Diabetes insipidus (DI) is caused by inflammation, edema, ischemia, and infarction or direct traumatic destruction of the posterior pituitary. It is characterized by polyuria with low urinary sodium, hypernatremia, and high serum osmolality. Hypertonic coma can ensue. Although usually transient in patients who recover from their brain injury, DI may become permanent (119). Vasopressin (1–5 units/hr) or ddAVP (1–4 µg/12 hr) is usually administered to treat DI.

### **Disturbed Glucose Metabolism**

Diabetes mellitus may occur secondary to the increased secretion of insulin antagonists following trauma. Following TBI, glucose response to insulin is subnormal (113). Non-ketotic hyperglycemia may be seen. ⚡ **Serum glucose must be closely controlled towards normal following TBI, because hyperglycemia is strongly associated with worse outcome (120).** ⚡

### **Hypothalamic and Pituitary Injury**

Loss of normal thermoregulation is a sensitive marker of hypothalamic dysfunction. Severe damage to the lower pituitary stalk or anterior pituitary causes low levels of all anterior pituitary hormones. No response to their respective releasing factors is seen.

Hypothalamic injury causes dissociated adrenocorticotrophic hormone (ACTH)-cortisol levels, hypothyroidism [with preserved thyroid stimulating hormone (TSH) response to TSH-releasing hormone (RH)], low gonadotropins (with preserved response to gonadotropin-RH), variable growth hormone levels, and hyperprolactinemia. Damage to both structures causes a mixed pattern (119,121).

### **Spinal Cord Pathophysiology**

The mechanism of spinal cord injury (SCI) is usually direct compression from fracture/dislocation of the vertebral column or disc rupture. The spinal cord is extremely vulnerable to injury without the capacity to regenerate. SCI leads to well-recognized clinical patterns, defined by the loss or impairment of motor/sensory modalities below the level of the injury. Total lesions above C3 result in the total loss of ventilatory function. Lesions above T1 cause sympathetic paralysis, resulting in distributive shock; bradycardia may also result secondary to unopposed vagal tone (see Volume 1, Chapter 26 and Volume 2, Chapter 13 for additional information).

Excitotoxicity, inflammation, necrosis, and apoptosis all occur after SCI and result in axonal loss, to which the term “diffuse axonal injury” may be applied (122–125).

Corticosteroids have proved effective in improving functional outcome in patients following SCI (126–128).

## **Drugs, Anesthesia, Intensive Care, and Neuroprotection**

### **Anesthesia and Intensive Care**

#### **Basic Interventions**

Laryngoscopy, intubation, extubation, pain and awareness all increase ICP and MAP. Positive pressure ventilation, positive end expiratory pressure (PEEP), coughing and straining, head down posture, and tight endotracheal tube ties increase central venous pressure, intracerebral venous pressure, and hence ICP.

#### **Drugs**

When using any drugs in the context of TBI, it is important to consider the effect that agent has on the cerebral circulation, ICP, and cerebral metabolic rate. A summary of the most commonly used agents is presented in Table 4. Etomidate (decreases CMRO<sub>2</sub> and maintains CPP) is the induction drug of choice in patients with TBI and other possible injuries. Barbiturates, mannitol, and hypertonic saline are often employed as ongoing therapy in the ICU, and will be considered in more detail.

**Barbiturates.** Barbiturates (thiopentone, phenobarbital) are general anaesthetic induction agents and anticonvulsants. They produce marked CNS depression, acting predominantly at inhibitory gamma amino butyric acid (GABA) receptors, and a marked reduction in cerebral metabolic rate that remains coupled to CBF. Cerebral vascular resistance is increased, CBV decreased, and therefore, ICP is also decreased. In the context of TBI, cerebral extracellular concentrations of lactate, glutamate, and aspartate are reduced, which provide neuroprotective benefit (129,130).

The use of high-dose barbiturates is recommended to treat refractory elevated ICP. It is effective at lowering ICP and decreasing mortality in this setting. The use of prophylactic barbiturates is not indicated (124).

**Mannitol.** Mannitol is an osmotic diuretic widely used for ICP control following TBI (131). Mannitol has two distinct effects on the brain (rheological and osmotic) and theoretically an antioxidant effect. Concerning rheology, there is plasma expansion, reduced blood viscosity, increased CBF, and increased cerebral DO<sub>2</sub>. The osmotic effects are delayed for 15 to 30 minutes and persist for over six hours. Once osmotic gradients are established between plasma and intracellular fluid, intracellular volume reduces and ICP is also therefore reduced. Mannitol may also provide beneficial antioxidant effects due to its free-radical scavenger properties. Mannitol may theoretically accumulate in areas of the brain where the blood–brain barrier is disrupted, causing a reverse shift of fluid and elevation in ICP. It may also cause renal failure when serum osmolality is allowed to exceed 330 mosm/L. Mannitol is recommended in most neurosurgical guidelines for the control of ICP following TBI (132). Uncertainty exists over the optimal treatment regimen, and its usefulness if given at other stages of TBI management (e.g., prehospital) (133).

**Hypertonic Saline.** If hypertonic saline is used for volume replacement following TBI, smaller volumes are required to maintain cardiovascular stability when compared to standard crystalloid solutions. There is decreased ICP and improved CBF and DO<sub>2</sub>. Cortical water in uninjured brain is decreased, improving intracranial compliance (134). Hypertonic saline also has vasoregulatory, neurochemical (extracellular glutamate concentration may be reduced)

**Table 4** Cerebral Circulatory Effects of Sedatives, Analgesics, and Other Agents

and immunomodulatory properties. It is better excluded via the blood–brain barrier than mannitol and does not possess osmotic diuretic properties. Accordingly, volume depletion and hypotension, rebound effects seen with mannitol, are avoided. The main concerns are osmotic demyelination syndrome (especially in previously hyponatremic patients), renal insufficiency, hemorrhage, coagulopathy, and red cell lysis (135). Meta-analysis of TBI patients treated with hypertonic saline-dextran has shown a marked survival benefit (136). Randomized controlled trials investigating the role of hypertonic saline in fluid resuscitation, following TBI, are currently underway (137).

### **Hyperventilation**

The potential benefits of hyperventilation are cerebral vasoconstriction for ICP control. However, CSF pH changes are short-lived, as bicarbonate is removed from

the CSF to re-establish equilibrium (138). A further disadvantage is vasoconstriction that may reduce CBF to ischemic thresholds (139). The use of prophylactic hyperventilation (PaCO<sub>2</sub> ≤ 35 mmHg) should be avoided during the first 24 hours, following severe TBI (140). Hyperventilation is used only for the treatment of elevated ICP as an acute temporising measure (141). Randomized controlled trials to assess target PaCO<sub>2</sub>, timing and duration of hyperventilation are warranted (142).

### **Neuroprotection**

Neuroprotection encompasses pharmacological and other interventional strategies that limit/prevent neuronal damage, reduce secondary injury processes, or promote regeneration, following TBI. The interval between the time of injury and the development of the complete pathological process represents a window of opportunity for such

strategies to be employed. Understanding the pathological mechanisms of cell death and damage allows for the application of neuroprotective therapies, which target specific points in the injury cascade.

#### *Targeting Excitotoxicity*

Many strategies have focused on limiting glutamate excitotoxicity. This may be achieved by decreasing glutamate release, preventing neurotransmission, or promoting the effects of inhibitory neurotransmitters (143).

Agents that block sodium or calcium channels reduce glutamate release. Riluzole, lubelazole, phenytoin, and fosphenytoin are among those agents studied (143,144).

The NMDA receptor antagonists (e.g., ketamine, phencyclidine, dizolcipine, and dextromethorphan) have shown promise in laboratory work (145). Magnesium causes voltage-dependent NMDA receptor blockade and may prove beneficial (143).

GABA is the main inhibitory neurotransmitter in the CNS that offers balance against the excitatory glutamate system. GABA agonists (vigabatrin, diazepam) are beneficial during experimental ischemia (146).

#### *Targeting Calcium and Mitochondria*

Calcium plays a key role in the evolution of TBI. Calcium channel blockers have been used in an attempt to prevent cerebral vasospasm after injury, and hence maintain CBF. The evidence for their use is unconvincing and side effects may outweigh benefits. A subgroup of patients with traumatic subarachnoid hemorrhage may benefit (147). Mitochondria have significant calcium-buffering capacity in the noninjured system. This capacity is lost early in the injury cascade. Cyclosporin A may delay or prevent mitochondrial dysfunction and attenuate the intracellular calcium rise (148). Calcium-sensitive proteases are another potential target. Blockade of the caspase pathway may, in particular, be useful in limiting apoptotic cell death (143).

#### *Targeting Inflammation*

Inflammation is a complex process involving the interaction of multiple molecular systems and causes widespread damage within the CNS following injury. Corticosteroids, aminosteroids, and free-radical scavengers have been investigated for their potential neuroprotective effects.

Corticosteroids act as both immunosuppressant and free-radical scavenger (143). Despite a quarter of a century of intense investigation, a beneficial role for corticosteroids in improving outcome following TBI has not been established. Their use is not currently recommended for this purpose (149,150).

Aminosteroids (e.g., tirilazad mesylate) have been shown to limit lipid peroxidation in laboratory animals. Currently there is no evidence to support their routine use following TBI (151).

Other potential therapies aimed at reducing free-radical formation and lipid peroxidation include superoxide dismutase, catalase, and vitamin E (143).

#### *Sex Hormones*

There is some evidence that sex hormones in males (progesterone and estrogen) reduce excitotoxicity, are antioxidant, reduce inflammation, provide neurotrophic support, and enhance neuronal regeneration, following TBI (152). Estradiol exerts a profound protective effect against ischemia if treatment precedes insult; it may act in part via genomic mechanisms (13).

#### *Other Potential Agents*

Preliminary findings indicate that activation of adenosine A1 receptors ameliorates trauma-induced central neuronal death. Adenosine may play a role in several steps of the injury cascade (154). Nitric oxide affects both excitotoxicity and microvascular tone, following TBI. Nitric oxide synthase inhibitors represent a potential strategy (143).

#### *Hypothermia*

With decreasing temperature, cerebral metabolic rate, CBF, and ICP decrease. In the context of TBI, there is decreased glutamate release, decreased free-radical production, and there maybe improved neuronal tolerance to insults (155). Despite encouraging results from small trials, there is no evidence that hypothermia is beneficial and the risk of pneumonia is increased. The use of this treatment modality is not recommended outside of controlled trials (156).

#### *Shortfalls in Neuroprotection*

Despite enormous experimental promise, the results of clinical studies have been disappointing. TBI is a complex disorder within a heterogeneous group of patients. Problems may arise with the timing of therapy, and animal models may not represent a true reflection of the pathophysiological processes involved in human TBI. The idea that a single agent will offer significant improvement may be over simplistic. For such a complex process, multimodal treatment may be required.

## EYE TO THE FUTURE

Although the basic principles of neurophysiology and neuropathophysiology have been unraveled, our understanding of cerebral function and the response to injury remain limited. The effects of hypoxia and hypotension on morbidity and mortality are clear, and the importance of early optimization of  $\dot{V}O_2$  and CPP in head injury is well established. Some areas of controversy still exist (157). Mannitol is recommended for the control of ICP, but uncertainty exists regarding the optimal treatment regime and its usefulness at other stages of TBI management. Hyperventilation is used as a short-term treatment for acutely raised ICP. Randomized controlled trials to assess target PaCO<sub>2</sub>, timing and duration of hyperventilation are warranted. Hypertonic treatment improves CBF and reduces infarct size, following rat cortical vein occlusion (158). The use of hypertonic saline for fluid resuscitation in TBI patients has shown significant promise; controlled trials are currently underway.

**☞ Secondary brain injury occurs almost without exception in patients with severe head injury. ☞** The goal of ameliorating secondary injury must begin with a deeper understanding of the molecular pathways of the pathophysiological process. The future of neurophysiology lies at a molecular level. As this chapter has made clear, there are large numbers of molecules involved in normal and pathological responses whose exact role remains to be elucidated. The response to injury is a complex integrated cascade, the modification of which is likely to involve an understanding of all processes rather than the action of individual molecules.

Many agents which target excitotoxicity, including riluzole, lubelazole, phenytoin, ketamine, phencyclidine, magnesium, and GABA agonists, have shown promise in laboratory and/or animal work. Cyclosporin A may delay or prevent mitochondrial dysfunction. New pharmacological

agents with neuroprotective effects continue to be discovered (159,160); further research is required. Despite intense research over nearly 25 years, corticosteroids have not found a role in TBI management. However, aminosteroids, superoxide dismutase, catalase, and vitamin E may prove to be useful in the limitation of free-radical formation and lipid peroxidation. Indeed, the immune system plays a vital role in both injury and recovery, and posttraumatic vaccination to boost repair mechanisms may be an option for the future (161).

With the sequencing of the human genome, it is also likely that genetic influences will be shown to have a strong bearing on the outcome from head injury, and with this may come the ability to alter the genetic response to neuropathophysiology (162).

The development of cell replacement therapies (cell lines transplanted into injured CNS in order to provide repair) may represent a further opportunity for late intervention, following TBI (163).

However, prevention is better than cure, and changes in society infrastructure to reduce death and injury from head trauma will remain the biggest single factor in reducing the burden of head injury on society.

## SUMMARY

The nervous system may be divided anatomically into the CNS, the PNS, and the ANS. The CNS is further divided into brain, brainstem, and spinal cord. The CSF system provides a buffer against movement for the CNS, and the blood-brain barrier provides for some separation of the CNS from the systemic environment. The brain is contained within a noncompliant bony vault: the skull.

Normal physiology is a complex, tightly regulated process, based on the generation of action potentials. The action potential involves depolarization, repolarization, and propagation to create a wave of depolarization. Pathological processes that alter the resting potential of the cell membrane can have profound effects on the generation of action potentials. Alterations in cellular metabolism also affect neurophysiological processes. The brain is one of the most metabolically active organs in the body. It has a mass of 1500 g (2% body weight), receives 15% Q and uses 20% and 25% total body oxygen and glucose consumption, respectively. The extraction ratio for oxygen is approximately 50% and that of glucose approximately 10%. Delivery of oxygen and metabolites to the brain tissue is dependent upon adequate CBF, which in turn is related to CPP. Autoregulation through myogenic responses, oxygen tension, carbon dioxide tension, and neurogenic control regulates CBF. Pathological processes resulting in increased intracranial volume increase ICP, reducing CPP and  $\dot{V}O_2$ . Hypotension also reduces CPP and below a MAP of 50 mmHg, autoregulation fails.

Both primary (initial insult) or secondary (due to ischemia), and focal or diffuse damage occurs, following TBI. Injury is often a combination of primary damage to neurons and supporting glia, with hemorrhagic injury. Cell death is conventionally divided into two main types: necrosis and apoptosis, which differ both morphologically and biochemically. Hybrid forms of cell death with features of both are also seen. Mechanisms of cell death are complex and diverse. However, nearly all modes of cell death result in the final common pathway of calcium influx across a

damaged cell membrane, resulting in the disruption of mitochondrial and cellular homeostasis. Release of excitatory amino acids, oxidative stress, and calcium-sensitive enzyme activation are all mechanisms resulting in cell death. TBI causes variations in gene expression that have a bearing on pathogenesis, repair, and ultimately recovery. Apolipoprotein, chaperone, and growth factor expression have been identified as important genes in inflammation and repair from neurotrauma.

Changes in blood flow are an important mechanism in the pathophysiology of TBI. Most severely head-injured patients show a trimodal pattern of change in CBF: an initial decline, a period of relative hyperemia, and finally a decrease in flow. This latter decrease is often to extremely low levels, the degree of impairment in CBF increasing with injury severity. In the region of contusions or hematomas, CBF is decreased even further than globally. Current recommendations for the management of cerebral hemodynamics are based on maintaining adequate CPP, which results in maintenance of CBF irrespective of ICP.

TBI also disrupts metabolic and neuroendocrine pathways. Immediately following TBI, there is a short-lived, but intense, period of hyperglycolysis, as neurons attempt to normalize membrane gradients. This is followed by a profound state of metabolic depression that may be longstanding. Eventually, a hypermetabolic and hypercatabolic state ensues. Glucose stores are rapidly depleted, and amino acids become the major substrate for gluconeogenesis. A patient can lose approximately 1 kg/day muscle mass if the situation goes unchecked, resulting in severe protein/energy malnutrition. Current guidelines recommend the provision of 140% resting metabolic expenditure in nonparalyzed and 100% resting metabolic expenditure in paralyzed patients. A SIADH secretion is common, due to excessive ADH release. The free water retained promotes cerebral edema formation. Glucose metabolism may also be disturbed, with diabetes mellitus occurring secondary to the increased secretion of insulin antagonists, following trauma. Hyperglycemia is associated with a worse outcome following head injury.

The mechanism of SCI is usually direct compression from fracture/dislocation of the vertebral column or disc rupture. The spinal cord is extremely vulnerable to injury without the capacity to regenerate. SCI leads to well-recognized clinical patterns, defined by the loss or impairment of motor/sensory modalities below the level of the injury. Corticosteroids have proved effective in improving functional outcome in patients, following SCI.

## KEY POINTS

- ☞ The blood supply of the brain derives from the Circle of Willis.
- ☞ Although influenced by higher brain centers, such as the limbic cortex, the autonomic nervous system operates to control the homeostatic environment in a purely reflex fashion.
- ☞ Almost all right-handed people and 70% of left-handed individuals have speech and language centers located in the left cerebral hemisphere.
- ☞ The brain is one of the most metabolically active organs in the body and requires a constant supply of  $O_2$  and glucose.

- 9 For ICP to remain constant (normal = 1–15 mmHg), the sum of the volumes of the intracerebral components must remain constant.
- 9 A normal value for CPP is approximately 70 mmHg.
- 9 Within the range PaCO<sub>2</sub> 25–60 mmHg, vasodilation and hence cerebral blood flow increases linearly with PaCO<sub>2</sub> (13).
- 9 The cerebral metabolic rate is markedly increased during seizure activity.
- 9 Hemorrhage usually presents as a space-occupying lesion, with increased ICP, and when severe, as brain or brainstem herniation.
- 9 Neuronal apoptosis and necrosis may be occurring simultaneously in the injured brain.
- 9 Excitotoxicity is the uncontrolled release of excitatory amino acids, causing massive sodium and calcium influx, further amino acid release, and ATP depletion culminating in cell death.
- 9 A sustained rise in ICP above 20 mmHg, following severe head injury, is a highly significant predictor of poor outcome.
- 9 Most severely head-injured patients show a trimodal pattern of change in CBF: an initial decline, a period of relative hyperemia (high CBF relative to cerebral metabolism), flow again decreases.
- 9 Following TBI, a hypermetabolic and hypercatabolic state ensues.
- 9 Serum glucose must be closely controlled following TBI, because hyperglycemia is strongly associated with worse outcome.
- 9 Secondary brain injury occurs almost without exception in patients with severe head injury.

## Pulmonary Physiology Review

Shamsuddin Akhtar

Department of Anesthesiology, Yale University School of Medicine, New Haven, Connecticut, U.S.A.

### INTRODUCTION

Atmospheric air is a mixture of oxygen (O<sub>2</sub>, 20.95%), nitrogen (N<sub>2</sub>, 78.09%), argon (0.93%), carbon dioxide (CO<sub>2</sub>, 0.03%), and water vapor (0–2%). For practical purposes we usually assume O<sub>2</sub>, 21% and N<sub>2</sub>, 79% and ignore the contributions from CO<sub>2</sub> and argon. The degree of humidification determines the water vapor pressure and proportional dilution of other gases.

In order for the cells to utilize the O<sub>2</sub> in the atmosphere, it has to be transported efficiently to the tissues and cells (Fig. 1) (1). The first step is inspiration and ventilation, the transfer of atmospheric air (or gases) to the alveoli, where it is brought in close proximity to the blood to allow efficient gas exchange, with the subsequent movement of alveolar air back to the outside. Ventilation is closely coupled with adequate perfusion of the alveoli. The interaction of ventilation and perfusion [ventilation-perfusion ( $\dot{V}/\dot{Q}$ ) relationship] ultimately determines the gas exchange in the lungs. The transport of O<sub>2</sub> requires reversible binding of O<sub>2</sub> to hemoglobin (Hb), which is then unloaded at the tissues. The O<sub>2</sub> flows through its concentration gradient to the extracellular space and cells. Intracellular concentrations of O<sub>2</sub> also varies within the cell, and the mitochondrial pO<sub>2</sub> is 1–0.6 mmHg. The process of ventilation is tightly regulated by neural and nonneural mechanisms. Furthermore, interaction of the circulatory system with the respiratory system adds another level of fine-tuning and complexity to the process of perfusion, ventilation, and ventilation-perfusion interaction. Pulmonary function does not remain static throughout life. Significant differences in respiratory physiology are evident in neonates and the elderly. There are alterations in pulmonary physiology during pregnancy as well. Lungs also have very important nonpulmonary metabolic and humoral functions.

### MECHANICS OF RESPIRATION

#### Lung Volumes and Capacities

The diaphragm is the most important muscle used for breathing. Contraction of the diaphragm forces the abdominal contents downward and forward, which increases the vertical diameter of the chest cavity. In addition the intercostal muscles lift the rib margins outward and upward, increasing the transverse diameter of the thorax. During normal tidal breathing, the diaphragm moves about 1 cm, while under forced inhalation and exhalation it can move up to 10 cm (2). The contraction of the internal intercostal muscles also increases the lateral and anteroposterior diameters of the thorax because of the “buckle-handle” movement of the ribs. Exhalation is passive during quiet breathing. However,

during active expiration (e.g., exercise, voluntary hyperventilation), abdominal muscles play the most active role. The internal intercostal muscles also assist by pulling the ribs down and inward (“reverse buckle-handle”).

Normal breathing volume (tidal volume, V<sub>T</sub>) is about 7 mL/kg. Vital capacity (VC) is the maximum volume of gas exhaled after maximal inspiration. In health, the VC is about 70 mL/kg. Residual volume (RV) is the gas that remains in the lung even after maximal exhalation. However, the amount of gas that remains in the lung at end exhalation during normal tidal breathing (or apnea) is referred to as the functional residual capacity (FRC) and is the combination of RV and expiratory reserve volume (ERV) (Fig. 2). ⚡ **The FRC has important clinical significance as it is the major reservoir of oxygen in the body and is directly related to the time till desaturation following apnea. In addition, the FRC is inversely proportional to the degree of shunt (see below).** ⚡ The FRC changes significantly with posture (1). In the standing healthy individual the FRC is about half the VC (or about 35 cc/kg). FRC and RV cannot be measured by simple spirometry. They can be measured using any of the three techniques: (i) N<sub>2</sub> washout technique; (ii) gas dilution technique using helium or; (iii) body plethysmography (1).

#### Minute Ventilation (Alveolar Ventilation and Dead Space)

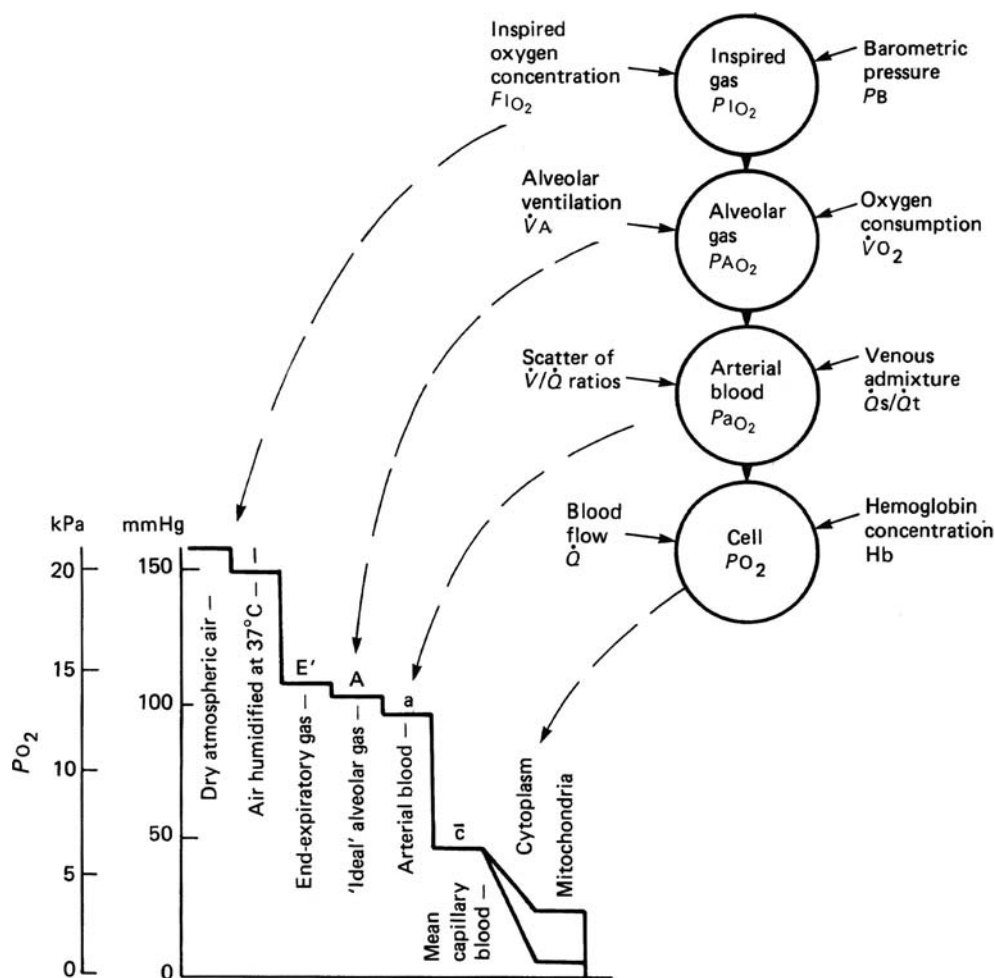

The exhaled total ventilation or minute volume (V<sub>E</sub>) is equal to volume of gas exhaled per minute. Thus total ventilation is equal to V<sub>T</sub> × number of breaths (f) in a minute.

$$\dot{V}_E = V_T \times f \quad (1)$$

Not all the gas that is inhaled (or exhaled) participates in alveolar gas exchange. However, they do participate in warming and humidification of air, or exchange of highly soluble gases (e.g., ethyl alcohol). There is a fraction of the gas that traverses the nose, pharynx, larynx, trachea, bronchi, and bronchioles and does not participate in gas exchange of O<sub>2</sub> and CO<sub>2</sub>; this is termed the anatomic dead space. Furthermore, a certain proportion of alveoli are not adequately perfused, although they may be adequately ventilated; this is termed the alveolar dead space. ⚡ **Alveolar ventilation (V<sub>A</sub>) is referred to as the gas that participates in gas exchange; the amount of ventilation that is wasted is referred to as physiologic dead space ventilation (V<sub>D</sub>).** ⚡

$$\dot{V}_E = \dot{V}_A + \dot{V}_{D_{\text{physiol}}} \quad (2)$$

The volume per minute of alveolar ventilation is critical, because it determines the amount of air presented to

**Figure 1** Left: The oxygen cascade with  $PO_2$  falling from the level in the ambient air down to the level in mitochondria. Right: A summary of the factors influencing oxygenation at different levels in the cascade. Source: From Ref. 1.

alveoli into which  $CO_2$  can be added and from which  $O_2$  can be removed.

Dead space can be measured by nitrogen washout technique (Fowler’s method) (3). Since this method measures the volume of conducting airways down to the midpoint of the transition from dead space to alveolar gas it is called anatomic dead space ( $\dot{V}_{D_{anat}}$ ). It is dependent on

the geometry of the rapidly expanding airways and reflects morphology of the lung. The other method of calculating dead space is by using Bohr’s equation, which is based on the assumption that all  $CO_2$  comes from the alveolar gas, and none from the dead space.

$$\dot{V}_D/\dot{V}_E = P_A CO_2 - P_E CO_2/P_A CO_2 \quad (3)$$

Bohr’s method measures the volume of the lung that does not eliminate  $CO_2$  and is more of a functional measurement. It is referred to as physiologic dead space ( $\dot{V}_{D_{physiol}}$ ). Physiologic dead space ventilation consists of wasted ventilation in conducting airways (anatomic dead space ventilation,  $\dot{V}_{D_{anat}}$ ) and wasted ventilation of nonperfused alveoli (alveolar dead space ventilation,  $\dot{V}_{D_{alv}}$ ) as shown in Equation 4.

$$\dot{V}_{D_{physiol}} = \dot{V}_{D_{anat}} + \dot{V}_{D_{alv}} \quad (4)$$

$$\dot{V}_A = \dot{V}_E - (\dot{V}_{D_{physiol}}) \quad (5)$$

$$\dot{V}_A = \dot{V}_E - (\dot{V}_{D_{anat}} + \dot{V}_{D_{alv}}) \quad (6)$$

**Figure 2** Lung volumes. Note that residual volume (and thus total lung capacity and functional residual capacity) cannot be measured with the spirometer. Source: From Ref. 2.

In normal subjects, the alveolar dead space ventilation is small and volume of anatomic dead space and physiologic dead space are nearly the same. The  $\dot{V}_{D_{physiol}}$  is frequently

expressed as a fraction of the tidal volume (e.g.,  $V_D/V_T$ ). The normal  $V_D/V_T$  (dead space to tidal volume ratio) is 0.2 to 0.35 (2). In patients with lung disease, physiologic dead space may be considerably larger due to increased alveolar dead space ventilation. In normal patients,  $V_{D_{alv}}$  can be increased during mechanical ventilation when excessive tidal volumes or positive end-expiratory pressure (PEEP) is applied, as well as by conditions that decrease the cardiac output ( $\dot{Q}$ ) during normal tidal breathing.

### Lung Compliance

The lung can be regarded as an elastic chamber, which is connected to the atmosphere by a tube. Thus, the amount of ventilation depends on the compliance of the chamber and resistance of the tube. The elasticity of the lung originates from the basic component of the lung "skeleton," which is a continuous network of elastin fibers. The collagen fiber network also contributes to this elasticity. Change in the ratio of collagen with elastin contributes to decreased compliance with aging (4).

Lung compliance, which is a measure of its distensibility, is defined as the change in lung volume per unit change in transmural pressure gradient (i.e., between the alveolus and pleural space),  $\Delta V/\Delta P = \text{compliance}$ . Normal compliance is 100 mL/cm/H<sub>2</sub>O. Stiff lungs have low compliance. Under experimental conditions one can evaluate lung compliance without the effect of the chest wall by developing pressure-volume (P-V) curve at inflation and deflation (Fig. 3). As is evident from the Figure 3, the inflation and deflation curves are not identical and the difference is described as hysteresis. Furthermore, even at zero pressure around the lung, a certain volume of air is held in the alveoli due to closure of small airways. The volume of gas required to be in the lung to keep the small conducting airways open is referred to as the "closing volume." It is difficult to measure compliance in spontaneously breathing patients. However, in mechanically ventilated patients, lung compliance can be readily measured. Furthermore, compliance can be used clinically to monitor respiratory function and severity of disease.

There are many factors that affect lung compliance. Foremost, lung compliance is related to lung volume. At high or low lung volumes the lung compliance is low (Fig. 3). Compliance is greatest at mid lung volume (i.e., FRC). If the alveoli collapse in the lower zones, the compliance at low lung volumes is particularly poor. This partly explains the utility of PEEP. It improves ventilation by pushing the system to a favorable part of the P-V curve, thus decreasing  $\dot{V}/\dot{Q}$  mismatch during pathological states. Posture changes lung volume, and hence, alters lung compliance. Pulmonary blood vessels also contribute to the stiffness of the lung. Increased pulmonary venous congestion, as in congestive heart failure, decreases lung compliance. Hypoventilation without periodic deep breaths leads to atelectasis, and may also lead to decreased compliance. Emphysema increases pulmonary compliance. However, in most other pulmonary pathologies (pulmonary fibrosis, acute lung injury, consolidation, collapse, vascular engorgement, fibrous pleurisy) pulmonary compliance is decreased.

The total compliance of the lung and the chest wall is determined by the P-V curve in vivo (Fig. 4). The chest wall has a tendency to expand, while the lungs, due to their elastic recoil, tend to collapse. This creates a negative intrapleural pressure. The balance where tendency to collapse matches the tendency to expand is the FRC of the

**Figure 3** Compliance (volume/pressure) curves of lungs filled with saline and with air (*upper panel*). The vertical axis units are mL of volume; the horizontal axis units are cm H<sub>2</sub>O pressure. The amount of force required to expand the tissue, surface forces, and hysteresis are shown in the *bottom panel*. *Source:* Modified from Ref. 2.

lung. Mathematically, the total compliance is not strictly additive. Rather, they are related by the following formula:

$$1/C_T = 1/C_L + 1/C_{CW} \quad (7)$$

where  $C_T$  is the total compliance of the lung and chest wall;  $C_L$  is the compliance of the lung;  $C_{CW}$  is compliance of the chest wall. ⚡ **The formula for compliance is analogous to the mathematical formula used to calculate capacitance in electronics.** ⚡

Resistance from the surface forces at the alveolar gas/liquid interface also impact on the elastic property of the lung. Other factors that can impede ventilation are collectively described as nonelastic resistance. They are: (i) frictional resistance to gas flow through the airways; (ii) frictional resistance from deformation of thoracic tissues (visco-elastic tissue resistance); and (iii) inertia associated with movement of gas and tissues. Work done in overcoming nonelastic resistance is usually wasted as heat, while the work done in overcoming the elastic resistance is stored as potential energy and utilized in recoil of the chamber.

Another important component affecting elasticity of the lungs is surfactant. The phospholipids component

**Figure 4** Relaxation pressure-volume curve of the lung and chest wall. The subject inspires (or expires) to a certain volume for the spirometer, the tap is closed, and the subject then relaxes his respiratory muscles. The curve for lung + chest wall can be explained by the addition of the individual lung and chest wall curves. *Source:* From Ref. 2.

(90%) of the surfactant favorably alters the surface tension at the alveolar gas interface, while the protein component (10%) provides stability to the molecule and is responsible for its immunological properties (5,6). If not for the surfactant, surface tension would make the small alveoli empty into a large alveolus. In the presence of surfactant, surface tension in the smaller alveoli decreases, as the molecules of surfactant are pushed closer, which helps to maintain their patency. Lack of surfactant is the major cause of respiratory distress syndrome in premature infants.

**Airway Resistance**

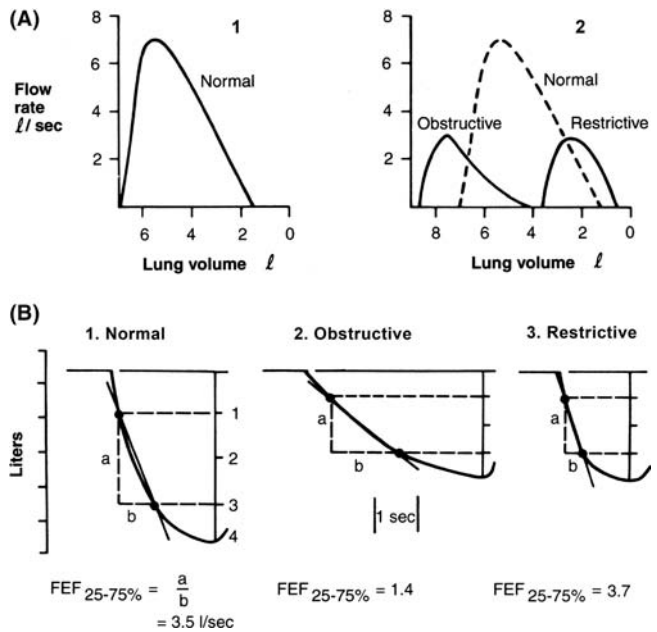

The second factor that significantly affects the ventilation (flow of gases) is the size of the airways. Airway resistance is the pressure difference between the alveoli and mouth, divided by a flow rate. Flow of gases in the airways is a mixture of turbulent and laminar flow. Flow is mostly turbulent in large airways and becomes near laminar in smaller airways (7). Flow of gas in the lungs can be demonstrated by developing flow-volume loops. Over most of the lung volume, flow rate is independent of effort and is due to dynamic compression of the airways by intrathoracic pressure. Maximal flow decreases with lung volume (Fig. 5), as the difference between alveolar and intrapleural pressure (driving pressure) decreases, the airways become narrower. Driving pressure is also reduced if compliance is increased. One common pulmonary function test is the measurement of forced expiratory volume in one second (FEV<sub>1</sub>). The other is forced expiratory flow between 25% and 75% of the volume (FEF<sub>25-75%</sub>). The FEV<sub>1</sub> is normally 80% of forced vital capacity (FVC). The ratio of FEV<sub>1</sub>/FVC is decreased with increase in airway resistance or a reduction in elastic recoil of the lung as seen in emphysema. In restrictive lung disease, the FEV<sub>1</sub>/FVC ratio is not altered, however, the flow-volume curve is significantly changed (Fig. 6) (8).

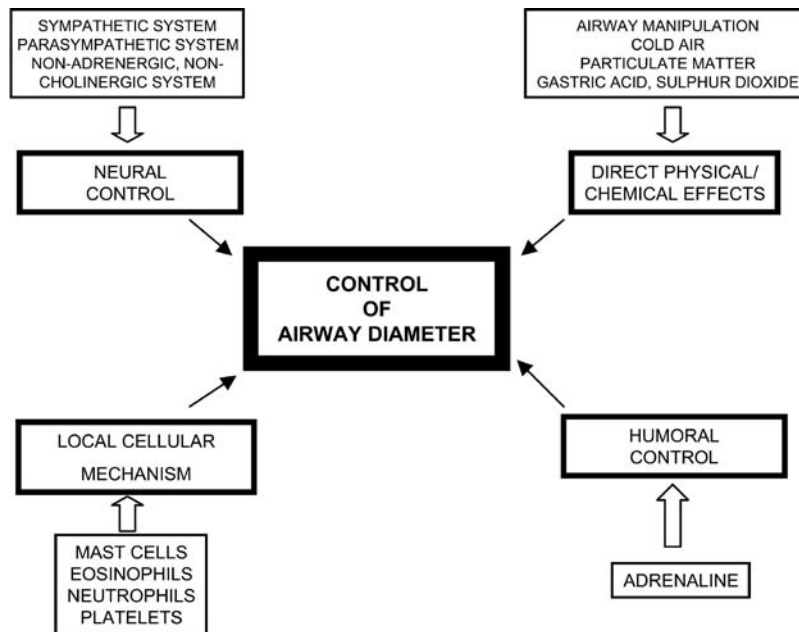

**Figure 5** Flow-volume curves. (A) Maximal inspiration was followed by a forced expiration. (B) Expiration was initially slow and then forced. (C) Expiratory effort was submaximal. In all three, the descending portions of the curves are almost superimposed. *Source:* From Ref. 2.

Based on Poiseuille's equation (resistance  $\propto 1/\text{radius}^4$ ), decreasing the radius by half would increase the resistance by 16-fold. This would lead one to believe that the major part of the airway resistance lies in the very narrow airways. However, this has been disproven by direct measurements (9). Major resistance lies in the medium-sized, seventh generation airways, while only 20% is attributable to airways less than 2 mm in diameter (about eight generation) (2).

Factors that affect airway resistance include lung volume, bronchial smooth muscle tone, carbon dioxide, and the density/viscosity of the inhaled gas. Airways are imbedded in the lung tissue and are held open by traction. Thus, low lung volume decreases the diameter of the

**Figure 6** (A) Calculation of forced expiratory flow (FEF<sub>25-75%</sub>) from a forced expiration. (B) Expiratory flow-volume curves: (1) normal, (2) obstructive, and (3) restrictive patterns. *Source:* From Ref. 8.

**Figure 7** Factors that control bronchial smooth muscle contraction and airway diameter.

airways and increases airway resistance. Bronchial smooth muscle contraction controls the diameter of the airway and itself is controlled by many factors (Fig. 7). Sympathetic stimulation via  $\beta_2$ -adrenergic receptor activation relaxes airway smooth muscle, while parasympathetic stimulation and acetylcholine increase bronchoconstriction. There are also many other mediators that impact on airway smooth muscle contraction. A fall in the  $\text{CO}_2$  of alveolar gas also causes contraction of airway smooth muscle. The exact mechanism is not known. The density and viscosity of inspired gases offers resistance to flow. This is the rationale for using HELIOX (mixture of helium and  $\text{O}_2$ ) in deep dives and acute bronchoconstriction, as it offers less resistance than  $\text{O}_2$  or air, due to decreased density.

**Figure 8** Pressure-volume curve of the lung showing the inspiratory work done overcoming elastic forces (area OACD0) and viscous forces (hatched area ABCEA). Source: From Ref. 2.

### Work of Breathing

Work done in moving the lung and chest wall can be represented as pressure ( $P$ )  $\times$  volume ( $V$ ). This is represented on P-V curve (Fig. 8). The total area represents the total work done in each respiratory cycle. It includes work done to overcome airway, tissue, surface, and elastic resistances. In physical terms the efficiency of the system is believed to be 5% to 10% and significant amount of work is dissipated as heat (2).

The higher the rate of breathing, airway resistance or the inspiratory flow rate, the greater the viscous work of breathing, while with larger tidal volume and slower respiratory rate there is increased elastic work of breathing. Abnormal breathing patterns also increase the percentage of  $\dot{V}\text{O}_2$  that is spent on the work of breathing. For example, the  $\dot{V}\text{O}_2$  for quiet breathing is about 5% of the total resting  $\text{O}_2$  utilization, which can increase to 30% with hyperventilation.

### PULMONARY CIRCULATION

**Blood flow has to be closely coupled to adequate ventilation to allow for optimal exchange of  $\text{O}_2$  and  $\text{CO}_2$ .** The amount of blood flow through the pulmonary circulation is the same as through the systemic circulation. However, pulmonary pressures and pulmonary vascular resistance (PVR) are significantly lower. Mean pressure in the pulmonary artery is 15 mmHg, which is six times less than in the aorta (100 mmHg). Pulmonary vascular resistance is about eight times less ( $100 \text{ dynes/sec/cm}^5$ ) than the systemic circulation.

### Factors Affecting Regional Pulmonary Blood Flow

Normal pulmonary circulation is also able to accommodate significant changes in cardiac output ( $Q$ ) (e.g., from 6 to 25 L with exercise) without significant changes in PVR. The exact pressure in pulmonary capillaries is uncertain, and is thought to be somewhere between pulmonary artery and venous pressure. It also varies throughout the lung due to hydrostatic effects of gravity. Furthermore, as

**Figure 9** Zones of West, an explanation of the uneven distribution of ventilation and blood flow in the lung, based on the pressures within the alveolus ( $P_A$ ), the pulmonary artery ( $P_a$ ), and the pulmonary veins ( $P_v$ ). *Source:* From Ref. 2.

pulmonary capillaries are embedded in the lung parenchyma and have minimal independent structural support. Their caliber is significantly affected by arterial, alveolar, and venous pressure. Collectively, these four variables (arterial, alveolar, venous pressure, and gravity) determine the blood flow in any particular region of the lung.

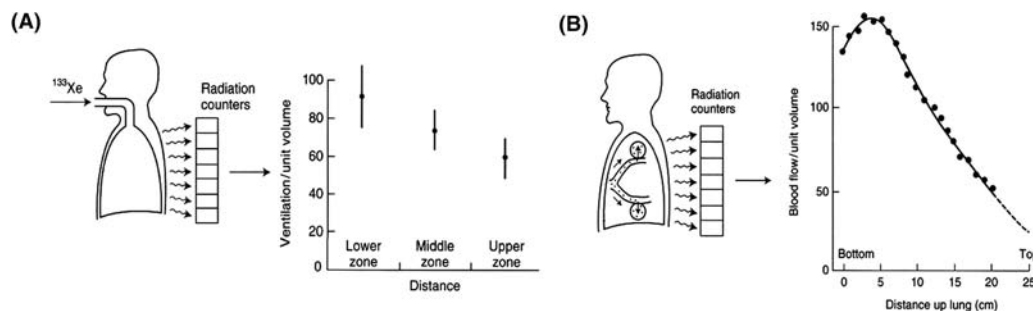

### Zones of West

Classically, lung can be divided into three zones based on the abovementioned pressures and the effect of gravity (Fig. 9) (10).

**Zone 1:** It is the upper third of the lung, where alveolar pressure ( $P_A$ ) exceeds arterial pressure ( $P_a$ ), and pulmonary venous pressure ( $P_v$ ). Both ventilation (Fig. 10A) and blood flow (Fig. 10B) are decreased. However, ventilation is slightly greater than flow, thus Zone 1 has relatively high  $\dot{V}/\dot{Q}$ .

**Zone 2:** It is the middle third of the lung, where  $P_a$  exceeds  $P_A$ . However,  $P_v$  is still lower than  $P_A$ , resulting in some impediment to blood flow.

**Zone 3:** It is the lower third of the lung, where  $P_a$  and  $P_v$  exceed  $P_A$ , allowing capillaries to be patent and permitting best perfusion of the three zones. In normal circumstances, as discussed earlier, the lower portion is also the best ventilated. This allows for appropriate perfusion and ventilation matching and efficient gas exchange (Fig. 10).

**Figure 10** Distribution of ventilation and perfusion and gas exchange down the upright lung. (A) Measurement of regional differences in ventilation with radioactive xenon. (Note that the ventilation decreases from the lower to upper regions of the upright lung.) (B) Measurement of the distribution of blood flow in the upright human using radioactive xenon. (Note the small flow at the apex.)

However, there is slightly less ventilation than perfusion (i.e., a zone of low  $\dot{V}/\dot{Q}$ ). The absolute position of the zones changes with posture; for example, Zone 3 becomes the most dependent zone in the supine patient.

### Factors Affecting Pulmonary Vascular Resistance

Based on simplification of pulmonary blood flow, pulmonary vascular resistance (PVR) can be calculated using Ohm's law ( $E = IR$ ). Thus, PVR equals driving pressure divided by  $\dot{Q}$ . Many factors affect PVR. These include  $\dot{Q}$ , perfusion pressure and lung volume. There are also other factors that control PVR by active constriction and relaxation of the smooth muscle. There is some evidence to suggest that pulmonary vasculature is modulated by pulmonary endothelium and is normally kept in state of vasodilation by nitric oxide (11). PVR is also modulated by hypoxia, metabolic and neuro-humoral factors (1).

### Cardiac Output/Perfusion Pressure

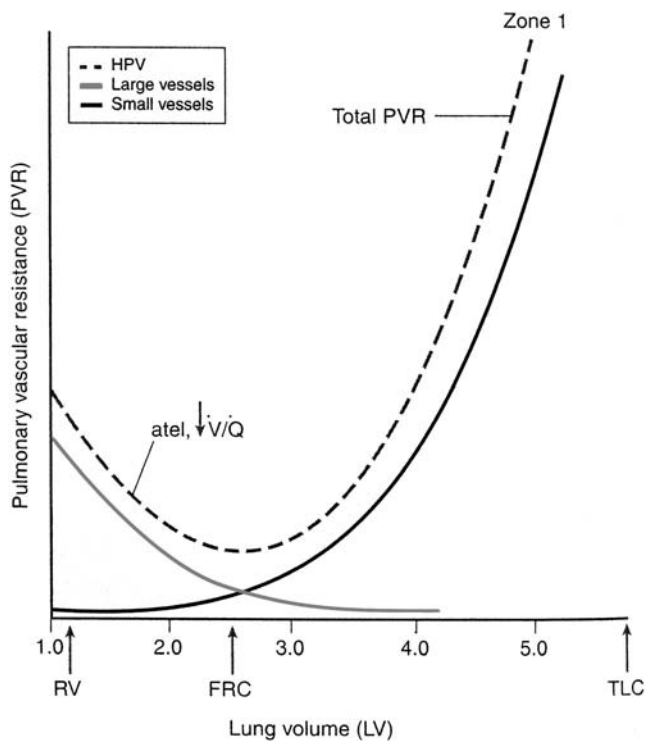

Since capillaries have minimal structural independence, they can collapse easily. However, with increased  $\dot{Q}$  or perfusion pressure, they expand. Two processes occur simultaneously. There is either recruitment of collapsed capillaries or distension of existing open capillaries. The later process seems to be more important in vivo (1,12,13). Paradoxically, this can lead to decrease in pulmonary vascular resistance with increase in pulmonary arterial or venous pressures.

### Lung Volume

PVR is significantly influenced by lung volume. PVR is lowest at FRC (Fig. 11) and increases with higher or lower volume than FRC. At higher lung volume, increase in PVR is thought to be due to compression of intraparenchymal blood vessels, while at lower lung volume it is thought to be due to the compression of extraparenchymal vessels at the hila (2).

### Hypoxia

Unlike systemic vessels, pulmonary vessels constrict in response to hypoxia, hypercarbia, and acidosis. This phenomenon of hypoxic pulmonary vasoconstriction (HPV) is mediated predominantly by alveolar hypoxia, with some influence of mixed venous  $PO_2$ . When pulmonary blood flow is plotted against alveolar  $PO_2$ , the shape of the curve is very similar to the  $O_2$ -dissociation curve.  $P_{50}$  of the curve is around 30 mmHg with marked vasoconstriction happening at 70 mmHg. Short-term regional HPV can be a

**Figure 11** Total pulmonary vascular resistance relates to lung volume as an asymmetric U-shaped curve. The trough of the curve occurs when lung volume equals functional residual capacity. Total pulmonary resistance is the sum of the resistance in small vessels (increased by increasing lung volume) and the resistance in large vessels (increased by decreasing lung volume). The end point for increasing lung volume (toward total lung capacity) is the creation of zone 1 conditions, and the end point for decreasing lung volume (toward residual volume) is the creation of low ventilation-perfusion ( $\dot{V}_A/\dot{Q}$ ) and atelectatic (atrel) areas that demonstrate hypoxic pulmonary vasoconstriction.

beneficial means of diverting blood away from the poorly ventilated areas of the lung and would optimize  $\dot{V}/\dot{Q}$  relationships. However, chronic or intermittent hypoxia leads to pulmonary hypertension (e.g., altitude), with its

deleterious clinical effects. The mechanism of HPV is unclear. Mechanisms involving nitric oxide inhibition, prostacyclin ( $\text{PGI}_2$ ) and endothelin have been proposed (14). Other proposed mechanisms suggest involvement of  $\text{O}_2$ -sensitive  $\text{K}^+$  channels or adenosine triphosphate (ATP)-sensitive ion channels (15). Current consensus suggests that it is probably multifactorial in origin.

**Metabolic and Humoral Control**

Both respiratory and metabolic acidosis augment HPV, while respiratory or metabolic alkalosis cause pulmonary vasodilation and reduce or abolish HPV. Many humoral factors are involved in control of pulmonary vascular tone. Some of these are locally mediated (autocrine/paracrine) humoral factors (Table 1). Others circulate through the cardiovascular system and interact with the pulmonary vasculature. Circulating epinephrine tends to increase PVR, as does 5-hydroxytryptamine (5HT), which is released from activated platelets. This may be one of the reasons pulmonary hypertension can occur following pulmonary embolism.

**Neural Control**

Pulmonary vasculature is supplied by sympathetic, parasympathetic and nonadrenergic, noncholinergic nerves (NANC). The sympathetic system plays little role at rest. However, it is activated via peripheral chemoreceptor in response to hypoxia.  $\alpha_1$ -adrenergic stimulation causes vasoconstriction, while  $\beta_2$ -adrenergic stimulation and  $\alpha_2$ -adrenergic stimulation are involved in vasodilatation. As for cholinergic nerves, their activation via acetylcholine causes pulmonary vasodilatation via activation of endothelium and NO-dependent mechanisms. In the lung most NANC nerves are vasodilatory (and exert their effect) via NO or peptide pathways (14).

**GAS EXCHANGE IN THE LUNG**

**Ventilation-Perfusion Relationship in the Lung**

As mentioned before, for optimal exchange of gases to occur, ventilation and perfusion should be matched. For example, no gas exchange would occur if one lung was ventilated and the other lung is only perfused. One can consider the relationship between ventilation and perfusion in terms of

**Table 1** Local Tissue (Autocrine/Paracrine) Molecules Involved in Active Control of Pulmonary Vascular Tone

Molecule	Subtype (abbreviation)	Site of origin	Site of action	Response
Nitric oxide	NO	Endothelium	Sm. muscle	Vasodilation
Endothelin	ET-1	Endothelium	Sm. muscle	Vasoconstriction
	ET-1	Endothelium	Endothelium (ET-A receptor)	Vasodilation

ventilation-perfusion ratio ( $\dot{V}/\dot{Q}$ ). As each quantity is measured in liters/min, considering ventilation to be 4 L/min and perfusion 5 L/min, we get a ratio of 0.8. Thus, if ventilation/perfusion was uniform in all alveoli, each alveolus  $\dot{V}/\dot{Q}$  ratio would be 0.8. However,  $\dot{V}/\dot{Q}$  ratios are not uniformly distributed. Though ventilation and perfusion increase with decreasing height, in upright position, each does not change to the same extent. Blood flow per unit lung volume increases by 11% per centimeter descent through the lung, while ventilation decreases less dramatically (Fig. 10) (2). There are also more alveoli in the lower part of the lung. Thus,  $\dot{V}/\dot{Q}$  ratios decrease down the lung.

As shown in (Fig. 12), in a young adult, ventilation and perfusion are mainly confined to alveoli with  $\dot{V}/\dot{Q}$  ratio in the range of 0.5–2.0. However, in older individuals the  $\dot{V}/\dot{Q}$  ratio widens significantly (ratio 0.3–5.0). Also, blood flows through the areas which are poorly ventilated (due to dependency and airway closure),  $\dot{V}/\dot{Q}$  ratio can be in the range 0.01–0.03. Furthermore in disease states, the  $\dot{V}/\dot{Q}$  ratios can alter significantly and give rise to hypoxemia (vide infra).

### Shunt, Dead Space, and Effect of $\dot{V}/\dot{Q}$ Inequality on Overall Gas Exchange

Shunt and dead space are essentially two extremes of  $\dot{V}/\dot{Q}$  mismatch. When there is no ventilation in the presence of perfusion ( $\dot{V}/\dot{Q}$  ratio = 0), it is called shunt. Conversely, when there is no blood flow in fully ventilated alveoli ( $\dot{V}/\dot{Q}$  = infinity), it is functionally  $V_{D\text{alveolar}}$ . In the shunt region, alveolar  $pO_2$  and  $PCO_2$  would be the same as mixed venous blood (e.g.,  $PO_2 = 42$  mmHg), while in the dead space areas the alveolar gas partial pressure would be unchanged from the inspired gas. As described above in vivo,  $\dot{V}/\dot{Q}$  ratios are unevenly distributed throughout the lung and so is the concentration of alveolar gas in different regions of the lung. The concentration of gases impacts the saturation of arterial blood. Thus, the final  $PO_2$  is dependent on the combined value of concentration of  $O_2$  from all the regions of the lung. To simplify, one can consider a

three-compartment model of gas exchange (Riley), where the final gaseous concentration is reflective of blood coming from the areas of shunt, dead space, and ideal alveolar gas exchange (Fig. 13) (16). Increasing shunt causes hypoxemia, as the proportion of blood not oxygenated is increased, while increasing dead space should cause an increase in  $CO_2$ . However, due to tightly controlled negative feedback and near linear  $CO_2$ /ventilatory curve, hyperventilation effectively blows off the excess  $CO_2$ . It is difficult to compensate for hypoxemia with hyperventilation, as increasing  $O_2$  concentration in the alveoli, which are on the flat part of the  $O_2$ -dissociation curve, does little to increase the overall  $O_2$  saturation and content. Areas of low  $\dot{V}/\dot{Q}$  ratios contribute to hypoxemia by behaving functionally as areas of shunt. However, with supplemental  $O_2$  it is possible to mitigate their effects, unlike in true significant shunt situation (>30%), it is difficult to improve hypoxemia with 100%  $FiO_2$ . Normal shunt is less than 5%, however, it can increase significantly in acute lung injury (ALI), adult respiratory distress syndrome (ARDS), atelectasis, lobar pneumonia, and lung collapse.

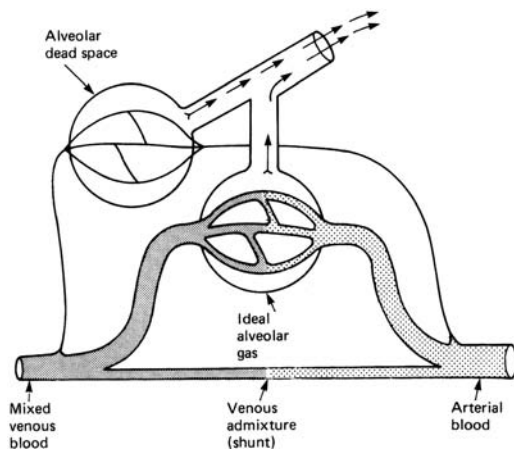

### Diffusion of Gases: The Blood–Gas Barrier

All gases move across the alveolar wall by passive diffusion. Diffusion through the tissues follows Fick's law, which states that rate of transfer is (i) proportional to tissue area, (ii) the difference in partial pressure between two sides, (iii) the diffusion constant (which is dependent on the solubility and inversely proportional to the square root of the molecular weight of the gas) and (iv) inversely proportional to the thickness of the tissue. Lung with its large surface area (50–100  $m^2$ ) and minimal thickness 0.3  $\mu m$  in many areas is ideally suited for diffusion (1,2).

✎ Under typical resting conditions, the RBC  $PO_2$  virtually reaches that of alveolar gas when it is about one-third of the way along the capillary. ✎ Thus, under resting conditions the  $O_2$  transfer is perfusion limited. However, when diffusion properties of the lung is impaired, the

**Figure 12** The distribution of ventilation and blood flow in relation to ventilation/perfusion ratios in two normal subjects. (A) A male aged 22 years with typical narrow spread and no measurable intrapulmonary shunt or alveolar dead space. This accords with high arterial  $PO_2$  while breathing air. (B) The wider spread in a male aged 44 years. Note in particular the “shelf” of blood flow distributed to alveoli with  $\dot{V}/\dot{Q}$  ratios in the range 0.01–0.3. There is still no measurable intrapulmonary shunt or alveolar dead space. However, the appreciable distribution of blood flow to underperfused alveoli is sufficient to reduce the arterial  $P_aO_2$  to 10 kPa (75 mmHg) while breathing air. Source: From Ref. 1.

**Figure 13** Three-compartment (Riley) model of gas exchange. The lung is imagined to consist of three functional units comprising alveolar dead space, “ideal” alveoli, and venous admixture (shunt). Gas exchange occurs only in the “ideal” alveoli. The measured alveolar dead space consists of true alveolar dead space together with a component caused by  $\dot{V}/\dot{Q}$  scatter. The measured venous admixture consists of true venous admixture (shunt) together with a component caused by  $\dot{V}/\dot{Q}$  scatter. Note that “ideal” alveolar gas is exhaled contaminated with alveolar dead space gas, so it is not possible to sample “ideal” alveolar gas. *Source:* From Ref. 1.

blood  $PO_2$  does not reach the alveolar value by the end of the capillary, which suggests diffusion limitation.

It would be incorrect to assume that all resistance to movement of  $O_2$  resides in the barrier between the blood and gas. Another factor that has to be taken into account is the combination of  $O_2$  with Hb. Though the reaction is very fast (0.2 seconds), it is still an important rate-limiting step as oxygenation of pulmonary blood is extremely fast (17). Thus, actual diffusing capacity of the lung is made up of two components, that due to the diffusion process itself, and the other attributed to the time taken for  $O_2$  to react with Hb. Though the capacity for gas exchange is referred to as diffusion capacity of the lung, some prefer to denote it as “transfer capacity,” to emphasize that factors other than diffusion also play a part in effective transfer of gases. Since transfer of carbon monoxide is diffusion dependent, clinically, it has been used to measure diffusing capacity of the lung ( $DL_{CO}$ ) (18). There are many factors that affect diffusing capacity. Some effect by changes in the area of the membrane, alteration in diffusion barrier itself, or factors related to uptake by hemoglobin. Other factors like gender, exercise, racial origin, and smoking also influence diffusion capacity (1).

### Alveolar Gas Composition

Saturation of Hb with  $O_2$  is dependent on  $PaO_2$  as determined by  $O_2$  dissociation curve.  $PaO_2$  is dependent on alveolar partial pressure of  $O_2$  ( $P_AO_2$ ). The level of alveolar  $O_2$  tension reflects a balance of two processes: (i)  $O_2$  entry within the alveoli and (ii)  $O_2$  removal from the alveoli by the capillary blood (Fig. 14) (19).  $O_2$  entry within the alveoli is determined by the alveolar ventilation ( $\dot{V}_A$ ) and the fraction of inspired  $O_2$  ( $F_I O_2$ ). But  $O_2$  is also carried away in exhaled air. The air leaving alveoli has the alveolar  $O_2$  concentration ( $F_A O_2$ ). Thus, net  $O_2$  entering the alveolus

**Figure 14** Alveolar oxygen tension ( $P_AO_2$ ) is determined from the dynamic equilibrium established between the alveolar oxygen delivery (arrow A) and the alveolar oxygen extraction (arrow B). Alveolar oxygen delivery is a function of the minute ventilation ( $\dot{V}_E$ ) and the inspired oxygen fraction ( $F_I O_2$ ). Alveolar oxygen extraction is a function of the pulmonary arterial oxygenation status ( $S_V O_2$ ) and the capillary blood flow ( $\dot{Q}_c$ ). *Source:* From Ref. 19.

is given by  $\dot{V}_A \times (F_I O_2 - F_A O_2)$ .  $O_2$  removal is governed by  $\dot{V}O_2$ . In steady-state situations,  $O_2$  entering the alveolus and  $\dot{V}O_2$  are equal. Writing the relationship as a conservation-of-mass equation, taking into account the barometric pressure and water vapor pressure and converting to partial pressure, one obtains the equation:

$$P_I O_2 - P_A O_2 = \dot{V}O_2 / \dot{V}_A (P_B - 47) \quad (8)$$

However,  $CO_2$  occupies space within the alveoli and is also a byproduct of  $\dot{V}O_2$ . The quantities of  $\dot{V}O_2$  and  $\dot{V}CO_2$  are linked. If the respiratory quotient (RQ) is equal, then the decrease in  $PO_2$  from inspired to alveolar air is exactly the same as the increase in  $PCO_2$  from zero to the alveolar level. Thus:

$$P_I O_2 - P_A O_2 = P_A CO_2 \quad (9)$$

Rearranging

$$P_I O_2 - P_A CO_2 = P_A O_2 \quad (10)$$

Since,  $P_A CO_2$  is very similar to  $P_a CO_2$ , one can write:

$$P_I O_2 - P_a CO_2 = P_A O_2 \quad (11)$$

However, in vivo,  $RQ < 1$ ,  $\dot{V}CO_2$  is less than  $\dot{V}O_2$ . A more complete form of alveolar gas equation that accounts for the change in gas volume is:

$$P_A O_2 = P_I O_2 - P_a CO_2 [F_I O_2 + (1 - F_I O_2 / R)] \quad (12)$$

For typical normal values ( $R = 0.8$ ;  $F_I O_2 = 0.21$ ;  $P_I O_2 = 150$  mmHg;  $P_a CO_2 = 40$  mmHg),  $P_A O_2$  turns out to be about 102 mmHg. In clinical situations, when interpreting blood gases it is useful to estimate  $P_A O_2$  as alveolar-arterial  $PO_2$  differences increase significantly in situations of

increased shunt and  $\dot{V}/\dot{Q}$  mismatch. Another way to denote abnormalities in gas exchange is to calculate ratio between arterial  $PO_2$  and inspired  $O_2$  ( $P_aO_2/F_I O_2$ ).

## GAS TRANSPORT BETWEEN LUNGS AND TISSUES

### Oxygen Delivery Concepts

$\dot{D}O_2$ , also known as  $O_2$  transport, is the product of  $\dot{Q}$  and  $O_2$  Content. The respiratory and cardiovascular systems are series linked to carry out their important functions of  $\dot{D}O_2$  to and  $CO_2$  removal from the tissues.  $\dot{D}O_2$  increases and decreases as the metabolic needs dictate over a wide range. Indeed there is a capacity for increasing the  $\dot{D}O_2$  30-fold from rest to heavy exercise. The functional links in the  $\dot{D}O_2$  chain are as follows: (i) ventilation and ventilation with respect to perfusion; (ii) diffusion of  $O_2$  across the alveolar epithelium, through the interstitial space, and across the capillary endothelium into the blood; (iii) chemical reaction of  $O_2$  with Hb; (iv)  $\dot{Q}$  of arterial blood; and (v) transport of blood to tissues and release of  $O_2$  (Table 2). In healthy patients the system has abundant reserve and is seldom stressed, except with exercise. Accordingly, the first signs and symptoms of cardiopulmonary disease often present during exercise. The content of  $O_2$  in the arterial blood is directly related to the concentration and saturation of hemoglobin, and a very small amount that is dissolved in plasma (as per Equation 13).

$$O_2 \text{ Content} = \text{Hb} \times 1.34 \times \text{sat} + 0.003 \times PO_2 \quad (13)$$

### Determinants of $O_2$ Delivery

$\dot{D}O_2$  is dependent on two factors, namely,  $O_2$  content and  $\dot{Q}$ .  $O_2$  content is dependent on Hb concentration and its percentage saturation ( $SaO_2$ ) with minimal addition from the dissolved amount of  $O_2$  in the plasma, which is dependent on the  $PaO_2$ . Decreased  $O_2$  delivery to the tissues will result if there is decrease in  $\dot{Q}$  (stagnant hypoxia), decreased hemoglobin (anemic hypoxia), or decreased saturation of hemoglobin (anoxic hypoxia) or combination thereof. Finally, the tissues may not be able to utilize the  $O_2$  delivered to it because malfunction of oxidative enzymes (cytotoxic hypoxia e.g., due to cyanide). Under physiological conditions the body compensates for the fall of one parameter with changes in the other. For example, a fall in hemoglobin is compensated by increase in  $\dot{Q}$ , or chronic hypoxia is compensated by increase in hemoglobin concentration (altitude). Decrease in  $PaO_2$  ultimately

decreases  $SaO_2$  which would decrease  $O_2$  content and  $\dot{D}O_2$  even if Hb concentration and  $\dot{Q}$  are kept constant.

### Structural Biology of Hemoglobin

Hemoglobin is the major protein of the RBC. It allows transport of  $O_2$  from the lungs to the tissues and return  $CO_2$  from the tissue to the lungs (20). Hemoglobin is a protein tetramer consisting of 574 AA. Hb consists of a protein part, the globin, and a component that binds to oxygen, the heme group. Both components interact with each other in that the protein controls the  $O_2$  binding properties of heme, which in turn reports the absence or presence of oxygen to its protein environment (21,22).

$O_2$  is a nonpolar molecule and therefore its solubility in the polar water phase of the extra- and intracellular space of the human body is very poor. The fact that the heme part is literally embedded in the globin part of Hb is biologically very important. Normally, ferrous iron, even if bound within the heme group, reacts with  $O_2$  irreversibly to yield ferric heme. When embedded in the folds of the globin chain, ferrous heme is protected in such a way that its reaction with  $O_2$  is reversible. This type of situation is unique and occurs because of the amino acid histidine, which donates a negative charge to the iron and helps create a loose bond with  $O_2$  (22).

Hemoglobin consists of four polypeptide chains, two identical alpha subunits with 141 AAs and two identical beta subunits with 146 AAs. The surface of the Hb tetramer is studded with many polar residues that are all hydrated, which contributes to the high solubility of Hb. Erythrocytes are densely packed with Hb (5 mmol/L), each of which contains 300 million molecules of tetrameric Hb, and four times as many  $O_2$  binding sites (21). This increased solubility of Hb and potential to bind  $O_2$  increases the capacity of blood to transport  $O_2$  70 times more than if it was being transported only in the dissolved form.

### $O_2$ –Hemoglobin Disassociation Curve

The main function of Hb is the reciprocal transport of  $O_2$  and  $CO_2$  between tissue and lungs. The relationship between the fractional saturation of Hb with  $O_2$  ( $SaO_2$ ) and  $PaO_2$  under equilibrium conditions is the familiar  $O_2$  hemoglobin dissociation curve (oxy-heme curve) of Hb (Fig. 15). Its position is often represented by the value of  $P_{50}$ , the  $PO_2$  at half saturation. **Increased  $O_2$  affinity shifts the oxy-heme curve to the left (i.e., reduces  $P_{50}$ ), while decreased  $O_2$  affinity**

**Table 2** Functional Capacities and Potential Maximum Oxygen ( $O_2$ ) Transport of Each Link in the  $O_2$  Transport Chain in Normal Humans<sup>a</sup> at Sea Level

Link in chain	Functional capacity in normal humans	Theoretic maximal $O_2$ transport capacity
Ventilation	200 L/min (MVV)	$0.030 \times \text{MVV} = 6.0 \text{ L } O_2/\text{min}$
Diffusion and chemical reaction	$87 \frac{\text{mL } O_2/\text{min}}{\text{mmHg } O_2 \text{ gradient}}$	$DLO_2 = 6.1 \text{ L } O_2/\text{min}$
$\dot{Q}$	20 L/min	
$O_2$ extraction (a-v $O_2$ difference)	75% (16 mL $O_2$ /100 mL or 0.16)	$0.16 \times \dot{Q} = 3.2 \text{ L } O_2/\text{min}$

<sup>a</sup>Hemoglobin = 15 g/dL; physiologic dead space in percentage of tidal volume = 0.25; partial alveolar pressure of oxygen > 110 mmHg.

Abbreviations:  $\dot{Q}$ , cardiac output; MVV, maximum voluntary ventilation.

**Figure 15** Rightward shift of the oxyhemoglobin dissociation curve is caused by increase of  $\text{H}^+$ ,  $\text{PCO}_2$ , temperature, and 2,3 diphosphoglycerate. In addition to the normal oxyhemoglobin dissociation curve, the family of curves that result from changes in temperature (Temp),  $\text{PCO}_2$ , and pH are shown. *Source:* From Ref. 2.

shifts the oxy-heme curve to the right (i.e., increases  $\text{P}_{50}$ ). Many different models have been proposed to explain the binding of  $\text{O}_2$  to Hb. It has been difficult experimentally to prove one model or the other in its entirety (23,24). However, the two-state model proposed by Monod (24), which is based on the two conformations for hemoglobin corresponding to deoxygenation and oxyhemoglobin, has been most successful. According to the two-state model the hemoglobin can exist in either R (relaxed, oxygenated) or T (tense, deoxygenated) conformation, each with its unique  $\text{O}_2$  affinity. Deoxygenated (T state) has low  $\text{O}_2$  affinity while the R state (oxygenated state) has  $\text{O}_2$  affinity, which is about 100 to 150 times higher than that of T state (23). Of fundamental importance in this model is that the T state is physically constrained by salt and hydrogen bonds to a much greater degree than is the R state. With successive oxygenation of the heme groups, some of these bonds break, the stability of T structure decreases, accompanied by release of the constraints and increase in  $\text{O}_2$  affinity. This transition accounts for the cooperativity with oxygenation and sigmoid shape of the oxy-heme curve. The equilibrium between the T state and R state is influenced by a number of other "effector molecules." These small molecules react with Hb at non-heme sites in such a way as to stabilize the T conformation. The overall reactivity of a mixture of R and T conformation depends on the R-T equilibrium.

### Factors Affecting Oxy-Heme Curve

The three major effector molecules that alter the binding of  $\text{O}_2$  to hemoglobin include: 2,3 diphosphoglycerate (2-3 DPG), the hydrogen ions and  $\text{CO}_2$ . The oxy-heme curve is also very sensitive to temperature shifting rightward with increasing temperature (25). Other molecules that decrease  $\text{O}_2$  affinity include  $\text{Cl}^-$  and ATP, but their physiological roles are minor. 2-3 DPG: 2-3 DPG is present in normal human RBCs and is a metabolic intermediate in the glycolytic pathway. Its concentration within the RBC is approximately 5 mmol/L, which is 1:1 ratio with Hb (26). It binds to deoxyhemoglobin much more tightly than to oxyhemoglobin. In the normal arterial  $\text{O}_2$  oxygenation condition, the presence of 2-3 DPG helps in the transfer of  $\text{O}_2$  to the tissue. However, in conditions of diminished  $\text{O}_2$  availability (anemia, hypoxia), 2-3 DPG levels increase and oxy-heme curve is shifted to the right (Fig. 15). Bohr observed that when pH was lowered (or  $\text{PCO}_2$  was raised) the  $\text{O}_2$  affinity of the blood decreased. Though qualitatively the effects of pH and increased  $\text{PCO}_2$  are similar, they are separate, and the effect of pH (now called the "Bohr effect") is much stronger than the  $\text{CO}_2$  in lowering the  $\text{O}_2$  affinity.  $\text{H}^+$  shifts the R-T equilibrium towards T, stabilizing T conformation, thus decreasing  $\text{O}_2$  affinity (27).

### $\text{CO}_2$ -Binding

$\text{CO}_2$  can bind to the alpha-amino groups of amino acids. This decreases their  $\text{O}_2$  affinity.  $\text{CO}_2$  binding is diminished in the presence of 2,3-DPG, as both 2-3 DPG and  $\text{CO}_2$  compete for the B-chain amino-terminal amino groups (27).

Other RBC properties that affect  $\text{DO}_2$  include: (i) the rates of binding of physiologic ligands ( $\text{O}_2$ ,  $\text{CO}_2$ ,  $\text{H}^+$ , 2,3 DPG); (ii) buffering capacity; (iii) the barrier of diffusion presented by the RBC membrane; (iv) the layer of unstirred plasma immediately surrounding it; and (v) hematocrit-dependent blood viscosity.

$\text{O}_2$ ,  $\text{CO}_2$ , and Hb interact in a very complex way in blood to regulate the position and shape of the oxy-heme curve. The flux of  $\text{O}_2$  into the pulmonary capillary blood is proportional to the diffusing capacity of the lung, which is dependent on the membrane component of diffusing capacity and the reaction rate with Hb, and is also proportional to the difference in alveolar and capillary  $\text{O}_2$  concentrations. The  $\text{CO}_2$  affects the  $\text{O}_2$  affinity in two ways: (i) as an allosteric effector of the Hb- $\text{O}_2$  reaction, and; (ii) by its effect on the intracellular pH. Thus there are a multitude of effects that determine the actual in vivo shape and position of the RBC oxy-heme curve.  $\text{H}^+$ , perhaps the strongest physical effector, is regulated by  $\text{PCO}_2$  and by the buffering capacity of the Hb. Buffering by Hb is in turn determined by Hb concentration and by the degree of  $\text{O}_2$  saturation.  $\text{O}_2$  saturation is determined by the  $\text{PO}_2$  and  $\text{O}_2$  affinity of Hb. Thus, exact quantification of multiple effects in the determination of gas exchange by blood is extremely difficult (23).

### Carbon Monoxide Effect on $\text{O}_2$ Transport

As early as the 17th century, carbon monoxide (CO) was recognized as a potentially life-threatening gas. The toxicity is due to the very high affinity of CO for oxygen carrier proteins Hb and myoglobin (28). CO is not only present in  $\text{O}_2$ -poor environments (caves, ruins), smoke, and automobile engine exhaust, but is also produced in minute amounts physiologically. It is produced through the catabolism of hemoglobin when protoporphyrin is degraded to biliverdin by the heme-oxygenases in the spleen, liver, and the brain.

Physiologically, CO is an activator of guanylcyclase and could be a transmitter like NO (29). In the heart and skeletal muscle it can be oxidized to CO<sub>2</sub>. Normally, the blood CO concentration does not exceed 1% to 2% of the blood CO-carrying capacity and consequently it does not interfere with blood CO<sub>2</sub> transport. Its levels are increased in smokers (5%/pack), and symptoms of toxicity become evident at 15% to 20% (30).

Carbon monoxide disturbs  $\dot{V}O_2$  in essentially three ways decreasing the functional amount of hemoglobin, altering the oxy-heme curve, and binding to myoglobin and the electron transport chain.

CO binds chemically like O<sub>2</sub> to the divalent iron atom of the heme in the Hb. However, the affinity of CO is 200 to 250 times greater than that for O<sub>2</sub>. CO has an intrinsic affinity for "isolated heme rings," which is about 1500 times more than that of O<sub>2</sub> (31). However, the globin molecule imposes thermodynamic constraints on the bonding, which reduces the intrinsic affinity of the CO for the heme. Binding CO to the heme decreases the number of heme groups available to bind to the O<sub>2</sub>, functionally decreasing the O<sub>2</sub> content for the same amount of Hb (CO anemia).

In addition to decreasing the amount of functional Hb available for O<sub>2</sub>, CO increases the O<sub>2</sub> affinity for Hb (32,33). Increasing concentration of CO shifts the ODC curve to the left as the P<sub>50</sub> for O<sub>2</sub> is decreased. Dissociation of O<sub>2</sub> from heme is decreased at the tissue level, which translates to decreased O<sub>2</sub> supply to the tissue. Furthermore, with increasing levels of CO, the O<sub>2</sub> content is also decreased. It has been shown that tissue oxygenation is hindered more by a decrease in functional Hb through CO anemia, than by a reduction of equal percentage of the Hb concentration (i.e., simple anemia). Furthermore, CO binds 20 times more avidly to myoglobins than O<sub>2</sub>, while the affinity for cytochrome c is the same as for O<sub>2</sub> (28). The difference in affinity to different heme proteins is thought to be related either to the differences in the chemical structure of the protein part of the molecule or due to the effects of other molecules (H<sup>+</sup>, CO<sub>2</sub>, 2-3 DPG) that alter the O<sub>2</sub> affinity more than CO

affinity. Changes in oxidative phosphorylation have been shown, though quantitative measurements of the impact of CO binding to myoglobin and cytochrome c has been difficult.

### Carbon Dioxide Transport

Although CO<sub>2</sub> has an aqueous solubility approximately 20 times that of O<sub>2</sub>, it is still considered relatively insoluble in aqueous solution. **CO<sub>2</sub> is transported in the blood primarily in three different forms, namely: (i) physically dissolved in blood; (ii) bound to amino groups of proteins (e.g., hemoglobin), as carbamate compounds; and (iii) as bicarbonate ions.** The relative contribution of each of these forms to overall transport is dependent on PCO<sub>2</sub>, hydrogen ion concentration, 2,3-DPG concentration and degree of saturation of Hb (34). The relative contributions of each form of CO<sub>2</sub> to resting gas exchange are listed in Table 3 (35).

### Pathways of CO<sub>2</sub> Transport

CO<sub>2</sub> in solution: CO<sub>2</sub> dissolved in physical solution accounts for only 5% of the CO<sub>2</sub> content of arterial or venous blood, which is not sufficient to transport CO<sub>2</sub> generated by tissue metabolism. However, it plays an important role in CO<sub>2</sub> transport and exchange, as access to bicarbonate and carbamate pools is achieved only through dissolved CO<sub>2</sub>. Molecular CO<sub>2</sub> is lipid soluble and can cross cell membranes instantaneously. CO<sub>2</sub> diffuses across the normal pulmonary membrane with the same speed as inert gases. However, the time required for completion of CO<sub>2</sub> exchange in the lung capillary is dependent on rate of conversion of HCO<sub>3</sub><sup>-</sup> and carbamate to CO<sub>2</sub>.

Bicarbonate Pathway: Hydration of CO<sub>2</sub> produces carbonic acid (H<sub>2</sub>CO<sub>3</sub>), which is almost completely ionized to H<sup>+</sup> and HCO<sub>3</sub><sup>-</sup> ions. Bicarbonate ions can further dissociate into H<sup>+</sup> and carbonate ions, but in vivo little carbonate is formed because the pH of this reaction is >10.0. The hydration of CO<sub>2</sub> to H<sub>2</sub>CO<sub>3</sub> occurs naturally and is a very slow process. Similarly, the reverse reaction, dissociation of H<sub>2</sub>CO<sub>3</sub> to CO<sub>2</sub> and water, is also a slow process. Both reactions require a catalytic enzyme, carbonic anhydrase, which is present in the cells and virtually absent from the plasma. RBCs contain the highest concentration of carbon anhydrase while lower levels of the isoenzyme have been noted in capillary endothelium of the lung (36).

Carbamate Compounds: CO<sub>2</sub> and hydrogen ions reversibly bind to unchanged amino groups of proteins and form carbamic acid. The formation of carbamate compounds is markedly pH-dependent and increases with decreasing acidity. The concentration of carbamates in plasma is approximately 0.6 mM, and plasma carbamates have no appreciable role in the CO<sub>2</sub> exchange. However, carbamate formation by beta-amino groups of Hb is an important factor in CO<sub>2</sub> exchange. Release of O<sub>2</sub> by Hb in the tissues is accompanied by increased binding of CO<sub>2</sub> to beta-amino groups. Conversely, oxygenation of Hb in the lung promotes release of CO<sub>2</sub> bound as carbamate. Earlier studies suggested that this behavior accounted for 27% of all CO<sub>2</sub> excreted in the lungs. However, recent studies taking into account the role of 2,3-DPG suggest that oxylabile carbamate account for only 10% of the total CO<sub>2</sub> exchange (37).

### CO<sub>2</sub> Dissociation Curve

CO<sub>2</sub> dissociation curve is linear when plotted on a logarithmic axis. The slope of this relationship is essentially constant and is profoundly affected by concentration of Hb in the blood.

**Table 3** Contributions to CO<sub>2</sub> Transport and Exchange from Different Pathways

	Arterial content		Arteriovenous difference	
	(mL/dL blood)	(% of Total)	(mL/dL blood)	(% of Total)
<b>Plasma</b>				
Dissolved CO <sub>2</sub>	1.51	3.1	0.20	4.7
Bicarbonate	30.01	62.1	2.07	48.7
Carbamate	<u>0.67</u>	<u>1.4</u>	<u>0.00</u>	<u>0.00</u>

Hemoglobin is the major nonbicarbonate buffer in the blood and is essential to buffer the protons released during ionization of carbonic acid. Although the total quantity of  $\text{CO}_2$  contained in all forms in the plasma is twice as great as in the RBCs (table 3), plasma proteins have only one-eighth the buffering power of intracellular hemoglobin (35). Furthermore, Hb serves as a source of protons for the reversal of reactions which converts bicarbonate and carbamate into  $\text{CO}_2$ , when it reaches the lung. RBCs play a key role in enhancing blood's ability to carry  $\text{CO}_2$ . It is because of three characteristics of RBCs: (i) large internal buffering capacity of RBC; (ii) presence of intracellular carbonic anhydrase; and (iii) ability to exchange bicarbonate across the RBC membrane (38).

One other factor that significantly affects the  $\text{CO}_2$  dissociation curve is oxygenation. The Haldane Effect describes the influence of oxygenation on the  $\text{CO}_2$  dissociation curve. It accounts for one-half of  $\text{CO}_2$  excretion at rest (39).

## REGULATION OF BREATHING

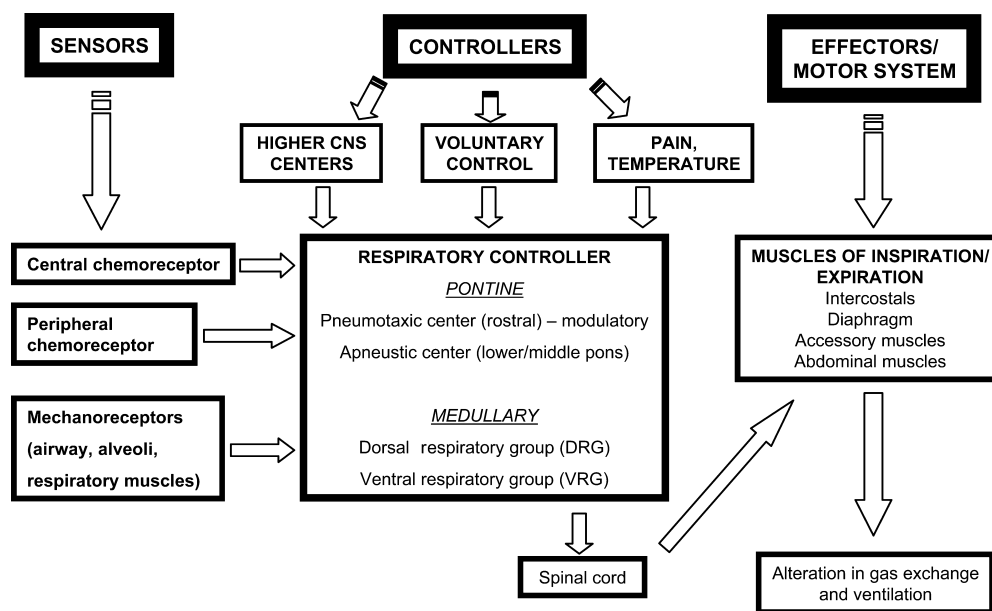

Breathing is a complex process. It is governed by a multitude of control systems hierarchically arranged to regulate ventilation and the pattern of breathing so as to meet optimally the prevailing metabolic needs. Furthermore, the control system also allows the pattern of breathing to automatically adapt to other activities like changes in posture, speech, voluntary movement, and exercise. This section begins by describing the origin of respiratory rhythm and basic organization of the efferent pathways that bring about respiration (neural control of breathing). This basic respiratory rhythm is then modulated by inputs from the cortex, pons, hypothalamus and peripheral inputs from airways and lungs (nonchemical influences on respiration). The metabolic needs of the body are gauged by changes in

the  $\text{pCO}_2$ , pH, and  $\text{pO}_2$  and described as the chemical control of breathing (Fig. 16).

### Neural Control of Breathing

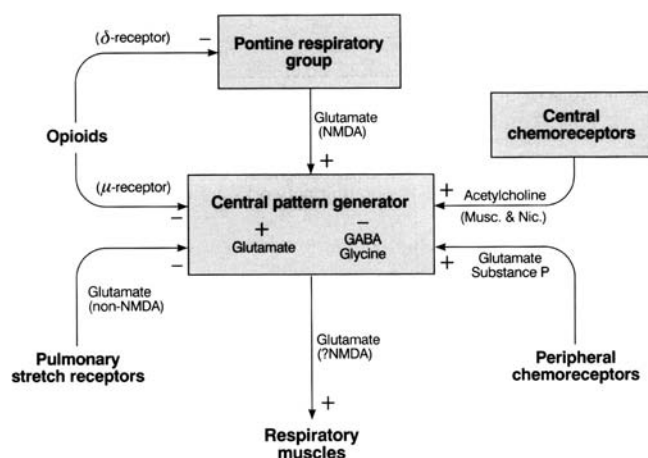

The medulla is the major respiratory center where the respiratory pattern is initiated and various voluntary and involuntary demands on respiratory activity are coordinated. **Autonomous respiratory pattern is generated in the medulla by synchronized activity of six distinct neuronal groups (central pattern generator, CPG).** CPG is governed by a combination of excitatory and inhibitory neurotransmitters. These neurotransmitters subsequently modulate potassium and calcium channels, which lead to depolarization and/or hyperpolarization of neurons. The excitatory neurotransmitters include amino acids like glutamate, which can activate fast-activating ion channels like N-methyl D-aspartate (NMDA) receptors or nonNMDA receptors, which are slow reacting receptors and mediate their effects via G-proteins. Inhibitory neurotransmitters include  $\gamma$ -amino butyric acid (GABA) and glycine, which act through  $\text{GABA}_A$  receptors and specific glycine receptors, respectively (40). Furthermore, the CPG is affected by neuro-modulators which modify the CPG output, but are not primarily involved in rhythm generation. These include agents like opioids, acetylcholine, and substance P, to name a few (Fig. 17). Furthermore, there are other neurons in the medulla involved in respiratory control. These are divided into two groups, namely, (i) dorsal respiratory neurons and (ii) the ventral respiratory neurons. They have numerous interconnections. The dorsal respiratory group neurons are primarily concerned with the timing of the respiratory cycle. While the ventral respiratory group of neurons is composed of four nuclei, each is involved with a specific aspect of ventilatory control, for example, function of pharyngeal muscles, larynx and tongue, force of contraction of inspiratory muscles, expiratory muscles (41).

The output from the CPG converges on the motor anterior horn cells, which control the inspiratory and

**Figure 16** Regulation of breathing is accomplished by a complex interactive system of sensors, controllers, and effector systems. Although there is voluntary override of the breathing system at rest, involuntary systems regulate most breathing and become more dominant when extreme conditions of exercise or disease are present.

**Figure 17** Neurotransmitters and neuromodulators in the respiratory center. Boxes indicate functional neuronal groups and bold type represents other influences on the respiratory center. Substances involved in neurotransmission are shown with the most likely receptor subtype, in parentheses, if known. + indicates excitatory effect increasing respiratory activity; - indicates inhibitory activity decreasing respiration. *Source:* From Ref. 1.

expiratory muscles. The synchronized firing of CPG neurons leads to activation of specific respiratory muscle groups. Alterations in the rate at which spontaneous neuronal activity increases or decreases and the point at which the next group of neurons are activated, allows for infinite variations in respiratory patterns and adjustment to constantly changing needs (1,41).

Two other sources also converge on respiratory motor neurons. These include direct input from the cortex and non-respiratory reflexes (swallowing, cough, hiccups etc.). These integrated inputs are responsible for voluntary control of breathing and execution of a multitude of involuntary reflexes (Fig. 16) (42).

### Chemical Control of Breathing

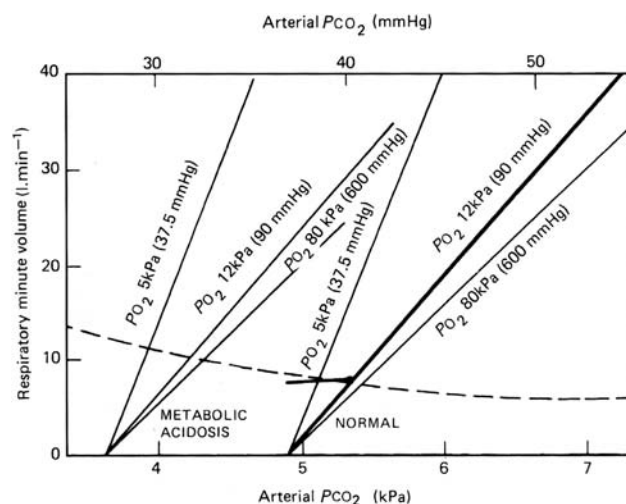

The effect of  $O_2$  and  $CO_2$  on respiration was first described by Pfluger in 1868 and later classified by Haldane and Priestly in 1905 (43). Changes in  $pCO_2$  and  $pO_2$  are sensed by central and peripheral chemoreceptors, respectively, which subsequently trigger an appropriate ventilatory response. Influence of  $CO_2$  and  $O_2$  on respiratory control is described followed by discussion of a combined responses of these gases to control of breathing.

#### Effect of $CO_2$ on Ventilatory Response (1)

Alveolar ventilation is extremely sensitive to changes in  $pCO_2$ . Changes in  $pCO_2$  are sensed by "central chemoreceptors," which are located in the medulla. They are separate from the respiratory neurons but are very close to the respiratory center. MRI and positron emission tomography (PET) scanning techniques during  $CO_2$ -stimulated breathing have confirmed that the surface of the anterior medulla is the primary site of chemosensitive neuronal activity (44). Though other areas of the brain (other regions in the medulla, midline pons, small areas in cerebellum, and limbic system) are also stimulated, their contribution in control of respiration is unclear (45,46). About 85% of the total respiratory response to inhaled  $CO_2$  originates in the medullary chemoreceptors.

A rise in arterial  $pCO_2$  causes an approximate equal rise in cerebrospinal fluid (CSF)  $pCO_2$ , which is about 10 mmHg more than the arterial  $pCO_2$ . Blood-brain-barrier (BBB) is permeable to  $CO_2$ . In the short term, increased  $CO_2$  permeates through the BBB; it gets hydrolysed to carbonic acid, which dissociates to yield hydrogen ions. This leads to a fall in the CSF pH, which stimulates to respiratory neurons indirectly through the stimulation of receptors in the chemosensitive area. The precise mechanism by which a change in pH causes stimulation of neurons in the chemosensitive area is not established. However, there is some evidence to suggest that  $M_2$  muscarinic receptors may be involved (47). Also, the response to respiratory acidosis is more than for metabolic acidosis, for the same change in pH. If the  $pCO_2$  in CSF is increased, the pH returns to normal over the course of many hours, as a result of changes in the CSF bicarbonate levels. Compensatory changes in CSF bicarbonate and restoration of its pH are evident not only in chronic respiratory acidosis, but also occur in respiratory alkalosis, chronic metabolic acidosis and alkalosis (48). Direct changes in the bicarbonate concentration of CSF also lead to changes in ventilation. For example, after intracranial hemorrhage CSF pH and bicarbonate levels fall, which causes hyperventilation (49).

Respiratory depth and rate increase with rise in  $pCO_2$  until a steady state of hyperventilation is achieved after a few minutes. Within acceptable experimental conditions the ventilatory response to  $CO_2$  is linear. Under normal conditions ( $pO_2 = 90$  mmHg) the slope of the curve is 2 L/min/mmHg while the intercept (apneic threshold) is at 36 mmHg. As depicted in Figure 18, the slope of the curve changes with changes in arterial  $pO_2$ . Furthermore, the apneic threshold will be altered in the presence of acid-base changes. It should be kept in mind that the  $pCO_2$ /ventilation response curve is the response of the entire respiratory system to the challenge of altered

**Figure 18** Two fan-shaped families of curves of  $PCO_2$ /ventilation response curves at different values of  $PO_2$ . The right-hand fan is at normal metabolic acid-base state (zero base excess). The left-hand fan represents metabolic acidosis. The broken line represents the  $PCO_2$  produced by the indicated ventilation for zero inspired  $PCO_2$ , at basal metabolic rate. The intersection of the broken curve and any response curve indicates the resting  $PCO_2$  and ventilation for the relevant metabolic acid-base state  $PO_2$ . The heavy curve is the normal response. *Source:* From Ref. 1.

pCO<sub>2</sub>. The CO<sub>2</sub> response curve will be altered by changes in the sensitivity of the central chemoreceptors, partial neuromuscular blockade, anesthetic drugs, opioids, obstructive, and restrictive lung disease. Inhalational anesthetics decrease the sensitivity to CO<sub>2</sub> responsiveness by altering the slope of the pCO<sub>2</sub>/ventilatory response curve and displace the curve to the right (50). The initial respiratory response to elevated pCO<sub>2</sub> is extremely rapid and takes place in just a few minutes. With sustained hypercapnia the minute ventilation continues to increase for an hour before reaching a plateau and can be sustained for eight hours (51). As pCO<sub>2</sub> is raised to pCO<sub>2</sub> (100–200 mmHg), a point of maximal ventilatory response is reached beyond which respiratory fatigue and CO<sub>2</sub> narcosis intervenes.

### **Influence of O<sub>2</sub> on Respiratory Control**

☞ The central chemoreceptors play an important role in monitoring pCO<sub>2</sub>, while the peripheral chemoreceptors which reside in the carotid body respond predominantly to changes in pO<sub>2</sub>. ☞ The peripheral chemoreceptor also responds to a rise in pCO<sub>2</sub>, H<sup>+</sup> ion concentration, temperature, fall in perfusion pressure, and chemicals (52). The response to changes is rapid (within one to three seconds), is processed by glomus cells and relayed by afferent fibers in the glossopharyngeal nerves. Type I glomus cells are predominantly involved in sensing of hypoxemia. Hypoxemia of glomus cells leads to decrease in ATP and release of calcium from the mitochondria. Furthermore, oxygen-sensitive K<sup>+</sup> channels and heme-based intracellular proteins also respond to changes in local pO<sub>2</sub> (53). Neurotransmitters that have been described in the carotid bodies include dopamine, noradrenaline, acetylcholine, substance P, and enkephalins. Dopamine (acting via D<sub>2</sub> receptors) and clonidine (α<sub>2</sub> receptor antagonist) reduce ventilatory response to acute hypoxia. However, no single receptor blocker prevents the hypoxic ventilatory response completely.

Peripheral chemoreceptors respond to decrease in pO<sub>2</sub> and not to decrease in O<sub>2</sub> content (1). There is minimal stimulation in anemia, carboxyhemoglobinemia, and methemoglobinemia. Acidemia, either secondary to metabolic or respiratory acidosis causes stimulation, which can lead to hyperventilation. Quantitatively, the response of peripheral chemoreceptors to increase in pCO<sub>2</sub> is one-sixth that of central chemoreceptors. However, the response is very rapid. Oscillations in pCO<sub>2</sub> within the respiratory cycle are detected by peripheral chemoreceptors and discharge rates are altered accordingly. Hypoperfusion of carotid bodies (systolic BP <60 mmHg) and increase in temperature causes stimulation and leads to hyperventilation. Nicotine, acetylcholine, doxapram, and almitrine stimulate ventilation directly, while cyanide and carbon monoxide increase ventilation by inhibiting the cytochrome system, which prevents oxidative metabolism. Hypoxia also has a direct effect on the respiratory center. Central respiratory neurons are depressed by hypoxia, and apnea follows severe medullary hypoxia whether due to ischemia or to hypoxemia. Phrenic motor nerve activity becomes silent when medullary pO<sub>2</sub> falls to about 13 mmHg. More intense hypoxia can cause resumption of the abnormal pattern of breathing possibly by activation of the gasping center.

### **Integrated Effects of pCO<sub>2</sub>, pH, and pO<sub>2</sub> on Respiratory Control**

Though the effects of pCO<sub>2</sub>, pH, and pO<sub>2</sub> on the respiratory control have been described independently, they are integrated in vivo. The acute hypoxic response is enhanced

at elevated pCO<sub>2</sub>, while the responses to both acute and prolonged hypoxia are depressed by hypocapnia. When pCO<sub>2</sub> is not controlled during hypoxic ventilation, hypoxia-induced hyperventilation immediately gives rise to hypocapnia and attenuates the ventilatory response to hypoxia. Similarly, changes in PO<sub>2</sub> alter the slope of the ventilatory response curve, while metabolic acidosis pushes the curve to the left and makes ventilatory response more sensitive to changes in pCO<sub>2</sub> (Fig. 18) (1,54).

### **Nonchemical Pulmonary Reflexes**

In addition to neural and chemical control of breathing, ventilation is significantly modulated and affected by pulmonary reflexes. These reflexes can result in a myriad of responses, from apnea, to alterations in airway caliber, to hemodynamic effects.

## **HEART–LUNG INTERACTIONS**

Because the heart and great vessels lie within the thorax, the respiratory system is the milieu within which the heart must function. Q is determined by the heart rate (HR) and stroke volume. Stroke volume is in turn dependent on preload, afterload, and contractility. Conceivably, effect on any one or more of these components would change Q. The major mechanical interactions of respiration and circulation are produced by changes in pleural and alveolar pressure (55). Changes in these pressures affect the circulation by producing changes in preload and afterload of the right and left ventricle (55). The magnitude of both preload and afterload is determined by a complex interaction of the heart and blood vessels. Discussion of all these changes is beyond the scope of this chapter, and the reader is referred to other references for full discussion (55). It is important to understand that it is the static recoil pressure of the systemic or pulmonary circulation relative to the right or left atrial pressure that provides the driving pressure that returns the blood to the heart (the resistance to venous return) and not the conventional vascular resistance (56). The magnitude of this static recoil is determined by blood volume and the elastic properties of the blood vessels. Increase in blood volume increases static recoil and thus increases preload.

### **Effect of Pleural Pressure on Preload and Afterload**

Because the right heart is surrounded by pleural pressure and the systemic vessels are not, a decrease in pleural pressure (e.g., during inspiration) reduces the right atrial pressure relative to the static recoil pressure of the systemic circulation, thus increasing venous return. The overall effect on preload is modified by systemic vascular compliance, accompanying changes in abdominal pressure, and the collapse of the extrathoracic venae cava.

Increase in pleural pressure (e.g., positive pressure ventilation) results in increased intrathoracic pressure and pressure around a portion of the heart and circulation. It is thought that this decreases the overall transmural pressure (intraluminal—intrathoracic pressure) across the wall of the ventricle. The transmural LV pressure is the measure of afterload. Intraluminal pressure approximates aortic pressure (as long as there is no obstruction to aortic outflow and no significant variation in intrathoracic pressure) and provides a good estimate of the afterload. However, if intrathoracic pressure fluctuates considerably

(+20 to -60 mmHg), transmural LV pressure and afterload can alter significantly. Hemodynamic benefits of positive pressure ventilation in patients with severe heart failure are attributable to decrease in preload and afterload with mechanical ventilation.

### Effect of Alveolar Pressure on Preload and Afterload

When lung volume is constant, any change in pleural pressure is accompanied by an approximately equal change in alveolar pressure. However, with any change in lung volume there is a change in alveolar pressure, relative to pleural pressure as determined by the static recoil of the lung. The effect of changes in alveolar pressure to preload and afterload becomes more complicated with varying effects on right and left cardiac chambers. The effect of an increase in alveolar pressure relative to pleural pressure is also different in zone II versus zone III states. With increasing alveolar pressure in zone II, there is a steady-state increase in right ventricular afterload (due to increase in back pressure from ejection) and transient decrease in LV preload. This can be seen in an asthmatic attack where large increase in lung volume gives rise to marked increase in right ventricular afterload (57). In zone III, there is a transient increase in RV afterload, but also in LV preload, which causes no significant steady-state changes.

### Effect of Positive End Expiratory Pressure on Cardiac Function

Positive end expiratory pressure causes significant effect on the cardiac function (58). These include: (i) reduced venous return, secondary to increased pleural pressure; (ii) increased right ventricular load, secondary to increased lung vascular resistance; (iii) decreased LV load secondary to rise in pleural pressure; and (iv) reflex changes in heart rate, systemic vascular resistance and perhaps cardiac contractility, caused by inflation reflexes and secondarily by changes in vascular pressures.

### Reflex Effects of Lung Inflation on Hemodynamics

Cardiovascular effects of changes in pleural and alveolar pressure have been described earlier. However, there are also direct reflex cardiovascular effects secondary to lung inflation. The lungs are significantly innervated by the vagus nerve (59). Cardiovascular response to low level of lung inflation (<10 mmH<sub>2</sub>O) and higher level of lung inflation is different. Low level of inflation decreases systemic vascular resistance (SVR) and has variable effect on HR (60). Static inflation of the lungs to distending pressures of 15 mmH<sub>2</sub>O depresses cardiovascular function. The reflex effect includes decrease in HR, arterial pressure,  $\dot{Q}$ , cardiac contractility, systemic vascular resistance. The afferent limb of the reflex arc is the ipsilateral vagus nerve (61). These reflexes play a role in normal physiology (sinus arrhythmia) and possibly during pathological conditions and mechanical ventilation of the lungs.

## RESPIRATORY PHYSIOLOGY AT EXTREMES OF AGE AND PREGNANCY

With the first few breaths changes occur in the cardiopulmonary system, which allow the fetus adapt to the extra-uterine environment. Significant anatomical and functional differences in the respiratory system are notable in the

neonates compared to adults. Furthermore, respiratory function continues to change with advancing age and alterations in the respiratory system are also evident during pregnancy. Salient changes in the respiratory system in neonates, the elderly, and during pregnancy are discussed.

### Respiratory Changes in the Elderly

#### Structural Alterations in the Upper and Lower Airways

With advancing age, structural changes occur both in upper and lower airways. There is loss of pharyngeal support. In addition, the protective airway reflexes of coughing and swallowing are depressed. Mean pulmonary artery pressure increases by 30%, and the pulmonary vascular resistance increases by 80% between age 20 and 70 years (62). Part of the pulmonary vascular changes results from a decline in the volume of the pulmonary capillary bed. Additionally, there is a progressive age-related decrease in surface area of at least 30% occurring from age 20 to the age of 70 years (63). Dilatation of the respiratory bronchioles and alveolar ducts (ductectasia) leads to increase in anatomical dead space. Molecular changes in protein structure leads to increased proteolysis of elastin, which leads to decreased elastic recoil. Though the absolute elastin content is not altered, the ratio of collagen to elastin is. There is increased interstitial collagen, which probably contributes to increased O<sub>2</sub> diffusing capacity (4).

#### Changes in Respiratory Mechanics and Lung Volume

The elastic properties of the lung and thoracic wall gradually change by aging. The chest wall becomes stiffer due to calcification of ribs and vertebral joints, while the lung parenchyma loses elastic recoil. The volume-pressure curve of the aged total system (lung + thorax) is flatter and shows less compliance. Loss of elastic recoil leads to increased overall tension, which can contribute to an increased pulmonary vascular resistance.

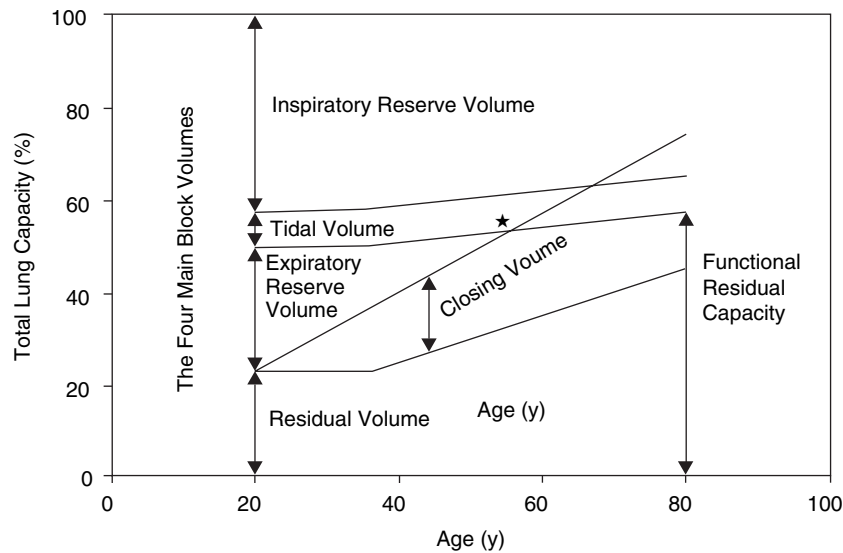

With aging, tidal volume decreases and respiratory frequency increases slightly; abdominal contribution to tidal breathing increases. The total lung capacity (TLC) does not change considerably, when corrected for age-related decreases in height. However, changes in chest wall and lung lead to barrel-like appearance of chest and flattened diaphragm.

FEV<sub>1</sub> (forced expiratory volume in one second) decreases annually by 30 mL. Closing capacity (CC), the volume at which the elastic recoil of the lungs becomes insufficient to support small bronchioles (<1 mm), reaches FRC in the erect 60 year old. In supine position, FRC equals CC at age of 44 years (Fig. 19) (64). Vital capacity is significantly decreased, however, FRC does not change.

The diaphragmatic efficiency in the elderly is also impaired by a significant loss of muscle mass. Though the reduction in diaphragmatic strength is small (10–20%), maximum pressures generated by full inhalation and expiration are significantly decreased. FEV<sub>1</sub>/FVC ratio may be as low as 65% to 55% in apparently healthy individuals. The work of breathing may be elevated by 30% during exercise.

#### Impaired Efficiency of Gas Exchange

Arterial oxygenation is progressively impeded with increasing age (65); whereas  $\dot{V}CO_2$  is less affected by aging in the absence of disease. Oxygen tension decreases progressively with aging (approximately 5 mmHg per decade from the age of 20 years), with significant drop between ages 40 and 75 years. Thereafter, arterial O<sub>2</sub> tension remains stable at about 83 mmHg. The drop in O<sub>2</sub> tension is primarily

**Figure 19** Changes in lung volumes with aging (*erect position*). Residual volume (RV) (5–10% per decade) and functional residual capacity (FRC = ERV + RV) (1–3% per decade) gradually increase by aging, while expiratory and inspiratory reserve volumes (ERV, IRV) and thus vital capacity (VC = ERV + IRV) decrease. Specific (height-adapted) total lung capacity does not change with aging. *Source:* From Ref. 4.

due to alterations in  $\dot{V}/\dot{Q}$  mismatch (Fig. 12) (66). Loss of hypoxic pulmonary vasoconstriction and hypocapnic bronchoconstriction prevents fine-tuning of ventilation/perfusion balance. Cumulatively,  $\dot{V}/\dot{Q}$  mismatch and loss of functional alveolar surface significantly decreases the diffusing capacity (0.24 mL $O_2$ /mmHg/yr in men and 0.16 mL $O_2$ /mmHg/yr in women) (67).

### Alterations in Ventilatory Drive

Respiratory response to hypoxemia and hypercapnia is roughly decreased by 50% in the 70-year old healthy individual (68). This is due to reduced central nervous system (CNS) activity, and reduced neuronal output to respiratory muscles. In the elderly, the response to hypoxemia during rapid eye movement (REM) sleep is profoundly impaired.

### Clinical Implications

☞ **Age-related loss of pharyngeal muscle support leads to an increased propensity for upper airway obstruction. Furthermore, loss of dentition make establishment of patent airway by bag and mask more difficult.** ☞ Loss of protective reflexes makes the elderly more prone to aspiration. Four vital capacity breaths prior to induction of anesthesia may not be sufficient to provide adequate preoxygenation as vital capacity is significantly decreased in the elderly (69). Impaired gas exchange makes them more prone to hypoxemia. Furthermore, in the elderly, response to chemical (hypoxia, hypercapnia) and mechanical stress (increased airway resistance) is significantly reduced in the presence of small amounts of opioids, benzodiazepines, and inhalational anesthetic agents.

### Respiratory Changes in the Neonate

#### Structural Alterations in the Upper and Lower Airways

Neonates are obligate nasal breathers and have a small pharynx and a large tongue (70). The larynx is located anteriorly and slightly higher in the neck. The epiglottis is

mobile. The cricoid cartilage is the narrowest portion of the trachea. At full term all major elements of the lungs are fully formed, but, the number of alveoli present is only about 15% of the lung (71). Division of saccules into alveoli continues following birth and is believed to be complete by two years of age (1,71).

### Changes in Respiratory Mechanics and Lung Volume

The chest wall of the neonate is highly compliant compared to the adult (where compliance of chest wall and the lung is nearly equal) (1,71,72). Most of the impedance to expansion is due to the lung and is dependent on the presence of surfactant in the alveoli. Though a small amount of surfactant is present at 24 weeks, significant synthesis of surfactant does not begin until 34 to 36 weeks. Compliance is about one-twentieth that of an adult and resistance is about 15 times greater (1). As in the elderly, the diaphragm is not as dome shaped as in adults. The lower portion of the rib cage has large anteroposterior and lateral diameters. As a result, the diaphragmatic insertions are spread out, limiting range of lengths of the diaphragmatic fibers.

Minute ventilation of a neonate is about twice that of an adult. This is due to significant respiratory rate 25–40/min, while the tidal volume, corrected for weight is not significantly different. Vital capacity is half of an adult when corrected for weight, while the functional residual capacity is not significantly different. Dead space is close to half that of tidal volume and shunt is about 10% immediately after birth.

### Impaired Efficiency of Gas Exchange

The single most important difference in respiratory parameters that distinguishes pediatric patients from the adult is  $\dot{V}O_2$ . In the neonate, the  $\dot{V}O_2$  is >6 mL/kg/min, which is about twice that of the adult. Increased demand is maintained by increased alveolar ventilation (*vide supra*). Because of increased shunt, the alveolar/arterial difference

is about 25 mmHg, which is about twice that in adults.  $\text{PCO}_2$  is slightly decreased to 30–36 mmHg.

### Alterations in Ventilatory Drive

Adult hypoxic ventilatory responses are not fully developed in the neonates (73). In normal babies under two months of age, there may be an excess of 200 apneic episodes and 50 minutes of periodic breathing per day, with short-lived desaturations (74). Though the ventilatory response to  $\text{CO}_2$  seems to be similar to adults, the response is depressed in REM sleep (75).

### Clinical Implications

Presence of large head, large tongue, floppy epiglottis, and anterior larynx requires slightly different maneuvering to achieve tracheal intubation (70). The size of the endotracheal tube (ET) tube also needs to be gauged to the cricoid cartilage rather than to laryngeal opening to avoid trauma to the trachea. High  $\dot{V}\text{O}_2$ , along with a relatively low total volume of FRC, predisposes neonates to develop hypoxia quickly, after apnea. Though cardiovascular responses to hypoxia (bradycardia, vasoconstriction) are well developed in the neonates, compensatory responses to hypoxia/hypercarbia are not fully developed (73). Thus neonatal hypoventilation is very likely after administration of respiratory depressant drugs and anesthesia.

### Respiratory Changes During Pregnancy

#### Structural Alterations in the Upper and Lower Airways

Several physiological changes occur during pregnancy that affect respiratory function (76,77). Fluid retention causes edema throughout airway mucosa. This causes difficult nasal breathing. Furthermore, edema of the upper airway increases the propensity of bleeding even with minimal trauma and makes airway management more difficult.

#### Changes in Respiratory Mechanics and Lung Volume

Lung volume does not change until about the fifth month of gestation. The diaphragm becomes displaced cephalad by the expansion of the uterus in the abdomen (78). This leads to decrease in residual volume and expiratory reserve volume by 20%. FRC also decreases significantly. However, vital capacity,  $\text{FEV}_1$ , and maximal breathing capacity are normally unchanged.

Increase in  $\dot{V}_E$  is one of the earliest and most dramatic changes in pulmonary function. The  $\dot{V}_E$  is increased about 50% above nonpregnant levels during the first trimester and is maintained for the remainder of the pregnancy. It is thought to be centrally mediated due to increased levels of progesterone which can rise sixfold during pregnancy. Increase in  $\dot{V}_E$  is due to increase in tidal volume with slight increase in respiratory rate. Airway resistance decreases by 35%.

#### Impaired Efficiency of Gas Exchange

Increase in blood volume contributes significantly to increase in  $\text{O}_2$  delivery. Though total  $\text{O}_2$  consumption is increased by 15% to 30% it is attributed to increased demands of the fetus, uterus, and placenta and not significantly different when expressed per kilogram of body weight. ⚡ **Due to the increase in alveolar ventilation, which is more than the increase in  $\dot{V}\text{O}_2$ , the  $\text{P}_{\text{A}}\text{O}_2$  is higher than normal, and the**

**$\text{PaCO}_2$  decreases to 30 mmHg during the first trimester of pregnancy whereas pH remains normal. ⚡**

### Alterations in Ventilatory Drive

The hyperventilation observed during the pregnancy is attributable to progesterone level. The mechanism is assumed to be a sensitization of the central chemoreceptors. Pregnancy gives rise to three-fold increase in slope of  $\text{PCO}_2$ /ventilation response curve (79). The hypoxic ventilatory response is also increased two-fold (80).

### Clinical Implications

Airway edema, swelling and easy propensity to bleed contribute significantly to difficulty in airway management in a parturient. Furthermore, the significant decrease in FRC and increased  $\dot{V}\text{O}_2$  contribute to quicker development of desaturation and hypoxemia (77). Adequate denitrogenation requires longer period of breathing 100%  $\text{O}_2$ . For preoxygenation to be beneficial to the fetus, it should be performed for about six minutes to allow for adequate maternal-fetal equilibrium (77).

## NONPULMONARY FUNCTIONS OF THE LUNG

The lungs primary function is gas exchange. However, due to its significant surface area and capillary network, it is an ideal organ to perform other functions. Some nonpulmonary functions are as follows: (i) *Filtration*: Thrombi are cleared most rapidly from the lungs than other organs. The lung possesses a well-developed proteolytic enzyme system, which dissolves small clumps of fibrin and platelets (81). Plasmin activator from pulmonary endothelium converts plasminogen to plasmin, which converts fibrin to fibrin degradation products. (ii) *Processing of compounds*: Table 4 shows the effects on various hormones while passing through the pulmonary circulation (81,82). Some pass through the circulation unchanged, others are activated (angiotensin I to angiotensin II, arachidonic acid), while many are inactivated. Lungs not only process endogenously produced substances, but metabolize a number of chemicals utilizing the mixed function oxidases and cytochrome P-450 systems as seen in the liver. Furthermore, the process involving the conjugation with glucuronide and glutathione also takes place in the lung. (iii) *Release of inflammatory mediators*: histamine, endothelium, and arachidonic acid derivatives are released from the lung following immunological activated by inhaled allergens. Some animal studies have demonstrated the presence of clusters of peptide and amine-secreting cells in the lung tissue (83). The cells degranulate in the presence of hypoxia, however, their function a significance is still not known. (iv) *Host defenses*: The lungs are exposed to the environment and are constantly being bombarded with pathogens. Lungs have developed an elaborate network of minimizing and handling of pathogens. Larger particles  $>5 \mu\text{m}$  are filtered in the nose and upper pharynx. The mucociliary layer helps to trap particles between 1 and  $5 \mu\text{m}$ , while particles  $<1 \mu\text{m}$  reach the alveoli. Local host defenses are provided by macrophages, neutrophils, and lymphocytes. They protect the tissues in the short term, but chronic long-term inflammation can cause significant destruction or remodeling of tissues. This can lead to alterations in ventilation/perfusion and ultimate gas exchange.

**Table 4** Effect on Hormones by Passage Through the Pulmonary Circulation

Molecule	Effect of compound passing through pulmonary circulation		
	Activated	Unchanged	Inactivated
Amines		Dopamine Epinephrine Histamine	5-Hydroxytryptamine Norepinephrine
Peptides	Angiotensin I	Angiotensin II Oxytocin Vasopressin	Bradykinin Atrial natriuretic peptide Endothelins
Eicosanoids	Arachidonic acid	PGI <sub>2</sub> PGA <sub>2</sub>	PGD <sub>2</sub> PGE <sub>1</sub> , PGE <sub>2</sub> PGF <sub>2α</sub> Leukotrienes
Purine derivatives			Adenosine ATP, ADP, AMP

## RESPIRATORY ADJUSTMENT IN HEALTH AND DISEASE

For significant range of O<sub>2</sub> extraction,  $\dot{V}O_2$  is independent of supply (Fig. 20) (84). However, below a critical  $\dot{D}O_2$  level,  $\dot{V}O_2$  begins to diminish and is directly dependent upon the supply of O<sub>2</sub>. In critical illness, "supply dependency" is observed at a much higher  $\dot{D}O_2$  level (Fig. 20) than occurs at baseline conditions. This observation leads some to believe and suggest that increasing  $\dot{D}O_2$  to supramaximal levels could improve outcomes in critically ill patients. However, this has not been proven conclusively (85).

Respiratory failure is defined as a failure of maintenance of normal arterial blood gas tension. Hypoxia due to cardiac and other extrapulmonary forms of shunting are excluded. As mentioned before, saturation of Hb with O<sub>2</sub> is dependent on PaO<sub>2</sub>, which is dependent on alveolar P<sub>A</sub>O<sub>2</sub>. Alveolar P<sub>A</sub>O<sub>2</sub> under

normal conditions is dependent on the balance of two factors: (i) amount of O<sub>2</sub> entering the lung, which is determined by alveolar ventilation and concentration of O<sub>2</sub> (F<sub>I</sub>O<sub>2</sub>), and, (ii) O<sub>2</sub> leaving the alveoli, which is determined by Q and O<sub>2</sub> saturation of mixed venous (PvO<sub>2</sub>) (Fig. 13). This presumes that there is no impediment to diffusion of O<sub>2</sub> across the alveoli to the blood. If  $\dot{Q}$  and PvO<sub>2</sub> are kept constant and  $\dot{V}/\dot{Q}$  is matched the two factors that would significantly affect PAO<sub>2</sub> are alveolar ventilation and fractional inspired concentration. Breathing a hypoxic mixture of gas (accidental, smoke inhalation), and low F<sub>I</sub>O<sub>2</sub> (as at high altitude) would lead to hypoxia even if ventilation is maintained. More often it is the decreased ventilation, in combination with  $\dot{V}/\dot{Q}$  mismatching and shunting, that causes decreased PaO<sub>2</sub>. Decreased PaO<sub>2</sub> with or without increases in PaCO<sub>2</sub> is described as acute hypoxic respiratory failure. The pathophysiologic reasons for acute hypoxic respiratory failure are reviewed in Volume 2, Chapter 23.

Management of acute hypoxemic respiratory failure (AHRF) requires mechanical ventilation. The parameters of mechanical ventilation are determined predominantly by the pathophysiologic process. For example, in situations of ventilatory failure secondary to neuromuscular dysfunction (myopathy, neuropathy, neuromuscular blockade) adequate  $\dot{V}_E$  with low F<sub>I</sub>O<sub>2</sub> would suffice. However, in situations of acute lung injury, where  $\dot{V}/\dot{Q}$  mismatch and shunts predominate as the major pathophysiologic process, ventilatory parameters that keep the alveoli open (PEEP), improve  $\dot{V}/\dot{Q}$  ratio, and increase F<sub>I</sub>O<sub>2</sub> will be required (see Volume 2, Chapter 27). Increased F<sub>I</sub>O<sub>2</sub> is able to improve PaO<sub>2</sub> (and SaO<sub>2</sub>) in states where  $\dot{V}/\dot{Q}$  mismatch is the primary pathophysiology, while it has limited effect in situations where there is a large shunt. If the shunt is more than 30% of the  $\dot{Q}$ , O<sub>2</sub> supplementation has less effect in improving the PaO<sub>2</sub>. However, decreasing the F<sub>I</sub>O<sub>2</sub> will drastically lower the PaO<sub>2</sub> due to the effect on alveoli that are participating in gas exchange.

**Figure 20** For an otherwise healthy subject, the thick horizontal line shows the extent to which oxygen delivery can be reduced without reducing oxygen consumption and causing signs of cellular hypoxia (supply independent oxygenation). Below the postulated critical delivery, oxygen consumption becomes supply-dependent and there are signs of hypoxia. *Source:* From Ref. 1.

## EYE TO THE FUTURE

Technological advancements are significantly contributing to our understanding of biological processes. Completion of

the human genome project has been a major development and is fueling research at a level which was incomprehensible a decade ago. Evaluation of gene activation and responses to specific stimuli, which was studied one gene at a time, is now being studied at the whole genome level using microarray and other technologies. Currently data is being generated at unprecedented levels adding to the understanding and complexities of biological processes. It is also being recognized that the evaluation of proteins (proteomics) and interaction of proteins and genes (interactomes) are equally important. Variations in biological responses are being linked to differences in specific genes. Alterations in nucleotide composition of genes, single nucleotide polymorphisms (SNPs), are being linked to variations in biological activity and pathological predispositions.

One area of pulmonary physiology that has seen great advancement in our understanding in the last decade is pulmonary vascular physiology. This is also an area where these new gene-based technologies are likely to be employed. The pulmonary vasculature is affected by many pathological processes (chronic obstructive pulmonary disease, acute respiratory distress syndrome, collagen vascular disease, pulmonary embolism, etc.), which lead to secondary pulmonary hypertension, culminating in acute and chronic right heart failure. Pulmonary hypertension and right heart failure are difficult to treat. Better understanding of mechanisms that lead to pulmonary hypertension are the focus of significant research. The exact mechanism of hypoxic pulmonary vasoconstriction, which is central to the development of acute and chronic pulmonary hypertension, continues to remain elusive (86,87). The recently described role of carbon monoxide in oxygen sensing/transduction mechanism in carotid glomus cells adds a new dimension to possible mechanisms of oxygen-sensing and hypoxic ventilatory control (88). Similar pathways may be involved in hypoxic pulmonary vasoconstriction; however, that remains to be determined.

Elucidation of the mechanisms by which the pulmonary vascular system is formed, maintained, or disrupted during development and disease represents a major challenge in contemporary lung biology. Though it is appreciated that processes involving cellular proliferation, differentiation, and apoptosis need to be carefully coordinated, knowledge of the underlying cellular and molecular mechanisms involved is limited. Discovery of homeobox genes represents a definitive advance in this area (89). However, the specific role of these genes in lung organogenesis and tissue remodeling is in its infancy. Many research initiatives are currently active to develop a systematic approach to biological processes integrating molecular, cellular, and interactive processes.

As molecular biology techniques have progressed, so have advances in the complexity and accessibility of imaging techniques. It is now possible to study physiological and pathological phenomenon noninvasively in vivo in animals and humans. High-resolution computed tomography (CT) scans and PET scanning are helping us test long-held hypotheses and theories. Functional MRI techniques are allowing us to better delineate areas of the brain responsible for specific physiological functions. Such studies will help us understand respiratory control mechanisms and sleep-related disorders.

## SUMMARY

The primary purpose of the respiratory system is to facilitate the uptake of  $O_2$  in the alveoli, where it combines with hemoglobin and is transported throughout the body by the

circulatory system, while at the same time removing  $CO_2$  which has been transported from the tissues to be exhaled via the alveoli. These functions are achieved by intricate coordination of the upper and lower airways, alveoli, pulmonary blood flow, respiratory muscles, metabolic sensors, and medulla-based neural control centers.

Cardiac and respiratory functions are also closely integrated with numerous feedback mechanisms designed to match ventilation with perfusion. The lungs and the heart are the only organs that receive full  $Q$ . Accordingly, the lungs are anatomically well situated to perform many of the secondary (nonpulmonary) functions. The list of nonpulmonary functions continues to grow. Pulmonary and nonpulmonary functions adapt to constantly changing needs of the body. They also vary significantly with age and pregnancy. Understanding the basic physiological mechanisms involved in pulmonary and nonpulmonary functions of the lungs is the key to appreciating pathophysiology of respiratory disorders and rational management of respiratory function following trauma, resuscitation, perioperative management, and critical care.

## KEY POINTS

- ☞ The FRC has important clinical significance as it is the major reservoir of oxygen in the body and is directly related to the time to desaturation following apnea. In addition, the FRC is inversely proportional to the degree of shunt.
- ☞ Alveolar ventilation ( $\dot{V}_A$ ) is referred to as the gas that participates in gas exchange; the amount of ventilation that is wasted is referred to as physiologic dead space ventilation ( $\dot{V}_D$ ).
- ☞ The formula for compliance is analogous to the mathematical formula used to calculate capacitance in electronics.
- ☞ Factors that affect airway resistance include lung volume, bronchial smooth muscle tone, carbon dioxide, and the density/viscosity of the inhaled gas.
- ☞ Blood flow has to be closely coupled to adequate ventilation to allow for optimal exchange of  $O_2$  and  $CO_2$ .
- ☞ Unlike systemic vessels, pulmonary vessels constrict in response to hypoxia, hypercarbia, and acidosis.
- ☞ Under typical resting conditions, the RBC  $PO_2$  virtually reaches that of alveolar gas when it is about one-third of the way along the capillary.
- ☞ Increased  $O_2$  affinity shifts the oxy-heme curve to the left (i.e., reduces  $P_{50}$ ), while decreased  $O_2$  affinity shifts the oxy-heme curve to the right (i.e., increases  $P_{50}$ ).
- ☞  $CO_2$  is transported in the blood primarily in three different forms, namely: (i) physically dissolved in blood; (ii) bound to amino groups of proteins (e.g., hemoglobin), as carbamate compounds; and (iii) as bicarbonate ions.
- ☞ Autonomous respiratory pattern is generated in the medulla by synchronized activity of six distinct neuronal groups (central pattern generator, CPG).
- ☞ The central chemoreceptors play an important role in monitoring  $pCO_2$ , while the peripheral chemoreceptors which reside in the carotid body respond predominantly to changes in  $pO_2$ .
- ☞ Age-related loss of pharyngeal muscle support leads to an increased propensity for upper airway obstruction. Furthermore, loss of dentition makes establishment of patent airway by bag and mask more difficult.

Due to the increase in alveolar ventilation, which is more than the increase in  $\dot{V}O_2$ , the  $P_{A}O_2$  is higher than normal, and the  $P_{a}CO_2$  decreases to 30 mmHg during the first trimester of pregnancy whereas the pH remains normal.

## Cardiovascular Physiology Review

Gerard R. Manecke, Jr. and David M. Roth

Section of Cardiothoracic Anesthesia, Department of Anesthesiology,  
UC San Diego Medical Center, San Diego, California, U.S.A.

### INTRODUCTION

A firm knowledge of cardiovascular physiology is necessary for the effective management of the critically ill. A complex interplay between compromised hemodynamic status, metabolic derangement, and preexisting cardiovascular disease is often present (Fig. 1). Thus, an appropriate diagnosis and treatment require an understanding of the cardiovascular signs and symptoms of acute catastrophic illness, as well as those associated with preexisting cardiovascular disease. Patients requiring intensive care and/or resuscitation frequently are unable to provide a complete history or cooperate for a comprehensive physical examination. Thus, the skillful use of the physiologic data, both invasive and noninvasive, is essential.

This chapter reviews the fundamentals of cardiovascular physiology directly applicable to the anesthetic and intensive care management of critically ill trauma victims. The relationships between physiologic processes and hemodynamic data are emphasized, since these are important components of critical care to some extent. First, the heart's pumping mechanism is presented. Mechanical functions of the myocardium and vasculature are reviewed, as are the effects of vascular tone on cardiac filling and performance. Second, cardiac myocyte metabolism, with particular emphasis on myocardial oxygen balance, is discussed, followed by reviews of cellular electrophysiology, cardiac electrical conduction, and a discussion of common mechanisms for dysrhythmia development. Finally, the physiologic aberrations associated with representative traumatic conditions are briefly presented. These include massive blood loss (hypovolemia), cardiac tamponade, pneumothorax, cardiac contusion, and head trauma. Although these clinical examples are presented in detail elsewhere in this book, they are presented in this instance to illustrate the application of physiologic principles to the clinical arena. It is hoped that these brief discussions will encourage the reader to approach the cardiovascular problems in patients who are critically ill from a "physiologic perspective."

### THE PUMPING MECHANISM OF THE HEART AND MECHANICS OF THE VASCULAR SYSTEM

#### The Flow of Blood in the Cardiovascular System

In 1628, the great English physician William Harvey provided the first modern description of the human circulatory system (1,2). As he described, it consists of two pumps and a system of vessels and capillaries arranged in series (Fig. 2). The left side pump (left ventricle) ejects blood to the systemic

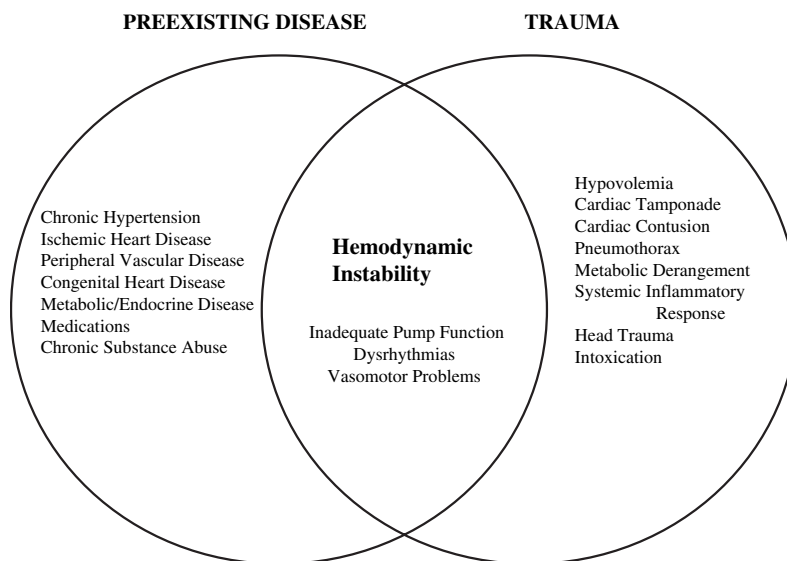

circulation, whereas the right side pump (right ventricle) ejects blood under relatively low pressure (approximately 1/6 systemic) to the pulmonary vasculature. Amazingly, the two pumps are housed in the same unit, functioning in a completely synchronous manner. The atria and the ventricles are adjacent to one another, sharing the septae that separate them. Thus, changes in geometry and function on one side have profound effects on the other. ⚡ **Cardiac contraction is a complex three-dimensional event.** ⚡ Each ventricle ejects its volume in a remarkably complex way, with concentric contraction (short axis), a rotating "wringing" motion, long axis contraction with downward movement of the mitral and tricuspid annuli, and contraction of the papillary muscles (3–5). With papillary muscle contraction, the atrio ventricular valvular leaflets become properly aligned in order to prevent regurgitation.

The performance of the heart is under local, humoral, and neural control. Intrinsic response to chamber filling, hormonal influence, and autonomic innervation combine to provide the mechanisms for the heart's response to changes in demand.

#### Local Control of Cardiac Function

The most significant local factor is chamber filling, which is related to the diastolic ventricular compliance and "venous return." The mechanism by which the myocardium increases its performance (stroke work) in response to increased diastolic volume is known as the Frank-Starling mechanism. ⚡ **The Frank-Starling mechanism causes enhanced myocardial performance when cardiac filling is increased.** ⚡ Stretch of myocardial fibers caused by increased chamber volume causes increased contractile force. This increased force results from improved alignment of actin and myosin filaments in the sarcomeres (Fig. 3), which results in the ejection of the extra volume, enhanced myocardial contractility, and increased myocardial oxygen consumption. This mechanism has a limit, however. The slope of the ventricular function curve depends on baseline myocardial performance. When volume is added, the curve eventually reaches a plateau, above which increases in performance do not occur (Fig. 4).

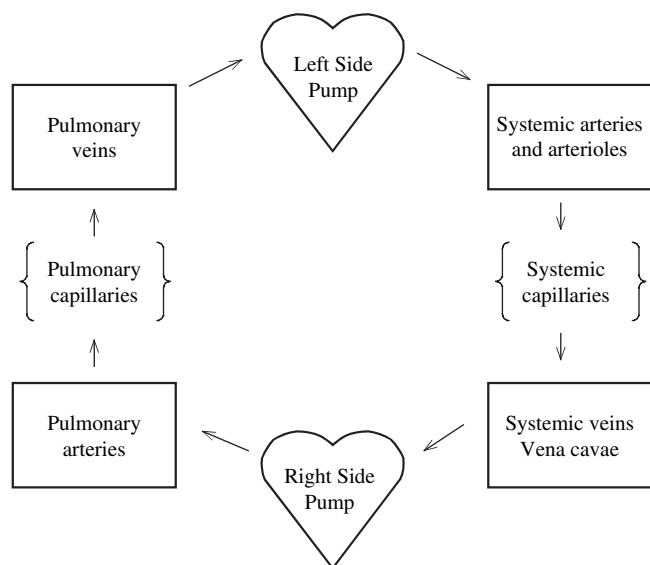

Increase in afterload (impedance to ejection) usually represents a rise in systemic vascular resistance (SVR). ⚡ **The healthy heart responds favorably to meet the demand of increased SVR, without exhibiting a decrease in output until the mean arterial pressure (MAP) is greater than 160 mmHg (6).** ⚡ When under physiologic stress and varying loading conditions, however, the heart can become quite sensitive to changes in afterload. Indeed, in the clinical setting, pharmacologic manipulation of afterload can be an effective

**Figure 1** The interrelationship between preexisting cardiovascular disease and cardiovascular compromise resulting from trauma.

means of influencing cardiac function. For example, in the setting of high afterload, vasodilation can significantly augment cardiac output without increasing myocardial oxygen consumption (7-9). **Although vasodilation will augment cardiac output in the setting of high SVR, it may also decrease perfusion pressure to the needy tissue beds, including the coronary arteries.**

In the interpretation of hemodynamic monitoring data, it must be remembered, "pressure is not analogous to volume." For example, when interpreting the central venous pressure (CVP), we tend to equate a high CVP to a "full" right atrium and ventricle, and a low pressure as an "empty" heart. In reality, a high CVP can be obtained in several clinical situations where the heart is actually empty (e.g., tamponade, noncompliant right ventricle, etc.).

**Figure 2** A schematic of the cardiovascular system, illustrating that the right and left sides of the circulation are arranged in series.

The relationship between venous return and right atrial pressure is shown in Figure 5. When the heart fails and  $\dot{Q}$  falls below venous return, right atrial pressure rises. In Figure 5, the venous return curve is flat for right atrial pressures less than zero. As the right atrial pressure increases (at a fixed capillary tone, intravascular volume,  $\dot{Q}$ , and contractility), the venous return decreases.

**Figure 3** The Frank-Starling mechanism: force of contraction depends upon sarcomere length. Improvement in performance associated with volume administration results from a transition from area "3" to area "2." Area "1" occurs when excessive stretching of fibers causes inadequate overlap of actin and myosin filaments. This overstretch condition (Area 1) seldom occurs in vivo in mammalian species. However, it can be seen in the laboratory (e.g., frog muscle prep). *Source:* From Ref. 44.

**Figure 4** The Frank-Starling mechanism at work in the intact circulatory system. Movement from A to B results from volume loading in hypovolemia, B to D from volume overload in the dysfunctional heart, and B to C from inotropic support. *Source:* From Ref. 45.

However, under the same steady-state conditions of contractility, the addition of one liter of blood to the system would result in an increased  $\dot{Q}$  and venous return (Fig. 5). Pressure may often be useful as surrogate measurement for volume or filling, but there are numerous clinical situations in which this relationship breaks down. Examples, such as cardiac tamponade and tension pneumothorax, are discussed later.

**The Cardiac Work Loop: “Pressure Work” and “Volume Work”**

Ohm’s law (Equation 1) for electricity can be applied to the global mechanics of the cardiovascular system:

$$E = I * R \tag{1}$$

**Figure 5** The interplay between right atrial pressure and venous return. Venous return is a function of venous capacitance, intravascular blood volume, cardiac output, and right atrial pressure. When venous capacitance, intravascular blood volume, and cardiac output are all stable and normal, venous return decreases linearly as the right atrial pressure increases above zero. When the pressure in the atrium becomes equal with the mean systemic venous pressure (point x), venous return ceases. If the cardiovascular system was augmented with a transfusion of one liter of blood (e.g., in a 70-kg patient, goes from 5 to 6 L), the cardiac output would increase as would the venous return. The new point x (at which venous return would diminish to zero) might be as high as 16 mmHg. *Source:* From Ref. 10.

where  $E$  is the voltage,  $I$  the current, and  $R$  the resistance. If one considers pressure in the vascular system to be analogous to voltage, and flow analogous to current, then Equation 2 results for the vascular system:

$$\Delta P = \dot{Q} * R \tag{2}$$

where  $\Delta P$  is the pressure drop across the system,  $\dot{Q}$  the flow through the system, and  $R$  the resistance to blood flow through the system. The formulae for calculating the pulmonary vascular resistance (PVR) and SVR are simply algebraic modifications of the aforementioned formula:

$$R = \frac{\Delta P}{\dot{Q}} \tag{3}$$

In Equation 3, Ohm’s law is restated in an algebraic equation that is the solution to obtain the resistance. In clinical practice the resistance calculated this way is either PVR or SVR.

$$PVR = \frac{MPAP - P_{pao}}{\dot{Q}} \tag{4}$$

Equation 4 is the formula used to provide the solution for PVR. In this situation the  $\Delta P$  is mean pulmonary artery pressure (MPAP) deducted from pulmonary artery occlusion pressure ( $P_{pao}$ ). When calculated this way, results are expressed as Wood’s units.

$$PVR = \frac{MPAP - P_{pao}}{\dot{Q}} * 80 \tag{5}$$

(units in dynes  $cm^{-5}sec^{-1}$ )

Equation 5 converts the units into dynes  $cm^{-5} sec^{-1}$  by multiplying Equation 4 by 80.

$$SVR = \frac{MAP - CVP}{\dot{Q}} * 80 \tag{6}$$

Equation 6 solves for SVR. MAP, CVP, and 80 is the multiplied conversion factor required to yield the standard units (dynes  $cm^{-5} sec^{-1}$ ).

☞ **The pulmonary vascular system is a low-pressure, high-compliant network in health, with pressures approximately 1/10 systemic.** ☞ A normal cardiac work loop is shown in Figure 6. The amount of work the heart does in one cycle is the “stroke work,” and can be calculated by determining the area of the work loop. This could be estimated by drawing a similar rectangle and multiplying the change in x axis (volume) by the change in y axis (pressure).

$$Work = energy = pressure * volume \tag{7}$$

Thus, one component of the cardiac work provides pressure generation, and the other volume ejection (Equation 7). In hemodynamic management, it is often necessary to balance these two factors. For instance, if most of the heart’s energy is invested in pressure generation, then there may not be sufficient flow to support the oxygen requirements of the body. Likewise, if the heart generates high volume but very low pressure (as occurs in low SVR states), the pressure generated may not be sufficient for adequate peripheral perfusion to organs such as the brain, liver, kidneys, or the myocardium itself.

**Figure 6** The left ventricular cardiac work loop. The area inside the shape A-B-C-D equals the work performed by the left ventricle during one cycle. At "A," the mitral valve opens. At "B" the mitral valve closes and the ventricle begins to contract. At "C" the aortic valve opens, and at "D" the aortic valve closes.

### The Effect of Respiration on Circulatory Mechanics

It has long been known that systemic blood pressure varies during each respiratory cycle. During spontaneous inspiration, blood pressure (BP) normally decreases. This is because the highly compliant pulmonary venous bed expands during enlargement of the chest cavity, and pulmonary venous pressure drops causing decreased venous return to the left side of the heart. Simultaneously, the venous return to the right side of the heart increases because of the negative intrathoracic pressure. When pathologic processes occur which impede cardiac filling, such as cardiac tamponade and constrictive pericarditis, this normal drop in BP with inspiration is exaggerated. The resultant drop of more than 10 mmHg is called "pulsus paradoxus" (11,12).

As Figure 7 indicates, this decrease is accompanied by the concomitant decrease in CVP and pulmonary artery pressure (PAP). When patients receive positive pressure ventilation, a reciprocal phenomenon occurs. Positive intrathoracic pressure "squeezes" pulmonary venous blood into the left side of the heart, initially raising systemic BP and left

ventricular output. This notion is supported by the echocardiographic demonstration that both transmitral early flow and pulmonary venous flow increase during mechanical inspiration (13). The rise in intrathoracic pressure is also thought to decrease left ventricular afterload, thereby facilitating the flow of blood to the periphery (14). Simultaneously, venous return to the right side is decreased.

If the increased intrathoracic pressure is sustained for a couple of additional beats, the BP drops, reflecting the decrease in right sided venous return and increased right ventricular afterload. The magnitude of cyclical variation in BP variation reflects the filling of the heart, and can be used in the assessment of volume status (15). Figure 8 depicts the respiratory variation in arterial blood pressure with positive pressure ventilation. "Δ Up" refers to the rise in systolic pressure above baseline during positive pressure inspiration, and "Δ down" refers to the drop in pressure below baseline that occurs with the next couple of heart beats.

✎ The "Δ down" component of the systolic blood pressure variation with ventilation is quite sensitive in detecting hypovolemia. ✎ In many patients it is possible to use the "Δ down" as a surrogate for PCWP (16). Caution should be exercised, however, since such variations may also depend on other factors such as ventilatory pressure, ventilatory volume, and vasodilator therapy (17,18). The ventilation-induced changes in BP, pulmonary artery pressure, and CVP have led clinicians to make these pressure measurements at the "end-exhalation" point of the ventilatory cycle (19). This minimizes the effect of ventilation, as well as allows for consistency between measurements.

### Neural Control of Cardiovascular Function

The heart (and entire cardiovascular system) responds to autonomic influences from both the sympathetic and parasympathetic nervous systems.

The parasympathetic innervation of the heart is via the vagus nerve, which profoundly affects automaticity in the sinoatrial (SA) node, as well as conduction and automaticity in the atrioventricular (AV) node. The vagus nerve (cranial nerve X) originates at the floor of the fourth ventricle as the dorsal vagal nucleus, sending afferent and efferent fibers through the medulla. It receives efferent fibers from the vasomotor center in the brainstem, and its end-organ ganglionic synapses are muscarinic.

The primary cardiovascular influences of the vagus nerve are to decrease heart rate and decrease conduction through the AV node. Also, particularly strong vagal

**Figure 7** Spontaneous forceful inspiration causes simultaneous decreases in arterial pressure, pulmonary artery pressure, and central venous pressure. *Abbreviations:* ART, arterial pressure; CVP, central venous pressure; ECG, electrocardiogram; PAP, pulmonary artery pressure. *Source:* From Ref. 19.

**Figure 8** Variation in arterial blood pressure with positive pressure ventilation. “1” is at baseline, “ $\Delta$  Up” is the rise in systolic pressure during a positive pressure breath, and “ $\Delta$  Down” is the decrease in systolic pressure occurring after a positive pressure breath. *Abbreviation:* ART, arterial pressure. *Source:* From Ref. 19.

stimulation can have a negative inotropic effect on both the atria and the ventricles. The parasympathetic system exerts relatively minor influences on vascular tone.

Sympathetic innervation of the heart is via the “cardiac accelerator fibers,” which exit from the thoracolumbar sympathetic chain at spinal vertebral levels T1–T4. These postganglionic neurons release norepinephrine, primarily causing stimulation of the cardiac  $\beta_1$  receptors. The  $\beta_1$  receptors have dramatic positive chronotropic and inotropic effects on the heart, via a cyclic adenosine monophosphate (AMP) mediated mechanism. **The heart and vasculature are under the constant influence of the autonomic nervous system. The resulting cardiac output and systemic blood pressure continuously reflect the intravascular blood volume and the relative parasympathetic and sympathetic “tone.”**

Cardiovascular stress, central nervous system activity, anesthesia, and other exogenous substances can profoundly alter the respective “tones” of both the sympathetic and parasympathetic systems.

### Humoral Control of Cardiovascular Function

Under stressful circumstances, catecholamines (epinephrine and norepinephrine) are released into the circulation by the adrenal medulla. Epinephrine has primarily  $\beta$  agonist activities, although in high concentrations it exhibits  $\alpha$  activity as well. The  $\beta_1$  receptors are found in the heart and mediate positive inotropic, chronotropic, and dromotropic (conduction) activities. The  $\beta_2$  receptors are found throughout the peripheral vasculature, mediating vasodilatation. Norepinephrine is a potent  $\alpha$  and  $\beta$  agonist. Stimulation of peripheral  $\alpha$  receptors ( $\alpha_1$ ) causes vasoconstriction whereas central  $\alpha$  receptor agonism yields a decrease in the sympathetic output from the central nervous system. The preponderance of effect of norepinephrine is on the peripheral  $\alpha$  receptors. The  $\alpha_1$  and  $\alpha_2$  receptors have been discovered in the coronary vasculature, located primarily in the epicardial conduit vessels (20,21). Under normal circumstances, these receptors appear to have little effect on coronary vascular tone. However, they may be important in mediating coronary vasoconstriction in patients with ischemic heart disease or vasospastic angina (21). Although minor increases in coronary vascular tone may occur after administration of alpha adrenergic agonists (22), a current Medline search reveals no reports of vasospastic ischemia precipitated by the clinical use of  $\alpha_1$  or  $\alpha_2$  agonists.

## CARDIAC CELLULAR PHYSIOLOGY

### Cellular Homeostasis and Excitation–Contraction Coupling

Cardiac muscle exhibits characteristics of both smooth and striated muscle. Morphologically it is more similar to

striated muscle, but differs from it in that it exhibits intrinsic automaticity and a longer action potential. The mechanism of cardiac muscle contraction is similar to that of skeletal muscle, and has been reviewed in detail in numerous physiology texts (23).

Contraction depends on a mechanism consisting of actin and myosin filaments as well as an interlacing sarcoplasmic reticulum (Figs. 9 and 10). Depolarization of the sarcoplasmic reticulum causes intracellular calcium release, which results in interaction of the myosin and actin filaments. This interaction, regulated by troponin I, T, and C, as well as tropomyosin, involves the swiveling of the myosin heads, and results in the sliding of actin and myosin filaments past one another. This process is known as “excitation–contraction coupling.” The subsequent breakage of the actin–myosin linkage requires energy [adenosine triphosphate (ATP)], as does the calcium pump maintaining the intracellular sarcoplasmic calcium gradient.

**When a myocardial energy deficit occurs, actin and myosin bridges fail to break, resulting in inability of the muscle to relax.** This is one of the mechanisms for diastolic dysfunction (stiffness) and, ultimately, the mechanism for the rigor mortis to set in. The entire process of excitation–contraction coupling is modulated by a complex G-protein system, which involves cyclic guanosine monophosphate (GMP), cyclic AMP, protein kinase A, and troponin.

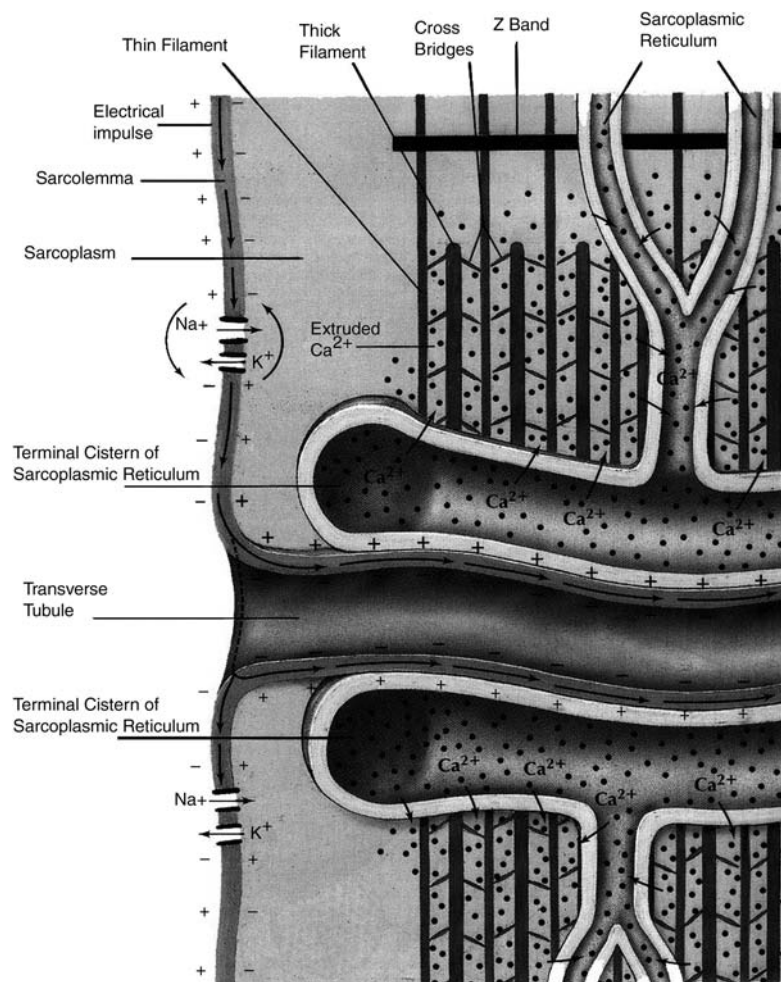

When energy or oxygen deficits occur, homeostatic and excitation–contraction coupling mechanisms break down. This results in cellular acidosis and cardiac failure (systolic and diastolic). It is also important to remember that the heart lives in the same metabolic milieu as the rest of the body. **Metabolic derangements resulting from abnormalities such as sepsis, systemic inflammatory response, hypovolemia, and diabetes can have devastating effects on the myocardium as well as other organs and tissues.** Obviously, cardiac dysfunction resulting from these aberrations responds best to their correction, when possible.

### Myocardial Oxygen Balance

The myocardium is designed for endurance, beating approximately 42 million times per year. Although it is magnificently efficient, it functions with a very high oxygen requirement. The heart extracts a maximal amount of oxygen from the coronary arterial blood, resulting in coronary sinus oxygen content of only 10 mg/dL. For this reason, it is extremely sensitive to perturbations in its oxygen supply/demand relationship. The left ventricular myocardium receives blood supply during diastole only, so its perfusion is dependent upon diastolic time. Coronary

**Figure 9** Muscle contraction results from actin and myosin filaments sliding past one another. This “sliding filament” mechanism is dependent upon formation of actin–myosin crossbridges, swiveling of the myosin filaments, and subsequent breakage of the crossbridges. *Source:* From Ref. 45.

**Figure 10** The anatomic physiologic relationships between the sarcolemma, sarcoplasmic reticulum, and contractile mechanism. *Source:* From Ref. 47.

perfusion pressure (CPP) for the left ventricular myocardium can be estimated using the formula:

$$\text{CPP} = \text{DBP} - \text{LVEDP} \quad (8)$$

where DBP is the diastolic blood pressure and LVEDP the left ventricular end diastolic pressure. Autoregulatory mechanisms maintain constant coronary blood flow when the perfusion pressure is between 50 and 150 mmHg. When coronary stenoses occur, however, autoregulatory mechanisms may break down, leaving coronary perfusion completely dependent on driving pressure (Fig. 11).

Tachycardia and bradycardia have opposite effects on coronary artery perfusion. Left ventricular perfusion occurs almost exclusively during diastole. An increase in heart rate will decrease the diastolic (coronary artery perfusion) time while increasing the amount of ATP used per minute (increased beats/min), because energy is required for each heart beat. ⚡ **Accordingly, the heart rate is by far the most significant factor in myocardial oxygen balance.** ⚡ The determinants of myocardial oxygen supply and demand are summarized in Table 1.

The aspect to be kept in mind is that, some of the very factors that are associated with enhanced myocardial performance, such as increased preload, increased contractility, and increased heart rate, cause an increase in oxygen demand. Even decreased afterload, which is a favored means of enhancing myocardial performance without increasing myocardial work, can cause oxygen balance problems by decreasing CPP. Thus, therapeutic maneuvers designed to enhance cardiac performance must always be undertaken with the concomitant effects on oxygen balance in mind. Likewise, efforts to decrease myocardial work such as beta blockade administration, and to increase CPP (peripheral vasoconstriction with vasopressin or  $\alpha_1$  agonists) may precipitate a significant decrease in systemic perfusion. ⚡ **In trauma and critical care management, a constant effort is made to balance the metabolic needs of the systemic tissues with the metabolic needs of the myocardium.** ⚡

**Figure 11** Autoregulation normally maintains constant coronary blood flow between perfusion pressures of 50 and 150 mmHg (A). When coronary stenoses occur, coronary blood flow becomes completely pressure dependent (B).

Source: From Ref. 44.

**Table 1** The Determinants of Myocardial Oxygen Supply and Demand

Oxygen supply	Oxygen demand
1/Heart rate (duration of diastole)	Heart rate
$\text{CPP} = P_{\text{CA}} - P_{\text{LVi}}$	Preload
Coronary patency	Afterload
Oxygen delivery	Contractility
Oxygen availability	Basal metabolic rate
Myocardial blood flow distribution	Activation energy

Note: "Activation energy" refers to the energy required for myocardial relaxation. During systole the  $P_{\text{LVi}}$  exceeds the  $P_{\text{CA}}$  and blood actually flows retrograde out of the heart muscle through the coronary arteries and into the aorta, whereas during diastole the pressure in the aorta (and coronary arteries) is far greater than the  $P_{\text{LVi}}$  promoting perfusion of the left ventricular myocardial tissues.

Abbreviations: CPP, coronary artery perfusion pressure;  $P_{\text{CA}}$ , coronary artery pressure (the aortic blood pressure can be used as a surrogate for this value when the coronary arteries are without plaque/stenosis > 70%);  $P_{\text{LVi}}$ , left ventricular intracavitary pressure.

## CARDIAC ELECTROPHYSIOLOGY

The heart contains cells that have intrinsic electrical automaticity resulting from spontaneous depolarization. These cells, which include the nodal cells (SA and AV), conduction fibers, and Purkinje fibers, make up the cardiac electrical system. The automaticity, together with the conduction characteristics and anatomical configuration of the "wiring," combine to produce atrioventricular contraction which is automatic, sequential, and coordinated.

### Cellular Electrophysiology and the Cardiac Action Potential

Nodal cells have a resting membrane potential of  $-55$  mV, which is maintained primarily by a potassium concentration gradient across the cell membrane. The effect of this concentration gradient on the transmembrane potential is quantified by the Nernst equation (Equation 9):

$$\text{EMF} = -61 * \log \frac{[K_i]}{[K_o]} \quad (9)$$

where EMF is the electromotive force in millivolts. As with other cells, the inside of the cell membrane is negative relative to the outside. The potassium gradient is maintained by a  $\text{Na}^+\text{-K}^+\text{-ATPase}$  membrane pump. Nodal cells are unique in that they depolarize because of a slow inward calcium flux, rather than a rapid conductance of sodium (Fig. 12). This is because voltage-dependent sodium gates are inoperative at this relatively high (less negative) resting membrane potential. Automaticity of the cells results from the spontaneous "phase 4 depolarization," which is caused primarily by steady background calcium conductance ( $\text{T-Ca}^{2+}$  channels) (24,25) as well as sodium leakage. This raises the membrane potential to  $-40$  mV, at which time  $\text{L-Ca}^{2+}$  channels open fully.

Repolarization results from outward potassium flux ("delayed rectifier"). Ionic concentrations are restored by membrane ion pumps. The action potentials of SA nodal cells are similar to those of AV nodal cells, except the phase 4 depolarization of SA nodal cells is more rapid.

**Figure 12** The action potential morphologies of nodal cells and ventricular myocytes. Nodal cells exhibit phase 4 depolarization, which likely results from gradual sodium leak and calcium influx. Phase 1 is caused by calcium influx. Ventricular myocytes exhibit a “phase 0,” resulting from rapid sodium influx. Phase 2 represents a balance between calcium influx and potassium efflux, and phase 3 repolarization is caused by unopposed potassium efflux. *Abbreviation:* SA, sinoatrial. *Source:* From Ref. 47.

Thus, under normal circumstances, the SA node is the instigator of cardiac electrical activity. The conducting fibers, Purkinje fibers, and ventricular muscle cells all exhibit a fast  $Na^+$  influx (phase 0 depolarization) followed by a plateau. The rapid depolarization results in rapid action potential propagation. These cells normally exhibit very slow phase 4 depolarization. To illustrate the rate of beats per minute, SA nodal spontaneous rate is typically 60 to 100 beats per minute (BPM), AV nodal rate 40 to 60 BPM, and ventricular escape rate 30 to 40 BPM.

### The Normal Cardiac Conduction System

The cardiac conduction system consists of the SA nodal cells, internodal pathways, left and right bundle branches, and the Purkinje fibers. This arrangement is depicted in Figure 13. The action potential initiated at the SA node is propagated via the internodal fibers to the AV node. Branches of the internodal fibers depolarize the atrium, resulting in atrial contraction and the “P” wave on the electrocardiogram (ECG) trace. From the AV node, the action potential travels

**Figure 13** The cardiac conduction system. Action potentials are generated at the sinus node, travel via internodal pathways to the A-V node, and then are distributed to the ventricles via the left and right bundle branches. *Source:* From Ref. 46.

along the common His bundle, the right and left bundle branches, and Purkinje fibers to the ventricular muscle. The depolarization pattern of the ventricles results in the “QRS” complex seen on the ECG trace.

Repolarization of the ventricles, resulting from outward potassium flux, results in the “T” wave. The direction of current at various points in the cycle causes the characteristic morphologies in each lead. The 12-lead ECG trace demonstrates these morphologies and allows anatomic placement of electrical abnormalities.

### The Pathophysiology of Common Dysrhythmias

Two common mechanisms of cardiac dysrhythmias are reentry and ectopic foci. Reentry results from slowing of conduction along one of the two divergent electrical paths (changes depicted in Fig. 14). If a conducting pathway branches, and the diverging branches reconnect, then under conditions of conduction slowing (or blockade) in one limb of a bifurcating pathway, the conduction can proceed to retrograde through the previously blocked pathway and reenter the initial pathway. This process sets up a “circuit” movement through the loop of cardiac tissue. A further prerequisite for this condition is a refractory period long enough to allow the completion of the refractory period (in the initially blocked limb of the circuit) prior to the return of the impulse. This “circuit” movement or “reentry” phenomenon is thought to be the mechanism for a wide variety of tachydysrhythmias, including atrial fibrillation, atrial flutter, and ventricular fibrillation (26,27).

Ectopic foci usually occur at irritable areas of myocardium or conduction. These areas can result from myocardial ischemia, infarction, cardiac contusion, and mechanical irritation. Ectopic foci may result in premature atrial contractions, premature ventricular contractions, and reentrant dysrhythmias (28). ⚡ **Various electrolyte abnormalities, such as hypokalemia (29,30) and hypomagnesemia (31), particularly when they occur together (32), as well as hypocalcemia (33) increase the likelihood of cardiac dysrhythmias.** ⚡ Enhanced atrial and ventricular excitability and prolonged Q-T interval are often part of the pathogenesis. For example, hypocalcemia causes prolongation of the Q-T interval, and hypokalemia potentiates dysrhythmias caused by Q-T prolongation (34). Q-T prolongation predisposes to the “R on T” phenomenon, which leads to reentry dysrhythmias.

**Figure 14** The mechanism of reentry. The figure demonstrates four conditions (A–D) required for reentry. (A) Two pathways with differing conductivity (or refractory periods) that can form a closed electrical loop. (B) Unidirectional block in one pathway (dark stippled area). (C) Sufficient length in the circuit, or slow enough conduction, to allow recovery of previously blocked pathway. (D) Passage through blocked pathway and “reentry” into the initially open pathway sets in motion the “circus” rhythm. *Source:* From Ref. 48.

When dysrhythmias occur in trauma victims, every effort should be made to correct electrolyte and acid base abnormalities, aggressive antidysrhythmic treatment should be undertaken, and clinical suspicion for myocardial contusion should increase. Combinations of abnormalities, for example hypokalemia with hypomagnesemia, can be particularly troublesome.

### THE CARDIAC CYCLE AND THE CENTRAL VENOUS WAVEFORMS

Understanding the information obtained from invasive intravascular monitors such as transesophageal echocardiography, CVP, and pulmonary capillary wedge pressure (PCWP) requires familiarity with the timing of events in the cardiac cycle (Fig. 15). Left and right ventricular ejections result in the systemic arterial and pulmonary arterial waveforms respectively. The aortic valve closure results in the aortic valve closure (aortic, pulmonic).

Pressure changes in the heart and vasculature are preceded by their associated ECG tracing (Fig. 16). The venous pressure wave in the right atrium and superior vena cava result from mechanical events on the right side of the heart (right ventricle, tricuspid valve), and the venous waveforms of the left atrium and PCWP result from the left side (left ventricle, mitral valve).

Atrial depolarization results in atrial contraction, which in turn causes the “a” wave of the central venous waveforms. Right atrial contraction, which produces the “a” wave on the

**Figure 15** The cardiac cycle. Electrocardiographic (ECG) changes are shown below, and the pressure tracings for the left atrium, left ventricle, and aorta are shown above. 1 refers to the beginning of isovolumic ventricular contraction, 2 the opening of the aortic valve, 3 the closure of the aortic valve, and 4 the diastole. a, c, v, x, and y signify the components of the venous waveform (see text), and P, Q, R, S, and T refer to the components of the ECG waveform. *Source:* From Ref. 19.

**Figure 16** The cardiac cycle and genesis of “a,” “c,” and “v” waves. The “a” wave is caused by atrial contraction. The “c” wave is caused by the bulging of the atrioventricular (AV) valve into the atrium during isovolemic ventricular contraction. The “v” wave is caused by passive venous filling of the right atrium prior to the opening of the AV valve. The “x” descent is due to ventricular decompression following the opening of the ventricular outlet (which allows the AV valve to retract back toward the ventricle). The “y” descent is due to the opening of the AV valve. Mechanical pressure events in the right atrium are slightly delayed relative to the electrical events in the electrocardiogram. *Abbreviations:* CVP, central venous pressure; ECG, electrocardiogram; P, atrial depolarization; R, ventricular depolarization; T, ventricular repolarization. *Source:* From Ref. 19.

**Figure 17** The electrocardiograph tracing, plethysmograph, arterial, and central venous waveforms obtained from a patient with severe tricuspid regurgitation as noted on transesophageal echocardiography. Notice the “c-v” waves of regurgitation precede the systemic arterial upstroke. This illustrates that regurgitant waves are a systolic event. The arterial upstroke in this patient is delayed because of poor cardiac performance. The CVP tracing is in gray tone, the arterial in white. The traces overlap because the CVP scale is 30 mmHg, and the arterial is 120 mmHg. *Abbreviations:* CVP, central venous pressure; EKG, electrocardiograph tracing; PLETH, plethysmograph.

CVP waveform, precedes left atrial contraction. This is because the sinus node is in the wall of the right atrium adjacent to the superior vena cava, and atrial depolarization spreads from that point across the right atrium to the left atrium. Isovolemic ventricular contraction causes a retrograde bulging of the AV valve, resulting in the “c” wave. Ventricular ejection results in release of this “bulging” pressure (x descent). The “v” wave occurs at the juncture between systole and diastole. To understand this wave, one must consider three things.

First, atrial filling occurs primarily during ventricular systole. By the time ventricular diastole occurs, the atrium is essentially full. Second, in early ventricular diastole, the AV valve is still closed. Third, ventricular contraction is three dimensional, with shortening along the long axis (base to apex) being an important component. During systole, the AV valve annulus moves downward, and it rapidly moves upward during early ventricular diastole. It is likely that this upward annular movement against a full atrium causes the “v” wave. The “y” descent occurs when the AV valve opens and allows the blood previously held entirely in the atrium to enter the ventricle and hence transiently decrease the atrial pressure.

One should note that the “v” wave should not be confused with the pathologic “c-v” waves associated with AV valvular regurgitation. Regurgitant “c-v” waves occur earlier in the cycle, and are a continuation of the “c” wave. Figure 17 shows the regurgitant “c-v” wave with the concomitant arterial pressure trace to emphasize the timing and pathophysiology.

## THE PATHOPHYSIOLOGY OF CONDITIONS COMMONLY ASSOCIATED WITH TRAUMA

### Hypovolemia

Massive blood loss and multiple trauma tend to go “hand in hand.” Compensatory physiologic mechanisms, however, may either obscure the diagnosis or cause the clinician to

underestimate the severity of the situation. These mechanisms are mediated primarily by the sympathetic nervous system.

Baroreceptors, located in most of the major arteries, are found in particular abundance at the bifurcation of the carotid arteries (carotid sinus). The baroreceptor reflex is a negative feedback loop. An increase in arterial pressure causes an increase in the firing of the baroreceptor afferent fibers. These afferents travel via the vagus nerve to the glossopharyngeal nerve. These fibers ultimately signal the tractus solitarius in the medullary portion of the brainstem. This causes a decrease in sympathetic vasoconstrictor response, as well as an increase in vagally mediated parasympathetic output.

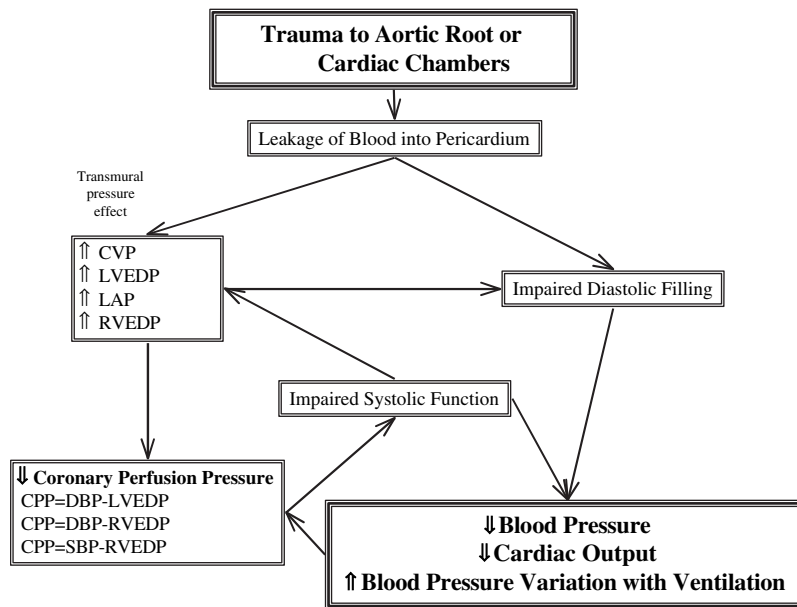

When BP drops, baroreceptor afferents are inhibited, resulting in activation of the medullary vasoconstrictor center. Sympathetic output from the central nervous system then causes increase in heart rate ( $\beta$  stimulation) and  $\alpha_1$ -mediated vasoconstriction. This vasoconstriction serves to maintain BP and distribute blood flow to the vital organs (brain, heart, splanchnic circulation). In otherwise healthy individuals, this mechanism maintains homeostasis until a large portion (30–40%) of the blood volume has been lost.

Medications causing vasodilatation or sympatholysis, for example, anesthetics, narcotics, beta blockers, can thwart this mechanism, resulting in catastrophic hemodynamic compromise. ⚡ **Elderly patients and/or patients chronically receiving beta blockade may not mount a dramatic tachycardic response to hypovolemia or stress.** ⚡ This is because of the effects of age and beta blockade on the baroreceptor reflexes and sympathetic nervous system responsiveness (35–37). Also, elderly patients, particularly those with chronic hypertension, may have a decreased central compartment volume of distribution, leading to a decreased capacitance vessel response to hypovolemia (38).

### Cardiac Tamponade

Cardiac tamponade can result from blunt trauma or stab wound to the chest. Typically, there is leakage of blood from the aortic root or one of the cardiac chambers into the pericardial sac. This leakage, if under pressure, can cause rapid accumulation of blood around the heart. As the pressure in the pericardium rises, cardiac diastolic expansion is impeded. The diagnosis should be considered in the presence of Beck’s triad (jugular venous distension, muffled heart sounds, and hypotension). Figure 18 depicts the complex interrelationship between impaired diastolic function, decreased BP  $\dot{Q}$ , and impaired myocardial perfusion that results from the accumulation of pericardial fluid.

⚡ **Cardiac tamponade triggers the same sympathetic response as hypovolemia (tachycardia and vasoconstriction), but can usually be differentiated from hypovolemia by the presence of high filling pressures (or distended neck veins, in the absence of central monitoring).** ⚡ Diagnosis can be rapidly confirmed by transesophageal echocardiography (TEE) as described in Volume 2, Chapter 21. Drainage of the pericardial fluid usually results in rapid improvement. In contrast to chronic pericardial effusions, which can be managed by subxiphoid window and pericardiocentesis, traumatic effusions are best treated by thoracotomy or median sternotomy, since the site of injury needs to be evaluated and repaired.

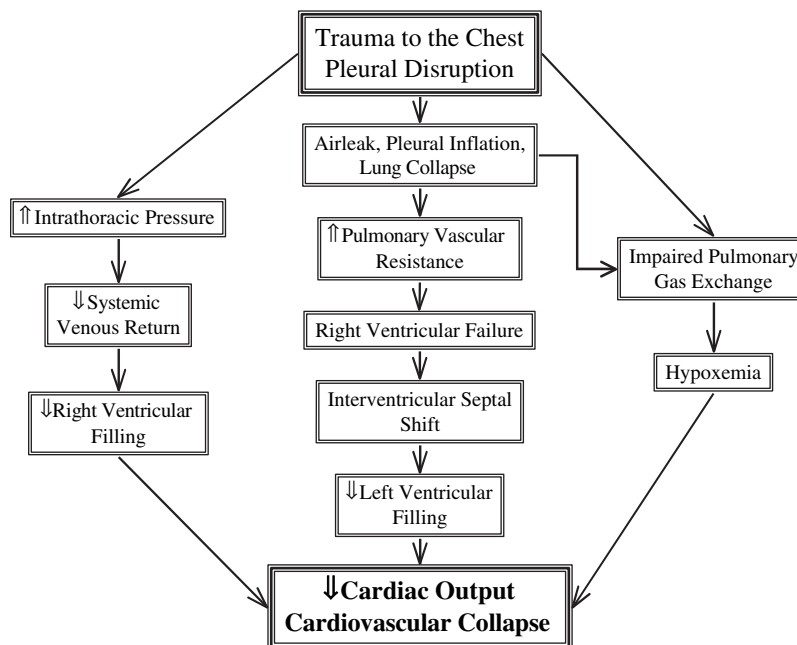

**Figure 18** The physiologic events of cardiac tamponade, leading to shock. *Abbreviations:* CVP, central venous pressure; CPP, coronary perfusion pressure; DBP, diastolic blood pressure; LAP, left atrial pressure; LVEDP, left ventricular end-diastolic pressure; RVEDP, right ventricular end-diastolic pressure; SBP, systolic blood pressure.

**Tension Pneumothorax**

The cascade of events resulting from pleural disruption is depicted in Figure 19. Air leakage into the pleural space, when combined with a one-way valve of egress into the pleural cavity, results in a tension pneumothorax. As this develops, intrathoracic pressure rises, resulting in decreased systemic venous return. Concomitantly, lung collapse causes hypoxemia and a precipitous rise in PVR. Right ventricular failure ensues, leading to interventricular septal shift. Impaired filling of both the right and left sides of the heart quickly results in cardiovascular compromise.

The cardinal signs of tension pneumothorax, cyanosis, hypotension, jugular venous distension, diminished breath sounds on the affected side, and tracheal shift, are thus easily explained by the pathophysiology of the disorder. Relief of the pressure can be achieved by the placement of a chest tube in the fifth intercostal space at the midaxillary line, or with an angiocatheter placed in the second intercostal space at the midclavicular line. This results in rapid clinical improvement. Whenever possible, the chest tube approach is preferred because it is not associated with internal mammary artery injury, and a chest tube will need

**Figure 19** The cascade of events associated with tension pneumothorax.

to be placed anyway whenever a needle is inserted to decompress a tension pneumothorax.

### Cardiac Contusion

Cardiac contusion usually results from blunt trauma or deceleration injury. The right ventricle, because of its anterior anatomic location, is the most commonly involved chamber. Direct injury to the myocardium may result in areas of electrical irritability, manifested as ventricular or atrial premature beats (39). ⚡ **Conduction blockade is the most common mechanism of dysrhythmias in cardiac contusion patients (27). It results in reentrant dysrhythmias such as ventricular and atrial fibrillation (40,41), as well as heart block (42).** ⚡ If extensive myocardial injury is present, cardiac failure or ventricular rupture may occur. Diagnosis can be made by measuring troponins, as well as by TEE. Treatment is mainly a supportive care and a dysrhythmia monitoring in a telemetry unit or the intensive care unit.

### Head Trauma

Severe head trauma, with its associated cerebral edema, may result in increased intracranial pressure (ICP). When a severe increase in ICP occurs, bradycardia and systemic hypertension may ensue. The pathophysiologic mechanism for this is referred to as “Cushing’s reflex.” This is a vasoconstrictive response to cerebral ischemia, causing reflex bradycardia. The only successful treatment is the relief of the intracranial hypertension.

Head injury may also be associated with S-T and T wave ECG abnormalities, as well as myocardial dysfunction (43). These abnormalities appear to be unrelated to any cardiac pathology, indicating that the central nervous system control of electrical cardiac function is more complex than often appreciated.

### EYE TO THE FUTURE

Transgenic research into cardiomyopathy involves the injection of adenylate cyclase genes into the cardiac muscle using viral vectors. The overexpression of adenylate cyclase in these animals shows improvement.

Mitochondrial regulation of oxygen consumption and energy metabolism is particularly pertinent in cardiac muscle. Indeed, the venous blood leaving myocardial tissue is the most desaturated of any vascular bed in the body for nonexercising patients. The mitochondrial story is recently just emerging and is a fascinating area of research.

Eukaryotic cells originally lacked the ability to undergo aerobic metabolism. These primordial eukaryotic cells were colonized by aerobic bacteria over a billion years ago. A symbiotic relationship developed, the bacteria evolved into mitochondria and the relationship became permanent. Structurally, mitochondria have four compartments: the outer membrane, the inner membrane, the intermembrane space, and the matrix (the region inside the inner membrane). They perform numerous tasks, such as pyruvate oxidation, the Krebs cycle, and metabolism of amino acids, fatty acids, and steroids, but the most crucial task is probably the generation of energy as ATP, by means of the electron transport chain and the oxidative phosphorylation system (the “respiratory chain”).

Over the past 30 years there has been an explosion in technology for cardiovascular monitoring, and thus an expo-

stantial rise in knowledge of cardiovascular physiology. Techniques such as pulmonary artery catheterization and transesophageal echocardiography have become bedside procedures, thus revolutionizing our approach to cardiovascular problems. These technologies and improved understanding will continue to be applied to newer noninvasive techniques as well as improved therapies. Within the next 30 years, methods will be developed allowing complete assessment of the cardiovascular system with noninvasive tools.

Integrating such factors as pulse wave characteristics, echocardiographically derived Doppler flow attributes, heart sound characteristics, the timing of cardiovascular events, and advanced computerized analyses will allow such global assessments. These assessments, in turn, will themselves advance our understanding of cardiovascular function. Before long we will be narrating to our students, “Can you imagine, we used to put big catheters into the great veins and thread them into the heart...” The close relationship between cardiovascular physiology and hemodynamic diagnosis and treatment will continue to strengthen over time.

### SUMMARY

Understanding the physiology of the cardiovascular system, as well as the pathophysiology of common traumatic disorders aids in the interpretation of physiologic data and choice of treatment modalities. Study of the physiologic basis of cardiac dysrhythmias and other acute pathological conditions facilitates their management, and guides future research. It is hoped that this chapter provides a framework for further study, as well a paradigm for the approach to the cardiovascular problems that critically ill patients present.

### KEY POINTS

- ⚡ Cardiac contraction is a complex three-dimensional event.
- ⚡ The Frank-Starling mechanism causes enhanced myocardial performance when cardiac filling is increased.
- ⚡ The healthy heart responds favorably to meet the demand of increased SVR, without exhibiting a decrease in output until the MAP is greater than 160 mmHg.
- ⚡ Although vasodilation will augment cardiac output in the setting of high SVR, it may also decrease perfusion pressure to the needy tissue beds, including the coronary arteries.
- ⚡ The pulmonary vascular system is a low-pressure, high-compliant network in health, with pressures approximately 1/10 systemic.
- ⚡ The “Δ down” component of the systolic blood pressure variation with ventilation is quite sensitive in detecting hypovolemia.
- ⚡ The heart and vasculature are under the constant influence of the autonomic nervous system. The resulting cardiac output and systemic blood pressure continuously reflect the intravascular blood volume and the relative parasympathetic and sympathetic “tone.”
- ⚡ When a myocardial energy deficit occurs, actin and myosin bridges fail to break, resulting in inability of the muscle to relax.

- 9 Metabolic derangements resulting from abnormalities such as sepsis, systemic inflammatory response, hypovolemia, and diabetes can have devastating effects on the myocardium as well as other organs and tissues.
- 9 The heart rate is by far the most significant factor in myocardial oxygen balance.
- 9 In trauma and critical care management, a constant effort is made to balance the metabolic needs of the systemic tissues with the metabolic needs of the myocardium.
- 9 Various electrolyte abnormalities, such as hypokalemia and hypomagnesemia, particularly when they occur together, as well as hypocalcemia increase the likelihood of cardiac dysrhythmias.
- 9 Elderly patients and/or patients chronically receiving beta blockade may not mount a dramatic tachycardic response to hypovolemia or stress.
- 9 Cardiac tamponade triggers the same sympathetic response as hypovolemia (tachycardia and vasoconstriction), but can usually be differentiated from hypovolemia by the presence of high filling pressures (or distended neck veins, in the absence of central monitoring).
- 9 Conduction blockade is the most common mechanism of dysrhythmias in cardiac contusion patients, It results in reentrant dysrhythmias such as ventricular and atrial fibrillation, as well as heart block.

## Clinical Pharmacology Review

**Doug Humber**

Department of Pharmacology, UC San Diego Medical Center, San Diego, California, U.S.A.

**Farivar Jahansouz**

Department of Pharmacy, UC San Diego Medical Center, San Diego, California, U.S.A.

### INTRODUCTION

Drug therapy is an essential component of critical-care management. The principles of clinical pharmacology outlined in this chapter constitute the necessary knowledge for providing a rational approach to drug administration in critically ill patients. This chapter initially reviews the basic pharmacokinetic (PK) and pharmacodynamic (PD) principles of drug therapy. Subsequently, the focus changes to drug therapy in disease states which alter the PK and PD parameters. Therapeutic drug monitoring (TDM) is discussed as a means to adjust for these changes and to individualize drug regimens as required to provide optimal therapy in the intensive care unit (ICU).

### Pharmacokinetics

The concept of PK modeling describes how administered drugs are handled in the body during health and critical illness and the subsequent plasma concentrations that result. This includes an understanding of route of administration, absorption, bioavailability, distribution, metabolism, and clearance, whereas PD modeling describes the pharmacological effect produced by any specific drug concentration in both healthy and diseased patients. The PK/PD concepts are depicted in Figure 1 (1).

### Bioavailability

Bioavailability is defined as the fraction of a dose that reaches the systemic circulation. This fraction will vary depending on the route of administration, the chemical form of the drug (e.g., salt, ester), dosage form (e.g., extended-release vs. elixir), and the extent of "first-pass" elimination (when administered orally) (2).

Drugs administered as intravenous (IV) infusions have, by definition, 100% bioavailability. Administering a drug by the oral or rectal routes has variable bioavailability (1), as illustrated in Table 1. Two main processes are responsible for the bulk of this variability: incomplete absorption and first-pass metabolism. Incomplete absorption can be caused by a number of factors, including drug lipophilicity, drug hydrophilicity, the p-glycoprotein export pump system, and even bacterial degradation of the drug in the gut lumen (1). Enzymatic metabolism within the gut wall can also contribute to a reduced amount of drug reaching the circulation.

Enteral administration has the greatest number of factors affecting blood levels. After a drug has been absorbed across the gut wall, it is delivered to the liver by the hepatic portal system where it can undergo additional hepatic metabolism or biliary excretion. Removal of the drug by this process prior to reaching the systemic circulation is known as the first-pass effect. This effect can substantially decrease the amount of drug reaching the systemic circulation.

Some nonparenteral routes of administration can avoid or reduce the extent of first-pass metabolism (e.g., rectal, sublingual). In addition, parenteral routes (e.g., IV and transdermal preparations) also avoid the first-pass effect of the liver. The amount of drug that ultimately reaches the systemic circulation is calculated by multiplying the administered dose by the bioavailability factor (F) and the fraction of a dose that is active drug "salt form factor" (S) (Equation 1) (2).

$$\text{Amount reaching systemic circulation} = (S)(F)\text{dose} \quad (1)$$

Many drugs are administered as a salt form (e.g., erythromycin ethylsuccinate) and only a fraction of that salt would actually be the active drug.

### Volume of Distribution

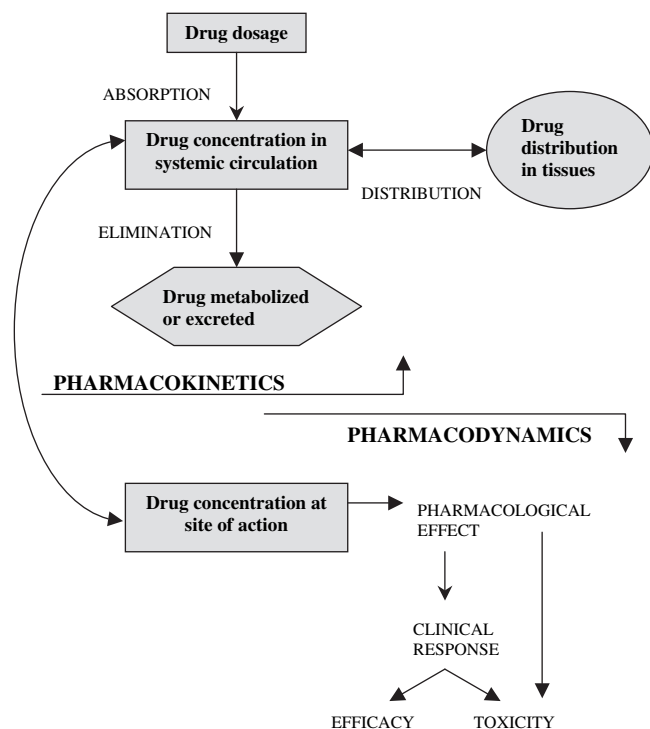

Once a medication reaches the systemic circulation, it is distributed in the body. The volume of distribution ( $V_d$ ) is equal to the amount of drug administered (dose) divided by the concentration of the drug in the blood (Equation 2). The distribution of some drugs will be restricted to the vascular fluids and others may be distributed into fat, muscle, bone, or total body water.

$$V_d = \frac{\text{Amount of drug (dose)}}{\text{Concentration of drug}} \quad (2)$$

Factors that alter a drug's  $V_d$  include the lipophilicity, protein binding, and tissue binding (2,3). If a drug has extensive protein binding and little lipid solubility, the  $V_d$  is typically small (i.e., contained within the vascular compartment). In contrast, if a drug has a high degree of lipid solubility and tissue binding and low protein binding, then the  $V_d$  becomes very large. The  $V_d$  can also be altered by a number of pathological conditions. If the  $V_d$  changes, then the plasma concentration changes as well.

Perhaps the easiest way to conceptualize PK principles is to think of the body as one large compartment. However,

**Figure 1** A schematic relationship between the concepts of pharmacokinetics (PK) (dose/concentration) and pharmacodynamics (PD) (concentration/effect). The key elements of pharmacokinetics include absorption, distribution, and elimination. The drug concentration at the site of pharmacological action links these two (PK and PD) concepts together. *Source:* Adapted from Ref. 1.

a multicompartment model is more appropriate when examining drug distribution, elimination, and movements between different parts of the body. Figure 2 represents a schematic of a two-compartment PK model where the drug is distributed between a central compartment ( $V_c$ ) and a peripheral compartment ( $V_{d\beta}$ ) (3).

### Protein Binding

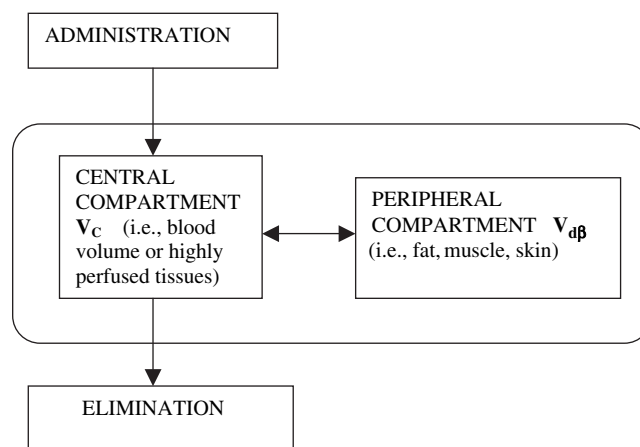

The plasma concentration that is reported by the laboratory represents protein-bound drug plus drug that is unbound.

**Table 1** Routes of Administration and Bioavailability

Route	Bioavailability (%)	Comments
IV	100	Most rapid onset
IM	75 to $\leq 100$	Increased volume of injection, may be painful
SC	75 to $\leq 100$	Decreased volume of injection, may be painful
PO	5 to $< 100$	Most convenient, first-pass effect may be large
PR	30 to $< 100$	Less first-pass effect than oral
Inhalation	5 to $< 100$	Often very rapid onset, no first pass effect; may cause bronchospasm
Transdermal	80 to $\leq 100$	Slow absorption, no first-pass effect; convenience

*Abbreviations:* IM, intramuscularly; IV, intravenously; PO, by mouth; PR, per rectum; SC, subcutaneously.

*Source:* Adapted from Ref. 1.

**Figure 2** Schematic representation of a two-compartment pharmacokinetic model. Once the drug is administered and a percentage of it is absorbed (bioavailability), it will be distributed between all available compartments. Initially, the central compartment ( $V_c$ ) will be exposed to the drug, and then the peripheral compartments ( $V_{d\beta}$ ). During and after the distribution phase, elimination will occur. *Source:* Adapted from Ref. 3.

☞ The unbound (“free”) drug molecule exerts the pharmacological effect by interacting with the cell receptor. ☞ Two main plasma proteins bind drugs in the plasma:  $\alpha_1$ -acid glycoprotein (basic drugs) and albumin (acidic and neutral drugs). This binding phenomenon is non-selective, meaning that other drugs with similar physicochemical properties can compete for binding sites. This competition can be concentration dependent or related to binding affinity with the plasma protein (2). For example, drugs A and B both bind to albumin but drug A has a higher binding affinity. Therefore, drug B may be displaced from the binding site yielding an increased “free” plasma concentration of drug B and therefore a greater pharmacological effect. The property of protein binding is of greatest concern for drugs that have a narrow therapeutic index (i.e., small range between subtherapeutic and toxic concentrations).

☞ Protein-binding alterations occur in critically ill patients and must be considered in order to properly interpret measured drug concentrations and their predicted PD effects (4). ☞ Certain physiological and disease states may alter the concentration of plasma proteins and therefore change the fraction of drug that is bound to these proteins. For example, nephrotic and cirrhotic patients commonly have low plasma albumin levels.

Trauma and burn patients also commonly suffer from low albumin levels following massive resuscitation. If these patients were to receive a drug, which is normally highly bound to albumin (e.g., phenytoin), then the fraction of drug that is unbound or free would be higher because fewer protein-binding sites are available to take it up. Accordingly, the PD effect would be greater than expected for the same measured drug concentration in a patient with normal albumin levels.

### Clearance

Clearance (Cl) is defined as the volume of blood cleared of drug per unit of time. ☞ The primary organs involved in clearance are the kidneys and the liver, but other organ systems (e.g., lungs) may be involved. ☞ The total body

clearance is the sum of the individual clearances as represented in Equation 3 (2,3).

$$Cl_{\text{total}} = Cl_{\text{renal}} + Cl_{\text{liver}} + Cl_{\text{other}} \quad (3)$$

Numerous factors affect drug Cl including plasma protein binding, extraction ratio, renal function, hepatic function, and cardiac output ( $\dot{Q}$ ). The Cl is reported in units of volume/time or if normalized to body weight, units of volume/body weight/time. If a patient is very large or small, but has normal organ function, there is an underlying assumption that the kidney and liver are proportionally large or small as well and therefore, clearance capabilities would be changed proportionately.

The extraction ratio is defined as the amount of drug that is removed after a single pass through the organ responsible for its clearance. It is proportional to the plasma or blood clearance of a drug and the plasma or blood flow to the eliminating organ. The impact of renal, hepatic, and cardiac failure on PK parameters will be discussed later.

### Half-Life

The half-life ( $t_{1/2}$ ) of a drug is the time it takes for the drug concentration in the body or plasma to be reduced by one-half. The half-life can be calculated as a function of the Cl and  $V_d$  (2).

$$t_{1/2} = \frac{0.693 \cdot V_d}{Cl} \quad (4)$$

The value of  $Cl/V_d$  is known as the elimination rate constant ( $K_d$ ), so Equation 4 is often represented as shown in Equation 5:

$$t_{1/2} = \frac{0.693}{K_d} \quad (5)$$

In a similar fashion, the  $V_d$  can be calculated by combining the concepts derived in Equations 2–5, as shown in Equation 6.

$$V_d = \frac{Cl \cdot t_{1/2}}{0.693} \quad (6)$$

As the  $V_d$  and Cl change, the half-life changes also. In the simplest PK model (single compartment), the half-life is useful in determining an appropriate dosage interval as well as estimating the time it would take to eliminate the drug from the body. It takes five half-lives to reduce the concentration of a drug to about 3% of its original value once it has been discontinued.

It is also possible to estimate the time to reach steady state after the initiation or change of the maintenance dose. Steady state is defined as the state in which the amount of drug being administered in a given time period is equal to the amount eliminated in the same time period. In most clinical situations, it is appropriate to assume that steady state will be achieved after three to four half-lives have elapsed. However, many drugs display multiple compartment distribution and therefore equilibrate with each of the compartments at different rates. Half-lives reported in informational tables usually reflect the most clinically relevant half-life. For drugs administered intermittently, the clinical duration of action may be a more meaningful term (e.g., the time period that the drug concentration is within the clinically significant range).

### Pharmacodynamics

The pharmacological response to a specific plasma drug concentration is defined as the PD effect of the drug. These effects result from the interaction of drugs with cellular macromolecules or receptors in the host organism. A number of factors can alter the PD response in critically ill patients. The pharmacological response to a drug is usually proportional to the unbound plasma concentration (i.e., PK properties). However, the specific PD response represents the interindividual variability in receptor binding and effect. Interindividual variations of responses to a given plasma drug concentration occur commonly. For example, the geriatric population is routinely more sensitive to the sedative effects of benzodiazepines than their younger counterparts (3). In addition, opioid-tolerant patients will require higher doses and blood levels to obtain adequate analgesia in the surgical intensive care unit (SICU).

In order for a drug to elicit a pharmacological response, it must be delivered and bound to the appropriate receptor. This drug–receptor complex can then evoke an effect. If the target site is heavily perfused (i.e., central circulation), then the pharmacological response is typically rapid. An example would be isoproterenol stimulation of the  $\beta_1$ -receptors in cardiac tissue resulting in tachycardia. Highly protein-bound drugs (e.g., phenytoin, valproic acid) may produce an increased pharmacological effect in the setting of hypoalbuminemia because only the free or unbound drug molecule binds to the target receptor. Many drugs also cause different pharmacological responses at different plasma drug concentrations. A classic example is the shift of pharmacological response with respect to  $\alpha$ - and  $\beta$ -receptors which occurs as the dosage (and plasma concentration) of dopamine is increased.

### ALTERATION OF PHARMACOKINETIC AND PHARMACODYNAMIC PARAMETERS IN THE CRITICALLY ILL

☞ **Multiple variables (PK and PD) affect the critically ill patient. Accordingly, multidisciplinary involvement and careful monitoring is required to optimize drug therapy.** ☞

A drug's PK parameters can be used to calculate an individualized drug regimen to assure optimal dosing. However, published PK parameters are usually determined in normal volunteers, and these values may not apply to critically ill patients. The clinician must therefore account for potential changes in these values based upon the disorders affecting their patients.

There are numerous reasons for alterations of PK and PD parameters in the critical-care setting. Organ failure, hyperdynamic states, disease-induced alterations in body physiology, acid–base disorders, and drug–drug interactions list some of the common confounders. Of these causes, organ failure is responsible for the majority of the changes in PK/PD parameters.

#### Organ Failure

Renal failure has an enormous impact on most drugs used in the ICU. Renal failure is easily detected because of the simplicity in recognizing “abnormal serum creatinine”; and changes in the urine output are easily detected in critically ill patients. ☞ **Glomerular filtration rate (GFR) is often estimated based on a patient's serum creatinine and ideal body weight. Since critically ill patients may have a decrease in**

muscle mass, creatinine clearance (and GFR) can be overestimated. ⚡

Liver function tests (LFTs) can indicate potential liver dysfunction (see Volume 2, Chapter 35); but, depending on the site of dysfunction, abnormal LFTs may or may not indicate an alteration in the PK or PD properties of a drug. Gastrointestinal (GI) changes can impact the bioavailability by altering the first-pass metabolism of enterally administered drugs. Cardiovascular dysfunction can cause hepatic congestion, which can decrease the drug metabolizing capacity of the liver. The following sections further discuss the failure of individual organ systems and their influence on the PK/PD parameters.

### Renal

Many drugs depend at least in part on the kidneys for their excretion. Critically ill patients may already have or will develop renal failure during their course of stay in the ICU. Many medications can cause nephrotoxicity and renal insufficiency, and the clinician should assess whether medications are contributing to renal dysfunction (Table 2) (5,6). Renal dysfunction can alter both the  $V_d$  and ultimately the Cl of some drugs.

If renal excretion accounts for more than 30% of the total Cl of a drug, changes in renal function can have a significant impact on the PK of the drug. In drugs with a narrow therapeutic index, this change is much more important and alterations in renal clearance may necessitate dosage adjustment. Numerous sources of established guidelines for adjusting the drug dosages based on the degree of renal dysfunction exist (7). However, these guidelines are only first approximations to dose adjustments, and the physician must consider the patient's entire clinical picture and individualize the therapy. For drugs with a narrow therapeutic index, checking the serum drug level and performing a formal PK analysis is generally recommended.

⚡ If renal dysfunction is severe enough to require dialysis, dosage adjustment is often required. ⚡ Various types of dialysis require different dosage modifications. Intermittent hemodialysis is the most frequently employed modality outside of the SICU. Dosage adjustment guidelines for anuric patients on intermittent dialysis have been established for most drugs (7). A full or partial supplemental dose is recommended for some drugs that are cleared by hemodialysis.

Advances in continuous renal replacement therapy (CRRT) and the recognition that CRRT causes less perturbations to other organ systems have resulted in increased usage of this mode in unstable, critically ill patients. However, there are few well-established guidelines for dosage adjustments for many drugs that are given during CRRT. This is, in part, due to the fact that CRRT can be accomplished by several different modalities. Depending on the technique used, the dosage adjustments may be different. Continuous veno-venous hemodiafiltration (CVVHDF) has become a standard modality employed in most advanced ICUs.

Some drugs can be cleared by CVVHDF, and this clearance can be divided into three different processes (Table 3). Drugs can be cleared by diffusion (dialysis), convection (hemofiltration), and adsorption to the filter. The clearance by diffusion depends on the dialysate flow rate as well as on dialysate saturation (concentration of drug in dialysate divided by concentration of drug in plasma). This process depends on the molecular size, membrane pore size and its thickness, blood flow, and protein binding. During the convection process, as fluid (plasma water) gets filtered by hemofiltration, dissolved solutes (drugs) in the fluid are removed. This elimination depends on the drug's sieving

**Table 3** Three Different Processes for Drug Clearance by Continuous Veno-venous Hemodiafiltration

#### Diffusion process (hemodialysis)

Drugs pass through membrane from high concentration (blood) to lower concentration (dialysis)

Process depends on

Molecular weight

Small and medium size drugs can easily pass through

Larger (1000–5,000 dalton) drugs can pass through highly permeable membranes

Protein binding

Membrane pore size and thickness

Blood flow and dialysate flow

Concentration of unbound drug (only unbound drug can diffuse)

#### Convection process (hemofiltration)

As fluid (plasma water) is removed, drugs dissolved in fluid are removed

Process depends on

Sieving coefficient

Protein binding

Filtration rate

#### Adsorption to filter

Dependent upon type of filter used

High flux (has large pore size leading to enhanced clearance of larger drugs)

High efficiency (increased surface area leading to enhanced clearance of small solutes)

coefficient (the capacity of the drug to pass the membrane by convection) and the filtration rate. The sieving coefficient can be calculated directly by dividing the concentration of drug in the filtrate by the concentration of drug in the plasma. Drug removal via adsorption is not very well understood. Certain types of hemofilters (e.g., AN60S) are known to adsorb some drugs (e.g., aminoglycosides). This process is variable and can be a saturable process.

**In general, the CVVHDF removal of small drugs depends on the diffusion and convection process, whereas removal of larger drugs depends mostly on convection and perhaps adsorption properties.** The total clearance of a drug is equal to CRRT clearance plus all other non-CRRT clearance. The non-CRRT clearance can be defined as the sum of hepatic, pulmonary, and other types of clearance plus any residual renal clearance.

A simple dosage adjustment guideline for CVVHDF (Fig. 3) has been developed (7 – 13). First, if the drug is normally cleared primarily via nonrenal routes, then it most likely does not have appreciable CRRT clearance (rare exceptions occur, e.g., phenobarbital). If the drug is cleared primarily by the renal route (more than one-third of the total clearance), then most likely there will be some degree of CRRT clearance. Second, if the drug has a narrow therapeutic index, the estimate of CRRT clearance must be accurately

determined. In contrast, if it has a broad therapeutic index, the calculation of CRRT clearance can be estimated using clinical experience. Third, initial dosing for patients on CVVHDF should follow established guidelines tailored to the patient's clinical picture (7,8,14). Fourth, the patient's clinical course, as well as the CRRT parameters (blood flow rate, dialysis rate, ultrafiltrate rate, hemofilter), must be monitored closely. Fifth, significant changes in clinical status or CRRT parameters often require readjusting the dosage. For narrow therapeutic index drugs, the serum drug concentrations should be checked within the first 24 to 48 hours. Using the serum drug levels, PK analysis should be performed, and an individualized dosage can be developed. Finally, some inconsistencies exist with the CRRT drug clearance literature as there can often be more than one dosage recommendation for the same drug (15,16). The data may be derived from different modalities of CRRT in which CRRT parameters may have not been similar and the patient population may have been different. One must always account for the patient's residual renal function, and as the renal function improves, the possibility of improvement in renal clearance for some drugs exists.

If the renal function has not improved, but the patient is hemodynamically stable enough to tolerate intermittent dialysis, CRRT may be discontinued. In this case, the contribution of CRRT to the clearance of drugs is also stopped and dosage adjustments may be justified.

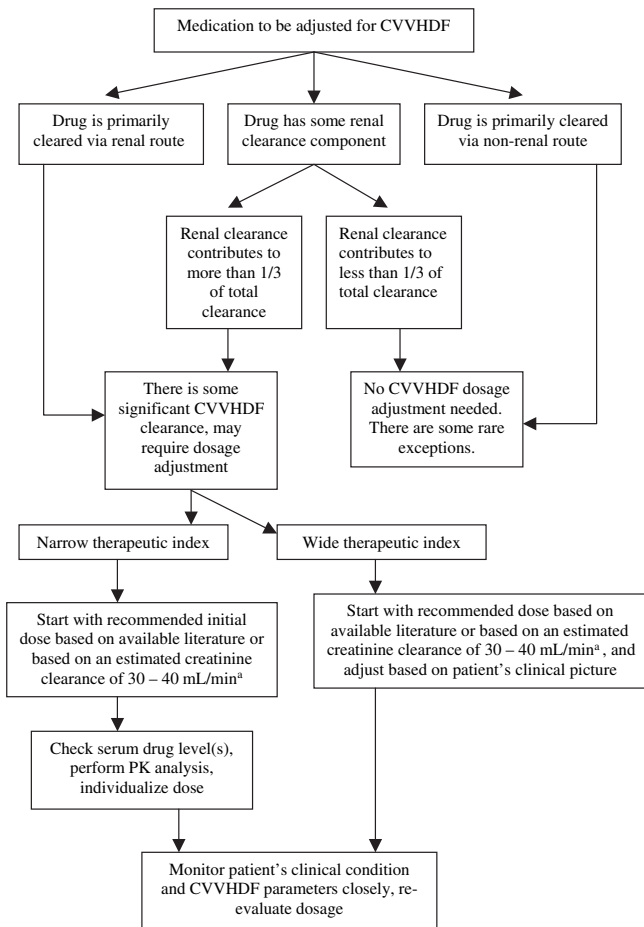

In summary, the CRRT clearance of a given drug is clinically important when it accounts for more than one-third of the total clearance. Drugs that are highly protein bound (e.g., phenytoin) or have large volumes of distribution (e.g., digoxin, cyclosporine) are not readily available for CRRT clearance. For narrow therapeutic index drugs, frequent monitoring of serum drug levels, clinical status, and CRRT parameters is essential.

**Hepatic**

**Up to 54% of critically ill patients will develop some degree of liver dysfunction (17).** This can result from hypoperfusion due to decreased liver blood flow due to hypovolemia or cardiovascular dysfunction or can occur because of intrinsic changes such as altered hepatic microsomal enzyme activities associated with age, fever, stress, drug interactions, and hepatocellular damage. Both of these factors (hypoperfusion and intrinsic liver disease) can contribute to a decrease in hepatic drug metabolism (Table 4). Unlike renal dysfunction, which is relatively easy to quantify, the degree of liver dysfunction can be difficult to assess and the correlation with drug clearance is less consistent.

**Table 4** Factors that Can Decrease Hepatic Metabolism of Drugs in Critically Ill Patients

- Hypoperfusion (decrease in hepatic blood flow)
  - Hypovolemia
  - Cardiovascular dysfunction
- Intrinsic (altered hepatic enzyme activities)
  - Age
  - Fever
  - Stress
  - Systemic inflammatory response syndrome
  - Hepatocellular damage
  - Drug interactions

**Figure 3** Decision tree for the management of drug dosing during continuous renal replacement therapy. <sup>a</sup>Estimated creatinine clearance of 30–40 mL/min based on a CVVHDF combined clearance of 2000 mL/hr (dialysis + ultrafiltrate). *Abbreviations:* CVVHDF, continuous veno-venous hemodiafiltration, PK, pharmacokinetic.

The liver is the site of metabolism for many drugs used in critically ill patients (4). In addition, some medications are hepatotoxic, especially if allowed to achieve high plasma concentrations, and can subsequently cause syndromes of hepatocellular necrosis, cholestasis, granulomas, fatty changes, or even chronic active hepatitis (Table 5) (18,19). Few well-established guidelines exist for adjusting medication dosages for hepatic dysfunction. One approach is to estimate the relevance of liver dysfunction by considering the contribution of liver metabolism to the total clearance of the drug. If this is more than 30%, then an empirical decrease in the drug dosage is often necessary in the setting of liver dysfunction.

A few specific drugs do have dosing recommendations based on the degree of hepatic dysfunction. For example, caspofungin, an IV antifungal agent, needs to be dose reduced based on the patient's Child–Pugh score (20). Metronidazole, a commonly prescribed antibiotic with anaerobic efficacy, carries a recommendation for a reduction in the dosage quantity or administration frequency depending on the clinical response and degree of hepatic dysfunction (20). The maintenance dose of sirolimus, an immunosuppressant, should be reduced by one-third for patients with mild to moderate hepatic impairment (20). Table 6 contains a select list of medications whose PK parameters may be affected by liver dysfunction and recommendations for dosage adjustments if available.

For drugs with a narrow therapeutic index, serum drug levels should be checked, PK analysis should be performed, and an individualized dose should be calculated. However, if the drug has a broad therapeutic index, the

patient's clinical picture and health care provider's assessment and experience can be used to guide an appropriate dosage. In either case, it is important to monitor the clinical course, therapeutic responses, and look for adverse effects.

In liver dysfunction, the effect of drug–drug interactions can be magnified. For example, if the hepatically cleared drug "A" can attenuate the metabolism of drug "B," and if the metabolism of drug "A" decreases as a result of liver dysfunction, not only can drug "A" accumulate and cause adverse effects, but also drug "B" could potentially accumulate and cause adverse effects. It may be difficult to evaluate whether decreased liver metabolism is due to liver dysfunction or decreased perfusion (21).

Drugs associated with increased elimination secondary to the first-pass phenomenon (described earlier) depend upon hepatic blood flow (22). If this blood flow is impaired, as in the setting of cirrhosis, portosystemic shunts are generated in order to bypass the liver. With this bypass, drugs that are normally subjected to a high degree of first-pass metabolism may have an increased bioavailability. Table 7 lists a select number of medications that undergo

this first-pass phenomenon. ⚡ **In critically ill patients with multiorgan failure, the net effect on drug metabolism is difficult to predict and must be carefully monitored.** ⚡

### Cardiovascular

Acute decompensated heart failure (ADHF) is characterized by low  $\dot{Q}$  and increased organ congestion. With the elevated right heart filling pressures and pulmonary hypertension seen with heart failure, renal, liver, and gut congestion may exist (23,24). With the associated low cardiac output state, perfusion to these organs is compromised as well. ⚡ **ADHF can lead to an impairment of drug clearance and/or a reduction in the  $V_d$  by underperfusing organs responsible for metabolism or elimination (i.e., liver and kidneys) (23).** ⚡ With changes in the clearance and volume of distribution, the half-life of a drug is usually affected. Medications that are titrated to effect (i.e., nitrates, diuretics, vasopressors) will be impacted to a lesser degree by the alteration of PK parameters.

Incomplete absorption of drugs from the GI tract can be related to the blood flow to the upper small bowel (primary site of drug absorption). If  $\dot{Q}$  is diminished, blood flow to the bowel is reduced and enteral absorption could be impaired. Congestion and gut edema have been implicated in the malabsorption of drugs (23). Other routes of drug administration may be affected by heart failure. Absorption of intramuscularly administered drugs is directly related to the blood flow to that muscle site. If  $\dot{Q}$  is reduced (as in cardiogenic shock or decompensated heart failure), absorption will be erratic and potentially impaired; therefore, intramuscular administration of drugs should be avoided unless no other administration options are available.

The main site of hepatic drug metabolism is the cytochrome P450 (CP450) enzyme system. This enzyme system is the rate-limiting step in drug metabolism, and decompensated heart failure can cause hepatic congestion, which may impair the metabolizing capacity of the P450 enzyme system (23). This impairment can lead to drug accumulation and potentially unwanted side effects.

Drugs that are eliminated from the body through the kidneys may accumulate during renal insufficiency. Decompensated heart failure and a low  $\dot{Q}$  state can lead to decreased renal perfusion and subsequent renal insufficiency. In this setting, modified administration regimens that decrease the dose or an increase in the dosing interval (or a combination of the two) should be employed. In particular, with ADHF and subsequent renal hypoperfusion, the renin-angiotensin system is stimulated to increase GFR. This process works independently of the effects on systemic blood pressure. In patients who have their angiotensin-converting enzyme (ACE) system inhibited, the decrease in

GFR can become more profound. This decrease in GFR can also contribute to drug toxicity (25).

One might incorrectly surmise that a drug's  $V_d$  would be increased in ADHF because of the commonly associated fluid retention. In fact, the excess fluid is generally restricted to the extravascular space and therefore is unable to directly participate in the distribution of drugs (23). The central volume in heart failure patients is actually reduced; therefore, the  $V_d$  of most drugs is reduced as well. Because the initial plasma concentration that results from a loading dose is dependent upon the  $V_d$ , an empiric reduction in the loading dose is often warranted to avoid toxic concentrations of narrow therapeutic index drugs (e.g., digoxin) (23).

The half-life of a drug is dependent upon the drug Cl and  $V_d$  (Equation 4). In ADHF, both of these parameters can be altered and therefore, drug elimination half-life may be altered. ⚡ **Drugs with a narrow therapeutic index (i.e., digoxin, lidocaine, procainamide) require enhanced drug monitoring in patients with heart failure.** ⚡

### Endothelial (Burn)

Burn injury can cause marked changes in the PK and PD properties of some drugs (Table 8). Depending on the extent of the burn, the  $V_d$ , protein binding and Cl of some drugs can be altered. It is important to understand different phases of burn injury.

The acute phase (first 48 hours) of injury is characterized by fluid loss from the vascular system (26). This causes a drop in  $\dot{Q}$  and a decrease in tissue and organ perfusion. This phase is often managed with aggressive fluid resuscitation (e.g., hypertonic saline solutions), which can cause an increase in the  $V_d$  of some drugs, whereas the renal and hepatic hypoperfusion can decrease the Cl of some drugs.

The next phase begins immediately after the burn and may worsen 48 hours after the burn injury and consists of a hypermetabolic state. During this phase, the  $\dot{Q}$  is increased (provided the fluid repletion was adequate) as are kidney and liver blood flows (26). As a result, the Cl of some drugs (e.g., vancomycin) and neuromuscular blockade (NMB) agents is increased. Therefore, some dosage adjustments are needed to avoid subtherapeutic levels. This is most important for narrow therapeutic index drugs. Burn injuries can also cause hypoalbuminemia, increasing the free fraction of drugs that are normally highly bound to albumin (e.g., phenytoin). Consequently, there will be more

**Table 8** Alteration of Pharmacokinetic Parameters After Massive Trauma or Burn Injury

Resuscitation phase (first 48 hrs)	
↓	cardiac output
↓	renal perfusion (↓ renal clearance)
↓	hepatic perfusion (↓ hepatic clearance)
↑	volume of distribution
↑	intestinal permeability (changes in enteral absorption)
↓	albumin (changes in protein binding)
Hypermetabolic phase (after resuscitation phase)	
↑	cardiac output
↑	renal perfusion (↑ renal clearance)
↑	hepatic perfusion (↑ hepatic clearance)
↓	albumin (changes in protein binding)
↑	$\alpha$ -1-acid glycoprotein (changes in protein binding)

unbound drug available to elicit its pharmacological action, increasing the potential for adverse effects. It may be necessary to calculate the total as well as free drug levels. Burn injury can also result in an increase in  $\alpha$ -1-acid glycoprotein production (26). Drugs that are highly bound to this protein (e.g., carbamazepine) will have a lower amount of unbound (pharmacologically active) drug available. Therefore, the dosage of these drugs may need to be increased.

☞ **The clearance of some drugs during the hypermetabolic phase of burn injury may be increased.** ☞ The dosage of drugs with a narrow therapeutic index may require adjustment based on PK serum level analysis. For wide therapeutic index drugs, some empirical adjustments, based on available recommendations and the patient's clinical picture, can be used.

### Central Nervous System

The PK and PD parameters of sedative and analgesics are altered in critically ill patients (27,28). The perception of pain can be affected by emotional and cognitive processes, as well as the physical restrictions of ICU patients. Sedative and analgesics are usually highly protein bound and depend on the liver for their metabolism. Change in protein binding, liver function, or perfusion can significantly impact therapeutic as well as adverse effects.

In the setting of decreased liver and kidney perfusion, the clearance of these drugs is often reduced, necessitating significant decreases in dosage. Most of the commonly used sedatives and analgesic drugs used in the ICU exhibit multicompartment PK characteristics. With a typically prolonged course of exposure, they can accumulate. Critically ill patients may have an increased peak effect, faster onset of action, and a prolonged duration of action (27).

Among the benzodiazepine class, lorazepam and midazolam are the most frequently used agents (29 – 32). Midazolam has a faster onset of action than lorazepam due to its increased lipophilicity and is metabolized to active compounds that are renally eliminated. Lorazepam has a longer duration of action; however, for prolonged use (continuous infusion over several days), lorazepam may be a better choice in critically ill patients because there are no active metabolites (29,30). Propofol, an IV anesthetic commonly used for ICU sedation, has a rapid onset and short duration of action. It does not appear to have major changes in its PK parameters in patients with renal and/or hepatic dysfunction (32).

Many drugs that are commonly used in critically ill patients can cause QT interval prolongation, leading to possible ventricular dysrhythmias (e.g., Torsades de Pointes). Some antipsychotic medications (e.g., haloperidol, thioridazine, mesoridazine, chlorpromazine) and some other centrally acting drugs (e.g., droperidol and venlafaxine) are just a few drugs that carry a risk of prolonging the QT interval. Close monitoring of the electrocardiogram and attention to normal levels of magnesium and potassium are required when using these agents in critically ill patients with underlying conduction defects.

The use of NMB drugs has been minimized in most modern ICUs. However, NMBs are still commonly employed for intubation and occasionally used during the treatment of patients with severe traumatic brain injury (TBI) and for acute respiratory distress syndrome (ARDS). The most common PK alteration for these NMB drugs in critically ill patients is related to changes in clearance.

Clearance is decreased by deterioration in renal, hepatic, cardiovascular, and endothelial systems (discussed earlier).

Pancuronium is mostly cleared by the kidneys and any decrease in renal function or perfusion can result in its accumulation (30,33). Liver failure can cause a decrease in clearance of hepatically metabolized NMBs such as vecuronium because of an increase in their volume of distribution. Vecuronium is 85% cleared via the biliary route. Thus, any decrease in liver metabolism or perfusion can decrease its clearance (30). Cisatracurium relies on pH-dependent Hofmann elimination and nonspecific enzymatic ester hydrolysis for its clearance rather than the liver or kidney (34,35). ☞ **Cisatracurium is the ideal NMB drug for critically ill patients with liver and renal failure who require only a brief period of NMB.** ☞ Hypothermia and acidosis can slightly decrease the clearance of cisatracurium (36). However, this is rarely clinically significant. Important drug–drug interactions involving NMB drugs include corticosteroids, aminoglycosides, magnesium, and other agents that affect neuromuscular transmission can lead to the development of an acute myopathy in ICU patients (33).

### Gastrointestinal

Critically ill patients often suffer altered GI motility (37). Changes in GI motility or changes in GI tract pH can affect the absorption and GI metabolism of some drugs. Postoperatively, patients can have hypoactive GI tracts secondary to the procedure or the use of opioid analgesics during the surgery or ICU stay. With some success, prokinetic agents have been used to improve gastric emptying and tolerability of enteral feeding (38,39). The effect of these prokinetic agents on drug absorption may not be easy to assess. Hyperactive GI motility is less frequently found in critically ill patients. This may be drug induced or result from the disease state. Often ICU patients are nutritionally supported with continuous enteral tube feedings which can interfere with the absorption of several drugs.

In many ICU patients, it is standard practice to use protective agents to prevent the development of stress-induced gastritis (e.g., H<sub>2</sub>-antagonists, proton pump inhibitors). Most of these agents cause an increase in gastric pH. This increase in pH can be detrimental to the absorption of some medications (e.g., itraconazole capsules) that require an acidic gastric environment for maximal absorption. Frequent presence of an ileus and decreased splanchnic perfusion may decrease the absorption of enterally administered drugs (40). Therefore, the IV route of administration is preferred in unstable ICU patients. However, this route of administration does have its inherent risks (infection) and costs. When GI absorption returns to a more reliable state, it is more desirable to give drugs by the GI route.

### Respiratory

Respiratory failure does not generally have any direct impact on the PK or PD of a drug. However, indirectly it can cause changes in hepatic (hypoxemia) and renal (respiratory alkalosis or acidosis) clearance of some drugs (30). The pulmonary circulation also plays an important role in the metabolism of norepinephrine, angiotensin, and serotonin (40).

### Muscle Disorders

Muscular disorders can be seen in critically ill patients. These can be associated with myopathy and neuromyopathy. In hemodynamically unstable patients the alteration in

muscle perfusion can alter the intramuscular absorption of some drugs. The use of NMB drugs have the potential for causing or exacerbating neuropathy and myopathy, especially in patients with sepsis, poor glucose control, and those receiving steroids. Therefore, NMB drugs should be carefully monitored, used only when absolutely necessary (30), and discontinued as soon as possible (also see Volume 2, Chapter 6).

### Hyperdynamic State

Some critically ill trauma patients experience an increased clearance of some drugs. For example, many patients with an extensive burn injury or closed head injury experience an early increase in metabolic rate. Therefore, for drugs with a narrow therapeutic range, it is important to monitor drug levels and perform PK studies early and repeatedly.

### Acid–Base Disorders

✎ **Acidosis or alkalosis can change the protein binding of drugs (40).** ✎ However, the direct effects of acid–base disorders on PK and PD parameters of drugs in critically ill patients are not well studied. For highly protein-bound drugs, these changes are more profound. If there is an increase in the free fraction of drugs, the risks of adverse effects will be increased. In contrast, a decrease in the free fraction of a drug can lead to decreased therapeutic effect and potentially treatment failure. Changes in protein binding also can alter the  $V_d$  of drugs and consequently affect their Cl. Some drugs (e.g., cisatracurium) rely on pH-dependent Hofmann elimination and nonspecific enzymatic ester hydrolysis for their Cl (34). Acidosis causes a decrease in this clearance with a corresponding increased risk of accumulation. Respiratory acidosis can lead to a trapping of fentanyl within the central nervous system (CNS), prolonging and potentiating its effects (32). Alkalosis increases the lipophilicity of morphine and fentanyl, which can generate higher CNS levels during the initial distribution phase (32).

### Drug Interactions

Mechanisms by which drugs can interact can be categorized into PK, PD, or combined interactions. PK interactions include those that alter absorption, distribution, metabolism, or excretion and are the most important. PD interactions include those that alter the effect of the drug on the body. Combined interactions are those that occur when two or more drugs are used together and increase the likelihood of combined toxicity (41).

### Absorption

✎ **There are several ways by which the GI absorption of drugs may be affected,** ✎ such as the concurrent use of other drugs that (i) bind or chelate, (ii) have a large surface area for adsorption, (iii) alter gastric pH, (iv) alter GI motility, or (v) affect the GI transport proteins (41).

A classic example of binding and chelation involves the fluoroquinolone antibiotic class and the presence of divalent or trivalent cations commonly found in antacids, iron salts, dairy products, or continuous enteral feeding. It is recommended to not administer these cations enterally for two hours before or up to six hours after an oral dose of fluoroquinolone (42).

Activated charcoal is an example of a substance with a very large surface area available for drug adsorption and is commonly employed for reducing the absorption of toxic

substances. Volume 1, Chapter 31 includes a discussion of the use of activated charcoal in treatments of poisonings.

Certain medications alter the pH of the stomach, and this can impact the degree of absorption.  $H_2$ -antagonists (e.g., famotidine) or proton pump inhibitors (e.g., lansoprazole) can raise the gastric pH and alter the absorption of certain drugs. For example, itraconazole is an antifungal that requires an acidic environment in the stomach for optimal absorption. If the gastric pH is elevated, absorption can be impaired. Drugs that modify GI motility can also impact drug absorption (30).

Promotility agents (e.g., metoclopramide) can decrease intestinal transit time and therefore decrease the time a drug is in contact with absorptive surfaces in the GI tract. Inhibition of the GI transport proteins (e.g., PGP) can hinder the transluminal movement of drugs and ultimately the extent of absorption. It is important to understand the difference between rate and extent of absorption when discussing drug interactions. If the rate of absorption is reduced, it may not be clinically relevant but if the extent of absorption is reduced, there are usually clinical consequences.

Most modern ICUs support the early initiation of enteral nutrition. Some oral medications are not compatible with enteral nutrition, and knowledge of these interactions will help the clinician decide whether the enteral route of drug administration is desirable. Most drug interactions that occur with continuous feeding involve decreased or unpredictable absorption (43,44). Some common medications known to interact with continuous enteral nutrition are listed in Table 9. Medications with incompatibilities with tube feedings should not be mixed into the enteral formula. Rather, these should be administered separately, after evacuating the stomach contents, and subsequent tube feedings should be held one to two hours. Alternatively, different drugs, or route of administration can be selected.

Many commonly used medications in the critical care setting should not be crushed and administered via a feeding tube. In general, any product that is enteric coated or labeled as delayed-release, sustained-release, or extended-release should not be crushed (45). Always consult a pharmacist for alternatives.

### Distribution

Drug interactions can alter drug distribution by two main mechanisms: (i) plasma protein binding competition and (ii) displacement from tissue-binding sites. When a drug competes with another drug for protein-binding sites, there is an increased concentration of free drug (i.e., unbound)

**Table 9** Common Oral Medications that Interact with Continuous Enteral Nutrition

that is displaced into the plasma. This could increase the risk of adverse effects. If a drug were to be displaced from its tissue-binding site, then there would be a corresponding increase in the plasma concentration of the displaced drug; however, the clinical importance of this specific alteration is not clear (41).

### **Metabolism (Cytochrome P450 Enzyme System)**

The CP450 isoenzymes are a group of heme-containing enzymes found primarily in the lipid bilayer of the endoplasmic reticulum of hepatocytes. They play a crucial role in the oxidative metabolism of exogenous (e.g., drugs) and endogenous substances (4,23,30,46,47). Other areas where these isoenzymes are found are the enterocytes of the small intestine and to a lesser extent in the kidneys, lungs, and brain. The way the isoenzymes are classified is based on family, subfamily, and individual gene (e.g., CP3A4). With the knowledge of individual substrates, inducers, and inhibitors of each isoenzyme, clinicians may be able to predict clinically important drug–drug interactions.

Differences do exist between patients, which include genetic polymorphism in the functional expression of some of the isoenzyme systems (e.g., CP2C9, CP2C19, and CP2D6) (47). This can lead to underexpression or overexpression of the enzyme system, which in turn can lead to adverse effects and/or therapeutic failures by either inhibiting or inducing metabolism. Other influences that can lead to variation in drug metabolism include age, nutrition, stress, hepatic disease, hormones, and other endogenous chemicals (48). The predominant enzyme systems responsible for most drug metabolism include CP3A4, CP2D6, CP1A2, and the CP2C subfamily.

Some drugs are metabolized by several isoenzyme systems, so it may be difficult to predict the magnitude of a drug–drug interaction if only one of the isoenzyme systems is being inhibited or induced. Also, some drugs may inhibit one isoenzyme system and be a substrate for another. For example, fluoxetine is an inhibitor of the CP3A4 enzyme, but it is metabolized by the CP2D6 enzyme system.

Inhibition of the CP450 system most often occurs as a result of competitive binding at the enzyme's active site (46). This inhibition is dependent on a few factors: binding affinity of both drugs, concentration of the substrate required for inhibition, and half-life of the inhibiting drug (46). Another important piece of information the clinician needs in order to interpret or predict drug–drug interactions is the onset and offset of enzyme inhibition. This is related to the half-life and time to steady state of the inhibiting drug. Classic examples would be cimetidine, which inhibits CP1A2 within 24 hours after a single dose, and amiodarone, which may take several months to inhibit CP3A4 because of its long half-life and considerable length of time to reach steady-state serum concentrations. Another common way by which inhibition may take place is noncompetitively, which results in inactivation of the enzyme by the inhibitor with normal substrate binding (46).

Enzyme induction is evidenced by an increase in hepatic blood flow or increased synthesis of the metabolizing CP450 enzymes (46). For example, enzyme-inducing anticonvulsants (e.g., phenobarbital) cause an increase in absolute liver size. Similar to enzyme inhibition, the effects of induction depend upon the precipitating drug's half-life. For example, rifampin has a relatively short

half-life and enzyme induction becomes apparent within 24 hours (46). Phenobarbital's half-life is much longer and therefore it may take 7 to 14 days before the effects of induction are seen (46). Once the causative drug is discontinued, the duration of induction depends on the half-life of the drug and the CP450 enzyme (half-life of one to six days). For example, once rifampin (half-life of three to five hours) has been discontinued, the duration or length of induction will be determined by the CP450 degradation time, not rifampin's presence in the body. Age, cirrhosis, and hepatitis may also impact the degree of induction.

With the knowledge of the CP450 enzyme systems and drugs that are known to be substrates, inducers, and inhibitors, health-care practitioners may be able to anticipate clinically important drug–drug interactions. This is most important for narrow therapeutic index drugs. Therefore, monitoring serum drug levels frequently and performing PK analysis to ensure appropriate drug regimens is essential. Lists of drugs commonly used in the ICU which are substrates, inducers, and inhibitors of various CP450 isoenzyme systems are readily available online and in pharmacology texts (46).

The following relevant examples illustrate how a health-care professional could utilize such information in predicting important drug–drug interactions. Example 1: a patient stable on warfarin with a therapeutic bleeding time gets initiated on amiodarone for atrial fibrillation. By identifying that both enantiomers of warfarin (*R* and *S*) are substrates of the CP450 enzyme system (CP3A4 and CP2C, respectively), one could predict that by adding an inhibitor of both isoenzyme subsystems (e.g., amiodarone) the bleeding time of the patient would probably rise and the chance of a clinically significant bleeding event would be elevated. Example 2: an intubated patient in the ICU is being sedated with midazolam by a continuous infusion. It was decided to treat his human immunodeficiency virus (HIV+) infection by initiating antiretroviral therapy, which included ritonavir. Noticing that ritonavir is an inhibitor of the CP3A4 isoenzyme subsystem and that midazolam is a substrate for that subsystem, the health-care practitioner may want to evaluate whether midazolam is the most appropriate choice of sedative in this particular patient.

☞ **Stimulation of the CP450 enzyme system in the liver and small intestine can lead to the increased metabolism of certain drugs; conversely, inhibition of this system can lead to elevated drug levels.** ☞

## **THERAPEUTIC DRUG MONITORING**

TDM is a process of individualizing the dosage regimen of drugs with narrow therapeutic indices (a small range between its toxic plasma concentration and subtherapeutic plasma concentration). Using PK analysis, TDM includes continuous assessment of the therapeutic response and potential adverse effects and becomes more important in critically ill patients. Drugs can be divided into two general TDM categories: narrow therapeutic index agents and broad therapeutic index drugs. Here we will discuss some of the common drugs in the adult ICU that have a narrow therapeutic index. Because critically ill patients exhibit wide variable PK parameters, it is particularly important to monitor these drugs closely.

## Antimicrobial Agents

### Aminoglycosides

Aminoglycosides (e.g., gentamicin, tobramycin, amikacin) require TDM because of their narrow therapeutic index and risk for adverse effects (ototoxicity, nephrotoxicity). Critically ill patients often will display a larger  $V_d$  (~0.4 L/kg) than noncritically ill patients (~0.25 L/kg) (30,49,50). Many acutely ill patients will develop renal impairment and since the aminoglycosides are primarily excreted unchanged by glomerular filtration, frequent dosage adjustment based on PK analyses is necessary.

Within the past few years, once-daily dosing of aminoglycosides has gained popularity, and for good reason (49). Although aminoglycosides are themselves nephrotoxic, they remain a mainstay in the antimicrobial arsenal against aerobic gram-negative bacteria, as well as enterococcal and staphylococcal species (see Volume 2, Chapter 53).

The once-daily strategy is advantageous for a number of reasons. Aminoglycosides have concentration-dependent bactericidal activity, increasing the eradication of the organism(s) in the presence of higher serum drug concentrations. Once-daily therapy diminishes the ability of the organism to shut down the intracellular transport of the aminoglycoside (a form of resistance). This adaptive resistance occurs more frequently with multiple dose regimens. Aminoglycosides also possess a postantibiotic effect (PAE), a bacteriostatic environment after antibiotic exposure (the higher the aminoglycoside concentration, the longer the PAE). Most single-daily dose regimens (5–7 mg/kg/day) of gentamicin or tobramycin produce peak serum level concentrations approaching 15–20 mg/L and trough levels that are undetectable even in mild renal dysfunction.

Human studies have shown saturable uptake of aminoglycosides into the renal cortex (51). Therefore, the higher serum concentrations associated with once-daily administration does not predispose the patient to an increased risk of nephrotoxicity when compared with multiple daily dosing of aminoglycosides.

### Vancomycin

Vancomycin is a bactericidal glycopeptide used for various gram-positive infections. It penetrates into most tissues well and is excreted almost entirely unchanged in the urine. Since compromised renal function is commonly seen in ICU patients, diligent monitoring of plasma levels is warranted. For intermittent hemodialysis patients, a dose of vancomycin ( $15 \pm 5$  mg/kg IV) every three to five days is common, whereas the same dose every 24 to 48 hours is common in those patients receiving CRRT. Since vancomycin primarily exhibits time-dependent killing, the routine monitoring of peak serum levels is generally not warranted unless an estimate of the patient's  $V_d$  is needed. Random or trough levels of vancomycin are generally sufficient to provide enough information to individualize a dosing regimen (30,52). For most indications, the goal vancomycin trough levels should be targeted between 5 and 15 mg/L. There are a few indications where clinicians might be more aggressive [e.g., methicillin-resistant *Staphylococcus aureus* (MRSA) bacteremia, endocarditis, meningitis, and osteomyelitis]. For these indications, the current trend is to target vancomycin trough levels of at least 10 mg/L (range 10–20 mg/L). For the treatment of MRSA-associated, ventilator-associated pneumonia, an even more aggressive dosing strategy is currently practiced to produce vancomycin trough levels approaching 15–20 mg/L. It is important to note

that vancomycin by itself infrequently causes nephrotoxicity. Only when it is administered in combination with other nephrotoxic agents (e.g., aminoglycosides) does the incidence of renal toxicity approach 30% (52).

### Cotrimoxazole

Trimethoprim-sulfamethoxazole (TMP-SMX) is a combination antibiotic with a broad spectrum of activity against gram-positive and gram-negative organisms. There is a paucity of data that evaluates PK variables of TMP-SMX in critically ill patients. However, in hyperdynamic, acutely ill trauma patients [e.g., those with systemic inflammatory response syndrome (SIRS)], the half-life of SMX appears to be shorter and the  $V_d$  and Cl are larger (53). These data are in conflict with a study evaluating PK parameters of TMP-SMX in critically ill and noncritically ill AIDS patients where the  $V_d$ , Cl, and the half-life were similar between the two groups (54). Since there is potential for renal and bone marrow toxicity, monitoring of sulfonamide levels would be prudent in the critically ill patient, especially those patients with underlying renal dysfunction. A serum sulfonamide level of 50 to 150 mg/L is considered adequate for optimal therapy (30).

## Miscellaneous Anti-infective Agents

### Fluconazole and Itraconazole

Other agents that infrequently require TDM are the “azole” antifungal agents (e.g., fluconazole, itraconazole). Intact oral itraconazole capsules (not suspension) depend on the acidity of GI tract for absorption. It may be helpful to check an itraconazole level to assess oral absorption in those patients who are concomitantly taking gastric acid suppressing agents (e.g.,  $H_2$ -antagonists and proton pump inhibitors) (55).

### Ganciclovir

Ganciclovir is an antiviral agent used primarily for the treatment or prophylaxis of cytomegalovirus (CMV). It is highly nephrotoxic and can cause leukopenia and thrombocytopenia. The elimination of ganciclovir depends upon renal excretion, and therefore dose adjustments for impaired renal function is necessary in order to avoid adverse side effects (30). Guidelines for dosage adjustments for renal dysfunction exist (7). Occasionally, (especially patients on dialysis), it may be necessary to check the ganciclovir serum level and perform a PK analysis.

## Cardiovascular Drugs

### Digoxin

In critically ill patients, the most common use of digoxin is to control the heart rate in the setting of atrial fibrillation. The bioavailability of digoxin tablets is 50% to 90%. Although there is better bioavailability with the capsule formulation, the most common route of administration in the adult ICU is the IV route. Digoxin has a large  $V_d$  (about 7.3 L/kg) because of its extensive tissue binding (40,56).

However, in the setting of renal failure (estimated creatinine Cl <20 mL/min or those patients dependent on hemodialysis), the  $V_d$  is reduced. Loading and maintenance doses of digoxin will need to be adjusted accordingly for this reduction in  $V_d$ . Digoxin is not distributed into fat, and therefore the loading dose should be based on an estimate of ideal body weight (7). Digoxin has a long two-compartmental distribution phase, that explains the delay in its pharmacological action.

The sampling time of serum digoxin levels is important because serum digoxin levels drawn during the initial distribution phase may be falsely elevated. Therefore, it is important to wait at least four hours after an IV dose and six hours after an oral dose to check a serum digoxin level. Normally, 60% to 80% of digoxin is eliminated unchanged in the urine. Metabolism and biliary excretion contribute to nonrenal elimination.

The elimination half-life of digoxin is about one to two days in subjects with normal renal function and may be as long as five days in anuric patients. In critically ill patients with renal dysfunction, it is necessary to monitor digoxin serum levels closely and adjust the dosage as needed. The generally accepted therapeutic range of digoxin is 0.8–1.2 mcg/mL (for heart failure) and 0.8–2.0 mcg/mL (for atrial fibrillation). It is important to note that the immunoassays used to measure serum digoxin are not specific and may react with certain drug metabolites or endogenous digoxin-like substances (7,40), which could lead to a falsely elevated level.

Digoxin can interact with several drugs. Some of the most important digoxin–drug interactions involve the calcium channel blockers (e.g., diltiazem and verapamil) and amiodarone, both of which can increase the serum digoxin level significantly. Therefore, the dosage must be reduced and the digoxin level measured as needed.

Critically ill patients with electrolyte abnormalities (hypokalemia, hypomagnesemia, and hypercalcemia) are at higher risk of developing digoxin toxicity (ventricular arrhythmias, heart block, and other arrhythmias) (7,40). Close monitoring of serum electrolytes, renal function, and digoxin levels, performing PK analysis, and calculating an individualized dosage are highly recommended in ICU patients receiving digoxin.

### Lidocaine

In critically ill patients, lidocaine is used to manage serious ventricular dysrhythmias. Because lidocaine has poor oral absorption, it is given initially by an IV bolus followed by a continuous IV infusion. Its  $V_d$  is about 1.3 L/kg (57). In ADHF, the  $V_d$  is decreased, whereas in chronic liver disease, it is increased (23). Lidocaine is mainly metabolized in the liver and its metabolites depend on renal clearance for their elimination. The usual elimination half-life of lidocaine is about 100 minutes, but in liver failure, the half-life may be prolonged. Frequent measurement of serum lidocaine levels is needed in critically ill patients with some degree of liver or heart failure. The therapeutic lidocaine level is 1–5 mg/L (57).

### Procainamide

In critically ill patients, procainamide may be used in the treatment of ventricular and supraventricular dysrhythmias. It is usually used as continuous IV infusion in the ICU and switched to an oral form when appropriate. Oral bioavailability is about 75% to 100%, and it has a larger  $V_d$  than lidocaine (1.7–2.2 L/kg) (58). The therapeutic procainamide level is 4–8 mcg/mL, and although higher concentrations have been used in some patients, levels exceeding 8 mcg/mL have been associated with electrocardiographic changes (prolongation of the PR interval, QT, or QRS intervals) (59). The elimination half-life of procainamide is about three hours. It is metabolized in the liver to *N*-acetyl procainamide (NAPA), which is an active metabolite and is eliminated renally. In critically ill patients with some

degree of renal dysfunction, NAPA can accumulate and cause adverse effects. Therefore, close monitoring of serum procainamide and NAPA levels are needed.

### Anticonvulsants

TBI patients often require treatment or prophylaxis for seizures. In these cases, the most commonly used agent is phenytoin. Carbamazepine, valproic acid, and phenobarbital may be used if phenytoin is ineffective or contraindicated.

#### Phenytoin

Phenytoin is the first-line agent for seizure prophylaxis following TBI. In the ICU, physical barriers or disease states can limit the appropriateness of administering medications enterally. Concurrent use of enteral feeding can further complicate the absorption of phenytoin; the intramuscular route is also unreliable and not recommended (60). The IV route is most commonly used in unstable, critically ill patients. Unlike the oral capsules, which are extended release, the injectable form of phenytoin is not and usually requires more than once-daily dosing.

Phenytoin is highly bound to albumin, and critically ill patients may have a significant degree of hypoalbuminemia, which results in an increased free fraction of phenytoin. There are formulas for adjusting the total phenytoin level that is usually reported by the laboratory in order to maintain a therapeutic-free level (60). However, the reliability of these equations is questionable; therefore, in critically ill patients, measurement of free and total phenytoin levels may be necessary.

Mainly metabolized in the liver, phenytoin is a low-extraction type drug; thus, changes in liver blood flow minimally affect its metabolism. However, induction or inhibition of liver microsomal enzymes will markedly affect the liver metabolism of phenytoin. This enzyme system is saturable, which explains the Michaelis–Menten elimination of phenytoin, that is, an increase in serum concentration of phenytoin beyond a certain point may not increase the rate of its clearance. So a small increase in dose can disproportionately increase the serum concentration and increase the risk of toxicity (60). The therapeutic range of serum phenytoin is 10–20 mg/L. The normal free fraction is about 10%, corresponding to a free plasma concentration of 1 to 2 mg/L.

In critically ill patients with oliguria and hypoalbuminemia, the free fraction of the drug can be increased; therefore, monitoring of both total and free serum phenytoin levels may be necessary. Following TBI, the rate of phenytoin metabolism may be increased (in the early hypermetabolic phase) and require an increased daily dosage. It is important to watch for changes in the rate of phenytoin metabolism in this subgroup. As the hypermetabolic state subsides, the rate of phenytoin metabolism may decrease substantially, and the dosage will have to be decreased.

#### Carbamazepine

Carbamazepine is usually the second-line anticonvulsant agent chosen in trauma patients. Carbamazepine is not available in an IV formulation and this limits its usefulness in the ICU setting. Oral bioavailability is about 75% but it may be variable and dissolution rate dependent (61). It is highly bound to  $\alpha$ -1-acid glycoprotein, which can explain the increase in dosage requirement in some burn patients. It is mainly metabolized in the liver, and carbamazepine has the ability to induce its own metabolism. This self-induced metabolism usually starts after three to five days of therapy.

Frequent monitoring of carbamazepine serum concentrations in critically ill patients may be necessary. The therapeutic range is 4–12 mg/L (62). The adverse effects of carbamazepine include bone marrow suppression manifested by leukopenia and/or thrombocytopenia. It also can cause a hyponatremic hypo-osmolar condition similar to the syndrome of inappropriate antidiuretic hormone secretion (61).

### **Valproic Acid**

Valproic acid is available in injectable form and this has increased its role in the ICU setting, usually as a second or third choice anticonvulsant in trauma patients. It is highly protein bound, mostly to albumin, and this binding appears to be saturable. The protein binding may actually decrease in TBI patients (61), so monitoring the free and total valproic acid levels may be necessary. Valproic acid is metabolized in the liver and because of its low extraction ratio, changes in liver perfusion usually do not alter its clearance. However, drugs that induce liver microsomal enzymes (e.g., phenytoin, phenobarbital, and carbamazepine) can increase valproic acid metabolism. Valproic acid itself is an inhibitor of liver enzymes and can affect the clearance of some drugs (63). The appropriate therapeutic range for valproic acid is not clear. It is thought that the minimum effective trough serum level for optimal seizure control is 50 mg/L (61) and the upper limit is probably about 120 mg/L. The most serious adverse effects are hepatotoxicity and thrombocytopenia.

### **Barbiturates**

Barbiturates are not used as much in today's ICU as they historically have been used. Pentobarbital is occasionally used in TBI patients for control of resistant-increased intracranial pressure, and phenobarbital may be used as an anticonvulsant for other patients in the ICU. Phenobarbital is about 50% protein bound; however, in trauma and burn patients (especially those with uremia), the free fraction may be much higher (61). Hepatic enzymes oxidize phenobarbital, and changes in liver blood flow do not alter its clearance. It is a powerful inducer of liver enzymes, which can affect the metabolism of other hepatically metabolized drugs. The therapeutic range is 15–40 mg/L. The major adverse effects seen are those involving the CNS (e.g., drowsiness, lethargy, hangover).

### **Immunosuppressants**

The immunosuppressant agent regimens used for both solid organ and bone marrow transplantations are usually metabolized in the liver and have drug interactions involving the CP450 enzyme system. In treating critically ill patients, clinicians must be familiar with these agents or seek the help of colleagues who are experts in this field. The interactions of immunosuppressants must be recognized and evaluated, and appropriate measures taken, if necessary.

### **Cyclosporine**

Cyclosporine is a commonly used immunosuppressive agent alone and in combination with other immunosuppressive drugs. It is extensively metabolized in the liver to metabolites that depend on the biliary pathway for elimination. Cyclosporine is associated with a high degree of nephrotoxicity and has numerous drug–drug interactions (64). Cyclosporine levels must be monitored frequently

because there is no practical PK model available for analysis. When evaluating cyclosporine levels, it is vital to consider the sample type (whole blood vs. plasma) and the technique used for measurement [(immunoassay vs. high performance liquid chromatography (HPLC))].

Different sample types and techniques used have different values. Therefore, care must be taken to assure that the desired serum level range is normalized for potential variables. The target immunosuppressant level is also highly variable and depends on the type of organ transplanted and the specific center that performed the transplant. Other variables that can help define the target level would include clinician experience, the clinical picture of the patient, the time after the transplant, past rejection history, adverse effects, and potential drug–drug interactions. Whenever a drug is added or discontinued, the effect on the cyclosporine level must be considered and the dosage should be reevaluated.

Cyclosporine can cause an increase in serum creatinine, which appears to be proportional to the cyclosporine level. Unless a decrease in the cyclosporine level is clinically indicated, there is no need for dosage adjustment for renal dysfunction or CRRT. With liver dysfunction, cyclosporine can accumulate resulting in an increased blood level. Cyclosporine can also increase the bilirubin level. Although this increase can be secondary to liver dysfunction, it is usually due to some degree of cholestasis. This is usually observed during initial cyclosporine therapy. After a few days, the bilirubin usually begins to decline; if not, the clinician should consider other causes including cyclosporine-induced hepatotoxicity. Drug interactions are extensive and can be divided into three types (Table 10) as those that can affect metabolism, bioavailability, or nephrotoxicity of cyclosporine.

### **Tacrolimus**

Tacrolimus is an immunosuppressant similar to cyclosporine. It is extensively metabolized in the liver and can cause nephrotoxicity (64). Daily checking of the trough tacrolimus level is often necessary as the target range is quite variable. In addition, most of the previous discussion about cyclosporine also applies to tacrolimus. It is about 100 times more potent than cyclosporine on a weight basis; therefore, tacrolimus dosage and serum levels are about one-hundredth those of cyclosporine.

### **Sirolimus**

Sirolimus is the newest immunosuppressive drug in the United States and its role is continually evolving. It is primarily used in combination with cyclosporine or tacrolimus to achieve an adequate level of global immunosuppression while minimizing the patient's exposure to the nephrotoxic immunosuppressants (e.g., cyclosporine and tacrolimus) (65). Many institutions strongly recommend monitoring sirolimus levels to avoid adverse effects, especially in critically ill patients. One of the serious unwanted effects of sirolimus is leukopenia (also see Volume 2, Chapter 57). More studies are needed to define an appropriate sirolimus level when it is used with cyclosporine- or tacrolimus-based immunosuppressive regimens. Investigators are studying sirolimus to determine whether it can be used without cyclosporine or tacrolimus. If so, the target level for various organ transplantations should be defined. Drug interactions with sirolimus are similar to those found with tacrolimus and cyclosporine (Table 10).

**Table 10** Major Drug Interactions with Cyclosporine, Tacrolimus, and Sirolimus

*Drugs that increase the absorption of cyclosporine (tacrolimus and sirolimus):* grapefruit juice, metoclopramide, oral erythromycin, cyclosporine (increases sirolimus)

*Drugs that affect the metabolism of cyclosporine (tacrolimus and sirolimus):* drugs that increase metabolism: carbamazepine, phenobarbital, phenytoin, rifampin, St. John's wort

*Drugs that decrease metabolism:* allopurinol, amiodarone, androgens, azole antifungal agents (fluconazole, itraconazole, ketoconazole), bromocriptine, clarithromycin, erythromycin, diltiazem, nefazodone, nifedipine, nifedipine, oral contraceptives, sirolimus verapamil

*Drugs that increase the nephrotoxicity of cyclosporine (tacrolimus):* acyclovir, aminoglycosides, amphotericin B, foscarnet, ganciclovir, tacrolimus (cyclosporine), NSAIDs, vancomycin, and other nephrotoxic agents

*Miscellaneous:* digoxin (decrease clearance of digoxin by cyclosporine); neuromuscular blockers (prolonged neuromuscular blockage); HMG-CoA reductase inhibitors (increase risk of myopathy with cyclosporine); caspofungin (decreased tacrolimus and sirolimus levels, increased caspofungin level with cyclosporine)

*Abbreviations:* HMG-CoA, 3-hydroxy-3-methylglutaryl-Coenzyme A; NSAIDs, nonsteroidal anti-inflammatory drugs.

### Miscellaneous (Mycophenolate and Azathioprine)

Azathioprine and mycophenolate belong to the antimetabolite class of immunosuppressive agents and are used in combination with corticosteroids and either cyclosporine or tacrolimus. The dosage ranges from 2 g/day up to 3 g/day and primarily depends on the type of organ transplanted. Azathioprine has an important drug–drug interaction with allopurinol. If used together, the dose of azathioprine should be reduced to avoid the accumulation of azathioprine's active metabolite (6-mercaptopurine). It is important to monitor for dose limiting adverse effects such as bone marrow suppression (neutropenia, pancytopenia), GI distress (nausea/vomiting, diarrhea, abdominal pain), and liver dysfunction (cholestasis, elevated hepatic enzymes).

## DRUG-INDUCED FEVER

☞ **Drug fever is defined as a febrile response to a drug without cutaneous manifestations and is estimated to occur in about 10% of hospitalized patients (66).** ☞ The incidence may be higher in critically ill patients because they are on more medications. It may be difficult to recognize drug fever in ICU patients, as there are potentially multiple causes of fever (see Volume 2, Chapter 46). Although it usually occurs one to two weeks after a drug was started, it can occur at any time. This can lead to prolonged hospitalization and unnecessary tests. The most common cause of drug fever is a hypersensitivity reaction. Altered thermoregulatory mechanism, idiosyncratic reactions, and the pharmacological action of drugs can also be the cause of drug fever (66). Some common ICU drugs that are associated

with drug fever are listed in Volume 2, Chapter 46. Treatment of drug fever consists of discontinuation of the suspected offending medication.

## DRUG-INDUCED RASH (TOXIC EPIDERMAL NECROLYSIS/STEVENS–JOHNSON SYNDROME)

The most common adverse drug reactions (ADRs) are those involving the skin. They affect about 2% to 3% of hospitalized patients (67). Among those, only a small percentage are life threatening. Stevens–Johnson syndrome (SJS) is fatal in about 5% of patient cases and toxic epidermal necrolysis (TEN) in about 30% of patient cases (67). The clinical features and prognosis of these two diseases are different, yet they have similar histopathological findings and are caused by similar drugs. Some consider SJS to be a mild form of TEN.

If epidermal detachment is less than 10% of the total body surface area, it is classified as SJS. If it is greater than 30%, it is classified as TEN. If the affected area is between 10% and 30%, then it is considered an overlapped case of SJS–TEN. The incidence of SJS is 1.2 to 5 per million per year and for TEN 0.4 to 1.2 per million per year (67). Drugs that are associated with SJS and TEN and are commonly used in an adult ICU are listed in Table 11 (68).

Among drugs that can cause reactions, sulfonamides are the most frequent. Phenytoin, phenobarbital, and carbamazepine all can cause these severe cutaneous reactions. These three drugs have related chemical structures and are metabolized by similar pathways to reactive compounds. It is these reactive compounds that are thought to be immunogenic, causing the cutaneous reaction (69). Because of extensive skin detachment, the treatment is the same as for burn victims and requires a burn intensive care facility. The seriousness of these reactions and the lack of definitively

**Table 11** Medications Associated with Stevens–Johnson Syndrome and/or Toxic Epidermal Necrolysis

Stevens–Johnson syndrome	Toxic epidermal necrolysis
Acetaminophen	Acetaminophen
Allopurinol	Allopurinol
Carbamazepine	Barbiturates
Cephalosporins	Carbamazepine
Cotrimoxazole	Chloramphenicol
Ibuprofen	Ibuprofen
Macrolides (e.g., erythromycin)	Imidazole antifungal agents (e.g., ketoconazole)
Penicillins	Indomethacin
Phenobarbital	Lamotrigine
Phenytoin	Macrolides
Propranolol	Penicillins
Quinolones	Phenytoin
Sulfadiazine	Quinine
Sulfonamides	Quinolones
Thiazides	Ranitidine
Valproic acid	Sulfonamides
	Sulindac
	Tetracyclines
	Valproic acid

Source: Adapted from Ref. 68.

effective treatment have produced a large body of literature on some effective and ineffective treatments (70).

As soon as the diagnosis of SJS/TEN has been made, the suspected agent(s) should be withdrawn. Early discontinuation of causative agents has been reported to improve the outcome (68,71). The principles of symptomatic treatments are the same as for burns, which include meticulous skin care, fluid replacement, nutritional support, and antimicrobial therapy (67). Plasmapheresis, immunosuppressive therapy, oral corticosteroids, human IV immunoglobulin, all have been used with varying degrees of success (70). Their role in the treatment of SJS and TEN remains to be established.

## EYE TO THE FUTURE

Personalized medicine is a concept that describes patients receiving the most appropriate drugs with the most fitting dosage based on their genetic makeup (72). This concept appears to be gaining clarity as our knowledge regarding the human genome expands. Poor drug tolerability, adverse drug events, and therapeutic failure may be explained by genetic differences. Patients may express different alleles on genes that are responsible for creating certain drug-metabolizing enzymes (e.g., CP450 enzyme system, namely CP2C9, CP2C19, CP2D6). These differences may lead to diversity among patients' metabolic transformation of a particular medication, leading to individual variability in the efficacy and toxicity of drugs (73,74). It is important to remember that genetic polymorphisms do not always translate into phenotypic changes (75). The study of the genetic basis for individual drug response is called pharmacogenomics. Initially, pharmacogenomics focused on drug metabolism but has recently expanded to evaluate drug transporters that can influence the absorption, distribution, and excretion of medications as well as drug receptors (75).

Several examples of genetic differences in drug metabolism reside within the CP450 enzyme system. For example, approximately 8% to 10% of Caucasians are deficient in the isoform CP2D6, which represents the main metabolic pathway of drugs such as antidysrhythmic agents,  $\beta$ -adrenoreceptor blockers, tricyclic antidepressants, and certain opioids like codeine (76). For patients with this deficiency,  $\beta$ -adrenoreceptor blockade will be more pronounced and the effect of codeine will be much less because of the impaired production of the active metabolite, morphine. Another example of genetic polymorphism lies in the CP2C9 isoform and warfarin metabolism. Individuals expressing this mutation can only tolerate low doses of warfarin because their clearance is about 10% of those without the mutation (48).

Perhaps one of the more popular proteins that have recently been studied is PGP, that is involved in energy-dependent transport of drugs and their metabolites into urine, bile, and the intestinal lumen. PGP also plays a large role in regulating drug concentrations in the brain (e.g., digoxin, cyclosporine, and dexamethasone) (75). It is understood that individuals express PGP in differing amounts, contributing to the concept that genetic makeup plays a critical role in the PK of drugs.

Finally, there are genetic alterations in drug receptors which can result in a wide variation in drug effect. Some of these examples include the  $\beta$ 2-adrenoreceptor and response to  $\beta$ 2-agonists, the ACE and the renal protective

effects of ACE inhibitors, and apolipoprotein E and the response to the HMG-CoA reductase inhibitors (77–81).

With the advent of genetic testing, pharmacogenomics may help health-care providers determine the most appropriate drug and dose for each patient. Until there is widespread availability of genetic testing (e.g., point-of-care), empiric, population-based treatment algorithms will probably remain the foundation of drug therapy. However, certain disease states may warrant a patient-specific genetic evaluation to identify the most effective treatment regimen and to minimize drug toxicity.

## SUMMARY

Rational drug therapy is an essential part in the management of critically ill patients. Clinical pharmacology provides the necessary tools for an individualized approach to drug therapy, using PK and PD principles. With all of the variables that potentially can change in the critically ill patient, it is important to individualize drug therapy. This challenge can be minimized with multidisciplinary involvement and careful monitoring of the patient to prevent iatrogenic adverse reactions.

Organ failure is responsible for a majority of the alterations of PK and PD parameters in the critical-care setting. Renal dysfunction can alter the  $V_d$  and ultimately the CI of some drugs. Liver dysfunction can be due to extrinsic causes such as decreased liver blood flow or as a result of some intrinsic changes such as altered hepatic microsomal enzyme activities. Both of these factors can contribute to a decrease in hepatic drug metabolism.

ADHF can lead to an impairment of drug CI and/or a reduction in the  $V_d$  by underperfusing organs responsible for metabolism or elimination (i.e., liver and kidneys). PK changes are difficult to predict in heart failure and will assume importance with narrow therapeutic index drugs (i.e., digoxin, lidocaine, procainamide). Depending on the extent of the burn injury and time after the insult, the volume of distribution, protein binding, and CI of some drugs can be altered.

In the setting of decreased liver and kidney perfusion, the clearances of sedatives and analgesic drugs are often reduced. Any change in their protein binding or changes in liver function may have a significant impact on their therapeutic or adverse effects. Changes in GI motility or changes in GI tract pH can affect the absorption and GI metabolism of some drugs. Often ICU patients are on tube feedings, which can interfere and lead to decreased or unpredictable absorption of many drugs.

There are several mechanisms by which drugs can interact, but most can be categorized into PK, PD, or combined interactions. PK interactions include those that alter absorption, distribution, metabolism, or excretion; PD interactions include those that alter the effect of the drug on the body. Stimulation of the CP450 enzyme system in the liver and small intestine can lead to an increased metabolism of certain drugs; conversely, inhibition of this system can lead to elevated drug levels. With the knowledge of the CP450 enzyme systems and drugs that are known to be substrates, inducers, and inhibitors, health-care practitioners may be able to anticipate clinically important drug interactions.

The critically ill patient's status can be dynamic and changes in bioavailability,  $V_d$ , protein binding, clearance, and half-life can generate suboptimal drug concentrations. There is great potential for diagnostic genetic tests to

elucidate patient-specific polymorphisms, which will help the clinician develop a specific pharmacotherapeutic plan. Finally, it is important to frequently sample serum drug levels of narrow therapeutic index medications, in order to individualize therapy as much as possible.

## KEY POINTS

- 🔑 The unbound (“free”) drug molecule exerts the pharmacological effect by interacting with the cellular receptor.
- 🔑 Protein-binding alterations occur in critically ill patients and must be considered in order to properly interpret measured drug concentrations and their predicted PD effects.
- 🔑 The primary organs involved in clearance are the kidneys and the liver but other organ systems (e.g., lungs) may be involved.
- 🔑 Multiple variables (PK and PD) affect the critically ill patient. Accordingly, multidisciplinary involvement and careful monitoring is required to optimize drug therapy.
- 🔑 GFR is often estimated based on a patient’s serum creatinine and ideal body weight. Since critically ill patients may have a decrease in muscle mass, creatinine clearance (and GFR) can be overestimated.
- 🔑 If renal dysfunction is severe enough to require dialysis, dosage adjustment is often required.
- 🔑 In general, the CVVHDF removal of small drugs depends on the diffusion and convection process, whereas removal of larger drugs depends mostly on convection and perhaps adsorption properties.
- 🔑 Up to 54% of critically ill patients will develop some degree of liver dysfunction (17).
- 🔑 In critically ill patients with multiorgan failure, the net effect on drug metabolism is difficult to predict and must be carefully monitored.
- 🔑 ADHF can lead to an impairment of drug clearance and/or a reduction in the  $V_d$  by underperfusing organs responsible for metabolism or elimination (i.e., liver and kidneys) (23).
- 🔑 Drugs with a narrow therapeutic index (i.e., digoxin, lidocaine, procainamide) require enhanced drug monitoring in patients with heart failure.
- 🔑 The clearance of some drugs during the hypermetabolic phase of burn injury may be increased.
- 🔑 Cisatracurium is the ideal NMB drug for critically ill patients with liver and renal failure who require only a brief period of NMB.
- 🔑 Acidosis or alkalosis can change the protein binding of drugs (40).
- 🔑 There are several ways by which the GI absorption of drugs may be affected.
- 🔑 Stimulation of the CP450 enzyme system in the liver and small intestine can lead to the increased metabolism of certain drugs; conversely, inhibition of this system can lead to elevated drug levels.
- 🔑 Drug fever is defined as a febrile response to a drug without cutaneous manifestations and is estimated to occur in about 10% of hospitalized patients (66).

### INTRODUCTION

Pain is defined as an “unpleasant sensory or emotional experience associated with actual or potential tissue damage” (1). It is a complex phenomenon that combines strong emotional responses with ensuing physiological and psychological changes. Trauma patients often experience severe, and at times, poorly controlled pain (2). The administration of analgesics and sedatives is sometimes delayed or altogether avoided because of the concern that these drugs may produce hypotension, respiratory depression, or altered mental alertness (which could mask important diagnostic symptoms). **Without compromising cardiopulmonary status, judicious use of analgesics and sedatives can relieve pain, provide a state of emotional calm, and facilitate the diagnostic evaluation of trauma patients.**

This chapter reviews the adverse effects of uncontrolled pain, and provides a clinical approach to analgesia and sedation for both acute trauma and critical care. The general approach utilizes the concept of the “analgesia and sedation pyramid” (Fig. 1), which emphasizes a graded hierarchy of treatment beginning with the removal of exacerbating factors and the baseline provision of a foundation of analgesia prior to administering any anxiolytic or sedative drugs. The pharmacology of the commonly employed analgesics and sedative drugs are extensively reviewed, and the assessment tools used in the evaluation of pain, sedation, and delirium are thoroughly surveyed.

Treatment guidelines are provided for the management of pain and anxiety in the prehospital period, in the trauma resuscitation suite (TRS), and surgical intensive care unit (SICU). Because delirium is an exceedingly common and difficult-to-treat condition in critical care, its evaluation, prevention, and treatment receives particular focus. In addition, sedation and analgesia guidelines for common trauma-related conditions are specifically reviewed. The “Eye to the Future” section provides a glimpse at a host of new analgesia and sedation therapies on the horizon.

### ADVERSE EFFECTS OF UNCONTROLLED PAIN

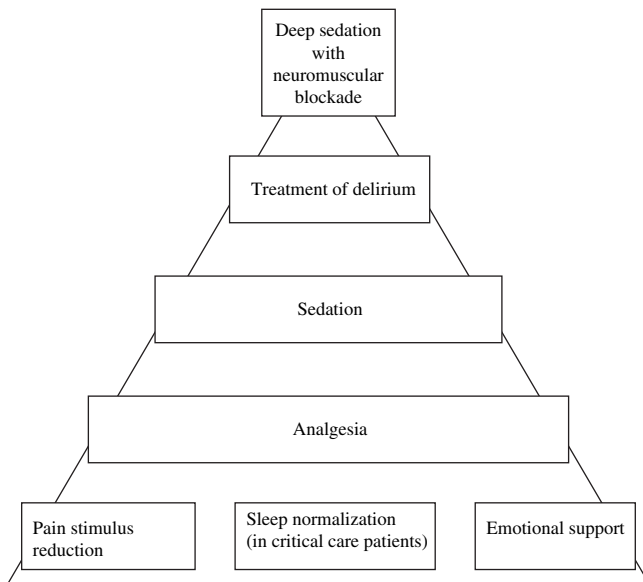

Poorly controlled pain in trauma and burn patients can result in severe psychological trauma (3). When particularly severe or emotionally laden, painful experiences can culminate as post-traumatic stress disorder (PTSD), (see Volume 2, Chapter 65). Despite the high prevalence of psychological sequelae, these phenomena have only recently received the focus they merit.

The acute physiologic derangements resulting from uncontrolled pain have been more widely recognized. These include cardiovascular, pulmonary, and gastrointestinal (GI) effects. In addition, a link between the opioid receptors and the inflammatory response and coagulation system has been recently established.

**PTSD affects up to 40% of major trauma patients (4,5).** Major trauma elicits a neurohumoral stress response manifested by the increased elaboration of catecholamines, antidiuretic hormone, cortisol, renin, angiotensin II, and aldosterone (6,7). Decreased insulin secretion, increased insulin resistance, proteinolysis, and glycogenolysis all contribute to hyperglycemia (with its own set of detrimental consequences). Physiological responses to the stress hormonal outflow include a hyperdynamic cardiovascular state, ileus, and urinary retention. The increased heart rate (HR), cardiac work, and O<sub>2</sub> consumption ( $\dot{V}O_2$ ) can lead to a higher incidence of myocardial ischemia (8).

Poorly controlled pain in the chest wall or the upper abdomen impairs pulmonary function. Splinting and inability to cough lead to hypoventilation, atelectasis, hypoxemia, and elevated risk of pneumonia. Pulmonary function studies following these injuries show decreased tidal volumes, increased respiratory rate (RR), decreased functional residual capacity (FRC) and vital capacity, among other findings (9). Successful pain control can partially restore most of these processes, improving pulmonary function.

Coagulopathy commonly ensues after major injury (see Volume 2, Chapter 58), and opioid agonists have recently been shown to partially mitigate this disorder.

**Figure 1** Analgesia and sedation pyramid. This figure graphically depicts the hierarchy of treatment with the most commonly employed drugs and techniques at the base of the pyramid, and the less often used drugs at the top. The base of the pyramid rests upon the three pillars of basic patient care techniques that, themselves, decrease the severity and emotional content of pain (emotional support, reduction of pain stimulus, and sleep normalization). Pain stimulus reduction techniques include splinting, immobilizing, and reducing fractures. Sleep normalization helps to decrease agitation and delirium; emotional support helps to decrease the secondary negative effects of pain. Considerations for analgesia consist of systemic administration and regional techniques. Emphasis with treatment begins on establishing adequate analgesia before ascending to anxiolysis (sedation treatment or to control delirium). Treatment of anxiety and agitation per se should be given after pain—an anxiety-provoking stimulus—has been addressed. Pharmacotherapy directed to treat delirium should be administered after delirium-inducing factors are mitigated. Neuromuscular blockade with deep sedation is reserved to the severely agitated or delirious patient unresponsive to a stepwise pharmacological approach.

Coagulation and inflammation are linked through numerous molecular pathways, including damaged endothelium, activated platelets, and the complexes of tissue factor, along with factors VIIa and Xa (10). In addition, G protein-coupled opioid receptors, expressed by T lymphocytes, neutrophils, monocytes, and macrophages have been found to modulate the inflammatory response (11) and (because coagulation and inflammation are linked) coagulopathy (10). Opioid agonists have also been shown to reduce the inflammatory response by inhibiting the expression of proinflammatory cytokines (11,12).

## GENERAL APPROACH: ANALGESIA AND SEDATION PYRAMID

Optimal pain management involves a stepwise, logical approach beginning with the elimination of obvious painful stimuli (e.g., fractures should be splinted), ascending to administration of analgesics prior to introducing sedatives or neuroleptic drugs; and, only in rare cases is

**Figure 2** Descartes' (1664) first conceptualized pain pathway. He writes: "If for example fire (A) comes near the foot (B), the minute particles of this fire, which as you know move with great velocity, have the power to set in motion the spot of the skin of the foot which they touch, and by this means pulling upon the delicate thread (C) which is attached to the spot of the skin, they open up at the same instant the pore (D, E) against which the delicate thread ends (F), just as by pulling at one end of a rope makes to strike at the same instant a bell which hangs at the other end." Source: From Refs. 15, 16.

**deep sedation with neuromuscular blockade (NMB) required.** This approach is summarized in the "Analgesia and Sedation Pyramid" (Fig. 1).

Initially, all patients should have their pain, discomfort, and anxiety treated by removal of exacerbating factors, reducing and splinting fractures, normalizing sleep, and becoming reintroduced to the environment (13,14). Next, analgesics are provided until the pain is adequately reduced. Dissipation of pain can by itself relieve anxiety and emotional distress. Only after adequate analgesia has been delivered, should antianxiety drugs be added.

Delirium can occur for numerous reasons, including the withdrawal or toxicity of psychoactive drugs, traumatic brain injury (TBI), and other causes of organic brain syndrome (OBS), including hypoxemia and organ dysfunction. Accordingly, delirium is treated medically only after considering all the precipitating factors and adjusting doses of all psychoactive drugs. Removing exacerbating factors and administering adequate analgesics, antianxiety drugs, and/or delirium drugs almost always provides adequate analgesia, sedation, and the desired level of consciousness. However, when normally adequate doses of analgesia and sedation fail to control severe agitation, deep sedation and occasionally the use of NMB drugs may be required.

## MECHANISMS OF PAIN

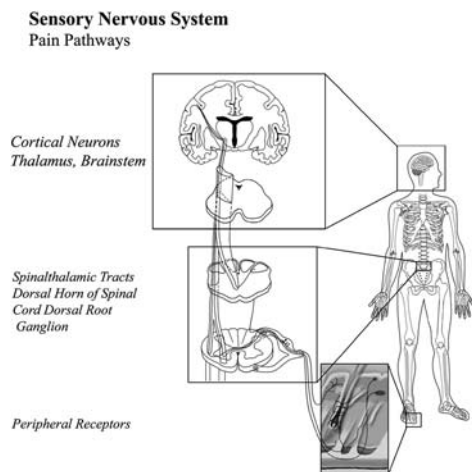

### Neural Pathways

Over 300 years ago, René Descartes deduced that pain signals are transmitted from the periphery to the central

nervous system (CNS) and interpreted in the brain. He hypothesized that the pain stimulus is analogous to pulling a string at the site of injury, while the other end of the string triggers an alarm bell inside the brain (Fig. 2) (15,16). Modern descriptions of pain pathways similarly refer to noxious stimuli that trigger signals from the periphery to the brain. However, in contrast to the model introduced by Descartes, the pain experience is now recognized as a dynamic process involving multiple humoral modulators and neurotransmitters, along with complex neural connectivity (Fig. 3).

Peripheral sensory nerve fibers that respond to noxious mechanical or chemical stimuli are known as primary nociceptors. These are typically thinly myelinated A $\delta$  or unmyelinated C fibers with the cell bodies located within the dorsal root ganglia. As with other primary afferent nerves, these fibers form synapses with second order ascending neurons within the dorsal columns of the spinal cord. Important ascending nociceptive pathways contained within the spinal cord include the anterior spinothalamic, spinoreticular, and spinomesencephalic tracts along with the postsynaptic dorsal column fibers. Descending neural pathways in the spinal cord also play a role in pain modulation.

Details have recently emerged about the complexity of the cerebral nociceptive neuronal network. The ascending spinal tracts converge at the nuclei of the lateral and medial thalamus, which then project nerve fibers to the somatosensory cortex. This supratentorial neural network is primarily responsible for the sensory-discriminative aspects of the pain experience. The motivational component of pain is processed within the association cortex, involving the limbic system and the anterior cingulate gyrus (both integral structures involved in PTSD—see Volume 2, Chapter 65).

**Figure 3** Sensory pathway from skin to brain. Specialized axon terminals in skin transduce pain and sensory events for processing by first-order (peripheral) sensory neurons in the ipsilateral, segmental dorsal root ganglion, whose pseudo unipolar extension terminates in the dorsal horn (substantia gelatinosa) of the spinal cord. Additional processing occurs in deeper layers of the dorsal horn at the same and higher levels. Major sensory and pain pathways including the lateral and ventral spinothalamic tracts and medial lemniscus organize sensory fibers in their progression through the brainstem and thalamus before cerebral cortical termination. *Source:* Courtesy of Robert R. Myers, UCSD School of Medicine peripheral nerve research group.

### Progression from Acute to Persistent Pain

The likelihood of developing chronic or persistent pain syndromes (pain that lasts longer than three months after injury despite the absence of ongoing trauma) is increased in patients who have inadequately managed pain in the immediate postinjury period (17). Sensitization of peripheral neurons takes place early after injury due to the release of inflammatory mediators such as H<sup>+</sup>, K<sup>+</sup>, prostaglandins, and bradykinin, as well as neuropeptides such as substance P and calcitonin gene-related peptide (CGRP). The sensitized peripheral nerves result in perception of pain in response to an innocuous stimulus (allodynia) and exaggerated pain response to a noxious stimulus (hyperalgesia).

Sustained stimulation of peripheral pain fibers can also lead to sensitization of the central neurons within the spinal cord. Following injury, persistent pain fiber stimulation activates N-methyl-D-aspartate (NMDA) receptors. This molecular change results in a facilitated pain state, now widely referred to as “wind-up.” It can develop within several minutes after injury and is manifested by enhanced sensitivity to mechanical stimuli around the injured tissue. With healing, injury-related pain (including wind-up) usually resolves within a few days to several weeks. However, sometimes long-term changes in the peripheral or central nervous system take place leading to pain that persists long after the tissue has healed. Persistent pain due to the abnormal peripheral or central nerve conduction is referred to as neuropathic pain.

### Preemptive Analgesia and Pain Reduction

Pre-emptive analgesia is a method of pain control aimed at reducing the initial intensity of pain, and thereby preventing the development of persistent or neuropathic pain syndromes (18). If transmission of the initial noxious stimulus is altogether prevented by the analgesics at the receptor sites, then the neuronal sensitization will be less likely to occur. In trauma, where significant secondary tissue injury occurs, very early postinjury analgesia can be preemptive if it improves pain control, reduces total analgesic requirements, and prevents progression to persistent pain.

☞ **The administration of analgesia at the earliest possible opportunity will likely have a beneficial effect on the long-term outcome of patients who sustain tissue injury from trauma or surgery.** ☞ This clinical consensus is supported by abundant experimental data; indeed, patients with initially poorly controlled pain are more prone to develop persistent pain than the patients who have received early satisfactory analgesia (17–19). However, contrary to this evidence and probably due to numerous confounding variables, some clinical studies of effectiveness of pre-emptive or early post-trauma analgesia in improving pain control and preventing persistent pain were inconclusive (20).

### PHARMACOLOGY REVIEW

Because pain mechanisms are complex, analgesic pharmacotherapy often consists of several classes of drugs, each targeting a different neural pathway. Such an approach, known as multimodal analgesia, capitalizes upon analgesic synergy between various drugs while mitigating their deleterious side effects.

## Nonsteroidal Anti-inflammatory Drugs/Cyclooxygenase Enzyme Inhibitors

Herbs containing nonsteroidal anti-inflammatory drugs (NSAIDs) were known by ancient Egyptians, and are referred to in the Ebers papyrus (21). In 1763, Edward Stone isolated salicin, the glycoside of salicylic acid, from the bark of a willow tree (*Salix alba*). Today NSAIDs are among the most commonly used medications worldwide. Although employed for centuries in the treatment of pain, fever, and inflammation, the molecular mechanism of NSAIDs was not elucidated until the 1970s by Vane et al. (22). It was then discovered that NSAIDs inhibit the enzyme cyclooxygenase (COX), and the subsequent formation of prostaglandin E (PGE). The predominant COX enzyme isoform, COX-1, is expressed constitutively in many tissues, including the kidneys, GI tract, platelets, and endothelium; whereas the COX-2 isoform is typically produced only following tissue injury. However, COX-2 is also expressed constitutively in some tissues, including the CNS, renal cortex, pancreas, and uterus.

Several well-known adverse effects, such as GI irritation, renal insufficiency, platelet inhibition, bronchospasm, and elevated liver enzyme levels, can complicate therapy with NSAIDs. Nonspecific inhibition of COX enzymes can cause platelet deactivation (irreversible with aspirin and indomethacin) (23), renal insufficiency, and GI mucosal erosion and perforation. COX-2 specific inhibitors are safer than nonspecific COX inhibitors, with respect to GI erosions and platelet inactivation (24,25). However, they retain the renal side effects seen with nonspecific COX inhibitors (26).

More recently, COX-2 enzyme inhibition has been shown to also retard angiogenesis and healing (27–29); however, these effects are probably mild. The ultimate decision for the use of NSAIDs and selective COX-2 inhibitors in trauma or critical care is based on the type and extent of injury (especially intracranial hemorrhagic lesions), and the presence of relative contraindications such as renal insufficiency or coagulopathy (including the concomitant use of anticoagulant or thrombolytic drugs), and so on.

Numerous NSAIDs are available as first-line analgesics for mild pain (Table 1). Among these, ketorolac is the only NSAID available in intravenous (IV) form in the United States. For this reason, and because of its relatively high analgesic efficacy, ketorolac is commonly selected for postoperative analgesia in trauma and critical care. Ketorolac inhibits platelet function; however, numerous studies were unable to define the risk of bleeding associated with this drug (30). Increase in bleeding time after administration of a high IV dose (60 mg) of ketorolac to healthy volunteers was shown to be mild and generally insignificant (31). Ketorolac can be administered IV or intramuscularly (IM) every six hours at 15- to 30-mg doses for five days. In trauma patients with massive tissue injury (especially in the CNS) and/or coagulopathy, ketorolac is contraindicated.

Acetaminophen (paracetamol) differs from typical NSAIDs in its mechanism of action and side effect profile. Its inhibition of prostaglandin synthesis appears to be limited to the CNS. Acetaminophen lacks anti-inflammatory activity in the peripheral tissues and, consequently, does not pose the same degree of bleeding risks as typical NSAIDs. However, at high doses acetaminophen (>100 mg/kg in adults or >150 mg/kg in children) can cause severe hepatotoxicity, and with chronic use has been shown to cause renal impairment (32,33).

**Table 1** Nonsteroidal Anti-inflammatory Drugs Used for Analgesia

Generic drug (trade name)	Recommended dose
Aspirin	325–650 mg every 4 hr
Ibuprofen (Motrin <sup>®</sup> )	200–800 mg 3–4 times a day
Ketorolac (Toradol <sup>®</sup> )	Maximum duration of administration is 5 days IV/IM: 15–30 mg every 6 hrs, maximum dose is 60 mg/24 hrs in patients 65 yr or older Oral: 10 mg every 4–6 hrs not to exceed 40 mg/24 hrs (Note: IM dosing not recommended.)
Naproxen (Naprosyn <sup>®</sup> )	250–500 mg twice a day
Diclofenac (Voltaren <sup>®</sup> )	50–75 mg twice a day or 50 mg 3 times a day
Etodolac (Lodine <sup>®</sup> )	200–400 mg every 6–8 hrs
Flurbiprofen (Ansaid <sup>®</sup> )	200–300 mg daily divided 2 to 3 times a day
Indomethacin (Indocin <sup>®</sup> )	25–50 mg every 6–8 hrs
Ketoprofen (Orudis <sup>®</sup> )	25–50 mg every 6–8 hrs
Nabumetone (Relafen <sup>®</sup> )	1000–2000 mg daily or divided twice a day
Sulindac (Clinoril <sup>®</sup> )	150 mg twice a day

Abbreviations: IM, intramuscularly; IV, intravenously.

Paracetamol is available in IV and oral (PO) forms in Europe, whereas acetaminophen is only available in PO form in the United States. Side effects from short-term use of this medication are rare. However, liver toxicity following overdose can be lethal (see Volume 1, Chapter 31 and Volume 2, Chapter 36). Contraindications are limited to patients with severe hepatic disease and those allergic to the drug. Analgesia occurs approximately 30 minutes after IV administration of paracetamol (2 g over 15-minute infusion).

## Local Anesthetics (Sodium Channel Blockers)

Structurally related to the prototype cocaine, local anesthetic drugs produce reversible block of voltage-gated sodium channels, thereby increasing the threshold required for electrical excitation of the neuron. These drugs can be applied topically, injected locally, IV, epidurally, intrathecally, and orally.

Lidocaine is available in the injectable form as well as in various topical formulations. This local anesthetic has relatively low levels of CNS and cardiovascular toxicity. The duration of action of subcutaneous (SQ) lidocaine can be prolonged by local vasoconstriction achieved by the addition of epinephrine. Lidocaine is also infused intravenously to treat ventricular dysrhythmias and has shown to be efficacious in the treatment of refractory pain in burn patients (34).

Bupivacaine is more potent, but has a slower onset than lidocaine. Its duration of action depends on vascular absorption at the site of injection and can persist for as long as 12 hours (more commonly three to six hours) with the peripheral nerve blocks and three hours with epidural or intrathecal blockade (more commonly 1.5–2 hours). Compared to other local anesthetics, bupivacaine exhibits greater sensory than motor blockade, and it is often used

**Table 2** Maximum Doses of Local Anesthetics in 70-kg Patient

Drug	Commonly employed concentration (%)	Plain solution	Epinephrine-containing solution
Lidocaine	0.5–1.0	300 mg (4.5 mg/kg)	500 mg (7 mg/kg)
Bupivacaine	0.125–0.5	175 mg (3 mg/kg) per dose, 440 mg per 24 hrs	Not established
Ropivacaine	0.2–0.5	Dose of 770 mg/24 hrs has not been reported	Not established

for local infiltration and regional nerve blockade. Ropivacaine, structurally similar to bupivacaine, is slightly less potent, but is safer with respect to cardiotoxicity (35).

Systemically administered local anesthetics can be used to block sodium channels involved in pain transmission, and to decrease ventricular irritability (e.g., lidocaine infusion). However, when doses are too high (Table 2), sodium channels of inhibitory nerves located in the CNS can become blocked causing seizures; at higher plasma concentrations, myocardial tissue becomes irritable, causing dysrhythmias. The excitatory neurotoxic effects range from tremors and agitation to generalized seizures.

Myocardial toxicity can occur after administration of any local anesthetic, but it is most characteristically associated with the highly lipophilic agents (e.g., bupivacaine), which are characterized by “fast in, slow out” kinetics. Cardiac toxicity is manifested by depression of myocardial contractility, atrioventricular blocks, and ventricular dysrhythmias. In order to avoid neurotoxic and cardiovascular complications, local anesthetics are administered for regional and topical anesthesia incrementally at submaximal doses (Table 2). Inadvertent intravascular injections of local anesthetics are avoided by repeated aspiration through the needle.

☞ **Local anesthetics do not work efficiently when injected in the vicinity of infected tissue.** ☞ Local tissue acidemia occurs in the presence of cellulitis, abscess, and other forms of tissue infections. The impaired function of local anesthetics in infected tissues occurs because they are weak bases, and in aqueous solution, the relative concentration of neutral or ionized molecules is pH dependent. The neutral (nonionized) form of the local anesthetics

preferentially permeates the cellular membrane of the neuron to its site of action at the sodium channel of the axon (Fig. 4). The fraction of neutral species decreases with a fall in tissue pH. Accordingly, their efficacy is diminished and onset of action is delayed in an acidic environment, where the polar (ionized) form predominates and is unable to traverse the nerve cell membrane.

## Opioids

### General Considerations

Opioids provide analgesia by stimulating  $\mu - 1$  and  $\kappa$  opioid receptors. These receptors are distributed throughout the CNS particularly along the pain pathways and processing centers such as laminae I and II of the dorsal column of the spinal cord, spinal trigeminal nucleus, locus ceruleus, and periaqueductal gray. Opioid receptor activity results in the inhibition of the ascending pain pathways, and by activation of the descending inhibitory spinal pathways.

### Specific Opioids

Morphine is a widely used opioid in treatment of acute pain. It conjugates in the liver to morphine-3-gluconoride (M3G) and morphine-6-gluconoride (M6G). M6G is a potent analgesic and probably contributes significantly to analgesia, particularly after prolonged morphine use. M3G, on the other hand, is neurotoxic and can result in hyperalgesia.

Following an IV administration, morphine provides peak analgesic and respiratory effects at 15 to 20 minutes with a clinical duration of two to three hours (Table 3).

**Figure 4** Schematic representation of ionized and neutral species of local anesthetic in the intracellular and extracellular media. The binding site of sodium channel receptor complex is located within the axon on the cytoplasm side of the cell membrane. Ionized (protonated) species of local anesthetics bind to the active site of the sodium channel protein complex, whereas neutral (deprotonated) local anesthetic species cross the cell membrane into the cytoplasm.

**Table 3** Pharmacokinetic Properties (Onset, Peak, Effect, Clinical Duration, and Half-Life) After Single IV Bolus of Commonly Used Opioids

Drug/property	Onset (min)	Peak <sup>a</sup> (min)	Clinical duration of analgesia
Morphine	3–5	15–20	2–4 hr
Fentanyl	1	5	Low dose (25–150 µg): 30–45 min Moderate dose (150–500 µg): 45 min to 2 hr High dose (>500 µg): 2–4 hr
Hydromorphone	3–5	15–20	3–4 hr
Meperidine	3–5	15–20	2–4 hr

<sup>a</sup>Peak analgesia and respiratory depression effects tend to occur at the same time.

Peak analgesia with IM or SQ morphine is less predictable, but typically occurs after 45 to 90 minutes, with a clinical duration of three to four hours. Compared to the IV dose, a much smaller dose of morphine is required to produce analgesia with epidural administration, and up to 100 times less with intrathecal injection. The onset of analgesia following epidural administration of morphine is 30 minutes, with peak effect at two to three hours, and dose-dependent clinical duration of 4 to 18 hours. Intrathecal morphine bolus has an onset of around five minutes, and may provide analgesia for up to 24 hours. Bioavailability of PO morphine is 30%. Several formulations of PO morphine are able to provide sustained analgesia for up to 24 hours.

Fentanyl is a synthetic opioid structurally similar to meperidine. Peak analgesia following IV administration of this highly lipophilic drug is achieved within several minutes (Table 3). Fentanyl exhibits a two-phase pharmacokinetic profile. It is first taken up by the central compartments (lungs initially absorb 75% of IV fentanyl bolus). Fentanyl is then widely redistributed in body tissues ( $\beta$ -elimination), followed by a slow metabolism in the liver ( $\beta$ -elimination). Although the  $\beta$ -elimination half-life of fentanyl is slightly longer than that of morphine, its plasma concentration falls rapidly after a single small bolus (due to  $\alpha$ -elimination), and its duration of analgesia is typically only 30 to 60 minutes following a small dose (50–100 µg), 60 to 90 minutes after moderate dose (150–250 µg) and two to four hours after larger doses (500–1000 µg).

Fentanyl is a potent opioid, and 100 µg of this drug is equianalgesic to 10 mg IV morphine. Because of its lipophilic properties and the propensity for redistribution, epidurally administered fentanyl provides analgesia at both the spinal level as well as at supraspinal CNS centers following systemic absorption and distribution. Fentanyl acts predominantly at the spinal level when administered as an epidural bolus, and at both spinal and supraspinal sites when continuously infused (36). In addition to the parenteral form, fentanyl is available as a sustained-release transdermal patch, and as a transmucosal lozenge applied to the buccal mucosa to treat breakthrough pain.

Other fentanyl derivatives are occasionally used in acute trauma and critical care. Alfentanil is an opioid that is approximately one-third as potent as fentanyl, and has a

very short duration of action (15 to 25 minutes). In contrast to fentanyl, accumulation of alfentanil in the tissue is insignificant. The brief duration of action of alfentanil limits its use in acute post-traumatic pain except for very short-term procedural analgesia. Sufentanil is 5 to 10 times more potent than fentanyl. It causes approximately the same degree of respiratory depression and sedation as fentanyl at equipotent dosing.

Remifentanyl is an opioid agonist with the most rapid onset (less than one minute) and the shortest duration of action of all clinically available opioids. It is metabolized via hydrolysis by tissue esterases; thus, its metabolism and elimination do not depend on hepatic or renal mechanisms. The blood concentration of remifentanyl decreases by 50% after only three to six minutes, and its rapid elimination is independent of the duration of its administration. The dose range of IV infusion of remifentanyl is 0.1–2 µg/kg/min. Rapid dissipation of analgesia and return of pain after remifentanyl discontinuation precludes its routine use for acute trauma. However, intensivists and anesthesiologists experienced in its use can safely administer remifentanyl for brief episodes of intense pain. Furthermore, as an IV infusion, remifentanyl may be indicated in patients with multiple organ dysfunction syndrome (MODS), in whom unwanted prolonged analgesic and sedative effects might occur with the use of other drugs.

Hydromorphone is a semisynthetic morphine analog that can be administered PO, rectally (PR), IV, and epidurally. A 2-mg IV dose of this opioid is equipotent to 10 mg of IV morphine (Table 3). Following IV administration of hydromorphone, full analgesic and respiratory depressive effects are achieved within 15 minutes, lasting up to three to four hours (37). Hydromorphone is commonly used for epidural analgesia. Its water–lipid solubility properties lie between those of morphine and fentanyl; consequently, hydromorphone does not spread cephalad within the cerebrospinal fluid (CSF) as much as morphine, nor does it redistribute into the systemic circulation as much as fentanyl.

Meperidine is a synthetic opioid that is approximately one-tenth as potent as morphine. In patients with normal renal function, meperidine is injected IV or IM at incremental 12.5 to 75-mg doses to a maximum of 800 mg in 24 hours. Peak analgesia and respiratory depression occurs within 10 to 15 minutes following IV administration, with a clinical duration of two to three hours. Meperidine, as a member of the phenylpiperidine class, has strong local analgesic properties (38). It also exhibits activity at  $\alpha_2$ -adrenoreceptors (39). Reported exacerbation of postoperative delirium and tachycardia are attributed to the anticholinergic properties of meperidine (40).

Meperidine has a neurotoxic metabolite, normeperidine. This renally excreted compound has a long elimination half-life and can induce myoclonus and seizures after repeated use, particularly in patients with renal impairment. Meperidine also interacts with monoamine oxidase inhibitors (MAOIs). This interaction can lead to accumulation of serotonin, resulting in hyperpyrexia (see Volume 1, Chapter 40 and Volume 2, Chapter 46), delirium, and seizures. Due to its severe side effects and potential complications, meperidine should be reserved for patients whose pain could not be adequately controlled with safer opioids.

Methadone is a synthetic opioid structurally unrelated to morphine. In addition to the opioid activity at the  $\mu$ -receptors, methadone has an additional analgesic effect manifested through antagonism of NMDA receptors. Parenterally administered methadone is equipotent to IV morphine;

however, its pharmacokinetic profile is quite distinct. Typical onset of analgesia is 10 to 20 minutes following an IV bolus, and between 30 and 60 minutes after a PO dose.

Methadone bioavailability (41–99%) and elimination half-life (15 to 120 hours) can vary widely among patients (41). Furthermore, because of a rapid initial redistribution phase, and a long and unpredictable elimination phase, there is an apparent dissociation between the relatively short duration of analgesic properties (six to eight hours) and cumulative plasma concentration. Consequently, initial doses of this drug should be low, with gradual and infrequent (every three days) upward dose titration. Due to the diminished euphoric effects and low abuse potential, methadone is widely used to treat opioid addiction as a once-a-day dosing of approximately 30 mg. When used for analgesia, dosing is scheduled three to four times a day.

Naloxone is a semisynthetic opioid antagonist devoid of agonist activity. The competitive antagonism of opioid receptors is brief in duration, typically lasting less than 45 minutes. Therefore, repeated doses, or IV infusion, of naloxone are required to antagonize the effect of long-acting opioids. Onset of action is within one to two minutes after IV administration. Naloxone is primarily used to reverse opioid overdose. Administration of high dose (400 µg) of naloxone is recommended only in the situation of opioid-induced apnea accompanied by difficulty to maintain airway. Because of significant side effects, including pulmonary edema, prior practices of administering 2 mg of naloxone (equivalent to 5 ampules of naloxone each containing 400 µg) is no longer recommended as part of a routine prehospital or emergency department (ED) “coma cocktail.” Instead, titration of opioid antagonism to effect is currently recommended, as dictated by the clinical circumstances.

Nalbuphine is a mixed opioid agonist/antagonist. It provides analgesia via  $\kappa$  receptor agonism, with analgesic potency equivalent to that of IV morphine. Nalbuphine is associated with opioid-specific side effects, including respiratory depression. Nalbuphine-produced analgesia, somnolence, and respiratory depression, are however, limited by a ceiling effect. Although nalbuphine is a potent analgesic, as a  $\mu$ -receptor antagonist it reverses some of the opioid effects; it is accordingly used to treat opioid-induced pruritis, sedation, and respiratory depression.

### Relative Potencies of Opioids

Clinicians are often faced with the need to change opioid regimens. Examples of such changes are conversion from the IV to PO route, and substitution of one opioid for another because of intolerable side effects.

When switching from one opioid to another in nonopioid-tolerant patients, equianalgesic doses are initially recommended. There is large variability in individual responses to different opioids; therefore, opioid equianalgesic conversion tables (Table 4) are used only as an approximate guide in establishing opioid therapy. In addition, it is generally recommended that only 75% of the calculated dose of the next opioid drug should be used in chronic pain patients, to account for the incomplete cross-tolerance effects. Particular caution should be exercised when the opioid regimen is changed to methadone, because of its long and unpredictable half-life.

### Adverse Side Effects of Opioid Therapy

☞ Among the side effects associated with opioids (Table 5), respiratory depression, loss of airway, and hypotension are

**Table 4** Equianalgesic Doses of Parenterally and Orally Administered Opioids

Drug	Intravenous (mg)	Oral equivalent (mg)
Morphine	10	30
Fentanyl	0.1	NA
Hydromorphone	2	7.5
Meperidine	100	300
Methadone	10	10–20
Oxycodone	NA	20

Abbreviation: NA, not available.

**potentially the most dangerous. Indeed, fear of respiratory depression is a common cause of inadequate analgesia in critically ill patients.** ☞ Opioids exhibit a dose-related increase in apneic threshold and CO<sub>2</sub> responsiveness (increasingly higher CO<sub>2</sub> partial pressure is required to stimulate spontaneous breathing). They also decrease the RR and, consequently, the  $\dot{V}_E$ . Longer-acting opioids such as morphine have slower onset and longer duration of respiratory depression than shorter-acting fentanyl. Opioid-induced respiratory depression can be mitigated by gradual titration. Monitoring of oxygen saturation, end-tidal CO<sub>2</sub>, RR, and respiratory effort can provide accurate and continuous assessment of the respiratory status. ☞ **Pain stimulates the respiratory drive and counteracts the sedative effects of opioids. Consequently, patients on relatively high doses of opioids, who then undergo regional nerve blockade, can develop acute respiratory depression because of abrupt abolition of the afferent pain stimulus.** ☞

Decrease in GI motility and constipation develops in many patients treated with opioids. These patients are at increased risk of not tolerating enteral nutrition. In order to reduce this risk, it is prudent to administer bowel promotility agents early in critically ill patients who are receiving opioids and demonstrating decreased gut motility.

A progressive program involving a combination regimen, consisting of oral cellulose (e.g., Metamucil®) a softening agent (docusate), a cathartic (senna compounds), and an osmotic (lactulose, polyethylene glycol), is usually more effective than single-drug treatment. In refractory cases, patients require colonic lavage or oral bowel preparations. Severe GI stasis may respond to PO naloxone, starting at doses of 0.4–1.2 mg every four to six hours to induce bowel movement. Because of the risk of bowel perforation, PO naloxone is strictly contraindicated in patients with bowel obstruction. In addition, metoclopramide and/or erythromycin can be used as gastropropulsive drugs (both also contraindicated in the setting of bowel obstruction).

Opioid-induced nausea occurs in 10% to 40% of patients; however, it tends to abate gradually in most patients due to tolerance. Several mechanisms may be responsible for nausea, including delayed gastric emptying, vestibular sensitivity, and effects on the chemoreceptor trigger zone. Drugs effective for treating opioid-induced nausea include scopolamine, prochlorperazine, and serotonin receptor antagonists such as dolasetron or ondansetron, antihistamines, neuroleptic agents (haloperidol, chlorpromazine, and droperidol), benzodiazepines, and corticosteroids. Metoclopramide can treat nausea caused by delayed gastric emptying.

Sedation is a common opioid side effect that can be both beneficial and deleterious. The first step in reducing severity of this side effect is the discontinuation of any

**Table 5** Opioid Receptor–Specific Analgesic Effects and Side Effects

Action or side effect	Receptor	Comments
Supraspinal analgesia	$\mu$ -1, $\kappa$	Cranial-level analgesia occurs with systemically administered opioids
Spinal analgesia	$\kappa$	Predominant-spinal level analgesia occurs with subarachnoid and epidural opioid administration
Respiratory depression	$\mu$ -2	Respiratory effects of opioids generally coincide with analgesic effects
Sympatholysis	$\mu$ -1, $\kappa$ , $\sigma$	In patients with preexisting hypovolemia, opioids can precipitate severe decrease in blood pressure driven by sympatholysis
Sedation	$\mu$ -1, $\kappa$	Tolerance to sedative effects develops with time
Bradycardia	$\mu$ -1	Bradycardia is more prominent with fast-acting lipophilic opioids such as fentanyl
Miosis	$\kappa$	Tolerance to this effect develops with time
Constipation, intestinal motility retardation	$\mu$ -2	More common with systemic opioids than neuroaxial opioids
Pruritus	$\mu$ -2	Pruritus is more common with neuraxial than systemic opioids
Nausea and vomiting	$\mu$ -2	Nausea occurs in more than 30% of patients
Dysphoria, delirium, hallucinations	$\sigma$	Opioids contribute to development of delirium in intensive care
Euphoria, addiction, physical dependence	$\mu$ -2	Physical dependence is a normal physiologic response that develops over time

other CNS depressants and correction of coexisting metabolic problems. Subsequent steps include adjusting the opioid dose, rotating to a different opioid (42), or treating somnolence with psychostimulants such as methylphenidate or dextroamphetamine.

Modafinil (Provigil<sup>®</sup>) is a newer psychostimulant that was initially developed for treatment of narcolepsy; it is now also approved by the Food and Drug Administration (FDA) for reduction of daytime somnolence in shift workers. Modafinil reportedly has lesser abuse potential than traditional psychostimulant drugs, and may have a role in persistently somnolent critical care patients.

High-dose-opioid-induced myoclonus requires an immediate reduction in dose. Patients treated with opioids can develop tolerance, physical dependence, and addiction (discussed subsequently).

### Sedative, Hypnotic, and Anxiolytic Drugs

Several classes of drugs are available for anxiolysis and sedation in trauma and critical care (Table 6). They include benzodiazepines, propofol, dexmedetomidine, and ketamine. Sedating properties of opioids are unpredictable

because of this property and respiratory depression, they are not used to primarily treat anxiety, agitation, or delirium. However, the early and adequate administration of opioid analgesia will often minimize the need for subsequent sedative administration. Benzodiazepines and propofol suppress respiration in a dose-related fashion. They also blunt and eventually lead to the obliteration of laryngeal airway protecting reflexes and pharyngeal muscle tone, thereby contributing to the risk of loss of airway and aspiration of gastric contents when heavily sedating doses are used. In contrast, dexmedetomidine does not depress respiration or airway reflexes and has other particular advantages as described subsequently.

### Benzodiazepines

Midazolam is a potent, short-acting benzodiazepine used extensively as a sedative/anxiolytic in perioperative, acute trauma, and critical care settings. As with other benzodiazepines, midazolam increases the affinity for gamma amino butyric acid (GABA) receptor by changing the conformation of GABA<sub>A</sub> receptor complex. Onset of action following IV midazolam administration is within 1

**Table 6** Pharmacology of Single-Dose Bolus of Sedatives, Hypnotics, and Neuroleptic Drugs

Drug	Typical dose IV	Onset time after IV bolus	Duration of action
Midazolam	1–2 mg	2–5 min	1–2 hr
Diazepam	1–5 mg	2–5 min	2–3 hr
Lorazepam	1–2 mg	20–30 min	3–4 hr
Propofol	50–100 mg	Less than 1 min	5–10 min
Dexmedetomidine	Loading dose: 1 $\mu$ g/kg for 10 min, followed by infusion: 0.2–0.7 $\mu$ g/kg/hr	Less than 5 min	15–30 min
Ketamine	20–50 mg	Less than 1 min	15–45 min
Haloperidol	1–5 mg	5–10 min	4–8 hr
Ziprasidone	10–20 mg	30 min	3–5 hr

Typical initial doses are generally on the lower dose range, with titration upward as patient response warrants. These doses can cause apnea in elderly or hypovolemic patients and are suggested only for fully resuscitated patients requiring bolus dose of drug. Abbreviation: IV, intravenously.

to 5 minutes. Sedation occurs 5 to 15 minutes after IM, and 10 to 30 minutes after PO administrations. It has an elimination half-life of one to five hours, and a clinical duration of action ranging from two to four hours depending upon dose and chronicity of use. Bioavailability of midazolam is approximately 35%. Typical adult IV anxiolytic dose is 0.5 to 2 mg; it may be repeated every five minutes until the desired level of sedation is delivered.

Lorazepam is an intermediate-acting benzodiazepine, and is available both IV and PO. Its half-life of 12 hours is intermediate between midazolam and diazepam. Despite the markedly longer half-life compared to midazolam, the clinical duration of action of lorazepam is only slightly longer (three to six hours). The durations of action of both midazolam and lorazepam are more predictable than that of diazepam (as described later). The onset of action following IV administration of lorazepam is, however, slower than that of midazolam or diazepam. Accordingly, lorazepam is less suitable for rapid treatment of titration and acute anxiety. Lorazepam does serve as an excellent drug for prolonged sedation (longer than 72 hours) in critically ill patients. It has no active metabolites, but the conjugated form (which is normally excreted in the urine) accumulates in patients with renal failure.

Diazepam is a longer-acting benzodiazepine than either midazolam or lorazepam. It can be administered IV, PO, or PR. In addition to its sedative and anxiolytic properties, diazepam is also used as an anticonvulsant and skeletal muscle antispasticity agent. Typical onset of action after an IV administration is one to five minutes. Diazepam has a half-life exceeding 30 hours; however, its clinical duration of action is only six hours. This discrepancy is presumed to be due to its extensive protein binding (98%). Diazepam is metabolized to active metabolite desmethyldiazepam, which accumulates in renal failure. Single-dose administration typically results in rapid onset as well as rapid dissipation of sedation. However, systemic absorption of diazepam even after a single IM dose can be slow and unpredictable. Repeated doses and continuous infusion cause accumulation of diazepam and its metabolites, resulting in delayed awakening.

Nonbenzodiazepine sedative-hypnotic drugs include zolpidem (Ambien<sup>®</sup>), zaleplon (Sonata<sup>®</sup>), and eszopiclone (Lunesta<sup>®</sup>). Although they are active at the GABA receptors, these drugs are chemically unrelated to classic benzodiazepines, and are less likely to produce residual sedation. After fast onset, the duration of action of zaleplon and zolpidem is approximately four hours and six to eight hours respectively.

Flumazenil is a specific benzodiazepine antagonist with strong affinity to the GABA receptors. It is useful in treating the respiratory depressant and sedative effects of benzodiazepines. In the absence of benzodiazepines, flumazenil is usually devoid of clinically significant intrinsic activity. However, it has been used to improve the mental state of critically ill patients with hepatic encephalopathy. The onset of action of IV flumazenil is less than one minute, with the peak effect in one to three minutes, and duration of action between 40 and 90 minutes. To reverse benzodiazepine-induced CNS depression, the typical initial adult dose of flumazenil is 0.2 mg; it may be repeated every minute to a total of 1 mg in five minutes. This titration sequence may be repeated at 20-minute intervals, up to a maximum of 3 mg/hr (43). **⚠ In long-term benzodiazepine users, and if given in too large of a dose (rather than titrated as recommended), flumazenil can precipitate seizures or**

**other withdrawal symptoms, including acute onset of severe anxiety, myoclonus, and tremors. ⚠**

### Propofol

Propofol is a sedative-hypnotic agent not related to other anesthetics or sedatives. Within the CNS it exhibits agonist activity at the GABA<sub>A</sub> receptors by activating the chloride channels. In addition, propofol inhibits the NMDA subtype of glutamate receptors (44). It is administered IV as a series of bolus doses for procedural sedation, or more commonly in the SICU by continuous infusion. Injection of propofol is often associated with transient burning pain in the injection site veins. Pain is decreased if administered approximately five minutes after fentanyl 1–2 mg/kg, and/or after IV lidocaine is administered.

Following IV administration of general-anesthesia-induction dose (2 mg/kg), unconsciousness occurs within 20 to 40 seconds. The time to onset of sedation, which requires significantly smaller doses than for anesthesia, is one to five minutes. Sedation with propofol continues as long as the infusion provides adequate drug serum concentration. Emergence occurs approximately 10 minutes after administration of a single bolus dose, and awakening usually occurs in less than 30 minutes following cessation of infusions shorter than 72 hours in duration. Sedation with propofol typically requires infusion rates ranging from 25–150 µg/kg/min depending upon the patient's baseline level of consciousness, metabolism, and concomitant psychoactive drug administration.

### Dexmedetomidine

Dexmedetomidine is a recently introduced selective  $\alpha_2$ -adrenoceptor agonist that exerts centrally acting sedative, analgesic, and sympatholytic effects. Among the distinguishing properties of this sedative drug is the preservation of respiratory drive and protective airway reflexes.

Dexmedetomidine is clinically indicated for sedation of intubated trauma and critically ill patients in preparation for extubation, and in nonintubated patients requiring sedation. The relative absence of respiratory depression is unique to this drug, and allows for its continuation throughout the weaning process, including the first few hours to days after extubation. However, dexmedetomidine is more expensive than most of the other sedative drugs.

Dexmedetomidine is particularly beneficial in patients with obstructive sleep apnea (they tend to be more sensitive to the respiratory depressant properties of opioids and benzodiazepines than patients without the disorder). It is also particularly useful in those with alcohol or drug addiction (whose sedation is often difficult to titrate using propofol or benzodiazepines).

Dexmedetomidine is administered by an IV infusion. It is distributed to the tissues with an onset of action occurring within five minutes and a  $\beta$ -elimination half-life of six minutes. Recovery from the effects of dexmedetomidine is rapid (15 to 30 minutes) at normal sedative doses, although its terminal elimination half-life is in the order of two hours. Dexmedetomidine is commonly infused by first administering a loading bolus of 1 µg/kg over 10 minutes, followed by an initial infusion rates between 0.2 and 0.7 µg/kg/hr titrated to an effect. Chronic pain patients, alcoholics, and drug addicts frequently require much higher doses. The authors often employ doses ranging between 1 and 2 µg/kg/hr in patients with long-term sedative or opioid use, including those patients with a current history of chronic pain.

Hemodynamic changes are frequently observed during dexmedetomidine administration. A short-lived hypertensive response will occasionally occur during the initiation of dexmedetomidine infusion (especially during the bolus load). This effect is almost always followed by a decrease in blood pressure (BP) and HR. Patients with prominent vagal tone, such as young athletes, and those on  $\beta$ -blockers are particularly susceptible to severe bradycardia (treatable with vagolytic or sympathomimetic drugs) during dexmedetomidine infusion. Some of the side effects from dexmedetomidine can appear similar to those of opioids, with decreased HR, BP, and small pupils. However, in contrast to opioid administration, dexmedetomidine does not depress respiration.

### **Ketamine**

Ketamine in doses of 2 mg/kg IV, 10 mg/kg IM, or 30 mg/kg PO serves as a sedative-hypnotic drug similar in structure and activity to phencyclidine (PCP). It produces profound analgesia even at subanesthetic doses. The analgesic and anesthetic effects of ketamine are achieved through several mechanisms. It inhibits cholinergic pathways and has strong sympathomimetic activity. Ketamine also noncompetitively inhibits NMDA receptors. Despite this theoretical neuroprotective property, ketamine also increases cerebral metabolic rate of oxygen (CMRO<sub>2</sub>) and cerebral blood flow (CBF); thus, it has not been used in TBI patients for fear of increasing intracranial pressure (ICP).

In addition to contributing to analgesia, NMDA receptor blockade is responsible for psychosis-like side effects. Ketamine is particularly active within the limbic system and the cortex and thereby produces a feeling of dissociation from the environment. Its administration is typically followed by increased HR, BP (sympathomimetic effect), and muscle tone; a cataleptic state ensues with most patients, requiring only intermittent reassurances from the anesthesiologist. As this dissociative state occurs, horizontal nystagmus becomes evident.

The strong sympathetic activity is observed in most hemodynamically normal patients who have received ketamine. However, hypovolemic and other patients who are under physiologic stress, are often unable to mount strong adrenergic response, due to depletion of, and insensitivity to, already massively elaborated catecholamines and the direct myocardial effects will become predominant. **☞ The hemodynamically unstable, hemorrhaging trauma patient is a classic example where ketamine predominantly exhibits cardiac depressant effects (45).** ☞

On the other hand, at therapeutic doses, ketamine offers several advantages, including preservation of pharyngeal and laryngeal reflexes and spontaneous respiration. Thus, in adequately resuscitated patients, ketamine is extremely useful and widely used by injection or infusion during painful procedures (e.g., wound debridement, or burn wound dressing changes). These beneficial properties make ketamine a good choice for use in austere military settings. Ketamine also possesses potent bronchodilator effects, and is particularly useful in the treatment of patients with bronchospasm. Ketamine also produces significant salivation and bronchorrhea; accordingly, small prophylactic doses of glycopyrrolate are recommended prior to its administration.

### **Neuroleptic Drugs**

Several neuroleptic (antipsychotic) medications are available for the treatment of delirium. Haloperidol is arguably the

most commonly used neuroleptic drug in the treatment of delirium and acute psychotic disorders in the trauma and critically ill patients. Its mechanism of action involves the blockade of postsynaptic dopamine-2 (D<sub>2</sub>) receptors. Haloperidol has an FDA indication for PO and IM use. However, it is most commonly injected, a route of administration still without FDA approval. Onset of action after an IV dose of haloperidol occurs within 3 to 20 minutes, and the tranquilizing effect typically lasts two to four hours. Some mental status changes may, however, last as long as 12 hours.

Droperidol has long been used by anesthesiologists as both a neuroleptic drug and an antiemetic. The CNS properties of droperidol are similar to those of haloperidol; however, droperidol has a more pronounced  $\alpha_1$ -adrenergic receptor blocking effect, which can exacerbate hypotension in hemodynamically unstable patients. Droperidol is also associated with prolongation of the QTc interval, with theoretically increased risk of serious ventricular dysrhythmias including Torsade de Pointes. Although the increased risk of cardiac dysrhythmias with droperidol has been recently widely publicized, many believe that this risk has been overemphasized in the literature (Volume 2, Chapter 20).

**☞ The slightly elevated risk of Torsade de Pointes associated with droperidol is also present with other antipsychotic drugs including haloperidol.** ☞

Ziprasidone, olanzapine, and risperidone represent newer atypical antipsychotic drugs. They tend to cause less sedation, fewer mental status changes, and extrapyramidal symptoms than the traditional neuroleptic drugs like haloperidol. The likelihood of developing tardive dyskinesia (TD) is reportedly reduced with the atypical compared to traditional neuroleptics. If PO administration of these drugs cannot be tolerated, then ziprasidone and olanzapine can be administered parenterally. Ziprasidone is administered IM to a total of 40 mg per 24 hours at 10-mg doses every two hours or 20-mg doses every four hours. Olanzapine is dosed at 5- to 10-mg IM every two hours to a maximum of two doses per 24 hours.

### **Skeletal Muscle Antispasticity Drugs**

Muscle spasms contribute substantially to the pain due to injuries of spine and the extremities. For this reason, skeletal muscle antispasticity drugs play an important role in controlling acute postoperative and postinjury pain. These drugs are not related to NMB agents, which cause temporary skeletal muscle paralysis, and consequent complete apnea (Volume 2, Chapter 6). Drugs used for the purpose of relieving or preventing skeletal muscle spasms belong to various classes and include benzodiazepines (Table 7). Diazepam is the usual first-line drug for short-term spasticity; however, in presence of excessive somnolence or renal insufficiency, other drug categories, for example, cyclobenzaprine or baclofen, are typically used instead. Tizanidine, a newer antispasticity agent, also has analgesic properties through the activity at the central  $\alpha_2$ -adrenergic receptors. Although muscle antispasticity drugs work by a variety of mechanisms, they all cause a certain degree of CNS depression manifested by drowsiness and sedation.

### **Other Analgesic Agents**

Neuropathic pain conditions generally develop over time, yet there is mounting evidence that nerve sensitization and abnormal sensory nerve conduction originating at the initial time of trauma can serve to establish the pathologic neural pathways. Opioids are generally the most effective

**Table 7** Antispasticity Drugs

Drug	Mechanism of action	Dosing	Common side effects
Diazepam	GABA agonist	5–10 mg IV or PO q6 hrs PRN	Sedation
Cyclobenzaprine (Flexeril <sup>®</sup> )	Unknown, centrally acting	5 mg PO TID, titrate to 10 mg PO TID	Sedation, dizziness
Baclofen	GABA <sub>B</sub> agonist	5 mg PO TID, titrate to 80 mg a day	Sedation, delirium, urinary retention
Tizanidine (Zanaflex <sup>®</sup> )	Centrally acting $\alpha_2$ -adrenergic agonist	4–8 PO q6 hrs, maximum 36 mg per 24 hr	Dizziness, fatigue, dry mouth
Carisopodol (Soma <sup>®</sup> )	Unknown, centrally acting	350 mg PO TID	Sedation, tremor, dizziness
Chlorzoxazone (Parafon Forte <sup>®</sup> , Paraflex <sup>®</sup> )	Unknown, appears to be sedation-related	250–500 mg PO TID to QID	Sedation, dizziness
Methocarbamol (Robaxin <sup>®</sup> )	Unknown, centrally acting	1–3 g IV/IM QD for 3 days; 1.5 g QID for 2–3 days	Sedation, dizziness
Orphenadrine (Norflex <sup>®</sup> )	Unknown, centrally acting, anticholinergic	60 mg IV/IM q12 hr; 100 mg PO q12 hr	Dry mouth and other anticholinergic effects

*Abbreviations:* GABA, gamma amino butyric acid; IV, intravenously; IM, intramuscularly; PO, orally; PRN, as needed; TID, three times a day; QD, once a day; QID, four times a day.

medications for systemic treatment of most categories of severe pain states. However, improved analgesia can be provided for some patients using adjuvant analgesics (anticonvulsants and antidepressant drugs) in concert with opioids.

Anticonvulsants constitute a class of several unrelated compounds that interfere with peripheral and central nerve conduction. Their mechanisms of action include sodium channel blockade, and modulation of calcium channels and GABA receptors. Gabapentin is a first-line anticonvulsant drug used in the treatment of neuropathic pain. Due to its pronounced sedative side effects, gabapentin is gradually titrated over one to two weeks from a single nightly dose of 300–900 mg three times a day. Pregabalin is a recently introduced anticonvulsant drug that also has received an FDA approval to treat several neuropathic pain states. It offers quicker onset of analgesia than gabapentin, with generally fewer side effects, and can be titrated to its maintenance dose of 300 mg per day in seven days (half the time of gabapentin).

The analgesic effects of tricyclic antidepressant (TCA) drugs probably result from sodium channel blockade and activity at the adrenergic  $\alpha$ -receptors in the descending spinal pathways. Amitriptyline (Elavil<sup>®</sup>) is typically the first-line TCA employed in the treatment of neuropathic pain. It is usually administered at bedtime because of the profound sedative effects. If sedation is not desired, then other TCAs, such as nortriptyline or desipramine, can be used instead. The experience with selective serotonin reuptake inhibitors (SSRIs) for analgesia has been largely disappointing. In contrast, the new norepinephrine/serotonin reuptake inhibitor, duloxetine, is quite effective in treatment of neuropathic pain. Indeed, it has been approved by the FDA to treat diabetic peripheral neuropathy at a 60-mg-per-day dose.

## Routes of Administration

### Intravenous Route

#### Intermittent Bolus vs. Continuous Infusion

The IV route of administration is preferred for the initial titration of analgesic and sedative drugs in acute trauma and critically ill patients, since it is associated with the shortest onset time and the most predictable effect. Continuous IV infusion is advantageous in that it provides steady serum concentration of the drugs. However, continuous infusion can also result in the accumulation of the drug in the

tissues, and consequently delayed awakening. This requires vigilance and frequent reassessment of sedation and analgesia. Intermittent, demand-based, clinician-administered boluses are often helpful in avoiding excessive accumulation of the drug, but they can lead to undesirable peaks and troughs in the drug serum concentration (Fig. 5).

### Patient-Controlled Analgesia

Because of relatively narrow therapeutic index of opioids, the concentration of the drugs tends to fluctuate widely between above and below the therapeutic level whenever administered as a bolus or on an “as needed” basis by the bedside nurse (Fig. 5). This often results in respiratory depression and oversedation alternating with poorly controlled pain. Whenever the patients are awake and cooperative, patient-controlled analgesia (PCA) can mitigate the problem of widely fluctuating drug serum concentrations. The use of PCA results in a decreased total opioid dosage during hospitalization and better pain control with smaller,

**Figure 5** Serum concentrations of opioid analgesic delivered by patient-controlled analgesia (PCA) devices, versus clinician-administered doses. The serum concentration of opioid analgesics fluctuates within a narrower range in patients using PCA than patients receiving clinician-administered boluses only.

**Table 8** Initial Intravenous Patient-Controlled Analgesia Schedule for Patients Who Are Not Opioid Tolerant

Modality	Opioid drug and dose		
	Morphine	Hydromorphone	Fentanyl
Continuous infusion (moderate pain)	None	None	None
Continuous infusion (severe pain)	1–1.5 mg/hr	0.2–0.4 mg/hr	0.005–0.01 mg/hr
Bolus dose (moderate pain)	1 mg	0.2 mg	0.01 mg
Bolus dose (severe pain)	1.5–2 mg	0.3–0.4 mg	0.015–0.02 mg
Lockout interval	8 min	8 min	8 min
Hourly clinician-activated dose	3 mg	0.6 mg	0.03 mg

For patients who are not opioid tolerant, continuous infusion is not recommended. The initial recommended dose may be incrementally increased to an effect. Moderate pain—fracture of lower or upper extremity. Severe pain—multiple rib fractures, large upper abdominal incision, or gunshot wound.

more frequent dosing. Typical IV PCA schedules for adult patients who are not tolerant to opioids are summarized in Table 8. Patients in a stable physiological and emotional state, who are awake and are able to operate the PCA button, are the most likely to benefit from IV PCA.

### Intramuscular Injections

☞ Intermittent IM injections of drugs, although still widely practiced, are ill suited for analgesia and sedation in trauma and critical care. ☞ With IM injections, plasma concentrations can vary two-fold, and the time to peak concentration can vary three-fold in the same individual. In terms of interpatient variability, the maximum plasma concentration can differ five-fold, whereas the time to peak concentration can vary seven-fold (46). Furthermore, the patients must overcome the fear and unpleasantness of a needle puncture every time their trauma or surgical pain requires relief.

### Enteral Administration

The GI tract provides unpredictable absorption of medications in hemodynamically unstable trauma and critically ill patients and those with impaired bowel function, such as ileus or bowel obstruction. However, patients with intact intestinal motility and the ability to tolerate enteral feeding are also capable of processing PO medications, and can generally receive analgesics and sedatives orally with predictable results. Some drugs, such as gradually released morphine and oxycodone, are absorbed systemically at a predictable rate only if the tablet or capsule is ingested intact. Ingestion of crushed tablets or opened capsules results in immediate, instead of gradual, systemic delivery of the drug and the risk of initial opioid overdose.

## CLINICAL ASSESSMENT OF PAIN AND SEDATION

The clinical evaluation of pain is challenging, partly because of an inherently subjective nature of the pain experience. Emotional turmoil can exacerbate, while stoicism can diminish the outward expression of pain. Successful management of pain and emotional distress requires frequent assessments of pain, level of consciousness, and delirium. Several scoring systems have been developed for this purpose.

### Pain Assessment Scores

The numeric rating scale (NRS) is an 11-point system widely used to assess acute pain in trauma and critical care. With this scale, the patients identify their pain level on a scale of

zero (no pain) to 10 (the most severe pain imaginable). The NRS is a valid (47) and reliable (48) tool that is easy to administer and does not require any specialized tools or training.

The visual analog scale (VAS) represents another common pain assessment tool used in both clinical and research settings. The VAS pain score is obtained using a 100-mm ruler with “no pain” marked on the left, and “maximum pain” on the right ends. Patients slide the cursor along the ruler to a position that they believe reflects the intensity of their pain. Alternatively, the patients can report their pain by placing a mark along a 100-mm line drawn on a sheet of paper. Compared with the NRS, VAS ratings require greater attention and patient effort. It is therefore slightly less reliable than the NRS in acute trauma and critical care (48), but easier to use in awake, but nonverbal (e.g., intubated) patients.

Pain intensity in children and other individuals unable to respond to either the NRS or the VAS can be quantitatively assessed using scales showing a variety of facial expressions. These scales typically contain photographs or drawings of facial emotions ranging from laughing to crying (Fig. 6). These scales, usually displaying six to nine faces, are considered suitable for adults and children three years of age or older. Other nonverbal pain scores utilize behavioral and/or physiological parameters that reflect pain intensity. Such behavioral and physiologic variables as facial expression, activity, guarding, BP, RR, and pupil size can be scored (49). An inherent shortcoming of nonverbal pain scoring methods is the recognition that the behavioral and

**Figure 6** Facial expression pain scale. This universal scale can be used with patients from all geographic areas of the globe and does not rely upon language. However, certain cultures (and individuals within any society) respond differently to the same level of pain. For instance, certain stoic patients may provide a facial score of 3–4, but may have pain only in the mild to discomforting range (2–4 of 10), yet have a hysterical component appearing like a 10 due to either their emotional make up or due to the stress they attribute to the event (see Volume 2, Chapter 65 for a review of acute stress disorders and posttraumatic stress disorder).

physiologic parameters associated with pain can also be exhibited in pain-free, but emotionally distressed or agitated patients. Distinguishing pain from agitation, delirium, or frank psychosis in these patients can be challenging.

### Sedation Scoring Tools and Electric Brain Activity Monitoring

Nearly all sedative drugs result in varying degrees of respiratory depression; and, in higher doses, excessive sedation or delirium can occur. At the other extreme, inadequate sedation can result in physiologic stress and agitation leading to accidental self-extubation and the dislodgement of indwelling devices like intravascular catheters and feeding tubes (50,51). Frequent assessment of sedation is important for achieving and maintaining an optimal level of consciousness and avoiding the side effects of the drugs or the disruptive critical care environment.

#### Sedation Scores

Several sedation scoring systems are available for evaluating level of consciousness in trauma and critical care patients. Ramsay sedation score (RSS) is a semiquantitative scale based on the patient's response to the surroundings (Table 9) (52,53). This six-point scoring system describes the levels of consciousness ranging from the awake and agitated to an unconscious state with absent light glabellar tap response.

The Riker sedation agitation scale (SAS) evolved from the RSS and consists of seven points describing the states of sedation and agitation in terms of observed behavior of the patient, with calm and cooperative state located in the middle of the scale (Table 10) (54). SAS is highly correlated with the RSS in assessing sedation and agitation in the SICU. However, the SAS provides additional information by stratifying agitation into three separate categories (compared to only two in the RSS).

The Richmond agitation sedation scale (RASS) has further expanded the scoring possibilities and oriented the range of responses in a more intuitive format, offering improved validity and reliability compared to the RSS, SAS, and other scoring systems (55,56). **RASS is the first, and so far the only, sedation measuring tool that has been validated for its ability to detect changes in sedation over consecutive days in critical care (55).**

Similar to other sedation scores, the RASS is designed to quantify the degree of sedation and agitation of the patient based on behavioral observation. In this scoring system, the patients who are alert and calm receive a balanced 0 score; others are assigned scores that deviate from the center in relation to their aberrancy with combative (score +4) at one extreme, and unarousable (score -5) at the other (Table 11).

**Table 9** Ramsay Sedation Score

Awake levels	Patient description
1	Anxious, agitated, or restless
2	Cooperative, orientated, or tranquil
3	Responds to command only
4	Brisk response to a light glabellar tap
5	Sluggish response to a light glabellar tap
6	No response to a light glabellar tap

**Table 10** Riker Sedation Agitation Scale

Score	Patient's state	Description of patient's behavior
7	Dangerous agitation	Pulls at endotracheal tube, tries to remove catheters, climbs over bedrail, strikes at staff, thrashes side to side
6	Very agitated	Does not calm despite frequent verbal reminding of limits, requires physical restraints, bites endotracheal tube
5	Agitated	Anxious or mildly agitated, attempts to sit up, calms down to verbal instructions
4	Calm and cooperative	Calm, awakens easily, follows commands
3	Sedated	Difficult to arouse, awakens to verbal stimuli or gentle shaking but drifts off again, follows simple commands
2	Very sedated	Arouses to physical stimuli, but does not communicate or follow commands, may move spontaneously
1	Unarousable	Minimal or no response to noxious stimuli, does not communicate or follow commands

#### Electric Brain Activity Monitoring

An established relationship exists between the electroencephalogram (EEG) and the effects of sedatives and anesthetics on the cerebral metabolic rate (57). In general, the observed decrease in EEG wave frequency is proportional to the lower neuronal firing rate produced by sedatives and anesthetics. However, interpretation of raw EEG wave patterns often requires considerable expertise. Furthermore, the unprocessed EEG signals do not always correlate well with drug-induced changes in neuronal activity except at very high doses.

**Table 11** Richmond Agitation and Sedation Scale

Score	Descriptor	Characteristics
+4	Combative	Combative, violent, immediate danger to staff
+3	Very agitated	Pulls or removes tube(s) or catheter(s); aggressive
+2	Agitated	Frequent nonpurposeful movement, fights ventilator
+1	Restless	Anxious, apprehensive, but movements not aggressive or vigorous
0	Alert and calm	
-1	Drowsy	Not fully alert, but has sustained awakening to voice (eye opening and contact >10 sec)
-2	Lightly sedated	Briefly awakens to voice (eye opening and contact <10 sec)
-3	Moderately sedated	Movement or eye opening to voice (but no eye contact)
-4	Deeply sedated	No response to voice, but movement or eye opening to physical stimulation
-5	Unarousable	No response to voice or physical stimulation

In contrast to the raw EEG, analyzed processed EEG patterns, such as the 95% spectral edge frequency, appear to accurately reflect the degree of sedation (57). Proprietary tools, including the Bispectral Index Encephalographic analysis (BIS<sup>®</sup>) and patient state index (PSI<sup>®</sup>), are empirically derived methods of EEG processing with conversion to a linear analog scale. Neuronal activity in the fully awake brain is assigned a score of 100, and absence of activity is defined as a score of zero with both BIS and PSI systems (58,59). Patients are likely to respond to verbal commands when the BIS number is over 70, but not have any recall unless the BIS is >80 (Fig. 7). Patients are unlikely to respond to commands when the BIS values are <50 (60).

The ability of processed EEG methods (e.g., BIS or PSI) to assess the degree of sedation and awareness has been demonstrated in some (58–62), but not in other studies (63–65). Interpretation of BIS and PSI scores is complicated by the fact that similar levels of sedation that are brought about by different classes of drugs (opioids, benzodiazepines, or propofol) can result in different processed EEG scores (60). However, consistent and anesthetic-independent measurements of the states of awareness have been recently demonstrated (66).

The American Society of Anesthesiologists (ASA) has recently issued a Practice Advisory for Intraoperative Awareness and Brain Function Monitoring (67). This ASA advisory recommends against routine and universal use of electric brain activity monitors. It has, however, issued a consensus “that the decision to use a brain function monitor should be made on a case-by-case basis by the individual practitioner for selected patients (e.g., light anesthesia).” The ASA practice advisory did not make any specific recommendations concerning the use of electric brain activity monitors in the trauma or critical care settings. **Processed electric brain activity monitoring appears to correlate reasonably well with other sedation assessment methods such as the RASS (as described earlier); however, it remains unclear whether routine use of this technique improves the outcomes, and additional studies in acute trauma and critical care are needed.**

**Figure 7** Relationship between BIS and probability of response to verbal command (*black line*) or ability to remember pictures or words (free recall test) (*shaded line*). Fractional probability of 1.0 = 100%. These relationships were determined using logistic regression analysis for volunteers receiving propofol, isoflurane, or midazolam. *Source:* From Ref. 60.

## Assessment of Delirium

Delirium is manifested by the acute onset of an altered level of awareness or consciousness, inattention, lethargy or agitation, worsening of symptoms at night, and disorganized thinking. It can be precipitated by many factors, including primary cerebral diseases, such as cerebrovascular accident, seizure, mass lesions, and contusions. Other common factors that can cause or exacerbate delirium include medications or toxins, stressful environment and circumstances, alteration in sleep cycles, metabolic and endocrine disorders, and intracerebral infection (68).

**Delirium in critical care is exceedingly common, with an estimated incidence between 60% and 80% (69–71).** Delirium is considered a psychiatric disorder with diagnostic criteria defined in the diagnostic and statistical manual of mental disorders (DSM-IV) (72). Delirium can appear as hypoactive (quiet), hyperactive, or mixed.

Patients with hyperactive delirium most commonly exhibit agitated and combative behavior. Administration of sedatives to patients in this state often results in a transition to hypoactive delirium (i.e., although the agitated behavior is apparently controlled, the patients continue to harbor disorganized thinking). Patients with hypoactive delirium appear withdrawn, lethargic, and apathetic. Mixed delirium describes the condition with fluctuating mental states between hyperactive and hypoactive.

Delirium invariably involves changes in consciousness, with the spectrum of states that include sedation or anxiety. Accordingly, evaluation of delirium is always entwined with assessment of sedation utilizing such tools as the RASS (as described earlier). In general, patients with hypervigilant altered level of consciousness (RASS = +4 to +1) are in need of evaluation for delirium. At the same time, presence of other conditions, such as dementia, psychogenic dissociative disorders, mania, and complex partial seizures, should be ruled out. Patients with RASS = -3 to -5 can also be suffering from an OBS causing a hypoactive form of delirium (or be oversedated with anxiolytic or antipsychotic drugs). Assessment and diagnosis of delirium on the basis of DSM-IV criteria requires extensive experience and knowledge of causes of OBS.

An additional diagnostic tool is available for characterization of delirium in patients with altered level of consciousness measured by RSS, SAS, or RASS. This tool, named CAM-ICU, is based on the confusion assessment method (CAM) scoring system (73). CAM-ICU allows rapid evaluation of delirium by clinicians who do not have extensive training in psychiatry. This test shows excellent validity and reliability when compared to determination of delirium using DSM-IV criteria (74). CAM-ICU evaluates delirium on the basis of four principal features: (i) acute or fluctuating mental status changes, (ii) inattention, (iii) disorganized thinking, and (iv) altered level of consciousness (Table 12). Delirium, according to CAM-ICU, is established when both features (i) and (ii), and either features (iii) or (iv) are positive.

## ANALGESIA AND SEDATION FOR ACUTE TRAUMA

Pain and anxiety in trauma patients present a variety of challenges and circumstances. In some patients, extreme combative behavior, respiratory distress, inhalation burn injury, and neurological or mechanical loss of airway protection

**Table 12** The Confusion Assessment Method for the Diagnosis of Delirium in the Intensive Care Unit (CAM-ICU)

Feature	Assessment variables
I. Acute onset of mental status changes or fluctuating course	Is there evidence of an acute change in mental status from the baseline? Did the (abnormal) behavior fluctuate during the past 24 hr, i.e., tend to come and go or increase and decrease in severity?
II. Inattention	Did the sedation scale (e.g., SAS or MAAS) or GCS fluctuate in the past 24 hr? Did the patient have difficulty focusing attention? Is there a reduced ability to maintain and shift attention?
III. Disorganized thinking	How does the patient score on the attention screening examination (ASE)? If the patient is already extubated from the ventilator, determine whether or not the patient's thinking is disorganized or incoherent, such as rambling or irrelevant conversation, unclear or illogical flow of ideas, or unpredictable switching from subject to subject For those still on the ventilator, can the patient answer simple, logical (yes/no) questions correctly?
IV. Altered level of consciousness [any level of consciousness other than alert (e.g., vigilant, lethargic, stupor, or coma)]	<i>Alert</i> : normal, fully aware of environment, interacts appropriately <i>Vigilant</i> : hyperalert <i>Lethargic</i> : drowsy but easily aroused, unaware of some elements in the environment <i>Stupor</i> : difficult to arouse, unaware of some or all elements in the environment, or not spontaneously interacting with the interviewer; becomes incompletely aware and inappropriately interactive when prodded strongly <i>Coma</i> : unarousable, unaware of all elements in the environment, with no spontaneous interaction or awareness of the interviewer

Patients are diagnosed with delirium if they have both features (I) and (II) and either feature (III) or (IV).

*Abbreviations*: SAS, sedation-analgesia scale; MAAS, motor activity assessment scale; GCS, Glasgow Coma Scale.

*Source*: From Refs. 51, 70.

dictate immediate intubation with relatively liberal analgesia and sedation. In other patients, the threat to safety or loss of airway is not immediate or severe; in these circumstances, analgesics and sedatives are administered gradually and judiciously. The discussion below reviews the analgesia and sedation considerations for trauma in the prehospital setting, during transport, and in the TRS.

## Prehospital Considerations

### General Approach and Recommendations

In general, pain in the field tends to be undertreated, and even in isolated limb injuries, only a minority (22%) of the patients receive analgesia before arriving in the hospital (75). Pain and anxiety should be treated as long as doing so does not interfere with patient's physiological status. Indeed, properly titrated analgesia can improve ventilatory and hemodynamic states, and facilitate patient evaluation. In all cases, IV analgesics and sedatives are withheld until IV access is established, O<sub>2</sub> is administered, pulse oximetry monitoring is applied, and the initial survey demonstrates that the patient is awake, alert, cooperative, and hemodynamically stable enough to tolerate medications.

Hemodynamic status is often deceptively stable immediately after the trauma; consequently, the ability to thoroughly assess the extent of injuries and blood loss in the field is limited. With this in mind, prehospital analgesia and sedation must be titrated gradually and with caution. In the presence of obvious major injuries, extensive blood loss, internal organ damage, or neurological compromise, analgesics should be withheld until the patient is transported to the hospital.

In patients meeting the above criteria for sedation and analgesia, opioids such as fentanyl (0.01–0.025 mg), morphine (1–3 mg), or hydromorphone (0.2–0.6 mg) can

be administered IV at 5-minute (fentanyl) to 15-minute (morphine, hydromorphone) intervals. In initially stable patients, analgesia can be titrated to a RR of 12 to 15 breaths per minute and a reassuring blood pressure. Oxygen saturation and exhaled CO<sub>2</sub> (if available), should be continuously monitored.

Severe pain is a common cause of agitation following acute trauma. But so is hypovolemic shock. Accordingly, opioid administration must be titrated to a state of emotional calm without causing respiratory or hemodynamic compromise. Only if agitation persists after achieving adequate analgesia and continued cardiopulmonary stability, should sedatives such as midazolam be administered. Gradual titration of this drug should be limited to 0.5–1 mg every five minutes. Vital signs and the level of consciousness are frequently monitored, because the interpatient variability in the response to sedatives can be extreme and unpredictable, and coadministered benzodiazepines and opioids can have synergistic depressive hemodynamic and respiratory effects.

☞ **Nitrous oxide (N<sub>2</sub>O) is not recommended in the acute trauma setting.** ☞ At therapeutic concentration it occupies substantial alveolar space, displacing O<sub>2</sub> and thus decreasing its partial pressure in arterial blood (PaO<sub>2</sub>). In addition, N<sub>2</sub>O causes rapid expansion of gas-filled spaces, such as pneumothorax or pneumocephalus (as described later).

N<sub>2</sub>O does possess amnestic, hypnotic, and analgesic properties, and is thus favored by some prehospital practitioners. Indeed, analgesic properties of N<sub>2</sub>O at a concentration of 20% to 25% are equivalent to 15-mg IV morphine dose (76). Because N<sub>2</sub>O is used for analgesia and sedation during transport by some emergency medical systems in Europe (77–79), some treatment guidelines are provided. Most importantly, oxygen should always be administered first, and O<sub>2</sub> saturation monitoring should be established in all patients prior to initiating administration of N<sub>2</sub>O. Secondly, oxygen must continue to be administered along

with N<sub>2</sub>O at all times, and N<sub>2</sub>O fraction should never exceed 50% with 50% O<sub>2</sub>.

N<sub>2</sub>O can exacerbate pneumocephalus, pneumothorax, and pneumoperitoneum by the following mechanism. N<sub>2</sub>O is carried in blood and rapidly accumulates in closed gas-filled spaces that are normally occupied with nitrogen. Because N<sub>2</sub>O is 34 times more soluble in blood than nitrogen, it enters the gas-filled spaces faster than nitrogen can exit. Potentially catastrophic increase in pressure or volume in the gas-filled spaces ensues. For this reason, N<sub>2</sub>O should not be used if injuries to the head, abdomen, or thoracic region are suspected.

### **Specific Prehospital Scenarios**

#### **Trapped Patient**

Immediate extraction, stabilization, and transport of trapped patients are not always possible. While waiting for extrication from vehicles or structures, patients can be conscious and awake, and experience overwhelming anxiety in addition to severe pain. This experience can increase the risk of developing PTSD (see Volume 2, Chapter 65). Limited access to the trapped patient dictates extreme caution in pain and anxiety management. In addition to gentle reassurance, some pharmacologic treatment of pain and anxiety may be appropriate; however, drug administration should occur only after establishing an IV, administering oxygen, monitoring O<sub>2</sub> saturation with pulse oximetry, evaluating the ABCs, and confirming that the patient is not in an immediate risk of developing hypovolemic shock.

Because the threat of losing the airway is particularly dangerous in trapped patients, establishing physical access to the airway and administering supplemental O<sub>2</sub> are crucial prerequisites to analgesia administration. In these patients, severe pain and agitation can be treated with IV ketamine (0.1 mg/kg). These doses can be repeated every 5 to 10 minutes. Alternatively, repeated small IV doses of fentanyl (25–50 µg every three to five minutes) can be administered with particular attention to the preservation of wakefulness, adequate ventilation, absence of likely TBI, and reassuring hemodynamic status.

If adequate analgesia has been achieved but the patient develops agitation or becomes uncooperative, hypovolemia should be immediately assumed, and no additional analgesics or sedatives should be administered. Only after hemodynamic stability is assured, and agitation or anxiety continues, should midazolam be titrated IV in small (0.25–0.5 mg) doses every five minutes. Patients who become extremely uncooperative and hostile may require intubation and deeper sedation; these patients should be considered at high risk for TBI, and their pupil size and reactivity should be continuously monitored.

#### **Long Transport**

The treatment of pain, anxiety, and delirium in the injured trauma patient during transport (see Volume 1, Chapter 7) can be complicated particularly if the transit time is prolonged. One problem is that during transport by air, the partial pressure of oxygen is reduced in proportion to the decrease in ambient atmospheric pressure. At 5000 feet the atmospheric pressure is approximately 85%, and at 18,000 feet 50% of the pressure at sea level. In order to preserve oxygen supply, its fraction in the inhaled gas should be increased in proportion to the decrease in atmospheric pressure. Nitrous oxide is contraindicated in altitude because of the risk of expansion or increase in pressure in closed gas-filled cavities (as described earlier).

Because the extent of injuries in the majority of transported patients remains largely unknown, administration of opioid analgesics should be conservative. IV doses of fentanyl (0.01–0.025 mg), morphine (0.5–1.5 mg), or hydromorphone (0.1–0.3 mg) are administered at 15-minute intervals. Vital signs, including O<sub>2</sub> saturation and end-tidal CO<sub>2</sub> (if available), are continuously monitored.

As an alternative to systemic opioids, pain from injuries to upper and lower extremities can be treated with peripheral nerve blockade, provided that contraindications are not present (see Volume 1, Chapter 20). This is particularly important when the limb is anesthetized. Casts should be bivalved during transport to accommodate pressure changes, otherwise, the development of a compartment syndrome can go unnoticed.

Pharmacologic sedation is provided to agitated patients only after adequate analgesia has been achieved and intravascular volume has been shown to be adequate. For this purpose, IV midazolam can be titrated at 0.5- to 1-mg doses every three to five minutes, as the vital signs and level of consciousness are monitored.

### **Trauma Resuscitation Suite Considerations**

#### **General Approach and Recommendations**

Analgesia and sedation guidelines for TRS are similar to those utilized in the prehospital setting. However, more monitoring and treatment resources are available in the TRS, and analgesics can be titrated to effect in a more controlled environment. Drugs are selected based upon the type of injury, severity, and location of pain along with the baseline mental and emotional status of the patient. Treatment choices include systemic analgesics, sedatives, and local and regional techniques. **☞ In the TRS, as in the prehospital setting, analgesics and sedatives are withheld until oxygen is administered, functioning IV is placed, O<sub>2</sub> saturation is monitored, and the patient demonstrates cardiopulmonary stability after the initial ABCDEs of the primary survey. ☞**

Administration of analgesia and sedation in presence of isolated injuries of the extremities is usually relatively uncomplicated (80). Severe pain associated with such injuries is typically treated with IV fentanyl (0.01–0.05 mg), morphine (1–5 mg), or hydromorphone (0.2–1 mg) at intervals of 5 minutes (fentanyl) to 15 minutes (morphine and hydromorphone). Pain, vital signs, including oxygen saturation and end-tidal CO<sub>2</sub>, are closely monitored during opioid titration. NSAIDs such as ketorolac or acetaminophen, and antispasmodic agents (diazepam 5–10 mg IV or PO) can be used to augment opioid analgesia and reduce opioid requirements in otherwise stable patients with isolated extremity injuries.

Regional analgesia can be used to treat pain in the emergency. Techniques include neuroaxial (spinal and epidural) and peripheral nerve blockades (see Volume 1, Chapter 20 and Volume 2, Chapter 25). Neuroaxial administration of local anesthetics, in addition to providing analgesia, causes loss of sympathetic tone. This effect can result in severe cardiovascular compromise in trauma patients who depend on the sympathetic tone to maintain hemodynamic stability. For this reason, epidural and spinal analgesia are rarely used in the acute management of patients, except for those with isolated lower extremity injuries.

#### **Specific Trauma Resuscitation Suite Scenarios**

##### **Procedural Analgesia**

Analgesia and sedation are frequently required during invasive studies and minor procedures in the TRS. Procedures

**Table 13** Analgesia and Sedation for Common Acute Trauma Procedures

Procedure	Local analgesia	Comments
Laceration repair	Yes	Local analgesia first, then systemic analgesia and sedation as needed
Fracture reduction	Yes <sup>a</sup>	Brief analgesia (+/-) sedation for severe transient pain
Dislocation	No	Brief sedation (to relax guarding muscle spasm, and to provide amnesia for severe transient pain) + minor postreduction analgesia
Chest tube placement	Yes	In hemodynamically unstable patients, only local anesthesia should be used. In others small doses of sedatives (+/-) analgesics are useful, but local anesthesia (at least 100 mg in 10 mL) is essential
Deep peritoneal lavage	Yes	Local analgesia is usually adequate in unstable patients. If fully stable (rare with this procedure), sedatives and analgesics are appropriate
Steinman pin placement	Yes	Local anesthesia does not cover the bone pain. Patients who are hemodynamically stable should receive analgesics +/- sedatives
Suprapubic catheter placement	Yes	Local anesthesia with supplemental sedatives and analgesics based upon patient status
Tongs/halo placement	Yes	Local anesthesia plus systemic analgesics +/- sedatives

<sup>a</sup>May use hematoma block (80)—especially for upper arm (distal radius fracture) reduction.

commonly performed in the ED and TRS are listed in Table 13, and include laceration repair and reduction of fractures and dislocations (81). Acute and transient pain exacerbation, which often accompanies such procedures, is optimally treated with short-acting analgesics or sedatives. The previously enumerated prerequisites for prehospital and TRS analgesia and sedation pertain to these patients as well, including the need for O<sub>2</sub> administration, functioning IV, and monitoring O<sub>2</sub> saturation, BP, echocardiogram (ECG), and RR. In addition, emergency airway management equipment must be available, and the patients must continue to be cooperative and stable.

Fentanyl and midazolam, with their rapid onsets and short durations of action, are commonly used for analgesia and sedation for minor procedures. In combination, these drugs provide a balance of analgesia and amnesia, with short-term sedation. During the titration of fentanyl and midazolam, the level of consciousness and vital signs, including oxygen saturation and end-tidal CO<sub>2</sub>, are continuously monitored. In hemodynamically stable and awake patients, midazolam (0.5–1 mg) and fentanyl (0.025–0.05 mg) are administered at five-minute intervals. Although midazolam primarily treats anxiety and provides amnesia and fentanyl primarily treats pain, sedative and respiratory depressant effects of these drugs are synergistic. Furthermore, severe pain provoked by manipulation of injured tissue can rapidly dissipate following fracture or dislocation reduction. With abrupt reduction in the pain stimulus, patients who have received relatively large doses of sedatives and analgesics are at increased risk of losing control of airway, respiratory drive, and consciousness.

Propofol, with its short duration of action, quick onset, ease of titration, and relative safety, has also emerged as a commonly employed drug for procedural sedation. It is particularly suitable for procedures associated with severe, but short-lived pain, such as the reduction of a dislocated limb. However, in larger doses propofol can result in inadvertent unconsciousness, apnea and loss of airway reflexes, and hypotension. Adherence to the initially low and gradually increasing infusion rates is therefore important during propofol dose titration.

Typical initial infusion rate of propofol is 25 µg/kg/min. To achieve desired level of sedation, the infusion rate can be increased by 20% to 30% every five minutes. Propofol

can also be administered by intermittent 0.1–0.2 mg/kg boluses immediately prior to painful manipulation. Additional doses are typically injected at one- to five-minute intervals to the desired clinical effect.

As with other sedatives and analgesics, supplemental O<sub>2</sub> should be applied first, and vital signs be monitored, including oxygen saturation and end-tidal CO<sub>2</sub>, and mental status (82). Throughout the procedure, the patients should be able to respond purposefully to verbal commands. Propofol and opioids, such as fentanyl, can be coadministered, however, propofol and opioid boluses should not be given simultaneously because of compounded risk of respiratory depression and excessive sedation (74).

Ketamine is another suitable procedural sedative-analgesic. It is commonly employed in the acute trauma due to rapid onset and dissipation of action, strong analgesic effect, sympathomimetic activity, bronchodilation, and preservation of laryngeal reflexes. Because of these beneficial physiological effects, which also support cardiopulmonary status and spontaneous ventilation, ketamine is frequently chosen in the military setting. However, because of other effects, particularly the unpleasant and emotionally disturbing dissociative mental state, ketamine is often supplemented with a benzodiazepine.

Ketamine can exhibit cardiovascular depressant effects in patients who are unable to mount additional sympathetic output, such as patients in hypovolemic shock (these patients should instead be promptly resuscitated, and may require intubation, positive pressure ventilation along with scopolamine for amnesia). Despite its unpredictable hemodynamic effects and contraindication in patients with TBI, ketamine remains a first-line drug for sedation and induction of anesthesia in the presence of severe bronchospasm, and in uncooperative patients without an IV access.

#### *Combative Patient in the Trauma Resuscitation Suite*

Evaluation and treatment of violent or combative patients can be uniquely challenging. Several factors can contribute to combative behavior in the acute trauma patient including TBI, hypoxia, hypovolemic shock, intoxication, psychiatric illness, and OBS from baseline organ failure. ⚡ **Hypovolemic shock and/or TBI need to be immediately ruled out in all combative patients, because prompt and successful management of these problems can markedly improve outcomes.** ⚡ Other

causes of combativeness that need to be considered include anxiety disorders precipitated by exposure to the confusing and chaotic environment of the TRS that are emotionally overwhelming to some patients.

Besides interfering with evaluation and treatment, combative patients are at risk of harming themselves and others. It is therefore essential for the treating clinicians to rapidly gain complete control of the patient. Some violent and completely uncooperative patients require deep sedation with induction of general anesthesia, with NMB and intubation. This measure is resorted to in circumstances where other means of analgesia and sedation are either ineffective or too risky, such as in patients with potential major organ compromise or tenuous airway.

Often agitated and combative patients identify severe pain as the main source of their distress. If these patients are not at risk of cardiovascular collapse or loss of airway, then their pain can, and should, be judiciously treated. The first choice for analgesia in severe pain (without concomitant TBI) is usually an opioid drug. Opioids are typically titrated to effect as a series of small sequential IV boluses of fentanyl (0.01–0.05 mg), morphine (1–5 mg), or hydromorphone (0.2–1 mg) every 5 minutes (fentanyl) or every 15 minutes (morphine and hydromorphone). Vital signs, especially RR and BP, and the level of consciousness are continuously monitored during opioid titration, with the endpoint being analgesia with a RR >10–12.

After achieving adequate opioid-based analgesia, midazolam can be administered to treat agitation. It is titrated in 0.5- to 1-mg doses every five minutes. Co-administered opioids and benzodiazepines can synergistically cause excessive respiratory depression and sedation (83).

Increasingly, dexmedetomidine (no intrinsic respiratory depression) is becoming the sedative of choice to supplement low-dose opioids in acute trauma patients. In those who require rapid recurrent evaluation of neurologic status, dexmedetomidine is particularly efficacious, because the sedative effect can continue without significant depression of mental acuity. In this setting dexmedetomidine is started as an infusion (without a bolus load) at 0.2–0.7  $\mu\text{g}/\text{kg}/\text{hr}$ .

## ANALGESIA AND SEDATION FOR CRITICAL CARE

Trauma patients in critical care exhibit diverse underlying pathologies, emotional states, pain levels, and analgesic and sedative dose requirements. The majority of these patients develop some degree of delirium during the intensive care unit (ICU) stay. Nonpharmacologic interventions, such as reduction of pain stimulus by repositioning, sleep normalization, verbal orientation and reassurance are the initial steps in treatment (Fig. 1).

Pharmacologic analgesia usually consists of opioids, whose doses are titrated and are empirically determined by clinical response. Titration of opioids should be rapidly completed with adequate serum drug levels achieved within 30 minutes of initiating therapy. Sedatives are introduced only after administering adequate analgesia and are likewise titrated to the desired effect. Deep sedation with muscle paralysis and mechanical ventilation may be initially required for some critical care patients.

### Analgesia

Opioids remain the cornerstone of treatment for moderate to severe pain in critical care. The IV route of drug adminis-

tration is usually preferred since IM or SQ drug delivery can be painful and have unpredictable absorption rates. The latter problem is accentuated in critically ill patients, who can exhibit highly variable responses to opioids. In general, choice of an opioid for each patient depends on its potency, side effects, and ease of titration.

Fentanyl is often the first-line opioid analgesic in critical care. It provides rapid onset of analgesia and a relatively short clinical duration in small bolus doses, and is easily titratable by infusion. Fentanyl can be administered at 0.025- to 0.1-mg IV boluses every five minutes, or infused at an initial rate of 0.002–0.005 mg/kg/hr. The bolus doses and infusion rates can be gradually increased as needed to provide an adequate analgesic effect. Occasionally, opioid-tolerant patients may require fentanyl doses as high as 0.03 mg/kg/hr.

Morphine is also routinely used for analgesia in critical care. It can be gradually titrated with typical boluses of 1–5 mg every 15 minutes. After initial stabilization, morphine is generally infused IV at 3–10 mg/hr. Considerably higher doses and infusion rates may be required in opioid tolerant patients. Hydromorphone can be titrated to an analgesic effect with 0.2- to 1-mg IV doses every 10 to 15 minutes, or infused at 0.5–3 mg/hr.

### Sedation for Treatment of Anxiety and Agitation

Assessment of the level of consciousness, including sedation and anxiety, is discussed earlier. Anxiety in the injured can arise from many causes, including pain, the circumstances, and sensory deprivation or overload. Treatment of pain often leads to dissipation of anxiety. Accordingly, sedatives should not be routinely administered until adequate analgesia has been delivered.

Because there is a continuum between light to deep levels of sedation, ultimately progressing to general anesthesia (84), the goals of sedation and its desired depth should be defined for each patient. This determination should be based on the nature and extent of injury, as well as the physiological and mental status of the patient. **Managing deeply sedated patients can be easier than those who are slightly sedated; however, deep sedation carries multiple risks, including delayed awakening, ventilator-associated pneumonia, postsedation delirium, muscle wasting, and pressure sores (85).** In most patients, the optimum level of sedation is achieved by titration to state of calm, or to comfortable but easily arousable states (e.g., RASS = 0). Deeper levels of sedation can be required when painful procedures are performed or to facilitate ventilatory support [i.e., patients with adult respiratory distress syndrome (ARDS) or TBI].

The sedative drug choice is generally guided by several factors, including the need for rapid awakening (e.g., to perform neurological exams) versus an anticipated prolonged sedation, without the need for awakenings. Other considerations include cost and the potential side effects. Drugs most commonly used for induction and maintenance of sedation are benzodiazepines, propofol, and dexmedetomidine.

Propofol with its rapid onset and short duration of action is well suited for short-term sedation in critical care, particularly in patients at risk for increased ICP, who may need frequent reversal sedation to conduct neurological exams.

Metabolism of propofol is minimally affected by hepatic and renal dysfunction, and its metabolites are inactive. Times of onset and levels of sedation with propofol and midazolam are similar, and after short-term sedation (less than 24 hours)

propofol and midazolam exhibit similar times to awakening though they wake up from propofol faster and are more clear-headed (51,86–88). After sedation between 24 and 72 hours, the times to awakening with propofol (0.25–2.5 hours) are considerably shorter than with midazolam (2.8–30 hours). Similarly, sedation with propofol for longer than 72 hours provides significantly faster awakening and extubation than with midazolam (0.25–4 hours with propofol compared to 2.8–49 hours with midazolam) (51,89).

Because of its numerous side effects, propofol administration requires a high degree of vigilance. It causes respiratory depression, and reduces systemic vascular resistance and ionotropy. In some patients these effects result in significant systemic hypotension; whereas in others BP is relatively preserved. It is often impossible to predict the extent of hypotensive effect in the patient. Prolonged infusion of high-dose propofol increases serum triglycerides (51,90) and elevation of serum pancreatic enzymes (91,92). Lactic acidosis, bradycardia, and hyperlipidemia were reported in pediatric patients after 48-hour infusion of high-dose propofol (66 µg/kg/min) (as described later) (93). Prolonged infusion of even higher dose (>83 µg/kg/min) is associated with increased risk of cardiac dysrhythmias and arrest (94). Propofol is also relatively expensive and commonly causes pain in the peripheral vein during the injection. In consideration of all the benefits and risks associated with propofol, it is often the sedative of choice when rapid awakening or extubation are required (51).

Benzodiazepines remain the mainstay of sedative and anxiolytic therapy in chronically sedated critical care patients and those without acute TBI, primarily because they are relatively inexpensive and lack some side effects associated with propofol. Benzodiazepines, however, also possess several deleterious side effects. Although generally less severe than with propofol, respiratory and cardiovascular depression can occur even at moderate doses. Prolonged respiratory depression and delayed awakening are common after extended periods of benzodiazepine infusion. In order to mitigate delayed awakening and avoid excessive accumulation of the drug, level of consciousness should be frequently assessed and downward titration in the infusion rate should occur as tolerated.

An important practice consideration in this regard is the need to allow critical care patients to benefit from sleep that is not unnecessarily disrupted. One such approach allows the night shift nurse (19:00–07:00) to obtain a complete neurological exam of the patient at the beginning and end of shift, but limits evening awakenings to the bare minimum in otherwise stable patients. Pupils can be checked in sedated patients who are at risk for TBI on an hourly basis. Many of these patients will also have an ICP monitor in place during the early and most vulnerable stages of recovery. In these same patients, the day shift nurse tries to decrease the sedation to as low of a dose that is tolerated, (while analgesia is maintained), and efforts are made to increase the patient's orientation and interactions with treatments such as physical therapy, weaning from mechanical ventilation, and other activities.

Midazolam, with its strong amnestic properties and ease of titration, is one of the first-line benzodiazepines used in critical care and is particularly recommended for acute anxiolysis, rapid sedation, and infusion for less than two to three days (51). Indeed, it has largely replaced diazepam in critical care due to its shorter and more predictable duration of action. Time to awakening is less predictable after infusing midazolam for longer than three days,

particularly in patients who are obese, or with liver or renal insufficiency. Prolonged sedation in these patients is attributed to the accumulation of midazolam and its active metabolite,  $\alpha$ -hydroxymidazolam.

Lorazepam has longer elimination half-life and slower onset than midazolam or diazepam (Table 6). It is, accordingly, less suitable for rapid titration of sedation because the responses to the dose changes are delayed. With prolonged high-dose infusion of lorazepam (over 18 mg/hr for longer than four weeks), its solvents (polyethylene glycol and propylene glycol) can be responsible for acute tubular necrosis (generally reversible), lactic acidosis, and hyperosmolar states (51). With this in mind, lorazepam is inexpensive and devoid of active metabolites. It offers predictable half-life and less variable time to awakening than even midazolam (51,95), and is a suitable choice for long-term (72 hours or longer) sedation at moderate doses (51).

Diazepam, similarly to midazolam, provides fast onset and is useful in acute sedation. Diazepam is, however, less suitable for continuous infusion or repeated boluses than midazolam or lorazepam because of gradual buildup of active metabolites with very long elimination half-life. In addition, diazepam can cause irritation of the veins and thrombophlebitis when injected peripherally. Because of unpredictable half-life of diazepam and its metabolites, it is not recommended for sedation in repeated doses or continuous infusion.

The benzodiazepine antagonist flumazenil is available, but not routinely used, in critical care for reversal of sedation after prolonged benzodiazepine administration. The duration of action of a single IV dose of flumazenil is approximately 30 minutes, and the reversal of benzodiazepine-induced sedation under these circumstances is likely to be short-lived. Several factors other than benzodiazepines could be responsible for prolonged sedation, and should always be considered prior to administration of flumazenil. Flumazenil at 0.5-mg doses can precipitate benzodiazepine withdrawal symptoms including seizures and increased cardiovascular oxygen demand (as described earlier). In patients who have received prolonged benzodiazepine infusion, residual sedation can be treated with short-term infusion of flumazenil (0.5 mg/hr) (96), instead of a single dose. However, only a single dose of flumazenil is recommended to test whether unexplained prolonged sedation is due to benzodiazepines (51).

Dexmedetomidine is increasingly utilized in critically ill patients whose sedation is difficult to manage with traditional (e.g., propofol or benzodiazepine) drugs. The pharmacologic properties of dexmedetomidine (described earlier) are distinct from those of other sedatives. ⚡ **In therapeutic doses, dexmedetomidine does not suppress respiratory drive or airway reflexes, making it a very useful drug during weaning to extubation, particularly in cases where airway or breathing are subject to compromise (e.g., obesity, sleep apnea, and thoracic cage trauma).** ⚡ Sedation produced by dexmedetomidine is characterized by a state of calm, in which patients are easily arousable to mild stimuli (97). Unlike propofol or benzodiazepines, dexmedetomidine is also an effective analgesic (98), whereas its hypnotic effects are insignificant (99).

Several prominent side effects require vigilance in administration of dexmedetomidine. Transient hypertension can initially occur especially when the loading dose is employed. Sympatholytic effects of dexmedetomidine result in often beneficial decrease in serum catecholamine levels (99). However, ensuing bradycardia and hypotension are also common.

Young and athletic patients with strong vagal tone are particularly susceptible to extreme bradycardia. These effects can be treated with vagolytic or sympathomimetic drugs.

With its unique pharmacologic properties, dexmedetomidine provides a balance of sedation, anxiolysis, and analgesia without respiratory drive suppression. In some patients dexmedetomidine is sufficient as a sole sedative-analgesic, and in other patients it is helpful in reducing the dose requirement of other sedatives and analgesics (36). Indeed, coadministration of dexmedetomidine with opioids decreases the opioid requirement and can produce optimal balance of analgesia and sedation (36). Similarly, combined infusion of propofol and dexmedetomidine produces a deeper sedation level than with dexmedetomidine alone, and decreases the dose requirement of propofol, thus mitigating its hypnotic and respiratory depressant effects.

### Treatment of Delirium

Assessment of delirium is required in all critical care patients with an altered level of consciousness. The principal causes of delirium in the ICU includes: physical illness, infection, metabolic disorders, sleep deprivation, and psychoactive pharmacologic agents both resulting in a loss of frame of reference person, place, and time. Delirium is associated with increased morbidity and should be promptly treated and, if possible, prevented.

Preventive and nonpharmacological approaches to delirium include repeatedly reorienting the patients during the daytime and promoting sleep at night by reducing disruptive noise and light stimulation. Another important method for limiting delirium is by mobilizing patients as early as possible, and promoting physical and cognitive activities (71). Since opioids, sedatives, and other psychoactive drugs can exacerbate and even induce delirium; the ongoing analgesic and sedative doses are reviewed and, if possible, reduced.

If nonpharmacological measures and opioid and sedative dose reduction are not successful in treating delirium, then antipsychotic drugs, such as haloperidol, can be used. Haloperidol can be administered PO, IM, and IV (IV route, however, is not approved by the FDA) (as described earlier). Although compelling evidence is still emerging, there are numerous reports of successful use of newer atypical antipsychotic drugs—olanzapine, risperidone, and ziprasidone in treatment of delirium in critical care (100,101). These drugs cause less sedation, mental status changes, and extrapyramidal symptoms than traditional antipsychotics. Reportedly, the risk of developing tardive dyskinesia with atypical antipsychotics is also reduced.

All antipsychotic medications active at the dopamine receptors carry the risk of inducing QTc interval prolongation and consequent ventricular arrhythmia. Patients with QTc >500 milli seconds, recent myocardial infarction, or uncompensated heart failure should be closely monitored if antipsychotic drugs are required. They should also receive concomitant magnesium infusion to a target serum magnesium ion concentration which is normal, or slightly above normal (typically 2–3 mg/dL). Tracking QTc changes with serial ECGs is necessary in all patients treated with antipsychotic drugs.

## SPECIAL CONDITIONS IN TRAUMA AND CRITICAL CARE

### Thoracic Trauma

Pain resulting from thoracic trauma, including chest wall contusions and rib fractures, severely restricts ventilatory

efforts and efficiency. Systemic opioids can further depress ventilation in these patients. Without regional analgesia, some of these patients require deep sedation, intubation, and positive pressure ventilation. For patients who, because of significant pulmonary contusions or parenchymal injury, pneumonia, or polytrauma, are anticipated to require prolonged mechanical ventilation; systemic analgesia and sedation is fully appropriate.

However, in the awake patient with trauma limited to thoracic cage (i.e., multiple rib fractures) and no underlying pulmonary parenchymal injury, thoracic epidural analgesia is beneficial as it will allow earlier weaning, extubation, and mobilization of the patient. Regional techniques that have demonstrated better pain relief and safety than systemic analgesics include epidural and intrathecal analgesia, intercostal and paravertebral nerves blockade, and interpleural analgesia (102). The specifics of regional analgesia for chest injuries are further discussed in Volume 2, Chapter 25.

Regional analgesia techniques in the thoracic segments bear inherent risks of nerve injury, pneumothorax, uncontrolled bleeding, and infection. Risks and benefits of these techniques should be carefully weighed for each patient. ⚡ **In general, thoracic regional analgesia should be considered in patients who are at risk of respiratory failure because of severe chest wall motion-related pain. Conversely, regional analgesia techniques should not be used in patients whose pain can be adequately controlled with systemic analgesics.** ⚡

### Burns

Burn injury, discussed in Volume 1, Chapter 34 often results in severe pain, which is markedly exacerbated during dressing changes. Analgesia for burn injury almost universally includes opioids, typically fentanyl, morphine, or hydromorphone (103). At the time of dressing changes, the pain is usually treated with short- or ultrashort-acting fentanyl, sufentanil, or alfentanil. Ketamine, with its anesthetic and analgesic effect, sympathomimetic activity, and relative absence of respiratory depressive effects, is particularly suitable for short-duration analgesia during dressing changes in spontaneously ventilating, nonintubated patients.

Sedation and amnesia can be achieved with short-acting midazolam or propofol. ⚡ **Titration of all sedatives and analgesics requires increased vigilance because protein-bound drugs often have increased bioavailability in the characteristically hypoalbuminemic burn patients (104).** ⚡ These patients also have elevated metabolic rates and develop early tolerance to sedatives and analgesics, resulting in higher infusion rates and, consequently, increased risk of vasodilatation or myocardial depression. Regional analgesia is rarely used in burn injuries because of the infection risks. Adjuvant drugs such as antidepressants and anticonvulsants, as well as IV lidocaine infusion, can reduce pain and hyperalgesia (3,34).

### Organ Dysfunction

The kidneys and liver are the primary organs of drug metabolism and excretion. Dysfunction of these organs inevitably results in significantly impaired drug and metabolite clearance. This usually results in markedly increased duration of action, enhanced pharmacological effect, and increased risk of dangerous side effects.

Accumulations of metabolic products of morphine and meperidine are particularly ominous. Renally excreted M3G is one of the main metabolic products of morphine.

Unlike M6G, it exhibits antianalgesic properties. It was also implicated in neurotoxic side effects, with resultant hyperalgesia, myoclonus, and seizures (as described earlier) (105). Clinically significant accumulation of morphine glucuronides have been clearly observed in patients with renal insufficiency (106). Accordingly, in these patients, morphine should be changed to opioids less affected by renal clearance (i.e., fentanyl or hydromorphone).

Meperidine is converted to a neurotoxic metabolite, normeperidine (as described earlier). It has long elimination half-life and can induce myoclonus and refractory generalized seizures. Meperidine should be used with caution even in patients with normal renal function, and completely avoided in all cases of renal insufficiency.

The effects of midazolam are enhanced in patients with hepatic or renal failure because of elevated unbound fraction of the drug (107). Furthermore, its plasma clearance is markedly decreased in patients with liver failure. Accumulation of renally excreted midazolam metabolites can result in prolonged sedation and coma (108). Even in healthy patients, midazolam tends to accumulate in the tissues, and after infusion longer than 48 to 72 hours, the time to awakening and extubation becomes prolonged and unpredictable (as described earlier).

Diazepam and its main active metabolite, desmethyl-diazepam, tends to accumulate in all patients, resulting in prolonged and unpredictable sedation. In the presence of liver or kidney dysfunction, the ability to predict the effects and duration of action of diazepam is further diminished. For this reason, diazepam, which is rarely used in critical care, should never be used for sedation of patients with hepatic or renal insufficiency.

Use of propofol and fentanyl are generally the best choices of sedation and analgesia in patients with organ failure. Clearance of these short-acting drugs appears to be unaffected by hepatic or renal dysfunction, and their principal metabolic products are inactive. Clearance of dexmedetomidine, on the other hand, is impaired in the presence of liver and kidney dysfunction. Recent, yet unpublished studies have shown systemic hypertension and cerebral vasoconstriction at very high doses. Accordingly, dexmedetomidine must be used cautiously when organ dysfunction could significantly increase blood levels.

### Drug Addiction, Dependence, and Tolerance

All opioid analgesics bear an inherent risk of developing tolerance, dependence, and addiction. ⚡ **In the acute trauma and critically ill patients, presence or suspicion of opioid addiction should not preclude aggressive treatment of pain with opioids.** ⚡ These behavioral and physiological manifestations of prolonged opioid use can be addressed and treated during recovery in the hospital or as an outpatient.

Physical dependence to opioids is defined by the development of an abstinence (withdrawal) syndrome when the opioid is discontinued. It is manifested by anxiety, irritability, chills, hot flashes, joint pain, lacrimation, rhinorrhea, diaphoresis, nausea and vomiting, abdominal cramps, diarrhea, and “flu-like” symptoms. Except for the patients who physiologically cannot tolerate a moderate increase in sympathetic outflow, opioid withdrawal symptoms are self-limiting and not life-threatening. Withdrawal symptoms can occur after as little as two weeks of opioid use. These symptoms appear 6 to 12 hours after discontinuing short-acting opioids. With long-acting opioids, the withdrawal symptoms are usually milder, and their onset

is slower. To prevent these symptoms, opioids should never be discontinued abruptly, but tapered gradually. Clonidine, in topical or PO forms, is routinely administered to counteract the symptoms of opioid withdrawal. Similarly, dexmedetomidine has been recently used to facilitate discontinuation of opioids (109).

Opioid addiction, unrelated to drug dependence or tolerance, is characterized by an aberrant behavior and psychological dependence. Addicted patients crave, request, and consume opioids to satisfy the emotional urge. In the presence of severe acute pain, some patients may exhibit pseudoaddiction symptoms with behavioral patterns similar to that in addiction. In contrast to addicted patients, the pseudoaddicted patients revert to normal behavior once adequate analgesia is achieved, without developing symptoms of opioid intoxication, such as somnolence or slurred speech.

Opioid tolerance manifests as a gradually increased drug requirement to maintain the same level of analgesia. Tolerance has been shown to develop in laboratory animals as well as in patients who have undergone surgeries with even short-term courses of opioids. Younger patients tend to become opioid tolerant more rapidly than older adults. The development of tolerance to opioids should be expected in all critical care patients who receive these drugs for more than five to seven days. However, other causes for increased opioid requirement, such as progression of disease, infection, compartment syndrome, pressure ulcers, and so on, should always be considered first.

Dependence on benzodiazepines can also develop in critically ill patients after several weeks of continuous daily use. Unlike the opioid withdrawal, the abstinence symptoms after abrupt discontinuation of benzodiazepines can be life-threatening. Depending on the half-life of the benzodiazepine, the onset of symptoms usually occurs within one to two days. The symptoms can range from mild agitation to generalized seizures and include anxiety, increased HR and BP, diaphoresis, nausea and vomiting, and hallucinations. These symptoms are typically treated with administration of benzodiazepines, followed by a gradual taper.

## Age-Related Considerations

### Pediatric Patients

Children, including infants and neonates, are susceptible to the complications of the pain-induced stress response (79). Accordingly, adequate analgesia and sedation can suppress physiological responses to noxious stimuli, thereby improving postoperative recovery (110,111). Assessment of pain in children may be difficult, particularly in the critically ill. Physiological responses, parental interpretations, and facial expression interpretation scales can be helpful in assessing pain (as described earlier) (112).

Opioids such as fentanyl, morphine, and hydromorphone are usually the primary analgesics in treatment of moderate or severe pain in children. In addition to their analgesic properties, opioids can be even more effective than benzodiazepines for sedation of infants and neonates. Ketamine is used for sedation and analgesia in patients with bronchospasm or who are hemodynamically unstable. In patients with adequately controlled pain, sedation and amnesia can be achieved with bolus injection or continuous infusion of midazolam. Pentobarbital and other barbiturates can be effective, but benzodiazepines and opioids are usually more suitable to the provision of adequate sedation.

Chloral hydrate, a CNS depressant, is still available in PO and PR forms, but is rarely used because of serious side effects and toxicity (113). These include severe respiratory depression and low blood pressure, cardiac dysrhythmias, and liver damage.

Propofol is an effective sedative in children and can be safely used short-term for procedures and in critical care (114). However, safety of propofol for prolonged sedation in children remains undetermined. In addition to cardiovascular and respiratory depression, propofol use has been associated with numerous reports of rare but sometimes fatal "pediatric propofol infusion syndrome" (PRIS). This syndrome is the constellation of metabolic acidosis, cardiac and renal failure, and rhabdomyolysis. Although PRIS occurs primarily after prolonged (>48 hours) infusion of propofol, metabolic acidosis has been reported even after short periods of infusion (115). Exact mechanism of PRIS is unknown, but it may be related to the impairment of intracellular free fatty acid utilization (116). In children, doses of propofol exceeding 4 mg/kg/hr should generally be avoided. Experience with dexmedetomidine in children is still limited, but numerous reports describe successful sedation with this drug in pediatric critical care and anesthesia (109,117,118).

### **Elderly Patients**

Although the age-related changes in the pharmacokinetic properties of drugs are not well defined, and can be gradual and unpredictable (119), the elderly often require reduced doses of sedatives and analgesics. Sedative effects of midazolam increase in intensity and duration with age. Indeed, it exhibits a twofold increase in the half-life between ages 20 and 80 (120). The elderly are also more susceptible than younger adults to the adverse side effects of benzodiazepines and often exhibit dizziness, confusion, hallucinations, hypothermia, urinary retention and constipation, and urinary or bowel incontinence (40,121). In general, it is prudent to use half or less the normal adult dose of the benzodiazepines in the elderly.

Propofol, in general, provides rapid recovery and relatively small propensity for accumulation or tolerance (122); however, in the elderly, clearance of this drug is decreased and its sedative effects are more pronounced. Consequently, the elderly generally require approximately one-half of the usual adult bolus doses or infusion rates of propofol.

In the elderly, fentanyl and related lipophilic opioids exhibit twofold potency with respect to analgesia and sedation, and their doses should be adjusted accordingly (123). Clearance of morphine and its active metabolites, M6G and M3G, decreases with age, resulting in increased apparent potency and risk of toxicity and overdose. Because of its slower metabolism, morphine is administered in smaller and less frequent doses in the elderly than in younger adults.

### **EYE TO THE FUTURE**

The management of pain and anxiety in acute trauma and critical care is poised for a major transformation with the clinical introduction of a number of recently discovered agents, along with the continued developments of monitoring technologies, and refinements in the usage of existing drugs. Opioids, local anesthetics, and NSAIDs will likely retain a role in pain management of acute trauma and critical

care, whereas sedative/anxiolytic and antipsychotic drugs will see major changes. The balance between the increased cardiovascular risk and the benefit of prevention of GI bleeding will determine the future of selective COX-2 inhibitors, including the long-anticipated IV form.

Recently, a new variant of COX enzyme, COX-3, has been described (124). This isoenzyme modulates pain, inflammatory, and febrile response primarily by a central mechanism, and is a potential target of future COX-3-specific inhibitors. Indeed, some existing drugs, including acetaminophen, exert their analgesic effect primarily by their inhibition of the COX-3 enzyme.

Expanding knowledge and understanding of pain mechanisms provides the potential targets for new classes of analgesics. Such targets include NMDA receptor, calcium channels, tumor necrosis factor $\alpha$  (TNF- $\alpha$ ), spinal mitogen activated protein (MAP) kinase, and genes responsible for sodium channel synthesis. Compounds active at these sites are currently in various stages of development. Ziconotide, a calcium channel antagonist, has recently been introduced as a potent analgesic for intrathecal use. This peptide, derived from sea-snail venom, has shown strong analgesic effects in patients with refractory chronic pain.

Interestingly, erythropoietin, a compound involved in suppression of TNF- $\alpha$  synthesis, has shown promising analgesic effects in neuropathic pain, and its efficacy and safety are currently studied in animal models (125).

An isoform of spinal MAP kinase, p38 $\beta$ , is identified as an important mediator of pain processing and sensitization. Down-regulation of p38 $\beta$  in the spinal microglia was shown to prevent the development of hyperalgesia in rats who have received injection of formalin or intrathecal substance P (126). Such down-regulation of p38 $\beta$  has been demonstrated with intrathecal administration of minocycline, also resulting in blocking inflammation-induced hyperalgesia (127). It appears that minocycline, an antibiotic, attenuates p38 $\beta$  as part of inhibition of microglia through a mechanism unrelated to its antibiotic activity.

A novel approach incorporating gene-related pain therapy has been recently described (128). This approach targets the synthesis of sensory nerve Nav1.8 sodium channels that are present in dorsal root ganglia and are implicated in pathogenesis of neuropathic and inflammatory pain. This in vitro study involved the synthesis of DNA fragments, designed to transcribe short hairpin RNA targeting synthesis the sodium channels. The DNA fragments were then incorporated in the recombinant lentoviruses. Infecting rat dorsal root ganglia cells expressing sodium channels with the lentoviruses resulted in a cessation of production of the sodium channel protein and its corresponding mRNA. Silencing sodium channel-producing DNA with internally transcribed RNA is conceptually attractive, particularly since the role of these sodium channels in mediating of neuropathic and inflammatory pain has already been established (129). Safety and efficacy of this technique in animals and humans is currently under investigation.

### **SUMMARY**

Treating pain is compassionate, and a new impetus exists for meticulous and timely analgesia. If pain is treated early, immediate and long-term psychological and physiological postinjury complications can be reduced. Addressing

analgesia is therefore imperative for all trauma and critically ill patients.

Management of pain and anxiety in the injured generally follows the path from the least to the more intensive and invasive approaches. In all situations, the treatment starts with reassurance, emotional support, and avoidance of pain-provoking stimuli. Pain is then treated with pharmacotherapy. Sedation should be added only after achieving an adequate foundation of analgesia (Fig. 1). Depending on the goals and desired results, sedation and treatment of delirium is a continuum ranging from mild sedation to a state of unconsciousness.

Most sedatives and opioids suppress respiratory drive, laryngeal reflexes, and hemodynamics. With vigilance and close attention to respiratory, neurologic, and cardiovascular parameters, administration of these drugs is performed by gradual titration. Peripheral or neuroaxial regional analgesic techniques are suitable for some acute trauma and critical care situations.

Children, the elderly, and those with substance abuse problems differ from the average adult patients in their responses to sedatives and analgesics. Like all humans, these patients exhibit severe stress response to injury and experience pain and anxiety.

Significant advances, both technical and conceptual, were made over the past several decades in the management of pain. However, to this day, opioids remain the mainstay of management of moderate to severe pain. It is becoming increasingly apparent that the pain signal is modulated in the periphery and within the CNS by multiple mechanisms. Some of these pain-modulating signaling molecules and receptors may in the future become targets for a new generation of analgesic drugs.

## KEY POINTS

- ✂ Without compromising cardiopulmonary status, judicious use of analgesics and sedatives can relieve pain, provide a state of emotional calm, and facilitate the diagnostic evaluation of trauma patients.
- ✂ PTSD affects up to 40% of major trauma patients (4,5).
- ✂ Optimal pain management involves a stepwise logical approach beginning with the elimination of obvious painful stimuli (e.g., splinting fractures), ascending to administration of analgesics prior to introducing sedatives or neuroleptic drugs; and, only in rare cases is deep sedation with NMB required.
- ✂ There is a general consensus that administration of analgesia at the earliest possible opportunity will likely have beneficial effect on the long-term outcome of patients who sustain tissue injury from trauma or surgery.
- ✂ Local anesthetics do not work efficiently when injected in the vicinity of infected tissue.
- ✂ Among the side effects associated with opioids (Table 5), respiratory depression, loss of airway, and hypotension are potentially the most dangerous. Indeed, fear of respiratory depression is a common cause of inadequate analgesia in critically ill patients.
- ✂ Pain stimulates the respiratory drive and counteracts the sedative effects of opioids. Consequently, patients on relatively high doses of opioids, who then undergo regional nerve blockade, can develop acute respiratory depression because of abrupt abolition of the afferent pain stimulus.

- ✂ In long-term benzodiazepine users, and if given in too large of a dose (rather than titrated as recommended above), flumazenil can precipitate seizures or other withdrawal symptoms, including acute onset of severe anxiety, muscle jerks, and tremors.
- ✂ The hemodynamically unstable, hemorrhaging trauma patient is a classic example where ketamine predominantly exhibits cardiac-depressant effects (45).
- ✂ The slightly elevated risk of Torsade de Pointes associated with droperidol, is also present with other antipsychotic drugs including haloperidol.
- ✂ Intermittent IM injections of drugs, although still widely practiced, are ill suited for analgesia and sedation in trauma and critical care.
- ✂ RASS is the first and so far the only sedation measuring tool that has been validated for its ability to detect changes in sedation over consecutive days in critical care (55).
- ✂ Processed electric brain activity monitoring appear to correlate reasonably well with other sedation assessment methods such as the RASS; however, it remains unclear whether routine use of this technique improves the outcomes, and additional studies in acute trauma and critical care are needed.
- ✂ Delirium in critical care is exceedingly common, with an estimated incidence between 60% and 80% (69–71).
- ✂ Nitrous oxide (N<sub>2</sub>O) is not recommended in the acute trauma setting.
- ✂ In ED and TRS, as in the prehospital setting, analgesics and sedatives are withheld until oxygen is administered, functioning IV is placed, O<sub>2</sub> saturation is monitored, and the patient demonstrates cardiopulmonary stability after the initial ABCDEs of the primary survey.
- ✂ Hypovolemic shock and/or TBI need to be immediately ruled out in all combative patients, because prompt and successful management of these problems can markedly improve outcomes.
- ✂ Managing deeply sedated patients can be easier than those who are slightly sedated; however, deep sedation carries multiple risks, including delayed awakening, ventilator-associated pneumonia, postsedation delirium, muscle wasting, and pressure sores (85).
- ✂ In therapeutic doses, dexmedetomidine does not suppress respiratory drive or airway reflexes, making it a very useful drug during weaning to extubation, particularly in cases where airway or breathing are subject to compromise (e.g., obesity, sleep apnea, and thoracic cage trauma).
- ✂ In general, thoracic regional analgesia should be considered in patients who are at risk of respiratory failure because of severe chest wall motion-related pain. Conversely, regional analgesia techniques should not be used in patients whose pain can be adequately controlled with systemic analgesics.
- ✂ Titration of all sedatives and analgesics requires increased vigilance because protein-bound drugs often have increased bioavailability in the characteristically hypoalbuminemic burn patients (104).
- ✂ In the acute trauma and critically ill patients, presence or suspicion of opioid addiction should not preclude aggressive treatment of pain with opioids.

## Neuromuscular Blockade for Trauma and Critical Care

Nitin Shah

Department of Anesthesiology and Critical Care, Long Beach VA Hospital, Long Beach, California, U.S.A.

### INTRODUCTION

Neuromuscular blockade (NMB) use in trauma and critical care presents several unique challenges. First and foremost is its interference with the ability to repeatedly evaluate the neurological status of patients, both during initial resuscitation and later in the intensive care unit (ICU). Second, altered renal and hepatic function changes the pharmacokinetic and pharmacodynamic profiles of many NMB drugs. Third, some patients requiring prolonged administration of NMBs during their ICU stay, increase their risk of postparalytic syndrome. Fourth, critical illness polyneuropathy (CIP) and steroid-related myopathy are additional complications that may compound the issue of prolonged weakness. Finally, the emergent nature of severe traumatic injuries further complicate the situation (especially head trauma), as incomplete information about the patient's pre-injury neurological status or other underlying medical conditions, may be unavailable to guide the proper use of sedatives and NMBs (1–8).

In an ideal situation, appropriate sedation allows patients to remain in a calm, communicative state during their ICU stay, and illness does not become so severe that prolonged NMB use is required. However, the reality is different when one is dealing with head trauma and critically ill patients with multiple organ dysfunction syndrome (MODS). Treatable causes of agitation and confusion (e.g., meningitis or other systemic infections, hypoxia, pain, drug or alcohol withdrawal, and cerebral vascular events) should be investigated before sedation and high-dose analgesia is administered (9). Similarly, analgesia and sedation should be administered prior to the use of NMB drugs. Furthermore, paralyzed patients may be able to process external auditory and tactile stimuli since NMB drugs are devoid of sedative, amnestic, or analgesic activity. Hence, once hemodynamically stable, all patients receiving NMB drugs must receive sedative, amnestic, and analgesic drugs to prevent recall and discomfort (10–12).

This chapter will review the clinically relevant history, physiology, and pharmacology of the NMB drugs commonly employed in trauma and critical care. This review will also discuss reversal agents, interactions caused by various disease states and other drugs, as well as the specific indications for NMB use and monitoring techniques. Finally, the chapter reviews the complications of prolonged blockade, CIP, and steroid-related myopathy. The eye to the future focuses upon improving drugs and monitoring and limiting the complications.

### HISTORY OF NEUROMUSCULAR BLOCKING DRUGS

As early as the 15th century, immediately following the explorations of Columbus, stories began to circulate through Europe of South American Indian tribes who used poisoned arrows. The preparation and use of the poisonous agent called curare (or Woorari), which probably meant "bird killer," was described by Peter Martyr, the royal chronicler for Spain following expeditions to Venezuela in a book entitled *De Orbe Novo* (13).

However, it was the noted geographer, Alexander von Humboldt (1807), who provided the first reliable eye witness accounts of the actual preparation of curare by South American natives. The concoction included the bark of *Strychnos toxifera* or *S. guianensis*, and especially *Chondrodendron tomentosum*. Other plant additives and, in some cases, venom from snakes or ants were also used depending upon the specific South American tribe making the curare (explaining the disparity in ingredients reported from various sources). The entire mixture was simmered in water for a couple days and condensed into a viscous resin. Dart tips were then dipped into the curare and fired through blowguns at small prey.

In 1811, Sir Benjamin Bodie discovered that during curare intoxication, the heart continues to beat even after breathing stops. By 1845, Claude Bernard had traced the action of curare to the neuromuscular junction (NMJ), by demonstrating that both neural conduction and direct muscular response were intact in the curarized frog. The work of Bernard and others led us to our current understanding of the structure and function of the NMJ. The nervous system innervates skeletal muscle to produce movement. Muscle depolarization results from a single action potential, which causes a brief contraction followed by relaxation. This response is called a muscle twitch (14).

However, curare's potential use as a medicinal agent was not realized until the 19th century. The first recorded clinical use of curare as a muscle relaxant during surgery occurred in Leipzig, Germany, in 1912, when a surgeon used it to facilitate abdominal closure (15). Curare was used by both American and English anesthetists in 1941–1943 with growing confidence and understanding about its dosing and side effects as it was beginning to be considered safe (16,17).

By 1946, one publication described a series of 1000 anesthetized patients where d-tubocurarine (dTc) was used as a muscle relaxant (18). The authors of that publication described the intentional use of paralytic doses of dTc in conjunction with adjuvants to provide unconsciousness,

analgesia, and relaxation (the components of a balanced anesthetic). However, a decade later, Beecher and Todd (19) report a sixfold increase in mortality of patients who had received an NMB. The increased mortality resulted from administering dTc to sicker patients and more widespread use by those who were less familiar with its pharmacology and reversal considerations. Additionally, the early anesthesiologists maintained spontaneous ventilation in their patients during curare anesthetics, further increasing the complexity of management and risk of complications.

During the last 60 years, a number of newer NMB drugs have been introduced to clinical practice. In addition, improved understanding of the prejunctional and postjunctional effects of drugs has helped explain some of the differences recognized between the benzyliisoquinolinium and steroidal drugs, and explains the synergism produced when used together.

Better understanding of the limitations as well as the more sophisticated use of twitch monitors (e.g., post-tetanic fade, and double burst technologies) has increased safety. A supershort onset-drug (rapicuronium) has come and gone from clinical use due to its significant histamine release-related complications. Conversely, two long-acting drugs, doxacurium (a benzyliisoquinolinium) and pipercuronium (a steroidal drug), have come and gone due to complications related to their excessively long duration of action.

Another newer drug (rocuronium) has filled a particularly important niche in emergency trauma airway management; and another newer NMB drug (cisatracurium) has special properties of value in critically ill patients suffering from hepatic and renal failure requiring short term NMB in the ICU and OR. These and other clinically relevant NMB drugs are reviewed in subsequent sections of this chapter.

## PHYSIOLOGY OF THE NEUROMUSCULAR JUNCTION

The nerve cell, together with the muscle fibers it innervates, is called the motor unit. The nerve impulse initiated in the nerve body travels along the axon to the nerve terminal, which synapses with somewhere between 15 and 1500 muscle fibers (depending upon the function). Muscles subserving fine movements, such as extraocular muscles, are richly innervated, with fewer muscle fibers per motor unit. Whereas, muscles such as the gastrocnemius, which do not require fine control, are less intensively innervated (i.e., large numbers of muscle fibers per motor unit) (20).

### Neuromuscular Junction Anatomy

The NMJ consists of a motor nerve terminal (prejunctional side) and a motor endplate (postjunctional side), separated by a synaptic cleft (Fig. 1). The motor end plate is a uniquely chemosensitive and highly involuted area of muscle membrane located opposite the motor nerve terminal. A gap, or synaptic cleft (20–50 nm wide), separates the nerve terminal from the muscle fiber. ⚡ **The neural signal is propagated along the axon electrically to the nerve terminal, but crossing the synapse requires the chemical messenger acetylcholine (ACh).** ⚡ Electrical transmission then resumes in a second neuron or in a muscle fiber (in the case of neuromuscular transmission).

### The Motor Nerve Terminal

The terminal portion of the motor axon is a specialized structure designed for the production and release of ACh (Fig. 2).

**Figure 1** Neuromuscular junction anatomy. The nerve terminal is separated from the motor end plate by a synaptic cleft (or gap) approximately 20–50 nm wide. ACh is present in vesicles of the axon for release in response to nerve impulses. ACh diffuses across the synaptic cleft and binds to receptors concentrated on the JF of the skeletal muscle endplate. Acetylcholinesterase is present in the JF to facilitate rapid hydrolysis of ACh. *Abbreviations:* ACh, acetylcholine; AChE, acetylcholinesterase; JF, junctional folds; M, mitochondria; V, vesicles. *Source:* From Ref. 183.

The axon terminal contains subcellular structures involved with energy production, protein synthesis, as well as calcium binding and storage. It also synthesizes choline and acetate to form ACh. This reaction is catalyzed by the enzyme acetyltransferase. Choline is also recycled (as described below). ACh is the chemical messenger (a quaternary ammonium compound) for neural communication at several locations besides the NMJ, including some central nervous system pathways, the autonomic ganglia, all postganglionic parasympathetic nerve endings, and a few postganglionic sympathetic nerve endings (see Volume 2, Chapter 1) (21).

When an electrical impulse arrives at the nerve terminal of the NMJ, approximately 200 to 400 synaptic vesicles (SV) fuse with the nerve cell membrane after a calcium-calmodulin-mediated activation of the SV–SNARE complex triggers docking and priming. Soon after fusion, the ACh molecules are released into the synaptic cleft by exocytosis (Fig. 2). Calcium is required for the process and magnesium inhibits it. Each SV (or quanta) contains 5000 to 10,000 molecules of ACh, which diffuse across the synaptic cleft and bind with nicotinic ACh receptors (nAChRs) on the motor end plate of the muscle fiber, triggering a conformational change in the receptor allowing entry of sodium and the propagation of an action potential in the muscle.

In the absence of nerve stimulation, quanta are spontaneously released at random. These result in small depolarizations of the motor end plate known as miniature end-plate potentials (MEPPs). Although MEPPs can be recorded, they are not strong enough to allow any significant  $\text{Na}^+$  entry and thus do not cause firing of the muscle cell.

### Postjunctional Acetylcholine Receptor

Each nAChR is a protein complex made up of five subunits: two alpha, one beta, one gamma, and one delta (Fig. 3). These subunits form a transmembrane pore, as well as

**Figure 2** Motor nerve terminal. Schematic depiction of the synaptic vesicle exocytosis–endocytosis cycle. After an action potential and  $\text{Ca}^{2+}$  influx, phosphorylation of synapsin is activated by calcium-calmodulin activated protein kinases I and II. This results in the mobilization of synaptic vesicles (SVs) from the cytomatrix toward the plasma membrane. The formation of the complex is an essential step for the docking process. After fusion of SVs with the presynaptic plasma membrane, acetylcholine (ACh) is released into the synaptic cleft. Some of the released ACh molecules bind to the nicotinic ACh receptors on the postsynaptic membrane, while the rest is rapidly hydrolyzed by the acetylcholinesterase present in the synaptic cleft forming choline and acetate. Choline is recycled into the terminal by a high-affinity uptake system, making it available for the resynthesis of ACh. Exocytosis is followed by endocytosis in a process dependent on the formation of a clathrin coat and of action of dynamin. After recovering of SV membrane, the coated vesicle uncoats and another cycle starts again. *Source:* From Ref. 21.

binding sites for ACh NMB drugs. The  $\text{M}_2$  transmembrane-spanning segment of each subunit lines the cation selective channel (Fig. 3) (21). The ACh binding sites are located on the  $\alpha\delta$  and  $\alpha\varepsilon$  subunits. In the absence of ACh the pore is closed. Simultaneous binding of two ACh molecules to a nAChR leads to a conformational change in the three dimensional shape of the subunits opening the pore (increased permeability to sodium). **If enough nAChR channels are opened (as occurs when 200–400 quanta of ACh are released into the synaptic cleft), the resultant change in transmembrane potential will exceed  $-50$  mV, and an action potential will be propagated to the entire motor unit, resulting in muscular contraction (21).**

The termination of normal, physiologic depolarization is caused by diffusion of free ACh from the cleft, unbinding of ACh from the receptor, and breakdown of the ACh molecule by fixed acetylcholinesterase (AChE) located in the invaginations of the motor end plate (Fig. 1). ACh is hydrolyzed by AChE to acetate and choline. The choline is reabsorbed into the nerve terminal, and in the presence of cholineacetyltransferase (CAT) combines with acetyl-CoA (produced in the axon terminal mitochondria, via the Krebs cycle) to reform ACh, which is then repackaged in vesicles (Fig. 2). The level of ACh falls below the threshold required for excitation before the end of the muscle's

**Figure 3** Subunit composition of the nicotinic acetylcholine receptor (nAChR) in the endplate surface of adult mammalian muscle. The adult AChR is an intrinsic membrane protein with five distinct subunits ( $\alpha_2\beta\delta\varepsilon$ ). Each subunit contains four helical domains labeled M1 to M4. The M2 domain forms the channel pore. *Top:* A single  $\alpha$  subunit (gray) with its N and C termini on the extracellular surface of the membrane lipid bilayer (black). Between the N and C termini, the  $\alpha$  subunit forms four helices (M1, M2, M3, and M4) that span the membrane bilayer. *Bottom:* The pentameric structure of the nAChR of adult mammalian muscle. The N termini of two subunits cooperate to form two distinct binding pockets for acetylcholine. These pockets occur at the  $\varepsilon$ – $\alpha$  and the  $\delta$ – $\alpha$  subunit interface. The M2 membrane spanning domain of each subunit lines the ion channel. The doubly liganded ion channel has equal permeability to  $\text{Na}^+$  and  $\text{K}^+$ ;  $\text{Ca}^{2+}$  contributes approximately 2.5% to the total permeability. *Abbreviations:* ACh, acetylcholine; AChE, acetylcholinesterase; ATP, adenosine triphosphate; CAT, choline acetyltransferase; CoA, coenzyme A; PK, protein kinase. *Source:* From Ref. 21.

refractory period. Therefore, a single nerve action potential can elicit only one twitch (20,21).

### CLINICAL PHARMACOLOGY OF NEUROMUSCULAR BLOCKADE DRUGS

The selection of NMB is based upon the clinical situation, the side effect profile, and cost. The clinical needs during the routine induction of anesthesia are different than during emergent intubation, and different still during maintenance of anesthesia—or during care in the ICU. For routine induction and intubation, a moderately rapid onset and brief duration of action are important NMB attributes, whereas in emergency intubation, an ultra rapid onset and minimal side effects are critical, while the duration of action is less important. This is true because in the emergency situation, waking the patient up and coming back another time

**Table 1** Classification of Neuromuscular Blockade Drugs

Drug	Type of block	Duration	Structure
Succinylcholine	Depolarizing	Ultrashort	ACh-like
Atracurium	Nondepolarizing	Short	Benzylisoquinolinium
Cisatracurium	Nondepolarizing	Intermediate	Benzylisoquinolinium
Mivacurium	Nondepolarizing	Short	Benzylisoquinolinium
Doxacurium <sup>a</sup>	Nondepolarizing	Long	Benzylisoquinolinium
Pancuronium	Nondepolarizing	Long	Aminosteroid
Vecuronium	Nondepolarizing	Intermediate	Aminosteroid
Rocuronium	Nondepolarizing	Intermediate-long	Aminosteroid
Pipecuronium <sup>a</sup>	Nondepolarizing	Long	Aminosteroid

<sup>a</sup>No longer available clinically in United States.

to attempt intubation is almost never an option. For maintenance of NMB, facilitated paralysis (e.g., during anesthesia and in the ICU), reliability of duration, affordability and minimized side effects are the most important characteristics (22,23).

The NMB drugs can be classified in one of three common ways (Table 1): (i) according to the type of block produced (i.e., depolarizing vs. nondepolarizing), (ii) based upon the duration of action (i.e., ultrashort, short, intermediate, long), and (iii) in relation to the molecular structure (i.e., ACh-like, benzylisoquinolinium compound, or aminosteroid compound) (22–24). In this review, drugs will be organized into depolarizing (chiefly succinylcholine) and nondepolarizing (all the rest). The molecular structure does have certain clinical impacts, and will be referred to where appropriate (22).

### Depolarizing Drugs (Succinylcholine)

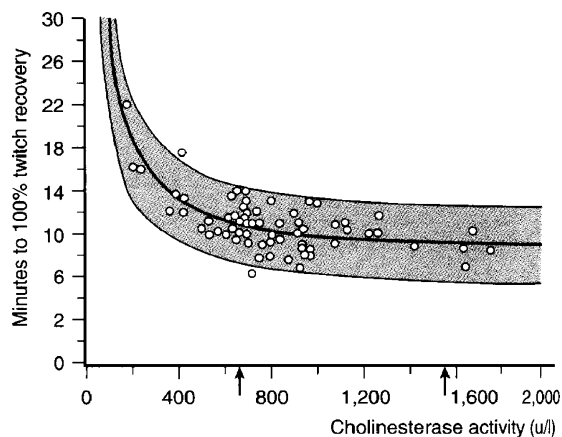

The only depolarizing NMB drug in current clinical use is succinylcholine, which acts as an ACh analog binding to the nicotinic cholinergic receptors, initially causing depolarization. The blockade that ensues results from the slow hydrolysis of succinylcholine by AChE (relative to the rapid hydrolysis of ACh) and, consequently, repolarization is delayed until the succinylcholine is hydrolyzed. This results in a brief period of repetitive depolarizations of various motor units, often manifested by transient muscular fasciculations (25), particularly in the hands, feet, and face (26). This “fasciculation” phase is transient and followed by blockade of neuromuscular transmission and flaccid paralysis (25). Succinylcholine has a sufficiently rapid onset (45 to 60 seconds) to allow endotracheal intubation within 60 seconds and remains the NMB drug of choice for rapid-sequence induction (RSI), unless contraindicated due to its many known side effects (27).

Succinylcholine is administered in doses of 1–1.5 mg/kg intravenously. The duration of NMB due to succinylcholine is typically three to five minutes (28). However, some patients (who may be otherwise healthy or suffering from certain medical conditions in which plasma cholinesterase levels are depressed) can experience a prolonged duration of action. ⚠ **Decreased quantity or quality of plasma cholinesterase results in a prolonged duration of NMB due to succinylcholine.** ⚠ Pregnant patients, and those with impaired hepatic function, have depressed plasma levels of pseudocholinesterase; others may have congenitally abnormal pseudocholinesterase activity, both situations resulting in prolonged drug effect when succinylcholine is administered (Fig. 4) (18,28,29). These patients will have a prolonged

duration of action of other drugs dependent upon pseudocholinesterase for metabolism (e.g., mivacurium). Table 2 lists conditions that can cause decreased or increased activity of plasma cholinesterases.

In the ICU setting, succinylcholine is not used as a continuous infusion. Rather, it is utilized for rapid-sequence intubation (RSI) only, in order to achieve rapid paralysis and facilitate intubation of the airway in patients at increased risk for regurgitation of gastric contents. Succinylcholine has a number of cardiac side effects including sinus bradycardia, junctional rhythms, or even sinus arrest due to the concomitant binding to cardiac muscarinic receptors. These effects are more prominent in younger patients, and after administration of a second dose of the drug very soon (within minutes) after the first dose (21). The administration of succinylcholine ordinarily results in a small rise in serum K<sup>+</sup> concentration (0.5–1 mEq/L) because of muscle depolarization and potassium release.

⚠ **In patients with denervated muscle, particularly following upper motor neuron injury or following muscle injury (burns, massive trauma), serum K<sup>+</sup> levels can increase by as much as 85% following succinylcholine administration (30), resulting in peaked T waves, widened QRS complexes, loss of P waves, and occasionally, ventricular fibrillation and cardiac arrest.** ⚠ The therapy for succinylcholine-induced hyperkalemic ventricular fibrillation and arrest includes: (i) immediate institution of

**Figure 4** Correlation between the duration of succinylcholine neuromuscular blockade and butyrylcholinesterase activity. The normal range of activity lies between the arrows. Source: Modified From Ref. 184.

**Table 2** Factors Affecting Plasma Cholinesterase Activity

Decreased activity of plasma cholinesterase	Increased activity of plasma cholinesterase
Inherited deficiency	Obesity, hyperlipidemia
Physiological variance: last trimester of pregnancy, newborns, infants	Essential hypertension
Acquired causes: liver diseases (acute hepatitis, hepatic metastasis), hyperpyrexia, myocardial infarction, acute infections, carcinomas, uremia, malnutrition, chronic debilitating diseases, burns, epilepsy	Thyrototoxicosis
Iatrogenic causes: radiation therapy, anticancer therapy, MAO inhibitors, neostigmine, esmolol, organophosphorus insecticides	Nephrosis
	Asthma, alcoholism, schizophrenia

Abbreviation: MAO, monaminoxidase.

cardiopulmonary resuscitation (CPR), (ii) administration of calcium chloride (to stabilize the membrane), (iii) alkalization by hyperventilation and  $\text{NaHCO}_3$  administration (to decrease the  $[\text{K}^+]$ ), (iv) concomitant administration of glucose and insulin (to drive  $\text{K}^+$  into cells), (v)  $\beta$ -agonist administration (to stimulate the  $\text{Na}^+/\text{K}^+$  ATPase), (vi) Furosemide to promote diuresis and  $\text{K}^+$  loss, and (vii) treatments using  $\text{K}^+$  binding resins (e.g., kayexylate) administered via the GI tract are not efficacious acutely, but can help decrease serum  $[\text{K}^+]$  over time. CPR must continue until potassium levels have returned toward baseline. Cardioversion will not be effective until the serum  $[\text{K}^+]$  is decreased towards normal and the membrane stabilized by specific treatment (i.e., ionized calcium administration), all of which should occur concomitantly with CPR (Table 3).

The exaggerated potassium release seen with dener- vated, traumatized, or debilitated muscles is related to the

proliferation of extrajunctional cholinergic receptors and the resultant increase in  $\text{K}^+$  release following succinylcholine administration (31). Because of the delay between injury and receptor synthesis, patients can be given succinylcholine safely 72 hours after acute upper motor neuron injury, and/or 24 to 48 hours following major burns (32). The risk of potassium release has been shown to persist for as long as two years after injury in some cases, and should be presumed to be present in any patient with persistent denervation. Further discussions of succinylcholine-induced hyperkalemia resulting from neurologic injury and burns are found in Volume 1, Chapters 23 and 34, respectively.

Succinylcholine has a number of other side effects resulting in several relative contraindications for its use. A number of studies have shown increases in intracranial, intraocular, and intragastric pressure after administration of succinylcholine. It can also act as a trigger for malignant hyperthermia, and can cause myoglobinuria, trismus, and phase II block (a complex phenomenon resulting in NMJ dysfunction following prolonged exposure to depolarizing agents).

### Nondepolarizing Drugs

Nondepolarizing NMB agents competitively inhibit the action of ACh at the NMJ through one of three mechanisms: (i) binding to nicotinic cholinergic receptors and preventing the conformational change that allows passage of sodium ions; (ii) physical obstruction of the channel, preventing passage of sodium; and (iii) presynaptic inhibition of ACh release (minimal clinical significance) (21). ⚡ **The nondepolarizing agents are all derived from one of two chemical groups, benzyliisoquinoliniums and aminosteroids (Tables 1 and 4).** ⚡ The benzyliisoquinolinium class of NMB drugs are characterized by the following main attributes: high potency, lack of vagolytic effect, propensity for histamine release (except for cisatracurium), and novel methods of degradation, for example, Hoffmann elimination (atracurium and cisatracurium) and enzyme-catalyzed ester hydrolysis (mivacurium). The oldest member of this class, dTc, also has a ganglion blockade effect, which may add to the hypotensive effect resulting from histamine release. Metocurine also has a

**Table 3** Specific Therapy for Hyperkalemia

Drug	Dose/delivery	Rationale/comments
Calcium chloride	250–1000 mg IV push	Does not actually decrease $[\text{K}^+]$ . Vitally important, however, and should be employed immediately to stabilize the myocardial membrane (separates the resting membrane potential from the threshold potential)
$\text{NaHCO}_3$	1–2 mEq/1 kg IV push	Alkalanization helps drive $\text{K}^+$ back into cells. Hyperventilation should also be employed, especially in the first 5–10 min
Epinephrine	0.1–0.2 mEq/kg/min IV drip	$\beta$ -agonists increase the $\text{Na}^+/\text{K}^+$ ATPase which brings $\text{K}^+$ into cells, while moving $\text{Na}^+$ out
Lasix® (furosemide)	10–40 mg IV push	Lasix helps promote $\text{K}^+$ loss in the urine. Slow (takes minutes to hours to work)
Glucose and insulin	Administer 1 Amp $D_{50}$ and begin $D_{5W}$ drip; then administer 5 units of regular insulin	Insulin and glucose will drive $\text{K}^+$ into cells. The $D_{50}$ administration and $D_{5W}$ drop should be started prior to insulin administration, unless patient has a known blood glucose > 150 at the time
Kayexalate® (sodium polystyrene sulfonate)	Depends upon starting $[\text{K}^+]$	Slowest (takes hours or days to work), only indicated if the patient's serum $[\text{K}^+]$ was high prior to the succinylcholine administration

ganglion blockade effect, but weaker than dTc. Both DTc and metocurine are more precisely categorized as isoquinolinium drugs, and are no longer available in the United States. None of the benzyloisoquinolinium drugs have a clinically significant ganglionic blockade effect.

Modifications of the steroidal nucleus of androstane resulted in potent synthetic NMBs, of which pancuronium was the first synthesized. Later, pipercuronium, vecuronium, rocuronium, and rapicuronium were synthesized. Renal excretion, elimination in the bile, and metabolism are all important characteristics of the steroidal NMBs. Uptake by the liver is more important for the intermediate-acting vecuronium and rocuronium, than for the longer-acting pancuronium and pipercuronium.

The onset of action of the nondepolarizing agents is dose dependent; as the dose is increased, the time to attain adequate intubating conditions is shortened (27). They produce a depression of evoked twitch amplitude, and they result in frequency-dependent suppression of neuromuscular transmission, which manifests either in tetanic fade or in train-of-four (TOF) fade (33). Metabolism of each nondepolarizing agent varies from drug to drug (34).

The use of muscle relaxants in ICU patients has increased significantly over the last 15 years, in large part because of their record of safe intraoperative use. However, it has become increasingly recognized that the long-term administration results in pharmacokinetics and side effect profiles are quite different from those found in the operating room (OR). A survey indicates that the NMB agents have been used in a variety of practices like bolus administration and continuous infusion with and without monitoring of degree of NMB (26). We will discuss the commonly used drugs in ICU in detail.

### Rocuronium

Rocuronium is less potent than its predecessor steroidal NMBs but has a more rapid onset of action. ⚡ **Rocuronium is mainly used as an NMB during RSI in patients with contraindications to succinylcholine [e.g., burns, upper motor neuron injury, chronic bedrest (>30 days), and history of malignant hyperthermia, etc.].** ⚡ Rocuronium in a dose of 1.2 mg/Kg provides intubating conditions at 60 seconds, which are similar to that produced by succinylcholine (Table 4) (35).

Although it may cause mild vagolysis, it does not characteristically cause any significant hemodynamic perturbation. Rocuronium is hepatically metabolized and renally excreted. It is rarely used in ICU as a maintenance infusion NMB drug because of the availability of less expensive alternatives, for example, pancuronium and vecuronium. Closely related rapicuronium has the most rapid onset, but was never useful clinically in trauma or other RSI situations due to its propensity for significant histamine release and subsequent hypotension. Rapicuronium is no longer available clinically.

### Vecuronium

Vecuronium is an intermediate-acting NMB drug, initially used during surgical anesthesia. Vecuronium has now come into widespread use in the ICU because of its negligible hemodynamic side effects and affordability, having become generic a decade ago. Vecuronium is an aminosteroid NMB drug produced by demethylation of the pancuronium molecule, with which it is roughly equipotent. Vecuronium undergoes spontaneous deacetylation in the liver to three metabolites with varying degrees of activity. ⚡ **The main vecuronium metabolite, 3,17-dihydroxyvecuronium, has only 2% of the activity of the parent compound, whereas the 3-hydroxy derivative has 60% of the activity of the parent compound, and is excreted renally.** ⚡ The half-life of vecuronium is moderately prolonged in both renal and hepatic failure. This effect is typically negligible after short-term use, but can become more significant with prolonged administration as in the ICU setting (36).

### Pancuronium

Pancuronium is the first synthesized aminosteroid NMB drug with a 40-year history of clinical use. It is excreted primarily as an unchanged drug by the kidneys, although biliary excretion of unchanged drugs also occurs (13). Minimal metabolism in the liver produces an active 3-hydroxy metabolite with roughly one-half the activity of the parent compound. The 3-hydroxy metabolite is excreted equally in the kidney and bile. ⚡ **Because pancuronium and its metabolites are mainly (70%) excreted in the urine, a prolonged duration**

**Table 4** Infusion Dosing Recommendations for Intensive Care Unit and Routes of Elimination for Neuromuscular Blockade Agents

Structural classification	Relaxant	ETT bolus dose, mg/kg	ICU continuous infusion (usual range)	Routes of elimination
Depolarizing	Succinylcholine	1–2	—	Plasma cholinesterase
Nondepolarizing	Benzyloisoquinolinium	Mivacurium	4 mcg/kg/min (4–20)	Plasma cholinesterase
		Atracurium	11–13 mcg/kg/min (4.5–29.5) 3 mcg/kg/min (0.5–10.2)	Ester hydrolysis and Hoffmann elimination
	Cisatracurium	0.15–0.2	Not recommended	Hoffmann elimination
	Tubocurarine	0.25–0.5 every 2–3 hrs		Primarily renal, some biliary
Aminosteroid	Rocuronium	0.6 (elective) 1.2 (RSI)	10–12 mcg/kg/min (4–16)	Primarily hepatic, some renal
	Vecuronium	0.1	1 mcg/kg/min (0.8–1.2)	Biliary and hepatic; active metabolite (3-desacetyl)
	Pancuronium	0.03–0	1 mcg/kg/min (1–2)	Primarily renal, some biliary

*Abbreviations:* ETT, endotracheal tube/induction; ICU, intensive care unit; RSI, rapid sequence intubation/induction (when speed of onset is critical).

of action occurs in renal failure. ⚠️ Pancuronium has a vagolytic effect, which may cause tachycardia, and rarely mild hypertension (22,24). Pancuronium should be avoided in patients who cannot tolerate the vagolytic mediated increase in heart rate (e.g., severe coronary artery disease, severe aortic stenosis, severe mitral stenosis). Conversely, clinically significant bradycardia is occasionally seen after cessation of prolonged pancuronium infusion. For all other patients, especially the typical young, previously healthy trauma victim, the inexpensive pancuronium appears to be a suitable drug for prolonged NMB infusion in the ICU.

### Atracurium

Atracurium is a short, acting benzyloquinolinium NMB; this bis-quarternary nitrogen compound was designed to be independent of hepatic and renal elimination. Its metabolism (and offset) depends upon two mechanisms: the first is known as Hoffmann elimination, the nonenzymatic, chemical degradation of quarternary ammonium salts; the second, and probably more important, is the nonspecific ester hydrolysis occurring in plasma and tissue. Atracurium is relatively stable at pH 3.0 and 4°C, but becomes unstable when injected into the warm bloodstream. There are several metabolites of atracurium, one of which (laudanosine), has been shown to cause seizures in dogs when given in very high doses. Laudanosine is very unlikely to be of any significance in humans, as the atracurium dose given to the dogs was far higher than used clinically. Laudanosine does not have any muscle relaxant properties but it does have neuroexcitatory properties. Laudanosine is excreted by the kidneys and may accumulate in patients with renal failure. The accumulation of laudanosine in human subjects can theoretically result in excessive neural stimulation and seizures. However, despite two decades of clinical use, there has never been a single documented occurrence of atracurium-induced seizures in humans. Atracurium has essentially no effects on nicotinic autonomic receptors or muscarinic cardiac receptors. However, atracurium administration may lead to vasodilation and hypotension caused by histamine release, especially when it is administered rapidly and in large doses (24).

### Cisatracurium

Cisatracurium is an intermediate-duration benzyloquinolinium NMB drug. It is a stereoisomer of atracurium but is three times as potent per milligram, so less of the drug is required for an equivalent response. Cisatracurium, like atracurium, is rapidly inactivated in the plasma via Hoffmann degradation (nonenzymatic breakdown at normal body temperature and pH) and ester hydrolysis (24). ⚠️ **Because its elimination does not depend upon renal or hepatic function, cisatracurium is often used in patients with renal and hepatic dysfunction.** ⚠️ The amount of laudanosine released after prolonged infusion of cisatracurium is much less than that compared to atracurium. Cisatracurium does not cause histamine release, and therefore is not associated with the bronchospasm, hypotension, and tachycardia seen with atracurium (37–43). Patients requiring prolonged NMB infusion will not necessarily benefit from cisatracurium. However, patients with liver and/or renal disease, especially those who require a complete and prompt recovery, are likely to benefit from cisatracurium use.

### Other Neuromuscular Blockade Drugs Seldom Used in Critical Care

A number of other NMB agents including mivacurium, doxacurium, and pipecurium, have been used in the operative environment but have not come into widespread use in the ICU setting. Mivacurium is short acting but never became popular in the ICU setting, partly due to its propensity for histamine release. Mivacurium is rapidly hydrolyzed by plasma cholinesterase (as occurs with succinylcholine), explaining its rather short duration of action in normal patients.

Mivacurium is useful for procedures such as bronchoscopies in intubated patients, when rapid return of neurological monitoring status is wanted. Doxacurium and pipecurium were never used to any significant extent in the ICU due to their long durations of action. Both drugs have been taken off the market due to complications related to prolonged NMB. Table 4 provides a summary of the dose and routes of elimination of the NMB drugs commonly employed in trauma and critical care.

### Pharmacokinetics and Pharmacodynamics

A useful way of distinguishing between pharmacodynamics and pharmacokinetics is that the former is what drugs do to patients; the latter is what patients do to drugs. Pharmacokinetics describes the time-dependent fate of a dosage of drug as it undergoes redistribution, metabolism and excretion. Because all NMBs are polar, highly ionized compounds and therefore very water soluble and fat insoluble, they have a small volume of distribution (mainly the extracellular fluid unless metabolized). The speed of onset of drug activity is best described as a function of dose and volume of distribution, whereas the offset depends on the method of elimination. The pharmacodynamics of NMBs are best described using a dose-response curve (Fig. 5) (24). This curve is determined at steady state (i.e., not during a period of drug administration or redistribution), and the effects of the drug are determined at several different doses. NMBs have a dose-response curve that is sigmoidal in

**Figure 5** Schematic representation of a semilogarithmic plot of muscle relaxant dose versus neuromuscular block. A drug of high potency would be represented by doxacurium, one of medium potency by atracurium, and one of low potency by rocuronium. The graph illustrates that the relative potencies of the muscle relaxants span a range of approximately two orders of magnitude. *Source:* From Ref. 185.

shape, demonstrating a direct relationship between dose and response (24). Once the maximal effect is achieved (total paralysis), no further effect occurs at the NMJ regardless of the dose.

## NEUROMUSCULAR BLOCKADE ANTAGONISTS

The muscle relaxant effects of nondepolarizing NMB drugs can be reversed in one of two ways: (i) spontaneously, as the NMJ and plasma concentrations of the relaxant declines; or (ii) by pharmacologic reversal with AChE inhibitors (44).

Reversal agents function by raising the concentration of ACh at the NMJ. This can be achieved by either reducing the breakdown of ACh (e.g., AChE inhibitors), or by facilitating greater release of ACh at the nerve terminal (e.g., aminopyridines). This section focuses mainly on the effects of anticholinesterases drugs (AChE inhibitors) (24).

🐾 **AChE inhibitors produce their effects by binding to, and inhibiting the enzyme (AChE). The resulting increase in ACh in the synaptic cleft of the NMJ helps the ACh compete more favorably with NMB drugs for available ACh receptors.** 🐾 The reversal agents currently in use are neostigmine, pyridostigmine, and edrophonium. Neostigmine and pyridostigmine bind with AChE to form inert enzyme–substrate complexes (44). Edrophonium acts differently. It forms a reversible electrostatic bond with the enzyme (45,46). Table 5 lists the dosages and other key parameters of the three AChE inhibitors currently used in clinical practice.

However, AChE inhibitors should only be used when patients have at least 1 to 2 twitches on TOF, as elicited by the peripheral nerve stimulator (PNS) described below. In other words, some receptors must be free for ACh to work. With <1 twitch, the free ACh does not have an adequate number of unoccupied receptors to bind with to provide a return to normal muscle strength. The more intense the block (the less twitches present), the greater the dose of reversal drug needed. However, there is no advantage to giving more than 0.07 mg/kg of neostigmine (the appropriate dose if 1 to 2 twitches are present on TOF). If 3 to 4 twitches are present, neostigmine 0.04 mg/kg is suggested, or edrophonium 0.05 mg/kg.

An unpredictable response occurs at the NMJ to AChE inhibitors in the setting of a phase II block. Accordingly, reversal by AChE inhibitors is not recommended for this circumstance or for other causes of prolonged blockade following succinylcholine administration.

There is a limited role for AChE inhibitors in critical care; because, in contrast to the OR, there is rarely an urgent need to reverse NMB in the ICU. However, some situations may arise when AChE inhibitors are useful (41). Pyridostigmine is frequently used in myasthenia gravis patients; neostigmine

**Table 5** Acetylcholinesterase Inhibitors

Agents	Dose (mg/kg)	Onset (min)	Duration (min)	Elimination
Edrophonium	0.5–1.0	0.5–1.0	50–73	70% renal, 30% hepatic
Neostigmine	0.025–0.075	3.0–7.0	70–82	50% renal, 50% hepatic
Pyridostigmine	0.1–0.3	4.0–12.0	123–137	75% renal, 25% hepatic

may be administered to patients with prolonged NMB, such as when the patient has only one twitch on PNS despite being many hours since the last NMB dose and a clinical benefit for early extubation is identified (i.e., following heart or lung transplantation).

Adverse effects commonly associated with the administration of AChE inhibitors include cardiac, gastrointestinal (GI), and respiratory effects, all of which are secondary to muscarinic stimulation. The cardiovascular effects are of greatest concern and include bradycardia, heart block, and cardiac arrest (24). Onset of bradycardia is rapid for edrophonium (45,46), slower for neostigmine (44), and slowest for pyridostigmine (47–49). GI side effects include increased salivary, gastric, and intestinal secretions and increased intestinal peristalsis (50). To prevent these side effects, anticholinergic agents such as atropine or glycopyrrolate are usually administered in conjunction with AChE inhibitors (44).

Atropine and glycopyrrolate have muscarinic blocking effects but exert almost no activity on the nicotinic receptors (46). In general, atropine is coadministered with edrophonium, and glycopyrrolate is given with either neostigmine or pyridostigmine. Atropine's more rapid onset of action closely parallels that of edrophonium, while the less rapid onset of action of glycopyrrolate more closely matches the slower onset of neostigmine and pyridostigmine.

## DISEASE STATE AND DRUG INTERACTIONS

Changes in disease processes (Table 6) alter drug requirements in the ICU patient (12,24). The diseases afflicting ICU patients may significantly impact NMB drug pharmacokinetics. The worsening condition of a patient leading to multiorgan system failure (including renal failure) may impact excretion of certain NMBs like pancuronium, and to a lesser degree vecuronium and rocuronium.

**Table 6** Significant Disease State Electrolyte and Acid–Base Interactions with Neuromuscular Blockade Drugs

Potential of NMB	Neuromuscular diseases: myasthenia gravis, Eaton-Lambert syndrome Electrolyte disturbances: hypermagnesemia, hyponatremia, hypokalemia, hypocalcemia Acidosis (conditions that prolong metabolism): atypical plasma cholinesterase, renal disease, hepatic disease
Antagonism of NMB	Neuromuscular diseases: hemiparesis or paraparesis, demyelinating lesions, peripheral neuropathies Other: hypercalcemia, alkalosis, burn injury
Increased risk for cardiac arrhythmias or cardiac arrest with succinylcholine	Acute phase of injury following: major burns, multiple trauma, spinal cord injury, extensive denervation of skeletal muscle, upper motor neuron injury Other: hyperkalemia, digitalis toxicity

Abbreviation: NMB, neuromuscular blockade.

**Table 7** Significant Drug Interactions with Neuromuscular Blockade Agents

Drug	Clinical effect	SUX	NDP	Management
Antidysrhythmics (e.g., quinidine, procainamide, lidocaine)	Enhanced NMB activity	+	+	Response should be monitored using lowest dose possible to achieve adequate blockade
Antibiotics (e.g., aminoglycosides, tetracyclines, polymyxins, clindamycin, piperacillin)	Potential for prolonged respiratory depression, excessive blockade	+	+	Observation for residual effects following NMB administration
Aprotinin (Trasylol <sup>®</sup> )	Enhanced NMB activity	+		Monitor with PNS, use lowest therapeutic dose
Azathioprine (various)	Reversal of NMB	+		Monitor effects of NMB agent and adjust dose as needed
Calcium channel blockers [nicardipine (various); verapamil (various)]	Enhanced NMB	+	+	Monitor effects of NMB agent and adjust dose as needed
Carbamazepine (various)	More rapid recovery time following NMB administration		+	Monitor patients for clinical response; may need higher/more frequent doses of NMB agent
Corticosteroids	Prolonged muscle weakness and myopathy		+	Minimize duration of coadministration; if prolonged concomitant use required, allow NMB-free periods to reduce total dose administered. Monitor with PNS, use lowest therapeutic dose
Digoxin (various)	Risk of cardiac arrhythmias	+	+	Noted specifically with succinylcholine and pancuronium; cardiac monitoring should be performed if used concomitantly
Fosphenytoin (Cerebyx <sup>®</sup> )	More rapid recovery time following NMB administration		+	Monitor patients for clinical response; may need higher/more frequent doses of NMB agent
Inhalation anesthetics	Enhanced NMB activity	+	+	When used concurrently, less NMB is required. Potentiation is greatest with enflurane and isoflurane
Lithium	Enhanced NMB activity		+	Monitor with PNS, use lowest therapeutic dose
Magnesium salts	Enhanced NMB activity	+	+	Monitor with PNS, use lowest therapeutic dose
Metoclopramide (various)	Enhanced NMB activity		+	Monitor with PNS, use lowest therapeutic dose
Oral contraceptives (when taken chronically)	Enhanced NMB activity	+	+	Monitor with PNS, use lowest therapeutic dose
Oxytocin (various)	Enhanced NMB activity		+	Monitor with PNS, use lowest therapeutic dose
Phenytoin (various)	More rapid recovery time following NMB administration		+	Monitor patients for clinical response; may need higher/more frequent doses of NMB agent
Tacrine (Cognex <sup>®</sup> )	Prolongation of NMB activity		+	Monitor with PNS, use lowest therapeutic dose
TCAs	Risk of ventricular arrhythmias		+	Documented in patients receiving chronic TCAs, who are anesthetized with halothane and administered pancuronium
Terbutaline (various)	Enhanced NMB activity		+	Monitor with PNS, use lowest therapeutic dose

Note: + indicates presence of interaction.

Abbreviations: NDP, nondepolarizing neuromuscular blockade drugs; NMB, neuromuscular blockade; PNS, peripheral nerve stimulator; SUX, succinylcholine; TCAs, tricyclic antidepressants.

Various electrolytes also have intrinsic effects on neuromuscular transmission also shown in Table 6.

Other drugs initiated or discontinued during the use of NMB drugs may have significant interaction with the duration of blockade (Table 7). Aminoglycoside antibiotics have synergistic actions with NMB drugs at the NMJ, and can influence both, the degree and duration of paralysis. They act by inhibition of presynaptic ACh release and depress postjunctional sensitivity (51). Anticonvulsants, conversely, can significantly increase the drug requirement for NMB drugs; phenytoin therapy has been shown to increase pancuronium requirements by 80% in neurosurgical patients (52).

The degree of paralysis should always be closely monitored to confirm adequacy of blockade. Monitoring may also help to recognize changes in organ function and NMB drug metabolism or excretion sooner than might be revealed by intermittent laboratory tests of organ function.

## DOSING STRATEGIES

The NMB drugs can be administered by bolus technique as needed “pro re nata” (PRN), or via a regularly scheduled regimen, or via a continuous infusion. The PRN bolus techniques are only appropriate for patients who can tolerate

intermittent movement in the ICU, without jeopardizing oxygenation, intracranial pressure (ICP) elevations, or life-sustaining therapy (e.g., intra-aortic balloon pump, etc.). Scheduled doses or infusions are best used in patients requiring constant paralysis. When tolerated, the intermittent lessening of the degree of NMB and occasional drug holiday may prevent or ameliorate the up regulation of ACh receptors seen with long-term blockade (53). Administration of NMB drug by infusion is convenient and minimizes the peak and valley effect typically seen with intermittent doses. However, if not monitored with PNS twitch monitoring, patients may receive an overdose of NMB drug. Drugs typically classified as shorter acting may be longer acting in the presence of organ failure because of the presence of active metabolites (36). Patients treated for long periods of time with NMB drugs often develop tolerance or resistance (54–56). Prolonged immobilization, by itself, results in muscle atrophy, enlargement of the ACh-sensitive area (31,57), receptor proliferation, and resistance to NMB drugs. There are a number of reports of neuropathy, myopathy, or abnormality of the NMJ in ICU patients treated with steroids and NMB drugs (58,59).

The appropriate dosing strategy varies from patient to patient, but it is clear that vigilance to prevent overdose,

conservative use of paralytics, and prompt discontinuation when the drug is no longer necessary are essential. In critically ill patients, organ function, blood flow, and caregiving personnel change constantly. The risks inherent in paralyzing a patient (e.g., ventilator disconnection) are compounded by the duration of paralysis in the ICU.

## INDICATIONS FOR NEUROMUSCULAR BLOCKADE DRUGS IN THE CRITICALLY ILL

### Relative Requirements

The relative requirements for NMB drugs (as well as sedation, amnesia, and analgesia) depend upon the admitting condition, severity of disease, and the intensity of treatment (60,61). Some form of analgesia is usually required for patients who have suffered from trauma or have undergone surgery (see Volume 2, Chapter 5). Opiates provide the foundation as they are useful in relieving pain and provide some degree of anxiolysis. Benzodiazepines, propofol, or dexmedetomidine are useful drugs for minimizing anxiety and agitation. NMB drugs should only be employed when appropriate use of these drugs alone fails to provide safe nursing conditions in the ICU (Table 8). We are still searching

**Table 8** Indications for Neuromuscular Blockade Drug Use in Critical Care

Indication	Comments
ETT placement or ETT change	Although intubation is best accomplished with complete paralysis, once the ETT tube is in place, there is no absolute need for continued NMB drug use.
Facilitate mechanical ventilation in ARDS patients	NMB drugs are never indicated to facilitate MV in normal patterns (adequate sedation and analgesia will accomplish this). However, in severe ARDS with stiff lungs and profound transpulmonary shunt, NMB drugs may be required to allow certain ventilatory techniques (i.e., prolonged I:E ratio) (also see Volume 2, Chapters 23, 24, 25, and 27).
Eliminate movement-related increased ICP in severe TBI	TBI patients with compliant cranial contents and normal ICP do not need, or benefit from, NMB drug use. However, very tight brains may have exacerbations in ICP associated with movement, coughing or bucking, and NMB drugs are appropriate, as long as maximum sedation and analgesia has already been employed (also see Volume 1, Chapter 23 and Volume 2, Chapters 1, 7, and 12).
Reduce $\dot{V}O_2$ and work of breathing in patient with shock	Temporary use of NMB drugs in this setting is acceptable. However, once the patient is resuscitated, NMB drugs should be halted, and sedatives should be titrated to effect.
Tetanus spasms	Tetanus spasms are painful, and are best treated with high-dose sedation and analgesics. However, supplementation with high NMB drugs while administering the antitoxin and penicillin is acceptable initial management.
Combative patients with severe injuries	Brief NMB drug use in this setting is appropriate as long as sedatives are also employed. Once life-threatening injuries are treated, or ruled out, paralysis should be discontinued and sedatives titrated to effect.
Following decompression of abdominal compartment syndrome or other surgical procedure where abdominal fascia is temporarily open	When patients are nursed in the ICU following procedures where the intra-abdominal contents are edematous, and the fascia is temporarily left open, NMB drugs are needed to maintain abdominal domain of the contents. However, after 3 to 5 days the fascia should be closed. If unable, then techniques not involving NMB drugs should be considered.
Abolish shivering; abolish status epilepticus; facilitation of hyperventilation	These are relatively unsubstantiated reasons for NMB drugs. In the case of shivering, adequate sedation analgesia and warming is usually satisfactory. In status epilepticus, the patient should receive increasing doses of antiseizure medications, monitored by EEG (paralysis may dangerously mask seizure activity). Brief initial hyperventilation to control ICP prior to operative management is acceptable treatment. However, prophylactic, prolonged hyperventilation is associated with worse outcomes for TBI and not indicated (see Volume 1, Chapter 23 and Volume 2, Chapters 1, 12, and 14).

*Abbreviations:* ARDS, acute respiratory distress syndrome; EEG, electroencephalogram; ETT, endotracheal tube; ICP, intracranial pressure; ICU, intensive care unit; MV, mechanical ventilation; NMB, neuromuscular blockade; TBI, traumatic brain injury;  $\dot{V}O_2$ , oxygen consumption.

for better individual patient factors, which would indicate the requirements for different drugs. The studies published so far have tried to identify the needs for various combinations of drugs in ICU patients using three basic approaches (informed anecdotes, subjective impressions, and objective assessment).

### **Informed Anecdote**

Informed anecdote is assessment of NMB needs on the basis of anecdotal experiences of medical and nursing personnel who have themselves been patients in an ICU before. Most commonly they reflect pain, anxiety, and disorientation. The use of NMB drugs causes particular concern. However, knowledge of the situation, diseases, and drugs might have influenced their fear and anxieties, causing bias.

### **Subjective Impressions**

Subjective impressions are the recollections of the experiences of patients who have stayed in the ICU. Bion et al. (62), interviewed 60 patients after their discharge from a general ICU and found that the most common recollections were of physical therapy and of the presence of a urinary catheter (75% of patients recalled these), although these were not found to be particularly distressing by the majority of patients. Those who recalled having thirst, pain, or anxiety most commonly reported this to be an unpleasant experience.

### **Objective Assessment**

Objective assessment occurs when the clinician uses a quantifiable bioassay to determine need and effect of NMB drugs. Objectively there are very few clinical tests available like the Glasgow Coma Scale, Visual Analog Scale for assessment of pain, and Ramsay Sedation Score for assessment of sedation. Rather, without a quantifiable bioassay, the only clinical endpoint is patient movement. Unfortunately, movement can be harmful in the few patient conditions that require NMBs [e.g., high ICP or severe acute respiratory distress syndrome (ARDS)]. PNSs, a form of bioassay, are used clinically to guide the titration of NMB drugs.

✦ **Neuromuscular blocking drugs should never be administered without concomitant amnesics, sedatives, and/or analgesics.** ✦ Patients too unstable to tolerate traditional analgesics or sedatives can receive scopolamine until stable. The administration of sedatives and analgesics also facilitates mechanical ventilation by improving patient comfort, suppressing cough-related bucking, and by minimizing responses to recurrent noxious stimuli such as suctioning (63).

Fentanyl, morphine, and dilaudid are the most commonly used parenteral narcotics. These drugs are potent respiratory depressants but have little direct effect on the cardiovascular system when administered as continuous infusions. These drugs do not increase Cerebral Metabolic Rate of Oxygen (CMRO<sub>2</sub>), Cerebral Blood Flow (CBF), or Intracranial Pressure (ICP) when administered in conventional doses (see Volume 2, Chapter 5).

The past 25 years have witnessed a tremendous increase in the use of NMB agents in ICUs for a variety of interventions, paralleling advances in technology such as newer modes of mechanical ventilation. Along with the increased use of NMB agents have come reports about dangerous and costly complications including persistent paralysis (discussed below) (21,24,26,40,64–71). In addition, a disconcerting lack of knowledge about NMB agent therapy has been recognized (40,72–77).

### **Goal-Directed Indications**

Goal-directed indications are those which dictate NMB use to achieve a specific goal (e.g., minimize perturbations in ICP). The most common indications for NMB drug use include those shown in Table 8 and discussed below. Intubation, control of ICP (Volume 2, Chapter 12), mechanical ventilation in ARDS patients (Volume 2, Chapters 24, 25, and 27), open abdominal fascia after damage control surgery (Volume 1, Chapter 21), release of abdominal compartment syndrome (Volume 2, Chapter 34), or control of hemodynamically unstable patients in shock, minimizes O<sub>2</sub> consumption (Volume 2, Chapter 18). Other indications are relative, and not necessarily based upon strong scientific principles (e.g., control of seizing or agitated patients), as these patients typically require sedation not more paralysis (78).

Although NMB drugs are occasionally required to help control ICP in patients with intracranial hypertension following traumatic brain injury (TBI), the routine use following TBI is not necessary (76). Chemical paralysis with minimal movement allowed (T1) (i.e., one twitch response out of four on a PNS) will mask neurologic deterioration that would normally be reflected in alteration of the motor examination. Pupillary changes, one of the few neurologic assessment tools available during NMB-induced paralysis, can indicate a cerebral event, but pupillary function can also be altered by certain anticholinergic drugs used during resuscitation, including atropine and scopolamine (16). Prolonged absence of the motor examination is never optimal following TBI and should only be tolerated in cases of very high ICP requiring NMB and appropriate sedation (i.e., propofol) or barbiturates-induced coma.

The administration of NMB drugs to minimize airway pressures in patients with severe oxygenation and ventilation failure (e.g., ARDS) and those requiring ventilatory modes with prolonged Inspiratory : Expiratory (I:E) ratios, and hypercapnia, is well established. The goals of therapy here are to decrease peak inspiratory pressure and improve oxygenation (63).

The administration of NMBs to control movement of patients with severe hemodynamic instability and compromised oxygen delivery states may also be beneficial (20,24,79). In shock states, skeletal muscle activity (e.g., work of breathing), may utilize up to 24% of O<sub>2</sub> consumption (58). This increased metabolic demand may cause ischemia to vulnerable tissues. The administration of NMB agents may temporarily diminish the excess oxygen consumption (VO<sub>2</sub>) allowing improved tissue oxygenation of at-risk tissue beds (e.g., myocardial endothelium, or renal cortex) until medical intervention can intercede.

NMB drugs have occasionally been administered to control muscle rigidity in tetanus (80,81). Indeed, the contractions are painful and should be treated with NMB drugs. However, the mainstay of treatment is tetanus antitoxin (to neutralize unbound toxin), penicillin (to prevent further bacterial growth and toxin elaboration), and sedatives and analgesics to control anxiety and pain.

Occasionally, NMBs are used to facilitate a motionless state in patients with gaping and unstable surgical incisions (79). Vascular or reconstructive surgeons may request that a patient be immobile for 48 hours after a major flap reconstruction with tenuous vascular anastomosis. Similarly, the use of NMBs to immobilize severely agitated patients is not recommended. Indeed, given that sedatives and analgesics are titrated to effect, maximum doses of sedation and analgesics do not exist in intubated, mechanically ventilated patients.

**Figure 6** Pattern of electrical stimulation and evoked muscle responses to train-of-four (TOF) nerve stimulation before and after injection of nondepolarizing (Non-dep.) and depolarizing (Dep.) neuromuscular blocking drugs (arrow). Source: From Ref. 186. Abbreviation: TOF, train-of-four.

## MONITORING OF NEUROMUSCULAR BLOCKADE

A combination of clinical oversight and a peripheral nerve stimulus monitoring (twitch monitoring) is recommended whenever patients are given NMB agents in an ICU. The goals of monitoring are to ensure adequate NMB effect during the therapeutic administration of the drug, and to verify full return of NMJ function after the drug is stopped. The clinical assessment of NMB drugs is dependent upon observation of muscle movement such as the ability to open the eyes, extend the tongue, or breathe spontaneously.

✎ **The most reliable single clinical measure of return of NMJ function is ability to head lift for five seconds or more.** ✎ However, this measurement requires patient cooperation and is influenced by sedatives and analgesics. When patients are capable of performing this task, they correlate with full return of TOF and absence of fade for five seconds. However, even with this full return of clinical function, as many as 50% of NMJ receptors may retain blockade.

✎ **The most objective measurement of the degree of blockade in noncooperative or sedated patients is obtained with the demonstration of sustained tetanus through the use of a PNS.** ✎ The PNS was first used to determine neuromuscular function during anesthesia in 1958 (82,83). Twitch monitoring with a PNS is the tool used to measure receptor occupancy. A supramaximal electrical stimulus (a stimulus sufficient to recruit all the motor units subserved by the stimulated nerve) is applied to a nerve and the motor response is measured. With depolarizing agents, the response to each stimulus in a series (a TOF successive stimuli, for example) is diminished equally. With nondepolarizing agents, on the other hand, each successive response is smaller than the previous one, demonstrating "fade" or fatigue (Fig. 6). The latter response is directly analogous to the response seen with myasthenia gravis, in which there is actual loss of ACh receptors, rather than pharmacologic blockade (21,24).

### Technical Aspects of Peripheral Nerve Stimulator Monitoring

The PNS delivers electric current to the nerve through electrodes, which may be of three types: needle, ball, or pregelled.

Pregelled electrodes, the most commonly used, are self-adhering, comfortable, and noninvasive. However, the large surface area of the regular adult electrode may minimize current density and reduce the likelihood of attaining supramaximal stimulation (84). This potential problem may be eliminated with use of pediatric electrodes, which are smaller. The skin underneath the electrodes must be clean, dry, and hairless. For substantial edema or obesity, the ball electrode system is a good choice, allowing a precise location of the electrical stimulus. Needle electrodes are seldom used in patients with adequate skin coverage; because, although they provide excellent electrical conduction, they are uncomfortable and present risks for infection and nerve displacement (85). However, in burned patients and those with other exfoliative dermatological conditions, sterile disposable needle electrodes are commonly employed.

Several patterns of nerve stimulation are available, such as single twitch, tetanic stimulation, post-tetanic facilitation or potentiation, TOF, and doubleburst. Of these, TOF is the least painful and most frequently used in ICUs (86). The PNS should be able to deliver 50–60 mA at all frequencies. However, in lightly sedated patients lower current should be used. The frequency with which the PNS impulse is applied depends upon the technique of twitch monitoring employed. For example, single twitch 0.1–0.15 Hz, TOF is 2 Hz delivered every 0.5 seconds, and repeated every 10 seconds, tetanus is typically achieved with frequencies in the 50–100 Hz range.

### Single Stimulus

The single twitch (aka single stimulus) mode involves one impulse with duration of 0.2 to 0.3 milliseconds. It may be repeated every 10 seconds and no sooner, to achieve optimum results, since more frequent stimulation may lead to ACh depletion, reduction of muscle twitch, and overstimulation of blockade (82). A positive response to a single stimulus is not synonymous with absence of NMB. Muscle response is still present when 75% of the nicotinic receptors are occupied by the NMB agents (87). The muscle response disappears completely when 90% of the receptors have been occupied (85,88).

### Train-of-Four Stimulation

The TOF method involves four electrical stimuli of 2 Hz delivered to a peripheral nerve at intervals of 0.5 seconds, repeatable every 10 seconds. Stimulation of the ulnar nerve with TOF evokes four twitches of the adductor pollicis muscle (83,89). The adductor pollicis muscle response is characterized by adduction of the thumb medially across the palm. In nondepolarizing block, the last thumb adduction of a TOF disappears first, and the first twitch disappears last. Blockade is quantified by counting the number of thumb adductions (90). Four twitches correlates with  $\leq 75\%$  receptor blockade. This level of blockade is clinically manifested by normal expiratory flow rate and vital capacity. Three twitches indicate a blockade of 80%; two, 85%; and one, 90%. When all four twitches are absent, 100% receptor occlusion is assumed to be present (82,83).

### Tetanic Stimulation

Also called tetanus, this nerve stimulation test involves rapid impulses (30, 50, or 100 Hz) delivered to the nerve in which large amounts of ACh are synthesized, mobilized, and released. The frequencies most commonly used for

**Table 9** Tests of Neuromuscular Junction Transmission and Reversal of Neuromuscular Blockade

Test	Acceptable value (results suggest normal clinical value)	% NMJ receptors occupied with NMB when acceptable value achieved	Comments
Single twitch	Qualitatively as strong as baseline	75–80	Uncomfortable, need to know twitch strength versus baseline. Insensitive as an indicator of recovery, but useful as a gauge of NMJ blockade depth.
TOF	No palpable fade	70–75	Still uncomfortable, but more sensitive as an indicator of recovery than single twitch is. Useful as a gauge of depth of block by counting the number of responses perceptible.
Sustained tetanus (50 Hz for 5 sec)	No palpable fade	70	Very uncomfortable, but reliable indicator of adequate recovery.
Double burst	No palpable fade	60–70	Uncomfortable, but more sensitive than TOF as an indicator of NMJ function. No perceptible fade indicates TOF recovery of at least 60%.
Sustained tetanus (100 Hz for 5 sec)	No palpable fade	50	Very painful—a “stress test.” Lack of fade at 100 Hz is the most reliable indicator of NMJ recovery.
Tidal volume	At least 5 mL/kg	80	Insensitive as an indicator of NMJ recovery.
Vital capacity	At least 20 mL/kg	70	Requires patient cooperation, is not the best for determining clinical recovery of NMJ blockade.
Inspiratory force	At least –40 cm H <sub>2</sub> O	50	Sometimes difficult to perform without endotracheal intubation, but reliable gauge of normal diaphragmatic function.
Head lift	Must be performed unaided with patient supine at 180° and sus- tained for 5 sec	50	Requires patient cooperation, but remains the gold standard test for determining clinical function (should be performed with patient in a completely supine position).
Hand grip	Sustained at a level quali- tatively similar to pre- induction baseline	50	Only reliable if patient is awake and cooperative. Sustained strong grip is good gauge of normal function, but not of patient alertness or ability to protect the airway.
Sustained bite	Sustained jaw clench or tongue blade	50	Only reliable if patient is awake and cooperative. Often a poor measure of patient alertness or ability to protect airway.

*Abbreviations:* NMJ, neuromuscular junction; TOF, train-of-four.

this test (50–100 Hz) when delivered for five seconds, stresses the NMJ to the same extent as a maximal voluntary effort (82). At these higher frequencies, the duration of the refractory period is increased, fatigue of the end-plate occurs, and fade may be elicited due to the decreasing capacity of ACh to compete with the NMB drug at the postjunctional receptor (91). Tetanic stimulation may be repeated every one to two minutes to allow the end-plate to return to a steady state between stimuli (82). This test is a sensitive assessment of NMB (88,92). At 100 Hz for five seconds, fade develops when 50% of the receptors are blocked. Absence of fade is the best test using the PNS for assuring that the patient has enough ACh available at the NMJ to tolerate extubation of the trachea, and correlates with head lift for five seconds (Table 9). However, tetanus is painful and unacceptable to the nonsedated ICU patient (20,83).

#### **Post-tetanic Facilitation or Potentiation**

Mobilization and enhanced synthesis of ACh occur during and immediately after cessation of tetanic stimulation. There is an increase in the readily releasable fraction of ACh. This event is manifested in the stronger twitch response to the single stimulus test within three to five seconds after tetanic stimulation. This phenomenon, referred

to as post-tetanic facilitation or potentiation (83–85,89), is seen only with nondepolarizing blockade (Fig. 7). This test is the best method for determining how soon a patient will likely begin to show a twitch in the absence of any detectable twitch with either TOF or tetanus by themselves.

#### **Double-Burst Stimulation**

Double-burst stimulation is a newer mode of electrical nerve stimulation developed with the specific aim of allowing manual (tactile) detection of small amounts of residual NMB under clinical conditions. It consists of two short bursts of 50-Hz tetanic stimulation separated by 750 milliseconds. The duration of each square wave impulse in the burst is 0.2 milliseconds. In the nonblocked NMJ, the response to double-burst stimulation over a peripheral nerve is two short muscle contractions of equal strength. In the partially blocked NMJ, the second response is weaker than the first (i.e., the response fades). Although useful and quantifiable for research purposes, this technique has not yet become popular in clinical use (83).

TOF stimulation is the most commonly employed method of peripheral nerve monitoring to assess the level of NMB, and is uncomfortable but not as painful as tetanus, and unlike single stimulus, the first twitch of a

**Figure 7** Pattern of stimulation and evoked muscle responses to tetanic nerve stimulation (50 Hz) for five seconds and post-tetanic stimulation (1.0 Hz) twitch. Stimulation was applied before injection of neuromuscular blocking drugs and during moderate nondepolarizing and depolarizing blocks. Note fade in the response to tetanic stimulation, plus post-tetanic facilitation of transmission during nondepolarizing blockade. During depolarizing blockade, the tetanic response is well sustained and no post-tetanic facilitation of transmission occurs. *Abbreviation:* Te, tetanic. *Source:* From Ref. 186.

**Figure 8** Ulnar nerve-innervated hand muscles suitable for monitoring of neuromuscular block. Stimulation of the nerve evokes contraction of the adductor pollicis muscle, which results in thumb adduction. Hence, the thumb is the recommended site for assessment of the mechanical twitch response. Other ulnar nerve-innervated hand muscles include the hypothenar (m. abductor digiti minimi) and the first dorsal interosseous (near the adductor pollicis, but on the dorsal side of the hand). *Abbreviations:* m, muscle; n, nerve. *Source:* From Ref. 187.

**Figure 9** Positioning of stimulating electrodes over the facial nerve. The electrode nearest the eye is negative. *Source:* From Ref. 187.

TOF serves as a control for the fourth. Furthermore, in residual NMB, TOF is more sensitive than the single stimulus test (93). The degree of blockade that optimizes a patient's outcome depends upon the clinical circumstances, and thus, has not been scientifically determined (94). It is generally agreed that at least one or two of four (1/4–2/4) twitches should be maintained throughout therapy if clinically feasible (83,95–99).

Clinically, the most commonly used peripheral nerves for twitch monitoring are the ulnar (Fig. 8), and facial (Fig. 9). However, in some situations, other peripheral nerves (including the posterior fibial and peroneal nerves) are also employed. The ulnar nerve, which innervates the adductor pollicis muscle, is the most widely used for scientific quantification. The most accessible portion of the ulnar nerve is between the tendon of the flexor carpi ulnaris medially and the ulnar artery laterally, about 2–5 cm proximal from the flexor crease of the wrist (83). Electrodes must be placed along the nerve; improper placement increases resistance and reduces nerve stimulation. The electrodes should be rechecked for placement with each use (at least hourly) and they should be changed daily to assure adequate contact and that underlying skin is in good condition.

Current of stimulation—"submaximal" current is used to stimulate the nerve in ICU patients. This level of current is less than what is used during general anesthesia, which is typically "supramaximal" (and painful in awake or lightly anesthetized patients). Submaximal current is determined by identifying the least amount of current required for a positive evoked muscle response and then by increasing the current on the PNS by a one-number increment on the output dial. The typical PNS has a number range from 1 to 10, with 10 being maximum current (50–60 mA). Submaximal current usually correlates with numbers 4 through 6 on the current output dial (which relates approximately to 25 mA) (100).

### Overestimation and Underestimation of Neuromuscular Blockade Using a Peripheral Nerve Stimulator

The degree of blockade may be overestimated when no muscle response is evoked, yet there are overt signs of muscle movement. Overestimation is usually due to improper technique, malfunction of the instrument, dead battery, increased resistance due to improper electrode placement, poor skin contact, or inadequate skin preparation. In case

of difficulty, check connections, verify electrode placements, change the battery, ensure proper skin preparation, and increase output to maximal power (83,100,101). A completely blocked NMJ of the ulnar-adductor pollicis motor unit will result in an absence of twitch (thumb movement) when stimulating the ulnar nerve with the PNS. However, the muscle itself retains contractile function and will exhibit four thumb adductions to the TOF test if the muscle is directly stimulated by the electrical current (83). Hence, the level of blockade may be erroneously underestimated with improper direct muscle stimulation and the patient may receive an increased dose of the NMB agent. A similar effect can occur while monitoring with the facial nerve, if facial muscles are directly stimulated. Peripheral edema and obesity increase the distance between the nerve and electrodes, thus decreasing the amount of stimulus delivered to the nerve (101,102). Peripheral hypothermia causes impairment of neuromuscular transmission and may be a source of error in TOF evaluation (103,104). Sepsis or CIP may also affect nerve transmission and, theoretically, TOF monitoring (105).

### Precautions While Using Peripheral Nerve Monitoring

Abnormal responses can occur in the presence of neuromuscular diseases, so an otherwise normal extremity should be used for TOF monitoring (106).

The frequency of TOF monitoring is dependent on whether the drug is actively titrated or is administered as an infusion (81,103). Testing has been advocated at least every four hours during active titration and every eight hours during maintenance infusion (81,103). Sensory alterations are experienced by chemically paralyzed patients who are inadequately sedated and those who do not receive any amnestic agents. This traumatic experience may be alleviated by frequent orientation, talking to patients before any procedure, and placing signs on the bedside to remind others about their unique needs (107).

Some people advocate discontinuing paralytics every so often (e.g., every 24 hours) to allow the NMJ to recover (20,108). The ability to do this will depend upon the patient's underlying condition.

Patients must be protected from the adverse effects of immobility (20,103,109). Changing body position every two hours and applying sequential compression stockings must be an integral part of their care. Passive range of motion exercises at regular intervals, as well as padding of elbows and bony prominences must be ensured. Low-dose anticoagulation may assist in the prevention of venous thrombosis. Because the ability to blink is absent, eyes should be lubricated and/or closed to prevent corneal drying and abrasions (81,103). To prevent aspiration, the head of the bed should be elevated, particularly during enteral feeding (unless spinal injury precautions don't allow).

### PROLONGED MOTOR WEAKNESS FOLLOWING NEUROMUSCULAR BLOCKADE (AKA POSTPARALYTIC SYNDROME)

Postparalytic syndrome is also known as prolonged or persistent weakness after NMB drug use. The incidence of this complication is unknown, but a small prospective study estimated the risk for developing prolonged weakness as 5% to 10% if muscle relaxants had been used for more than 24 hours (110). Patients with severe asthma have also

been reported to develop myopathy (111), while several retrospective reports suggest that up to 70% of critically ill patients who share certain characteristics remain weak after prolonged administration of pancuronium or vecuronium (75,112–115). Although the majority of the cases reported in the literature are following the use of the more commonly employed aminosteroidal NMB drugs, there are case reports following the use of benzyliisoquinoliniums as well (116).

✎ **The etiology of postparalytic syndrome is incompletely understood, but may result from injury mediated directly by the drug, its active metabolites, or by drug–drug or drug–disease state interactions.** ✎ Persistent NMB is most frequently associated with changes in pharmacokinetics secondary to renal or hepatic failure or to accumulation of active metabolites (117). All three metabolites of vecuronium (3-desacetylvecuronium, 17-desacetylvecuronium, and 3,17-desacetylvecuronium) have neuromuscular blocking properties. This has caused some to believe that atracurium or cisatracurium may be preferable in patients with renal and/or hepatic failure as they are metabolized spontaneously at body temperature and pH via Hoffmann elimination and also via hydrolysis by plasma esterase. Although their metabolite laudanosine may accumulate in patients with renal failure and/or hepatic failure (118), it does not have any muscle relaxant properties, and even after 71 days of infusion of atracurium the accumulation of laudanosine was minimal (119). The half-life of laudanosine is increased in patients with renal failure (120,121) and in animals with hepatic failure (122). Laudanosine is not eliminated by dialysis (123). Patients recovered faster after atracurium (105 minutes), compared to vecuronium (6 to 37 hours) in a study of ICU patients with renal impairment (36).

Intermittent dosage or continuous infusions of nondepolarizing relaxants can cause peripheral storage compartments to become saturated, resulting in decreased clearance of the drug (124–126). Prolonged weakness may also be caused by functional defects in the motor unit (nerve, muscle, or NMJ), that is, both myopathies and/or neuropathies may occur (131). Long-term use of NMB drugs in trauma patients is associated with other complications as well. For example, trauma patients are already at increased risk of infectious complications, and prolonged use of NMB drugs is characterized by significantly longer ICU stay, more frequent pneumonia, and a trend toward a higher rate of sepsis (8,127).

Additional factors contributing to prolonged duration of NMB include inadvertent overdosing (125), drug interactions (in particular with aminoglycosides and quinidine) (128–130), electrolyte abnormalities (e.g., hypermagnesemia, hypophosphatemia) acidosis (131–134), underlying muscular disorders (e.g., myasthenia gravis) (133–135), and hypothermia (136). Antibiotics and magnesium work on pre- and postsynaptic levels while several cardiovascular drugs (lidocaine, beta-blockers, calcium channel blockers, quinidine) influence ion transport at the NMJ and can potentiate NMB. Completeness of NMB must be monitored in these patients to guide the administration of drugs, to avoid overdoses, to maintain muscle activity, and to detect a chain of reactions among concomitant medications or pathophysiologic changes (137).

Neurologic examination of these patients often reveals paresis, or flaccid paralysis of distal and proximal muscles and the diaphragm in the presence of normal sensory function (117). Serum creatine kinase levels may be normal or increased up to 100-fold (115,138,139). Clinical examination

may not be adequate for diagnosis and electrodiagnostic studies, and biopsies of muscles revealing degeneration of type I and II muscle fibers and nerves are often needed for accurate diagnosis of the cause of weakness in ICU patients. Electrophysiologic studies demonstrated reduced amplitude of motor-evoked responses and of compound action potentials, consistent with myopathy with unaltered sensory conduction (139,140). A general decrease in myofibrillar protein content, absence of myosin messenger RNA with very low thick-filament/thin-filament protein ratios were also found (140). Histopathologic features include degenerative changes, fiber atrophy, evidence of regeneration with predominant involvement of the type I muscle fiber, and necrosis (141).

The complexities associated with pharmacological paralysis in critically ill patients warrants the comprehensive approach to care that multidisciplinary team members can provide (142). The weakness may persist from weeks to months. The management largely involves the same care that was given while patients were paralyzed. Regularly evaluate the patient for signs of recovery from NMBs. When patients can breathe on their own (i.e., weaned from mechanical ventilation—see Volume 2, Chapter 28), and are able to clear secretions and maintain some degree of pulmonary reserve, they can be discharged from the ICU.

### CRITICAL ILLNESS POLYNEUROPATHY

☞ **CIP is acute axonal neuropathies involving both sensory and motor nerves, developing during critical illness, especially with sepsis or systemic inflammatory response syndrome (SIRS).** ☞ The severity of CIP can begin to remit spontaneously once the critical condition is under control (143). CIP was first reported by Bolton, Zochodne, and others in the 1980s (144). It is a sensory motor polyneuropathy as opposed to a myopathic polyneuropathy. The increased jitter in patients with CIP indicates that it is primarily an axonal neuropathy with a lesion of terminal motor axons (145). It is increasingly recognized, and occurs particularly in sicker, older patients with sepsis. Seventy percent of reported cases had sepsis during their stay in ICU (146–152). Other risk factors for the development of CIP include hyperosmolarity, parenteral nutrition, nondepolarizing NMBs, and neurologic failure (153). Investigators have speculated that the peripheral nerves are another organ system that is affected adversely by SIRS (see Volume 2, Chapter 63) (146,154). CIP can be seen in up to one-third of critically ill patients with SIRS (usually due to sepsis) (155). Disturbances in the microcirculation to peripheral nerves occur with sepsis and diabetes mellitus and can induce axonal hypoxia and degeneration. The local balance of leukocyte activities is of importance in the pathophysiology of muscle weakness in CIP and myopathy (156). Furthermore, the neurologic effects of SIRS are thought to be mediated by released mediators like cytokines and free radicals, affecting the microcirculation of the central and peripheral nervous system (157). The reduction in the risk of polyneuropathy with intensive insulin therapy (Volume 2, Chapter 60), regardless of the concomitant use of corticosteroids or aminoglycosides, suggests that hyperglycemia, insulin deficiency, or both contribute to axonal dysfunction and degeneration (146,158). The linear relation between blood glucose levels and the risk of polyneuropathy suggests that maintenance of the lowest possible level is necessary. The reduced need for mechanical ventilation in patients who received intensive insulin therapy is explained in part

by the reduced rate of critical-illness polyneuropathy, though a direct anabolic effect of insulin on respiratory muscles may also play a part (159).

The clinical picture of CIP is similar to that of the patient with an acute myopathy and may include delayed weaning from the respirator, muscle weakness, and prolonging of the mobilization phase. The onset is early, within 72 hours after onset of septic shock (160). CIP is an early feature of multiorgan dysfunction syndrome (142,140). Nerve conduction studies typically exhibit a reduction in amplitudes of compound muscle action potentials and sensory nerve action potentials (161). Abnormalities in phrenic nerve conduction also are observed frequently, and that may further contribute to delayed weaning from the ventilator in many patients (157,162). On needle electromyography (EMG) examination of the limb muscles and diaphragm, the most common finding is abnormal spontaneous activity (fibrillation potentials and positive sharp waves) (163). Biopsies of peripheral nerves reveal primary axonal degeneration of motor and sensory fibers. Inflammation of peripheral nerves is not observed in CIP; the absence of inflammation can help distinguish CIP from the Guillain-Barre syndrome. Muscle biopsies demonstrate denervation atrophy of proximal and distal muscles. Central chromatolysis of anterior horn cells and loss of dorsal root ganglion cells occur as the result of the peripheral nerve axonal changes (163,164). Because neuromuscular abnormalities seem to develop earlier than previously reported, EMG should be considered more frequently and earlier as a diagnostic test (165).

The specific course and long-term outcome of CIP remains unclear. The management of CIP is symptomatic, including the provision of adequate nutrition, sedation, analgesia, and amnesia, along with aggressive supportive care including long-term physical therapy and rehab (Volume 2, Chapter 66). Incomplete recovery within one to two years after the onset of disease occurs frequently in patients with CIP (166). If the underlying problem causing sepsis and/or SIRS can be treated successfully, full recovery from CIP can occur. This recovery often occurs in a matter of weeks in milder cases and in months in more severe cases (157). The longer the length of stay in the critical care unit, longer the duration of sepsis, and greater body weight loss were found to be significantly related with poor recovery (152). Mortality may be as high as 60% and relates to the medical rather than to the neurological condition (155). Advice to family and patients regarding long-term prognosis is related to the likely etiology of prolonged weakness (162).

### CRITICAL ILLNESS–RELATED MYOPATHY

Several reports suggest that the prolonged weakness following NMB agent use in ICU patients has an association with concurrently administered corticosteroids. Sepsis has long been associated with muscle weakness. Critical illness–related muscle weakness delays recovery and often causes prolonged ventilator dependence (75,115,137,138,155,167–170). This entity may not necessarily be related to the provision of NMB drugs. However, both the administration of steroids and sepsis are likely implicated.

#### Steroid-Related Myopathy

Ramsay et al. proposed that critically ill patients have susceptible skeletal muscle that awaits a trigger to create the muscle damage. Ramsay et al. speculated that long-term and large-dose steroids prime the muscle in the ICU

patient, and the NMB agent might then trigger a cascade of severe muscle damage, reflected by increased serum creatine phosphokinase (CPK), and characterized microscopically as damage to the muscle cell proteins and gross muscle atrophy. The muscle membrane loses its ability to contract due to altered membrane sodium currents and loss of myosin thick filaments, resulting in profound and prolonged weakness (143,155,163). In a prospective study, Douglass et al. demonstrated elevated CPK in 19 of 25 patients who required mechanical ventilatory support for severe asthma and who received vecuronium for more than two days along with high-dose corticosteroids. Nine of the 25 patients developed a clinically apparent myopathy (114). Many other reports describe otherwise healthy asthmatic patients who remained quadriplegic days to weeks after simultaneous treatment with corticosteroids and NMB agents (114,115,138,168). In one instance after rapid tapering of systemic steroids, the patient quickly regained muscle strength, was extubated and sent for rehabilitation therapy (171). A recent case report shows that the metabolic alterations associated with hyperthyroidism may enhance the risk of developing critical illness myopathy after the administration of antibiotics, NMBs, and steroids in the ICU (171,172). Additional support for corticosteroid-induced muscular atrophy comes from animal studies. These studies have also shown that denervation increases the number of glucocorticosteroid receptors, which causes preferential depletion of myosin filaments and atrophy (164). ⚡ **Corticosteroid-related myopathy primarily affects type 2 fibers; routine EMG most precisely evaluates type 1 fibers, and therefore its results can be equivocal or normal (163).** ⚡ TOF monitoring was not employed in the studies published so far; although its use may be able to reduce the incidence of prolonged weakness, the assertion is speculative. While most reports of prolonged weakness involve the use of vecuronium and pancuronium, acute myopathy with atracurium and cisatracurium has also been reported (114,173–175).

### Sepsis-Related Myopathy

Critical illness myopathy not related to steroids is also encountered in patients suffering from systemic inflammatory response syndrome (SIRS) and multiple organ failure (MOF). Muscle biopsy reveals fiber atrophy, internalized nuclei, rimmed vacuoles, fatty degeneration, fibrosis, and single fiber necrosis (176–178). Electrophoretic determination of the myosin/actin ratio is an alternate method for diagnosing critical illness myopathy (178).

In contrast to steroid-induced myopathy, the nonsteroid-involved version is not usually associated with elevated CPK. This entity is probably sepsis induced, and muscle force can be shown to be altered early in the course of sepsis. The pathology may be related to mitochondrial dysfunction and decreased ATP or increased concentration of reactive oxygen species (ROS) (179). Recently, Brealey et al. demonstrated that muscle biopsies obtained from septic patients had increased amounts of inducible nitric oxide synthase (iNOS) (180). This finding raised the concern that nitric oxide (NO) or other products of NO degradation (i.e., the highly toxic peroxynitrate molecule) might be the active factor. Wray et al. have introduced supporting data with the finding that the ubiquitin pathway is activated in the muscle of septic patients (181).

The ubiquitin pathway is responsible for degrading abnormal proteins in normal cells and may be causing unin-

tended injury to skeletal muscle. Interestingly, ubiquitin is stimulated by peroxynitrate and other ROS and may also be involved in the pathway of corticosteroid induced muscle protein breakdown (182). Thus, the final common pathway for both sepsis-induced myopathy, and steroid-induced myopathy may be ROS-triggered activation of the ubiquitin pathway and resultant muscle protein degradation.

### EYE TO THE FUTURE

The need for NMB use in critically ill patients is expected to increase over time since we care for increasingly sick and complex patients in the ICU. Our knowledge about complications of NMBs in this patient population also continues to increase. There is a need for an NMB drug that will be free from all the long-term side effects (prolonged motor weakness CIP, and steroid-related myopathy). Furthermore, the drug should also provide hemodynamic stability and ideally be void of harmful metabolites.

Improved capabilities for continuous monitoring of NMB will also be helpful. Currently available methods are increasingly being used, even though errors may occur in critically ill patients, especially in edematous or obese patients, and when the PNS is improperly utilized. Besides improved training, better techniques for evaluating the nerve, muscle and NMJ are needed. Recognition that some elements of CIP occur early in the ICU course of sepsis/SIRS should alert the clinician to avoid unnecessary NMB drug use and closely titrate serum glucose in these patients. Additionally, early use of EMG in this population might provide additional data on pathophysiology (though interrogation of type 2 fibers requires further enhancement and development of EMG technology).

### SUMMARY

Several factors influence recovery after the use of NMB agents in ICU patients. These factors include concomitant drug use, length of therapy, end-organ function, primary disease process, and availability of neuromuscular monitoring devices. NMB drugs should be used only when their use is essential for optimal care. Clinicians need to be educated regarding the effects of NMB agents; in particular, they need to know that these agents are devoid of anxiolytic, amnestic, and analgesic properties. Prolongation of NMB carries the concomitant risk of prolonged ventilatory support, increased length of hospitalization, and higher associated costs.

Proposed methods to decrease the risk of prolonged blockade include peripheral nerve stimulation monitoring, periodic drug discontinuation, recognition of interacting drug therapy, and attention to electrolyte and acid-base management. Adjunctive therapies, such as early physical, occupational, and nutritional therapy, may also affect the length of blockade. Most importantly, patient-specific factors that may identify patients at risk for prolonged blockade, such as concomitant corticosteroid and/or aminoglycoside use, presence of renal and/or hepatic failure, should be assessed when deciding to use NMB agents.

The following is recommended if NMB agent use is indicated in the patient in ICU:

1. Never use an NMB unless absolutely required (Table 8).
2. Always administer an amnestic, analgesic and/or sedative agent before and throughout administration of an NMB agent.
3. Select NMB agent based on its pharmacokinetics, pharmacodynamics, and adverse-effect profile.
4. Carefully monitor the drug's effect by employing a PNS to prevent inadvertent overdosing. Intermittently discontinue the NMB agent to check for patient movement (and use this opportunity to revisit the need for NMB), whenever clinically feasible.
5. Recognize potential drug interactions and disease states that may potentiate or prolong the effects of the NMB agent.
6. Consider the cost of the agent, and also keep in mind the indirect costs of prolonged hospitalization secondary to prolonged NMB or persistent weakness.

## KEY POINTS

- ✂ The neural signal is propagated along the axon electrically to the nerve terminal, but crossing the synapse requires the chemical messenger ACh.
- ✂ If enough nAChR channels are opened (as occurs when 200–400 quanta of ACh are released into the synaptic cleft), the resultant change in transmembrane potential will exceed –50 mV, and an action potential will be propagated to the entire motor unit, resulting in muscular contraction.
- ✂ Decreased quantity or quality of plasma cholinesterase results in a prolonged duration of NMB due to succinylcholine.
- ✂ In patients with denervated muscle (particularly following upper motor neuron injury) or following muscle injury (burns, massive trauma), serum K<sup>+</sup> levels can increase by as much as 85% following succinylcholine administration (30), resulting in peaked T waves, widened QRS complexes, loss of P waves, and occasionally ventricular fibrillation and cardiac arrest.
- ✂ The nondepolarizing agents are all derived from one of two chemical groups, benzylisoquinoliniums and aminosteroids (Tables 1 and 4).
- ✂ Rocuronium is mainly used as an NMB during RSI in patients with contraindications to succinylcholine [e.g., burns, upper motor neuron injury, chronic bedrest (>30 days), and history of malignant hyperthermia, etc.].
- ✂ The main vecuronium metabolite, 3,17-dihydroxyvecuronium, has only 2% of the activity of the parent compound, whereas the 3-hydroxy derivative has 60% of the activity of the parent compound and is excreted renally.
- ✂ Because pancuronium and its metabolites are mainly (70%) excreted in the urine, a prolonged duration of action occurs in renal failure.
- ✂ Because its elimination does not depend upon renal or hepatic function, cisatracurium is often used in patients with renal and hepatic dysfunction.
- ✂ AChE inhibitors produce their effects by binding to and inhibiting the enzyme (AChE). The resulting increase in ACh in the synaptic cleft of the NMJ helps the ACh compete more favorably with NMB drugs for available ACh receptors.
- ✂ Neuromuscular blocking drugs should never be administered without concomitant amnesics, sedatives, and/or analgesics.

- ✂ The most reliable single clinical measure of return of NMJ function is the ability to head lift for five seconds or more.
- ✂ The most objective measurement of the degree of blockade in noncooperative or sedated patients is obtained with the demonstration of sustained tetanus through the use of a PNS.
- ✂ The etiology of postparalytic syndrome is incompletely understood, but may result from injury mediated directly by the drug, its active metabolites, or by drug–drug or drug–disease state interactions.
- ✂ CIP is acute axonal neuropathies involving both sensory and motor nerves developing during critical illness, especially with sepsis or SIRS.
- ✂ Corticosteroid-related myopathy primarily affects type 2 fibers; routine EMG most precisely evaluates type 1 fibers, and therefore its results can be equivocal or normal.

### INTRODUCTION

This chapter reviews the equipment and techniques available for monitoring the brain and spinal cord for trauma and critical care. A detailed neurological examination is still the gold standard to evaluate brain and spinal cord function. Traditional examination includes assessment of the level of consciousness, pupillary response, motor function, sensory function, and cranial nerves (1). In many instances, such basic clinical neurological assessments guide surgical interventions and other important clinical decisions. However, sedatives, muscle relaxants, as well as existing neuropathology or acute trauma conditions may significantly impair the sensitivity or even the ability to perform a standard neurological examination.

A host of neurological monitoring devices have been developed as surrogates for the clinical neurological exam. The improved monitoring technology has made it possible to obtain real-time assessment of several parameters of central nervous system (CNS) function. However, not all aspects of CNS function can be monitored with the current technology. Furthermore, no monitoring modalities presently employed provide prospective prediction of deterioration in CNS function, or adequately warn of impending progression of injury. Nonetheless, monitoring provides useful information for evaluating the patient's current condition, recent progress, and need for therapy.

Research efforts continue to improve monitoring techniques in terms of predictive value, reliability, accuracy, and safety. The most important monitoring modalities in current clinical use are reviewed in this manuscript. The major focus of this chapter is in describing the technical aspects of these monitors and the indications for use. Because intracranial pressure (ICP) monitoring is so widely used clinically, we briefly review the basic anatomy and physiology underpinning the ICP volume relationship (elastance). We also provide high-quality figures showing the precise locations of the various ICP monitoring devices, anticipating that this additional review will improve the understanding and safety of ICP monitoring (also see Volume 2, Chapter 1). After reviewing the basic monitoring modalities, the chapter closes with a section dedicated to the monitoring modalities of the future (including cerebral microdialysis catheters and pupillometry).

### INTRACRANIAL PRESSURE MONITORING

#### Anatomy and Physiology

Most neurosurgical catastrophes and much of the morbidity following traumatic brain injury (TBI) results from elevated ICP. Thus, a brief outline of the normal physiologic mechanisms that maintain the balance between pressure and volume inside the dural sac is useful to improve the understanding of the concepts underpinning ICP monitoring (2,3).

The normal adult produces approximately 500 mL of cerebrospinal fluid (CSF) in a 24-hour period. Approximately 150 mL is present in the intracranial space at any given time (see Volume 2, Chapter 1 for details of CSF production and removal). The intradural space consists of the intraspinal space plus the intracranial space. The total volume of this space in the adult is approximately 1700 mL, of which approximately 10% is spinal fluid, 10% blood volume, and 80% brain and spinal cord tissue. Because the spinal dural sac is not always fully distended, some increase in volume of the intradural space can be achieved at the expense of compression of the spinal epidural veins. Once the dural sac is fully distended, any further increase in volume of one component of the intracranial space must be offset by a decrease in volume of one of the other components. This concept is known by cerebral physiologists as the Monro-Kellie doctrine (summarized in Equation 1 later) (4,5).

The normal contents of the intracranial space are brain, blood, and CSF. When a formula is used to represent the intracranial volume–pressure relationships, a term is often included to represent the presence of any other intracranial mass (e.g., tumor or hematoma):

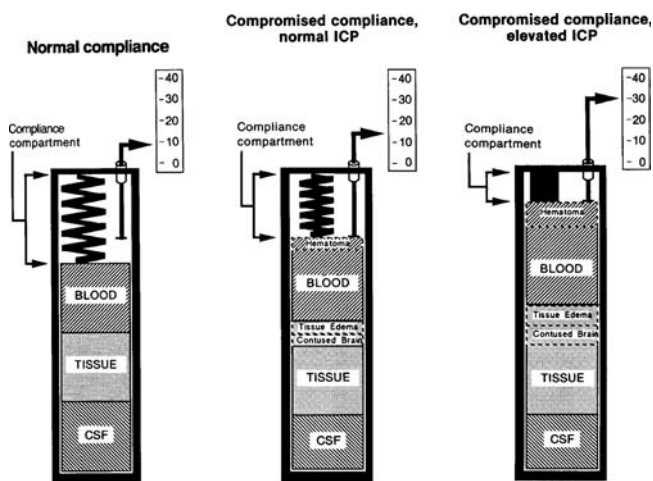

$$V_{\text{csf}} + V_{\text{blood}} + V_{\text{brain}} + V_{\text{other}} = V_{\text{constant}} \quad (1)$$

Thus with a pathologic increase in one component, at least one of the others must decrease to maintain a constant volume. If the accommodating component volume decrease is equal to the volume added, then pressure does not change. The most effective and earliest compensation is displacement of CSF from the cranial space into the spinal space (compressing epidural veins), followed by reabsorption of CSF across the arachnoid villi (a less immediate accommodative process). As the ICP rises, the CSF production rate begins to decrease, further aiding compensation (this is a slower process). The second major volume compensation is the displacement of intracranial pial blood volume into the venous sinuses. Finally, the brain itself can be compressed

to compensate for increases in volume. This is well exemplified by acute hydrocephalus, where the brain is compressed by the CSF resulting in ventricular enlargement, or in an acute epidural hematoma, when the brain is acutely compressed and distorted by the mass of the hematoma.

A diagrammatic summary of these principles is presented in Figure 1. The fundamental concept illustrated in the figure is that patients with the same ICP values may differ significantly in intracerebral compliance (i.e., ICP values taken in isolation can be quite misleading if they are not considered within the framework of compliance). Clinical factors affecting intracranial dynamics that should be considered when interpreting static ICP measurements include the intracranial pathology revealed in the computed tomography (CT) scan and/or witnessed in the operating room, the amount of therapy required to produce the present ICP value, and the sensitivity of the ICP reading to external stimuli (e.g., suctioning, turning, etc.).

The intracranial space is divided into a series of compartments by the foramen magnum and the folds of the dura, the falx, and the tentorium. The anterior fossa is separated from the middle fossa by the lesser wing of the sphenoid bone. The right half of the supratentorial space is separated from the left by the falx cerebri, and the supratentorial space is separated from the infratentorial space by the tentorium. Finally, the intracranial space becomes the intraspinal canal at the foramen magnum. Understanding

**Figure 1** The interrelationship of compliance and ICP. In this figure, compliance is represented by the spring and ICP by the sliding indicator. The three components of the intracranial volume are shown as boxes (cerebrospinal fluid). The *left* shows the representation of the normal situation, in which compliance is maximal and ICP is within the normal range. The *center* shows the situation in which a postulated brain injury has resulted in an intracranial hematoma with contused and edematous brain. The resultant expansion of intracranial volume has used up the intracranial compliance (i.e., compressed the spring), but the ICP has not risen beyond the normal range. The *right* shows the situation in which the lesions have expanded further, expending the intracranial compliance and raising the ICP. It is important to note that in *left* and *center* figures the ICP is within the normal range despite critically different intracranial dynamics. *Abbreviations:* CSF, cerebrospinal fluid; ICP, intracranial pressure. *Source:* From Ref. 10.

this compartmentalization is important because swelling or pressure increases in one compartment can result in distortion and displacement of brain into another compartment, with consequent tissue and vascular compression, resulting in brain dysfunction, damage, or death. These pathophysiological mechanisms create the clinical brain herniation syndromes.

Normally, the CSF pressure is slightly lower than the cerebral venous pressure, but slightly higher than the central venous pressure. Because cerebral venous pressure is difficult to measure clinically, the ICP is used as a surrogate. The cerebral perfusion pressure (CPP) is defined as the difference between mean arterial pressure (MAP) and ICP (as shown in Equation 2).

$$\text{CPP} = \text{MAP} - \text{ICP} \quad (2)$$

♣ Any decrease in MAP or increase in ICP will result in a decrease in CPP. ♣ Once the injured brain CPP falls below 50 to 60 mmHg, ischemia, compression, or herniation of the brain may occur (6–9). The interested reader may refer to Volume 1, Chapter 23 for a review of CPP within the context of TBI management.

Within the limits of autoregulation (CPP 50–150 mmHg) the cerebral vessels respond to decreased CPP by vasodilating, decreasing resistance to flow and thus maintaining the same cerebral blood flow (CBF), despite either a decline in arterial pressure or an increase in ICP. Below the limits of autoregulation, the CBF falls as the CPP is lowered. Cerebral metabolism is preserved to a CBF of about 50% of the normal level, after which some degree of cerebral ischemia begins. As blood flow falls below 25% of normal, irreversible damage begins. Thus, autoregulation is an additional brain protective mechanism against increased ICP. Unfortunately, autoregulation is not always preserved following TBI, and thus therapy is directed at maintaining normal or nearly normal ICP and MAP with the aim of preserving CBF (2,3,6–9).

It is also important to recognize that any obstruction to CSF drainage, such as jugular venous obstruction, increases intrathoracic pressure (pneumothorax, excessive PEEP), which in turn can increase ICP just as an acute increase in brain edema or hemorrhage in the cranium. When the ICP increases above 20 mmHg, CPP may be impaired.

Continuous ICP monitoring has been used to guide the management of patients with head injury (Volume 1, Chapter 23 and Volume 2, Chapter 12), intracerebral hemorrhage (Volume 2, Chapter 14), and brain tumors. ICP monitoring is indicated in patients with severe head injury (GCS 3 to 8 after resuscitation) with nontrivial findings on CT scan. ICP monitoring is also appropriate in patients with severe head injury with a normal CT scan if two or more of the following features are noted at admission: age over 40 years, unilateral or bilateral motor posturing, and systolic blood pressure  $\leq 90$  mmHg (3). The relationship between uncontrolled ICP elevation and mortality has been firmly established in patients with head injury, and ICP monitoring is becoming a standard method of care for their management (3).

The common denominator for many neurosurgical catastrophes is elevated ICP, along with a resultant cerebral herniation, focal ischemia or globally elevated ICP, and diffused cerebral ischemia. As cerebral herniation progresses and the subarachnoid spaces are occluded, the transmission of pressure within the craniospinal axis is impeded, setting the stage for a larger increase in pressure for any given increase in volume [Fig. 1 and (Fig. 3 in Volume 1, Chapter 23)].

The frequent waves of increased ICP may further abolish pressure autoregulation making the brain more prone to ischemia at the same CPP. A progressive loss of compensatory ability often follows an intracranial catastrophe, and an acute increase in volume that was tolerated (i.e., caused minimal increase in ICP) in the first few hours after the insult, may not be tolerated 24 hours later because of the exhaustion of the compensatory mechanisms (leading to dangerously elevated ICP). After TBI and cerebral aneurysm rupture, subarachnoid blood may clog the CSF reabsorption pathways (i.e., the arachnoid villi), further exacerbating ICP management.

Continuous ICP monitoring has been used to guide the management of patients with TBI and other causes of cerebral hypertension (e.g., intracerebral hemorrhage, large brain tumors, and hydrocephalus). The relationship between uncontrolled ICP elevation and fatality has been firmly established in TBI patients, and is the standard of care for the early management of severe closed head injury (GCS  $\leq$  8) (3,6–8). Although ICP monitoring does not measure neural function or recovery, its measurement does permit detection and prompt treatment of increased ICP (e.g., due to brain edema, hydrocephalus, or hemorrhage), which is known to impair neurological function (9). The techniques used to monitor ICP include ventricular catheters, subdural subarachnoid (Richmond) bolts, epidural transducers, and intraparenchymal fiberoptic devices (10).

**Intracranial Pressure Monitoring Techniques**

ICP monitoring can be performed with many different devices and requires knowledge of the indications, contraindications, and potential complications that may arise (Tables 1–3). Other than ventriculostomy, the remaining options for ICP monitoring do not provide the potential for CSF drainage in the management of ICP elevations. However, these other options (Richmond bolt, epidural

**Table 1** Indications for Intracranial Pressure Monitoring

Indication	Criteria and rationale
Trauma	GCS $\leq$ 8 Inability to follow neurological exam from trauma or during necessary sedation or anesthesia
Intracranial hemorrhage	When expansion of hemorrhage would lead to surgical intervention, monitoring can provide immediate information. General ICP management
Intracranial neoplasm	Patients who develop brain swelling during operative resection or during closure, monitoring can be useful in the perioperative period
Post–AVM surgery	AVM resection leads to redistribution of blood flow and often postoperative edema requiring slow awakening from anesthesia and often postoperative sedation

Abbreviations: AVM, arterial venous malformation; GCS, Glasgow Coma Scale; ICP, intracranial pressure.

**Table 2** Contraindications to Intracranial Pressure Monitoring

Contraindication	Rationale/comments
Coagulopathy	Ventricular catheterization should be avoided in thrombocytopenia (platelet count less than 100,000) or INR greater than 1.2. Other monitoring techniques are less risky; however, the patient should always have coagulopathy corrected prior to monitor placement
Immunosuppression	Patients with impaired immunologic status have an increased risk for infection creating a relative contraindication
Clinical irrelevance	Should not be used in patients with nonsurvivable prognosis

Note: International normalization ratio of the partial thromboplastin (PT) time (ratio of PT measured divided by the PT control).

Abbreviation: INR, international normalization ratio.

ICP monitors and intraparenchymal monitors) are associated with a decreased risk of intracerebral hemorrhage compared to ventriculostomy. Regardless of the ICP monitoring device employed, the ICP “number” should never be taken in isolation, and never substituted for a thorough neurological assessment, even when such examination is limited by coma or sedation.

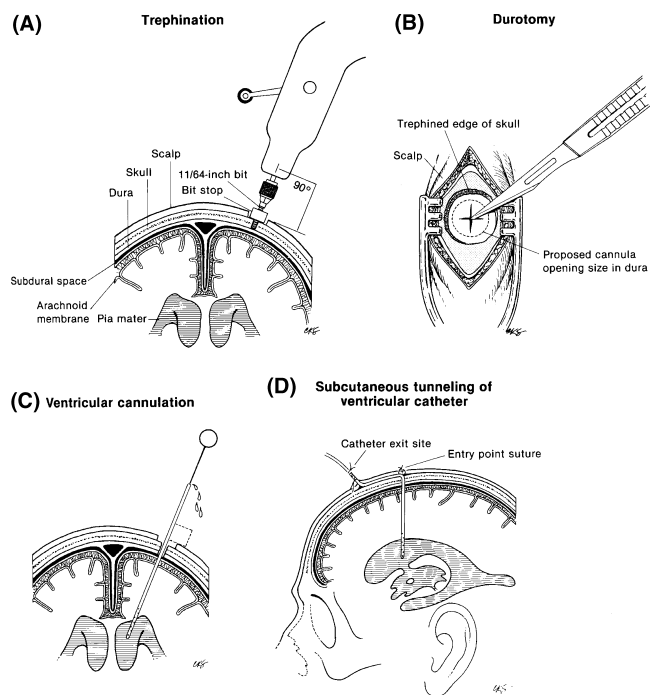

**Ventriculostomy**

✎ The intraventricular catheter, in addition to measuring ICP, allows therapeutic CSF drainage. ✎ The intraventricular catheter is the gold standard method of

**Table 3** Complications of Intracranial Pressure Monitoring

Complication	Rationale/comments
Infection	Placement of ICP monitors can lead to local wound infections, meningitis, ventriculitis, and brain abscess Risk of meningitis and ventriculitis greater with ventricular catheterization Unclear if routine replacement of devices prevents infection
Hemorrhage	Most morbid complication of monitor placement Can result from direct trauma (intracerebral or intraventricular) or overdrainage of CSF (subdural) Greatest risk with ventricular catheterization (1/70–100)
Measurement error	If devices are not placed and calibrated accurately, erroneous measurements may lead to inappropriate therapy or intervention

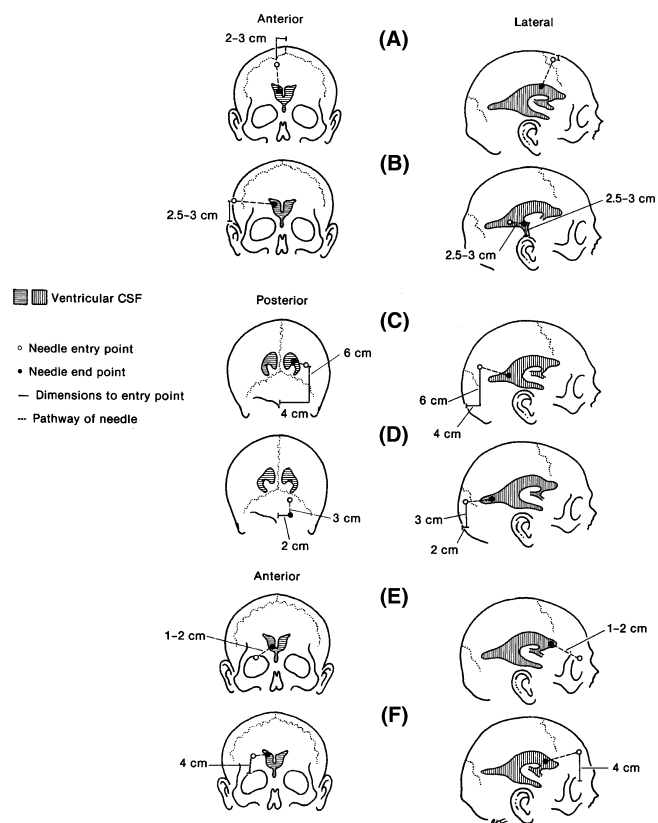

Abbreviations: CSF, cerebrospinal fluid; ICP, intracranial pressure.

**Figure 2** Ventriculostomy insertion technique including: trephination (A), durotomy (B), ventricular cannulation (C), and subcutaneous tunneling of catheter (D). Trephination (A) is accomplished with an 11/64-inch bit, care being taken not to lacerate the dura or plunge into the brain. Following trephination, the wound is thoroughly irrigated to remove all debris. A cruciate durotomy (B) is performed using a No. 11 blade. The size of the durotomy is limited so that the catheter will just pass through the opening, thereby avoiding a cerebrospinal fluid leak. Care is taken to avoid lacerating the underlying brain. The ventricle is cannulated (C) at no more than 5 cm from the dura, keeping the catheter at a right angle to the skull. The ventricular catheter is tunneled subcutaneously (D) external to the galea aponeurotica, and brought out through a separate exit wound, where it is well secured. *Source:* From Ref. 10.

monitoring ICP, which was first used in 1960 (11). A plastic catheter is introduced into the lateral ventricle and connected to an external transducer (Fig. 2). The intraventricular catheter measures ICP reliably, allows therapeutic CSF drainage, and is recommended for early ICP monitoring, following trauma in patients with anticipated ICP elevations (3,10). In the setting of trauma, ventricular size is often reduced subsequent to increased ICP, making the blind insertion of a ventricular catheter more difficult. If the ventricle cannot be cannulated by the third attempt, an alternative technique for ICP monitoring should be used, as the risk of complications increases with each passage.

Most neurosurgeons recommend using the frontal, parasagittal approach for the insertion site by employing Kocher's point (2–3 cm lateral to midline and just anterior to coronal suture). Other approaches do exist, however, the frontal approach offers good access to the frontal horn of the lateral ventricular system, minimizes the involvement of eloquent brain tissue during the passage of the catheter, and facilitates nursing care while the patient is supine in bed. Surgeon familiarity with whichever approach is chosen is paramount (Fig. 3). Some of the potential problems with ventriculostomies are occlusion and dampening,

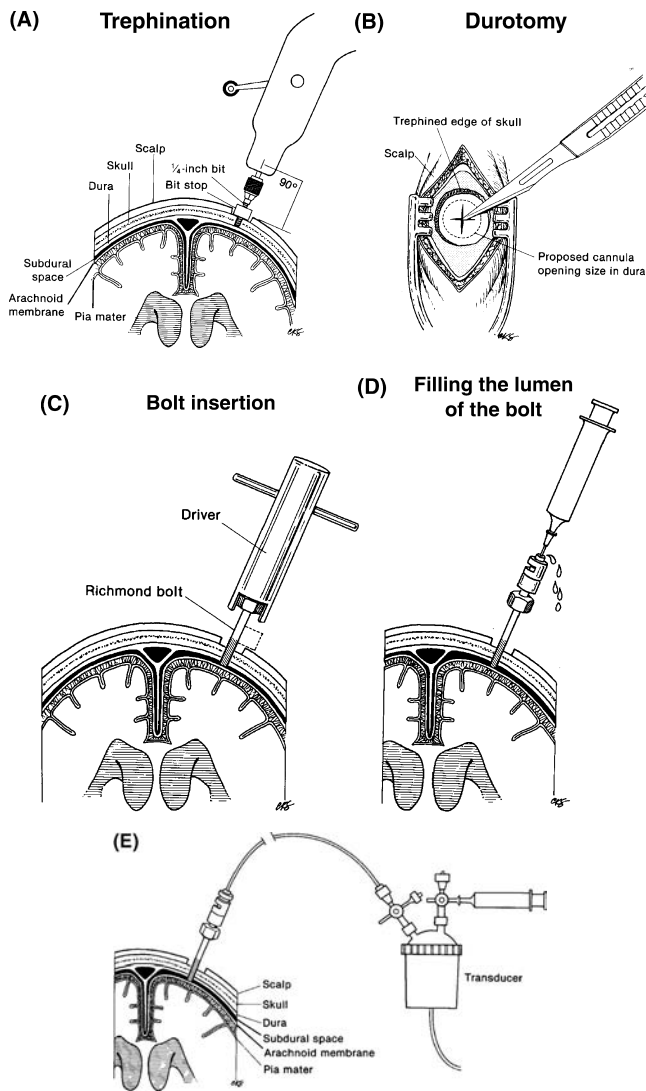

**Figure 3** Approaches for ventricular puncture. Six approaches for accessing the cerebral ventricles through trephines in the skull are shown in this figure. The ventricles are represented by the shaded areas, and the path of the ventricular cannula is shown as a dashed line. (A) Kocher's point: 2–3 cm from the midline, just anterior to the coronal suture. (B) Keen's point: 2.5–3 cm posterior and superior to the top of the ear. (C) Occipital parietal: 4 cm from the midline and 6 cm above the inion (external occipital protuberance). (D) Dandy's point: 2 cm from the midline and 3 cm above the inion. (E) Orbital: 1–2 cm behind the orbital rim. (F) Supraorbital: 4 cm above the orbital rim in the plane of the pupil. *Abbreviation:* CSF, cerebrospinal fluid. *Source:* From Ref. 10.

misplacement into important structures causing brain tissue damage, intracerebral hematoma, intraventricular hemorrhage and infection (12). The probability of clogging the ventricular catheter increases if it is left open in a collapsed ventricle, and it is not possible to monitor ICP with a ventriculostomy while it is left open to drain. In the setting of trauma we recommend one- to two-minute periods of drainage for ICPs >20 mmHg, with reclamping the catheter if no CSF is drained. This allows for CSF to build in the ventricle and the ICP measurements in the interim.

### Richmond Bolt

The Richmond (subdural-subarachnoid) bolt usually consists of a certain type of hollow screw with its tip passing through the dura and thus projecting 1–2 mm below the inner table of the skull and gets seated adjacent to the arachnoid, covering the brain surface. If the bolt is seated to superficial position, there is a risk of dislodgement and/or loss of pressure (Fig. 4). If it is seated too deeply the brain

**Figure 4** Richmond bolt trephination (A), durotomy (B), insertion (C), air evacuation (D), and completion (E). Trephination (A) is accomplished with a 1/4-inch bit, care being taken not to lacerate the dura or plunge into the brain. Following trephination, the wound is thoroughly irrigated to remove all debris. Durotomy (B) is performed in a cruciate fashion using a No. 11 blade. The two arms of the durotomy completely cross the orifice in the skull so that the resulting opening in the dura is of maximal size. Care is taken to leave the underlying arachnoid membrane intact. Insertion (C) is accomplished using the special driver; the bolt is screwed into the skull at right angle so that the tip projects 1–2 mm below the inner table. Air evacuation (D) is accomplished by gently filling the lumen of the bolt with nonbacteriostatic normal saline solution; continue until no air bubbles remain. The Richmond bolt monitoring system is completed when connected to the transducer as shown in (E). *Source:* From Ref. 10.

surface may be penetrated leading to herniation into the hollow screw and plugging up the system in the process.

The advantages of the Richmond bolt are its simple insertion technique and lack of brain tissue penetration. On the other hand, the bolt cannot be used to lower the ICP by CSF drainage, it can produce infection, epidural bleeding, and focal seizures. Furthermore, a blockage can occur in the

tubing, and the recording may get diminished or lost. Indeed, a significant shortcoming of the Richmond bolt is its tendency to become occluded with wound debris, dura and/or blood.

### Epidural Intracranial Pressure Monitors

Two types of epidural ICP monitors have been developed. One uses a pressure sensitive membrane contacting the dura, and the other system uses a pressure sensitive pneumatic switch that deforms as the dura changes. Although the risk of infection to the brain is lower because of the extradural placement, there are several disadvantages, which include technically difficult placement, bleeding, difficult calibration after placement, and inability to conduct the drain of the CSF therapeutically.

### Intraparenchymal Intracranial Pressure Monitors

♣ Intraparenchymal devices, for example, Camino® ICP monitors (Camino Laboratories, San Diego, California, U.S.A.), use a catheter that is inserted within cortical gray matter, which allows direct measurement of brain tissue pressure. ♣

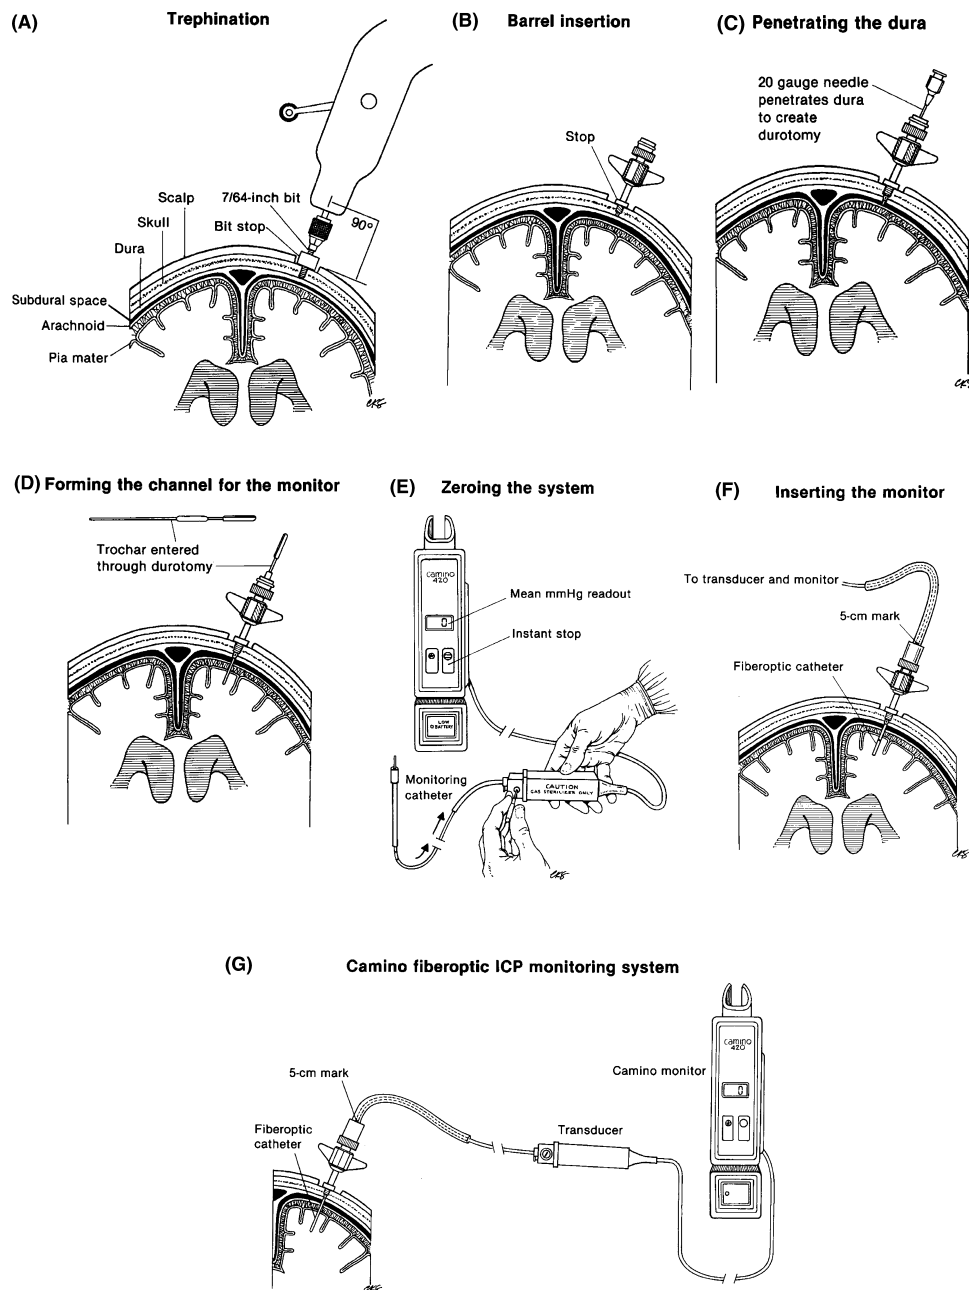

A right frontal site is usually chosen for insertion and, because the intraventricular insertion (using Kocher's point) is not required, any cosmetic site in the lateral, frontal region can be used (Fig. 5A). After trephination, the barrel is threaded into the skull until it comes up against the plastic stop, leaving its distal tip 1 to 2 mm below the inner table of the skull (Fig. 5B). After creating a small hole in the dura, the fiberoptic sensor is zeroed and then inserted until the 5 cm mark is aligned with the top of the barrel, which typically places the distal end of the fiberoptic sensor 10 to 15 mm into the brain parenchyma (Fig. 5D). Newly developed intraparenchymal fiberoptic devices sense changes in the amount of light reflected off a pressure sensitive diaphragm that is located at the tip; and pressure can be displayed digitally on the device (Figs. 5E and 5G). Output cables can also be used to send data to a standard operating room (OR) or intensive care unit (ICU) monitor, allowing real time display of ICP waveforms (5,13,14).

In comparison to a ventriculostomy, Camino monitors are easier to insert and the intraparenchymal probe is of a small diameter, generally causing imperceptible neurologic injury. The advantages of this device are that infection is minimized, and that leaks and catheter occlusion are nonexistent. In addition, errors due to transducer malpositioning are minimized. The main disadvantage of this device is that it cannot be recalibrated after placement and drift may occur, necessitating the replacement of the fiberoptic probe under sterile conditions. The most significant limitation of the fiberoptic device is that it cannot be used for therapeutic CSF drainage (14).

In the setting of trauma, when the ICP is increased and the ventricles are compressed, only a small amount of CSF egress is seen during ventriculostomy placement. This occurs from collapse of the ventricle around the catheter, and if it is not recognized, the catheter may be withdrawn, and it will be impossible to recannulate the ventricle at that time. In this situation, the catheter should be left in place and an additional second monitor such as the Camino should be placed to monitor the ICP. When the intraventricular catheter begins to drain as CSF collects in the ventricle, one of the two monitors may then be removed depending upon the clinical situation.

### Intracranial Pressure Waveforms

♣ The normal ICP waveform is pulsatile and coincident with the cardiac cycle. However, the entire baseline rises

**Figure 5** Insertion of the Camino fiberoptic intracranial pressure (ICP) monitoring system including trephination (A), barrel insertion (B), dural penetration (C), channel formation (D), zeroing (E), insertion (F), and completion (G). Trephination (A) is accomplished with a 7/64-inch bit, with care taken not to lacerate the dura or plunge into the brain. Following trephination, the wound is thoroughly irrigated to remove all debris. The barrel is screwed into the skull (B) until it comes up on the stop mounted on the device to control the depth of insertion. The dura is penetrated (C) with a 20-gauge needle passed only deep enough to create a small durotomy. Forming the channel for the monitor (D) is accompanied by passing the supplied trochar through the barrel and the durotomy as far as the trochar design allows. This forms a cavity for the monitor, which extends 15 mm beyond the tip of the barrel. Zeroing the system (E) must occur prior to insertion of the monitor. To accomplish this, the system is connected to the transducer and the small slotted knob is adjusted with the supplied screwdriver until the system is set to zero. Inserting the monitor (F) occurs after zeroing is accomplished. The monitor is passed through the barrel until the 5-cm mark is at the top. At this point, the catheter tip will project 13 mm beyond the tip of the barrel and will not touch the tip of the tissue cavity. The knurled knob is gently tightened to secure the fiberoptic catheter in place, and the collar is slid down over the top of the barrel, sealing the system. The complete Camino fiberoptic ICP monitoring system is shown in (G). *Source:* From Ref. 10.

**Figure 6** The intracranial pressure (ICP) volume (elastance) curve. Elastance is defined as the change (delta) in pressure ( $dP$ ) for a unit change in volume ( $dV$ ). The term elastance ( $dP/dV$ ) is the inverse of compliance ( $dV/dP$ ). The ICP waveform results from the arterial (and to a lesser extent venous) pressure waveforms occurring with the cardiac cycle, when the brain is compliant (low elastance), the  $dP/dV$  is small, whereas when the brain is noncompliant the elastance is large (i.e., the  $dP/dV$  is large), and the ICP waveforms have both a higher baseline, and a higher pulse pressure. *Source:* From Ref. 15.

and falls in concert with the respiratory cycle (as do all physiologic fluid waveforms). The normal fluctuations in the ICP waveform are characterized as having three pressure peaks (Fig. 6) (15). The initial, also the tallest peak ( $P_1$ ) is due to the arterial pulsation transmitted to the brain parenchyma and CSF. The second peak ( $P_2$ ) is termed as the tidal or rebound wave and reflects intracranial compliance. The third peak ( $P_3$ ) is almost always lower than  $P_2$ , and is called the dicrotic wave representing venous pulsations that is transmitted to the brain. In the normal compliant brain the magnitude of pressure wave is small whereas, in tight brains the change in pressure with any change in volume ( $dP/dV$ ) is large. Besides these characteristic three-peaked ICP waveforms, which occur with the cardiac cycle, additional changes to the entire baseline occur with alterations in intracranial compliance. Furthermore, changes in baseline occur with ventilation as follows: In the spontaneously breathing patient, inhalation decreases intrathoracic pressure and promotes venous drainage (lowering ICP). Whereas, exhalation leads to decreased venous outflow from the cranium causing increased ICP. The opposite is true with positive pressure ventilation. As ICP rises and cerebral compliance decreases (from any cause), the venous components disappear and the arterial pulses become more pronounced.

In 1960, Lundberg reported the results of direct ICP monitoring by means of ventriculostomy in 143 patients (11). In his report he outlined the pathophysiology and clinical significance of three pathologic ICP waveform patterns designated as "A" waves, "B" waves, and "C" waves.

Lundberg "A" waves, also known as plateau waves, are characterized by a steep ICP elevation to  $>50$  mmHg lasting for two minutes to 20 minutes followed by an abrupt fall to initial ICP levels. Usually the new baseline is slightly higher after the "A" wave. These "A" waves recur with increasing frequency, duration, and amplitude and often occur with a simultaneous increase in mean arterial

pressure. Lundberg recognized these waves as harbingers of impending uncontrollable ICP, probably resulting from an exhaustion of intracranial compliance and buffering capacity (Fig. 7A).

Lundberg "B" waves, also known as pressure pulses, are characterized by ICP elevations of 10 to 20 mm lasting between 30 seconds to two minutes. These waves are variations with types of periodic breathing and are more frequently seen with increased ICP and decreased intracranial compliance. Note the relationship is not entirely consistent and represents a qualitative finding during ICP elevations (Fig. 7B).

Lundberg "C" waves, reflecting Traube-Hering arterial waves, are characterized by variable ICP elevations with a frequency of four to eight per minute. They may represent preterminal state and are occasionally seen on top of plateau waves. Similar to "B" waves, they are suggestive but not pathognomonic of increased ICP (Fig. 7C) (11).

Currently the emphasis is on the early recognition and successful treatment of ICP elevations. Accordingly, the aforementioned Lundberg pathologic ("A", "B", and "C") pressure waves are infrequently seen. However, when they are seen in patients who are resistant to therapeutic interventions, they portend worse outcomes.

## BRAIN ELECTRICAL ACTIVITY

### Electroencephalogram

The electrical activity of the brain recorded by surface electroencephalogram (EEG) originates in the superficial layers of the cerebral cortex. Electrical activity of deep neurons adds to the complexity of surface signals. The analysis of EEG tracing primarily involves determination and evaluation of signal strength (amplitude) and pattern (frequency and morphology) (16,17). EEG is valuable in the investigation of intermittent or persistent brain dysfunction and remains essential in the evaluation of epilepsy. However, the role of EEG monitoring in trauma and critical care has been limited.

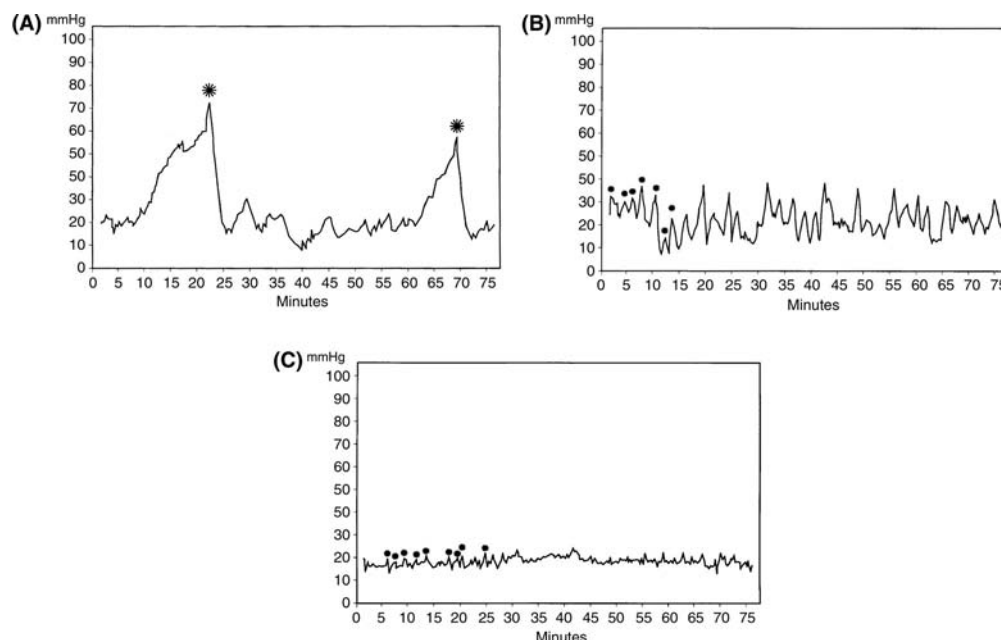

The classic EEG is recorded on up to 32 channels to improve sensitivity. The arrangement of electrodes is referred to as the "montage." Different montage patterns are designed to improve signal reception from the brain area of interest (16,17).

The different EEG patterns are characterized by their voltage, frequency, morphology, distribution, symmetry, persistence, and reactivity over the scalp. Brain electrical activity is commonly categorized according to its frequency: Delta,  $<4$  Hz; theta, 4–8 Hz; alpha, 8–12 Hz; and beta,  $>12$  Hz (Fig. 8). In 75% to 90% of the normal population, a dominant alpha range EEG is manifested, but this may be seen in only 28% to 50% of the elderly individuals. A dominant beta range is seen in 7% to 8%, whereas, 3% to 4% show dominant activity in the theta range. Only 1% has a mixed EEG without any classifiable dominant frequency (16,17).

### Effect of Anesthetic Agents, Analgesics, and Sedatives on Electroencephalogram

In the normal brain, the induction of inhaled anesthetics initially decreases alpha activity and increases beta activity. As anesthesia deepens, EEG frequency decreases further until lower-frequency theta and delta moves predominate. Further increase in anesthetic depth will lead to burst suppression. At 2 MAC isoflurane, an electrical silence can be

**Figure 7** Lundberg's "A," "B," and "C" waves (respectively). Lundberg's "A" waves, also referred to as plateau waves (A), are actually intracranial pressure (ICP) waveform trends measured over 30 to 90 minutes. These ICP trends are characterized by a steep ramp up to pressures of nearly 50 to 80 mmHg, over a duration of 2 to 15 minutes. The peak ("A" wave) is followed by an abrupt fall to a new baseline slightly higher than that of the initial ICP waveform. Lundberg's "A" waveforms tend to recur at increasing frequencies, durations, and amplitudes with progressively higher baselines. Lundberg "A" waves reflect extreme compromise of intracranial compliance and are harbingers of uncontrollable ICP. Lundberg's "B" waves (B) are pressure pulses of 10–20 mmHg that occur at a frequency of 0.5 to 2 waves per minute. Lundberg's "B" waves illustrated in this figure are highlighted with asterisks. They usually occur in the setting of increased ICP and generally indicate decreased intracranial compliance, although in a less consistent manner than "A" waves. Lundberg's "C" waves (C) are ICP waveforms reflecting arterial Traube-Hering waves. They suggest diminished intracranial compliance in a qualitative fashion similar to "B" waves. "C" waves illustrated in this figure are highlighted with asterisks. *Source:* From Ref. 10.

noticed. These deep anesthetic charges are similar to hypothermia and brain death.

In lower doses, narcotics tend to increase the amplitude of alpha and beta frequencies. In higher doses, theta and delta bands develop, indicating sedation. Very high narcotic levels result in a steady decline in EEG frequency until delta predominates. Burst suppression does not occur with narcotics. At extremely high doses, seizure, like activity has been recorded in dogs and rodents (18) (also seen with high normeperidine levels in humans). However, in the absence of normeperidine, narcotics have not reproducibly caused convulsive seizures in humans (19,20). Although epileptiform activity (21) and temporal lobe activation (18) have been reported in humans, these changes are not analogous to seizures.

In low doses, benzodiazepines and barbiturates cause a decrease in the percentage of alpha waves, and an increase in the beta activity. At high doses, theta and delta activities predominate. In very high doses, they can cause periods of electrical silence interspersed with brief episodes of activity this pattern is termed burst suppression. The EEG verification of burst suppression is valuable when determining the dose that is required to induce and maintain barbiturate coma (22).

Etomidate and propofol administration alters EEG tracings in a fashion similar to barbiturates. In small doses (0.1 mg/kg) etomidate enhances interictal activity of seizure foci. However, the myoclonic activity sometimes seen with etomidate is not related to seizures. In higher

**Figure 8** Electroencephalogram waves illustrated and labeled according to their classic frequency related distributions. Delta waves have frequencies <4 Hz but typically have higher amplitudes than beta or theta waves. Theta waves have frequencies between 8 and 12 Hz and typically have varying amplitude as shown. Beta waves have the highest frequencies (>12 Hz), but are low in amplitude. *Source:* From Ref. 150.

doses, etomidate causes EEG slowing and ultimately burst suppression. Propofol produces an increase in the alpha rhythm initially, followed by an increase in theta and delta activity, and finally (at very high doses) burst suppression (23). With regard to dexmedetomidine, human EEG data are not well characterized. However in the rat, dexmedetomidine causes progressive slowing of EEG with increasing doses of drug and some enhancements in amplitude (similar to the effects seen with opioids) (24).

### Electroencephalogram Changes Resulting from Critical Care Events

In addition to the pharmacological effects, physiological changes can cause important EEG effects (25,26). It is essential that any EEG changes should be interpreted within the clinical context in which they are observed.

#### Carbon Dioxide, Oxygen, and Body Temperature

Hypocarbica causes slowing of the EEG and increased susceptibility to sedative/hypnotic drugs. Mild hypercarbia (5–20% above normal) causes decreased cerebral excitability and an increased seizure threshold. High level (30% above normal) results in increased cerebral excitability and epileptic activity. Very high levels (50% above normal) produce EEG depression (27).

Hyperoxia causes a low amplitude and fast frequency EEG pattern, characteristic of (but not essentially indicative of) cerebral excitation. Decreased brain oxygenation initially causes increased cerebral excitability. If hypoxia persists to cause anoxic death of enough brain cells, burst suppression or diffuse alpha pattern may emerge (both also seen in drug intoxication) (28). With brain and brainstem death EEG slows further, ultimately resulting in EEG silence (17,28).

#### Cerebral Blood Flow

☞ **The EEG has never been demonstrated to correlate with CBF except at very low levels.** ☞ Specifically, EEG changes begin to occur when CBF decreases <30% of normal (Fig. 9) (29). However, the EEG threshold for detection of ischemia in injured brain is unknown. Additionally, at the threshold of electrical failure, aerobic metabolism may still be occurring. Most clinical studies of EEG and CBF have occurred during carotid endarterectomy (30–32). Overall, neurological outcome is more dependent on the duration of anaerobic flow deficits than on the EEG changes, during the periods of low flow (29–32). Nonetheless, the EEG has certain value as a warning that CBF may be decreasing, thereby reaching a dangerous level.

#### Brain Death

Persistent EEG electrical silence is characteristic of, but not pathognomonic of brain death (33–35). However, barbiturate coma, metabolic dysfunction (e.g., hepatic encephalopathy), severe hypothermia (temperature <18°C), and other confounding factors may also produce cerebral electrical silence on EEG. Indeed, hypothermia causes progressive slowing of brain activity below 35°C. Complete EEG silence occurs with marked hypothermia (below 18°C) (36–39). ☞ **Because an EEG silence pattern is not specific for brain death, it should never be used exclusively to diagnose brain death, but rather only as a confirmatory test.** ☞ Particularly in the presence of any of these confounding factors, other confirming data (e.g., brain flow study) must be used to make the diagnosis of brain death (see Volume 2, Chapter 16).

**Figure 9** Detection of cerebral ischemia with electroencephalogram (EEG) monitoring. The normal adult brain has baseline EEG waveforms in the alpha range (8–12 Hz). With increasing ischemia the waveform slows some into the theta range (4–8 Hz), and the amplitude continues to diminish until electrical silence ultimately occurs (not shown). *Source:* From Ref. 151.

### Processed Electroencephalogram Monitoring

Difficulty in using and interpreting the multichannel raw EEG stimulated the development of computerized processing of EEG data. The processed EEG generally does not employ many scalp electrodes to generate a satisfactory signal and typically uses adhesive contact electrodes that are easily replaceable. These electrodes have to be placed across the forehead. However, needles or standard cup electrodes can also be used.

Several signal processing techniques have been utilized; including compressed spectral array (CSA), power spectrum, zero cross, and a periodic analysis (40). The EEG signal is usually digitized, processed, and then graphically displayed. Advanced signal analyses such as source localization, quantitative EEG brain mapping, and high-resolution EEG are being developed, but their clinical applications are not yet fully defined (40).

☞ **The advantage of the processed EEG is that the real-time analysis can quickly interpreted with minimal training, resulting in a more rapid detection of clinical problems (e.g., ischemia, seizure), and institution of the treatment.** ☞

The processed EEG is potentially valuable in the ICU because it can be used to continuously monitor abnormal electrical activity and also the EEG effects of a given therapy, thus improving the titration of interventions in intensive care patients (40,41). For example, processed EEG monitoring can be used to assess and adjust sedation. Severe pain or discomfort increases EEG activity in the higher frequencies and increases the amplitude across all bands diffusely; while mildly sedated patients show decreased alpha and increased beta amplitude, and heavily sedated ones show decreased frequency and amplitude across all bands (40). Also, processed EEG may be useful for ischemia detection but sensitivity is decreased by electrode location and number of channels. Advanced signal analyses such as source localization, quantitative EEG brain mapping, and high-resolution EEG are being developed, but their clinical applications are not yet fully defined (26).

### Bispectral Electroencephalogram Signal Processing and Monitoring

The bispectral index (BIS) is a complex EEG parameter composed by using statistical data analysis to identify the

components of the EEG that were found to correlate with the clinical depth of sedation and amnesia with high accuracy and reproducibility (42). These data were normalized to a unitless scale from zero (no EEG activity) to 100 (awake). Its ability to measure these endpoints is thought to be significantly better than assessment by usual clinical signs alone (42). ⚡ **Intraoperative experience shows that anesthetic drugs can be titrated to a specific quantitative endpoint (BIS monitor range of 50–60); to avoid recall, a level between 60 and 80 can be chosen if sedation and amnesia are the desired endpoints in the ICU (42–47).** ⚡

### Evoked Potentials

Nerve stimulation to evoke responses is used for monitoring the functional integrity of specific sensory and motor pathways. An evoked potential (EP) is an event gated sequential recording and averaging of multiple EEG traces in repetitive specified time epochs. Each EEG epoch is a reproducible EEG response to a specific stimulus that tests a certain neural pathway. EP technology has a specific nomenclature for waveform description: polarity (negative, positive), latency (msec), amplitude (mV), etc. (Fig. 10) (48).

⚡ **Compromise of a neurological pathway is manifested as an increase in the latency, or a decrease in the amplitude of EPs, or both.** ⚡ Various types of EPs have been used for many years in the OR. There is an increasing interest in the use of evoked potentials as monitors in ICUs (48,49). It has not yet achieved the anticipated widespread use due to technological complexity, required skills, relative patient discomfort, and signal deterioration with patient movement and/or use of sedatives (though etomidate tends to increase EPs). However, newer techniques may allow more robust signal monitors for the ICU, thus these neuro monitoring techniques will be reviewed here.

### Brainstem Auditory Evoked Potentials

Brain stem auditory evoked potentials (BAEPs) are performed by the application of audible clicks to the ears by headphones or earplugs secured into one ear canal, while

**Figure 10** Evoked potential (EP) waveform. The latency is the duration in milliseconds (msec) between the stimulus and the EP waveform. The amplitude is typically recorded in microvolts ( $\mu\text{V}$ ), but varies according to the type of EP. For example, somatosensory evoked potentials typically have amplitudes in the 1 to 3  $\mu\text{V}$  range, whereas motor evoked potentials (MEPs) typically have amplitudes that range between 5  $\mu\text{V}$  (neurogenic MEPs) and 25  $\mu\text{V}$  (epidural MEPs), all the way up to 500  $\mu\text{V}$  (myogenic MEPs).

white noise is used to mask the opposite ear (50). BAEPs are relatively resistant to drug effects. Benzodiazepines have been reported to have minimal effects, decreasing amplitude and increasing latency (51). However, no correlation between early latency BAEP and the presence of amnesia has been shown but there is probably a correlation with late latency BAEP (52). Analgesic opioids have no significant effects on amplitude or latency (53). Propofol may increase BAEPs latency minimally without changes in amplitude (54). In summary, drug-induced alterations to BAEPs are generally not very substantial. Thus BAEPs can be used to assess brainstem function in a patient treated with various CNS depressants in the ICU.

### Visual Evoked Potentials

Visual evoked potentials (VEPs) are recorded by applying flashing lights to the eyes. In patients who are sedated or unconscious, the eyelids must be taped shut and the light is then applied through the closed lid or by light-emitting contact lenses applied under the lid. These patients present a challenge for recording VEPs because they cannot focus their eyes. Therefore, VEPs are technically difficult to obtain and questions have risen about their usefulness in monitoring. Also, VEPs are more sensitive than the other EP modalities, to the effects of different drugs further diminishing their usefulness in critical care (48).

### Somatosensory Evoked Potentials

Somatosensory evoked potentials (SSEPs) electrodes usually are applied to the median, ulnar, peroneal, or tibial nerves (55). SSEPs are mainly used in the OR to monitor the spinal cord ascending pathways, functional integrity during spine surgery. SSEPs are also used to assess deep brain structures during some vascular neurosurgical procedures. SSEPs use in critical care is still not as common as a monitor. SSEPs are more sensitive to the effects of CNS depressant drugs than BAEPs (55). Benzodiazepines were reported to cause decreased amplitude and increase latency (56–58). Opioids have been reported to produce no effect or minimal increase in latencies and decrease in amplitude even in high doses (59–61). Propofol produces depression of SSEPs, but it still allows effective monitoring (62,63), whereas, etomidate increases SSEP amplitude (55).

### Motor Evoked Potentials

Motor evoked potentials (MEPs) can be produced by direct (epidural) or indirect (transosseous) stimulation of the brain or spinal cord by either electrical or magnetic stimulation, causing contralateral peripheral nerve signals, electromyographic signals, or overt muscle contractions (64). MEPs are used to assess motor cortex, subcortical, and descending motor pathways. These are mainly used in the OR to monitor the spinal cord descending pathways, functional integrity during spine surgery. Further investigations with MEPs are needed to fully define their usefulness in critical care.

MEPs are extremely sensitive to depression by benzodiazepines, propofol, and inhaled anesthetic drugs (55). MEPs appear to be relatively unaffected by opioids and are less affected by etomidate (which actually enhances EPs) and dexmedetomidine (65,66). Neuromuscular blockade obviously affects the recorded electromyographic (EMG) response and must be carefully used (if used at all) to provide adequate monitoring conditions. Maintaining one or two twitches in a train of four can permit reliable MEP responses that has

to be recorded (55,64). Due to the limitations of current technology, neither SSEPs nor MEPS are used in the ICU. However, both are used operatively (see Volume 1, Chapter 26).

### **Clinical Interpretation of Evoked Potential Changes in Context of Critical Care Events**

The disease states commonly seen in the ICU produce EP changes due to ischemic insults and/or anatomic disruption of relevant neurological pathways. Compromise or injury of these pathways is manifest as an increase in the latency and/or a decrease in the amplitude of EP waveforms. It has been suggested that acute changes are more significant than gradual ones. Nonetheless, transient EP changes may occur without adverse effect (67). Also, in the ICU there may be considerable variability in the EP signals (related to temperature, PaO<sub>2</sub>, PaCO<sub>2</sub>, and artifacts related to nursing procedures) that make the interpretation of EP changes even more confusing.

Experimental reports of global cerebral ischemia describe monitoring of EPs to adequately reflect the integrity of CNS perfusion (68,69). Hypotension below levels of cerebral autoregulation produces progressive decreases in EP amplitudes until the waveform is completely lost (70). In addition, SSEPs have been noted to correlate with the severity of neurological deficits after cerebral ischemia (71,72). Persistence of SSEP waveforms, however, does not ensure the absence of infarction risk in nonmonitored areas. It has been shown that BAEPs are less sensitive than SSEPs to ischemia.

Several animal studies suggest that SSEPs can be used to detect focal ischemia (73,74). They have been used intraoperatively for that purpose (75), but up to date there have been few reports for EP use in the intensive care unit (76). In the ICU, EPs may find a role to monitor patients at risk of stroke (patients with transient ischemic attacks) or worsening of new strokes, to possibly assess the effects of peri-infarct edema, and in patients who already received thrombolytic therapy for probable recurrences (76).

Vasospasm can occur after subarachnoid hemorrhage and is characterized by increased blood velocity and decreased blood flow. SSEPs can be used to detect the onset of vasospasm (77,78). However, transcranial Dopplers (discussed later) are a better noninvasive monitor for vasospasm.

EPs are not yet developed to the degree that they can provide a prognosis of patients with head injuries. EPs are diminished in the setting of increased ICP (79,80). However, the minimal ICP required to begin altering EP signals is approximately 30 mmHg (81). Marked BAEPs changes occur with herniation (82). Thus, EPs lag behind other indicators such as IEP and Glasgow coma score in detecting danger or predicting the neurological outcome (83–85).

SSEPs can be used to monitor spinal cord integrity and may also be able to suggest prognosis after injury. Patients with spinal cord injury can experience ascent of the level of their deficit showing “spinal cord injury Potentials” (SCIPs) (55). SSEPs can be a useful device to detect progression of a deficit and instituting therapies to prevent or reverse this process (86). MEPS can be monitored in conjunction with SSEPs to evaluate the functional integrity of both motor and sensory pathways, although studies suggest that changes in only one modality are rare (55,87). EPs have not totally been studied in a controlled fashion for ICU monitoring of, spinal cord, and their utility remains to be studied.

Occasionally patients do not arouse quickly after lengthy neurosurgery even after procedures without expected anatomic neurological problem and an uneventful anesthesia. In this case, the routine postoperative neurological assessment cannot be performed in a satisfactory manner. In the setting of an unchanged brain CT, EPs may become useful in these unconscious patients to confirm the integrity of the central nervous system, until they regain consciousness (88,89).

Several reports document that EPs change with brain death, especially BAEP, which disappear in 80% of clinically brain dead subjects. Continuous BAEP monitoring may alert clinicians of the onset of brain death, sooner, and thus facilitate earlier decisions regarding organ donation (i.e., before hemodynamic instability ensues) (90–92). However, EPs cannot be used as a sole determinant of brain death. Accordingly, a change in EP is best used to trigger a review of patient status using other modalities.

## **CEREBRAL BLOOD FLOW**

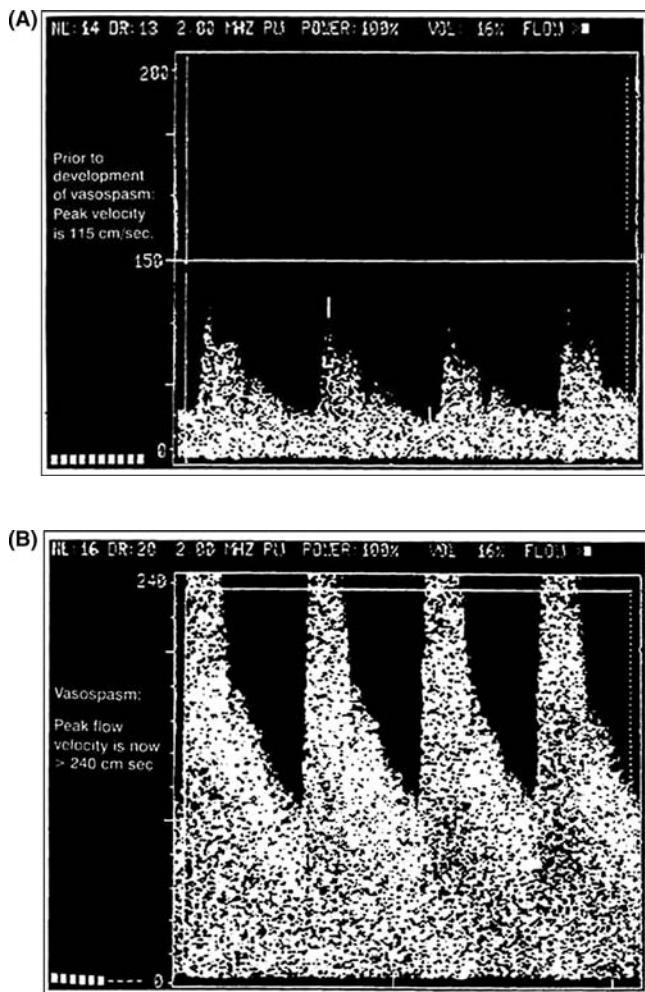

### **Transcranial Doppler Ultrasonography**

☞ **Transcranial Doppler (TCD) is a noninvasive method that uses sound waves for measuring CBF velocity.** ☞ The waveform displayed is related to the velocity and flow direction of the blood and provides real-time, beat-to-beat information. TCD has been used in the ICU to detect cerebral vasospasm and determine its severity, following subarachnoid hemorrhage or aneurysm clipping (93–96). As a cerebral artery constricts, velocity of blood flow within the lumen increases to maintain blood flow. Mean velocity of the middle cerebral artery (MCA) blood flow over 120 cm/sec generally correlates with the presence of vasospasm by cerebral angiography (Fig. 11). TCD may also be helpful in monitoring head injured patients who go through three phases postinjury: hypoperfusion, hyperemia, and vasospasm (97,98).

Another important potential application of TCD is in stroke. TCD provides a reasonably accurate way to characterize the vascular system in ischemic stroke. Moreover, TCD can also detect cerebral emboli and provide information that can aid in making the needed therapeutic decisions. Embolic events are unpredictable, infrequent, and may or may not be symptomatic. Thus, TCD monitoring may be used in the future to detect, count, and measure the size of cerebral emboli (99–101).

TCD has also been used as a screening aid in the diagnosis of brain death. TCD in brain death shows a characteristic blood flow pattern with brief systolic inflow of blood followed by flow reversal in diastole (Fig. 12). Because the dead brain no longer has blood flowing to the parenchyma, the MCA takes a brief inflow of blood during systole and distends (but does not transmit blood further into the brain), and that blood then exits the MCA during diastole (flow reversal). TCD cannot be used as a sole determinant for brain death. Nonetheless, observation of normal TCD waveform, in some cases, can be used to rule out the diagnosis of brain death (102–105).

All intravenous anesthetics (except for ketamine) decrease CBF. Thiopental, propofol, and benzodiazepines tend to decrease cerebral flow velocity (CFV), while narcotics have little increase or no effect on CFV (106). It must be noted that many other physiological variables (e.g., temperature, hypoxia, hyper- or hypocarbia, hematocrit level, and

**Figure 11** Transcranial Doppler (TCD) waves before (A) and after (B) the onset of cerebral vasospasm. Flow is shown on the X axis. Above zero is forward flow, and below zero is reverse flow. The top TCD profile (A) has a scale of 0 to 200 cm/sec with record flow peak velocity at 115 cm/sec. The bottom TCD profile (B), demonstrates vasospasm with peak velocities above scale (>240 cm/sec). *Source:* From Ref. 151.

atherosclerotic vascular disease) can also affect TCD values (106,107).

### Laser Doppler Velocimetry/Flowmetry

The laser Doppler technique measures blood flow in the microvasculature. This technique depends on the Doppler principle where emitted light is scattered by moving red blood cells. As a consequence it is either reflected, or detected, or both after the wave frequency has changed. The Doppler frequency shift is processed to provide a blood flow measurement in the microvasculature. Scanning of tissues enables blood flow mapping, and color coded images of the blood flow can be displayed. The term commonly used to describe blood flow measured by the laser Doppler technique is "flux." Regions of interest can be defined and statistical data calculated and recorded. Assessments can be made using invasive procedures (needle fiberoptic probe) or noninvasive with skin probes on the forehead (108,109).

**Figure 12** Reversal of transcranial Doppler (TCD) wave flow during diastole characterizing brain death. The top TCD profile shown has a scale of 0 to 120 cm/sec, above zero is forward flow, below zero is backward flow. During systole, a brief inflow of blood occurs in the middle cerebral artery (MCA), but due to the lack of forward flow beyond that point (due to brain death), the distended MCA expels its contained blood during diastole (flow reversal). *Source:* From Ref. 151.

### Cerebral Angiography

The development of other noninvasive diagnostic modalities and the advancements in CT and magnetic resonance imaging (MRI) technology has diminished the use of angiography. Angiography uses X-ray imaging of the cerebral vessels after injection of a contrast medium via a catheter threaded into the carotid and/or vertebral arteries. Digital subtraction angiography (DSA) can show the vessels in isolation by subtraction of bone images, and portable units may soon find utility in the ICU (110). Potential risks are reaction to the contrast material, bleeding from puncture site and stroke by dislodged plaques or injury to cerebral vessels, followed by vasospasm or thrombosis (97,111).

### Perfusion Computed Tomography (Helical Computed Tomography with Contrast Injection)

Continuous movement of the gantry of a CT scanner during ultrafast signal acquisition can create helical CT images. Overlapping the resulting two-dimensional (2-D) images creates virtual high-resolution, three-dimensional (3-D) images. Typical perfusion 3-D CTs have been carried out with intravenous bolus injection of contrast media. Helical CT scan can be extremely useful in the diagnosis of intracranial lesions and vascular abnormalities, but is not as important in most TBI patients (Fig. 14) (112-114).

### Magnetic Resonance Angiography

The development of MRI has led to much of the progress in the diagnosis and management of neurological disorders (115). MRI is a form of tissue analysis in which magnetic field waves are applied and their resonance is analyzed to probe tissue characteristics. Magnetic resonance angiography (MRA) has also become a clinically useful tool; selective MRA provides information about the origin and direction of flow and circulation in collateral vessels, including the

ability to visualize aneurysms and arterial venous malformations (AVMs) (Fig. 13) (115–117).

### Xenon-Enhanced Computed Tomography

Improvements in CT technology using inhaled xenon as a radio-dense substance allowed acquiring three parameters describing the cerebral hemodynamics: regional cerebral blood volume (rCBV), blood mean transit time (MTT) through cerebral capillaries, and rCBF at multiple levels (Fig. 14 and 15) (118). It has also been used for many situations, these include: autoregulation assessment following trauma, outcome prediction, detection of vasospasm (and resultant regions of ischemia), and bedside titration of blood pressure and ventilation to CBF. In general it is an excellent method to detect and quantitate the blood flow (118–120).

### Xenon-133 Clearance

The inert gas xenon-133 clearance technique relates the change in radiotracer activity over time (given intravenously or by inhalation) to blood flow. It is a valuable diagnostic and prognostic tool that allows bedside measurement of rCBF. Owing to xenon rapid clearance from the brain, multiple studies can be performed on the same day (121). Early post-traumatic findings are predictive of the outcome, whereas later measurements are correlated with functional recovery. Easily operated computerized systems are now available in which data are displayed as 2-D topographic brain maps (121). Stable xenon-enhanced CT ( $^{131}\text{Xe}/\text{CT}$ ) uses a non radioactive stable xenon (131) and has been well validated as a measure for rCBF (122). However,  $^{131}\text{Xe}/\text{CT}$ -induced rCBF activation may cause overestimation of actual rCBF in both TBI and subarachnoid hemorrhage (SAH) patients (122).

### Positron Emission Tomography

Positron emission tomography (PET) is a complex method of brain imaging that requires a cyclotron to provide the positron emitting isotopes. PET provides 3-D images about cerebral metabolic rate, CBF, and oxygen extractions (quantitative and functional images) (123). Recent studies are showing high correlations with neuropsychological testing (124).

### Single Photon Emission Computed Tomography

Single photon emission computed tomography (SPECT) technology uses a radionuclide to obtain 3-D images of its distribution with a gamma camera and CT techniques. The resultant images qualitatively reflect the regional blood flow and may be able to predict the likelihood of ischemia. Also, SPECT can differentiate neurological symptoms due to ischemia (hypoperfusion) from epilepsy (hyperperfusion) (125,126). SPECT is easily done but lacks the quantitative accuracy of PET and xenon-based techniques.

## INTRACRANIAL OXYGEN SATURATION

### Jugular Bulb Venous Oxygen Saturation

☞ Jugular bulb venous oxygen saturation ( $\text{SjvO}_2$ ) provides a measurement of the global balance between cerebral oxygen supply and demand. ☞  $\text{SjvO}_2$  can be measured by placing a fiberoptic catheter into the jugular bulb via the internal jugular vein retrograde. Assuming  $\text{CMRO}_2$  to be constant, acute changes in CBF will be reflected by the  $\text{SjvO}_2$ . However, smaller focal areas of cerebral ischemia

**Figure 13** Magnetic resonance angiography (MRA) images of cerebral vessels. The arterial phase of the MRA image is shown in (A), whereas the venous phase is shown in (B).

Source: From Ref. 152.

may go undetected with  $\text{SjvO}_2$  monitoring (127–131).  $\text{SjvO}_2$  measurements of below 50% are indicative of global cerebral ischemia. An increase in  $\text{SjvO}_2$  above 85% implies either a rise in cerebral blood flow, shunting of blood away

**Figure 14** CT perfusion xenon enhanced computed tomography—normal brain. The output can be displayed as: (A) contrast media evolution in artery (curve 1), vein (curve 2), and cerebral parenchyma (curve 3); (B) regional cerebral blood volume; (C) regional cerebral mean transit time; (D) regional cerebral blood flow; and (E) xenon perfusion mapping. *Source:* From Ref. 153.

from neurons, or a decrease in cerebral metabolism as occurs in head injury, barbiturate coma, and impending brain death. S<sub>ijv</sub>O<sub>2</sub> monitoring is susceptible to artifacts caused by baseline drift of the catheter or by lodging of the sensor tip of the catheter against the wall of the vein.

**Figure 15** Xenon-enhanced computed tomography (CT)—traumatic brain injury. Xenon-enhanced CT blood flow study in a patient with severe head injury. *Left*, anatomic reference section [arrow indicates tip of regional cerebral blood flow (rCBF) probe]; *right*, corresponding rCBF (mL/100 g/min) image shows severe right hemispheric hypoperfusion (corresponding to the severe right-sided lesion seen on CT scan). *Source:* From Ref. 122.

Finally, areas of focal ischemia can occur with entirely normal S<sub>ijv</sub>O<sub>2</sub> values (127–131).

**Near Infrared Spectroscopy**

Transcranial cerebral oximetry is a continuous, real-time, and noninvasive technique based on the measurement of infrared light wavelength’s absorption by hemoglobin. It uses a near infrared light emitter and a dual receiver placed usually over the lateral forehead. HbO<sub>2</sub>/Hb ratio is then determined. Interpretation principles afterwards are similar to those used with jugular bulb oxygen measuring (Fig. 16). Regional oxygen saturation (rSO<sub>2</sub>) can thus be measured transcutaneously with near infrared spectroscopy (NIRS) to assess physiologic, pathologic, and therapeutic events. Absolute levels <50% or decrements >10% from baseline readings are thought to indicate cerebral hypoperfusion. The saturation values are representative only of the region beneath the sensor, and the presence of cerebral extravascular blood collections may interfere with the recordings or result in wrong values (132–134).

**Brain Tissue PO<sub>2</sub> Probes**

Microprobes can be inserted directly into the brain parenchyma to measure PO<sub>2</sub>, PCO<sub>2</sub>, pH, temperature, and many other variables, which indirectly indicate perfusion changes of that particular region of the brain (134). One such monitor, the Neurotrend® Cerebral Tissue Monitoring System (Codman, Raynham, Massachusetts, U.S.A.) is commercially available, and has recently been shown to

track declining brain pH and tissue  $PO_2$  (Brain-PtiO<sub>2</sub>) as brain PCO<sub>2</sub> and lactate (measured by microdialysis catheter—see later discussion in “Eye To The Future”) increased in a feline model of fluid percussion injury (FPI) and secondary hypoxic injury (135). Insertion-related hemorrhagic and infectious complications are rare and the probes have little baseline drift (131).

Unfortunately, human studies in normal brain do not exist yet. Thus normal baseline and normal ischemic thresholds are not yet confirmed. However, decreasing human Brain-PtiO<sub>2</sub> values have correlated highly with outcome in patients with TBI (136,137). Brain tissue oxygen  $PO_2 < 25\text{--}30$  mmHg is most likely an indication of impaired brain oxygenation (138). However, the anarobic threshold is probably in the range of an approximate Brain-PtiO<sub>2</sub>  $< 20$  mmHg (139).

## EYE TO THE FUTURE

Recent technologies and improvement of monitoring techniques made it possible to have better, more accurate, and more user friendly equipment available for neurological monitoring in the ICU. However, most of the currently available monitors remain sensitive to interfering signals from other ICU equipment and patient movements, which causes frequent artifact recording. Improving monitor filters and sensitivity will allow better quality of signal detection and decrease both missed events and false alarms. As neurological monitors are becoming more popular every day, multimodal monitors will soon become available where different parameters can be detected simultaneously and displayed on a single monitor screen (140,141).

Pupillometry and microdialysis are two head-injury monitoring techniques on the horizon for clinical use. Quantitative pupillometry offers the possibility of measuring subtle changes in pupillary shape associated with intracranial volume expansion. Adding to the basic exam,

**Figure 16** Schematic representation of near infrared spectroscopy (NIRS). The NIRS probe contains a light source and two photodetectors. Photodetector 1 detects infrared light absorption of scalp/extracranial blood and photodetector 2 detects infrared light absorption of both cerebral and extracranial blood. Cerebral oxygenation is calculated by subtracting absorption measured at detector 1 from that measured at detector 2. *Source:* From Ref. 151.

pupillometry aims to provide earlier and more sophisticated information about corresponding changes in brain elastance (dP/dV). A relationship exists between ICP higher than 20 mmHg and a reduction of constriction velocity of the pupil and a reduction of pupil size of less than 10% appears to be associated with increases in brain elastance (the inverse of compliance). Pupillometry is becoming a reliable technology capable of providing data on quantitative papillary function and further investigation is warranted to establish its clinical relevance and application (142).

Cerebral microdialysis catheters are a recently developed technology capable of directly measuring extracellular cerebral metabolites at the bedside (143). Microdialysis is a technique by which a fine tube is inserted into the brain that measures the concentration of chemicals in the extracellular space of the brain by mimicking the action of a blood capillary. Molecules that pass through the semipermeable membrane are collected into vials and the very small volumes are then analyzed.

Several substances can be studied, for example: energy metabolites (e.g., glucose, lactate, and pyruvate), excitatory amino acids (e.g., glutamate), and markers of cell damage (e.g., glycerol), and inflammatory substances (e.g., cytokines). In the setting of head injury reports have shown glutamate levels to increase, lactate to increase, and glucose and pyruvate levels to fall. Some studies have shown an alteration of chemical substances with the institution of therapy. Further investigation aims to detect changes in tissue chemistry at a stage when secondary brain damage can be prevented (143). Microdialysis catheters may be a useful monitor in the intensive care unit, especially in patients with head injury, epilepsy, stroke, and SAH (144–146).

Given evidence of prolonged neuromuscular blockade–induced myopathy, the use of peripheral nerve stimulators is recommended during neuromuscular blockade in the ICU (147). Nerve stimulators are an essential tool, especially during prolonged muscle relaxant infusions (148). Although specific monitors of neuromuscular junction health have not yet been developed, electrodiagnostic testing of neuromuscular disorders is continuing to evolve (149).

## SUMMARY

The traditional means of clinically identifying neurological events is by conducting a periodic examination to detect neurologic deterioration. However, because of the high sensitivity of the brain to ischemia and anoxia, the reliance on intermittent examination may not immediately detect deterioration and therefore risks neurological damage to the patient.

Various neurological monitors are effective in detecting impending changes in brain electrical activity, cerebral ischemia, and anoxia, which make it possible that the onset of such neurological insult maybe detected earlier. It was proven that using these monitors in the ICU has dramatically improved the quality of patient care and outcomes.

Selection of the monitored parameter and modality depends on the clinical setting, diagnosis, and expected sequelae. However, frequent neurological examinations remain the gold standard of care.

## KEY POINTS

- ✎ The cerebral perfusion pressure (CPP) is equal to the difference between mean arterial pressure (MAP) and ICP (CPP = MAP - ICP). Accordingly, any decrease in MAP or increase in ICP will result in a decrease in CPP.
- ✎ The intraventricular catheter, in addition to measuring ICP, allows therapeutic CSF drainage.
- ✎ Intraparenchymal devices, for example, Camino® ICP monitors (Camino Laboratories, San Diego, California, U.S.A.), use a catheter that is inserted within cortical gray matter, which allows direct measurement of brain tissue pressure.
- ✎ The normal ICP waveform is pulsatile and coincident with the cardiac cycle. However, the entire baseline rises and falls in concert with the respiratory cycle (as do all physiologic fluid waveforms).
- ✎ The EEG has never been demonstrated to correlate with CBF except at very low levels.
- ✎ Because an EEG silence pattern is not specific for brain death, it should never be used exclusively to diagnose brain death.
- ✎ The advantage of the processed EEG is that the real-time analysis can be quickly interpreted with minimal training, resulting in a more rapid detection of clinical problems (e.g., ischemia, seizure), and institution of the treatment.
- ✎ Intraoperative experience shows that anesthetic drugs can be titrated to a specific quantitative endpoint (BIS monitor range of 50–60), to avoid recall; a level between 60 and 80 can be chosen if sedation and amnesia are the desired endpoints in the ICU.
- ✎ Compromise of a neurological pathway is manifested as an increase in the latency, or a decrease in the amplitude of EPs, or both.
- ✎ Transcranial Doppler (TCD) is a noninvasive method that uses sound waves for measuring CBF velocity.
- ✎ Jugular bulb venous oxygen saturation (SjvO<sub>2</sub>) provides a measurement of the global balance between cerebral oxygen supply and demand.
- ✎ Microprobes can be inserted directly into the brain parenchyma to measure PO<sub>2</sub>, PCO<sub>2</sub>, pH, temperature, and many other variables, which indirectly indicate perfusion changes of that particular region of the brain.

## Respiratory Monitoring

Jonathan B. Cohen, Enrico M. Camporesi, and Hans W. Schweiger

Department of Anesthesiology and Critical Care, University of South Florida College of Medicine, Tampa, Florida, U.S.A.

### INTRODUCTION

Monitoring of respiratory gases in critically ill patients is increasingly used, and with improved utilization and understanding come opportunities to improve outcomes. The widespread use of pulse oximetry in the late 1980s revolutionized anesthesia management and is responsible for saving countless lives. In the 1990s, this technology quickly spread outside the operating room (OR) to become a standard of care in the surgical intensive care unit (SICU) and the emergency department (ED). Carbon dioxide (CO<sub>2</sub>) monitoring has long been used in anesthesia practice and is likewise becoming more commonly used in critical care areas outside of the OR. This chapter reviews the practical benefits of respiratory gas monitoring techniques that are commonly employed in the OR and are increasingly utilized in the trauma resuscitation suite (TRS) and in the SICU.

### CARBON DIOXIDE MONITORING

The partial pressure of arterial CO<sub>2</sub> (PaCO<sub>2</sub>) is commonly measured by arterial blood gas (ABG) sampling, but inhaled and exhaled CO<sub>2</sub> values provide additional clinically relevant information, and can also be monitored in the SICU. **Exhaled gas CO<sub>2</sub> concentrations provide physiologic information about both systemic perfusion and pulmonary function.** Monitoring of exhaled gas CO<sub>2</sub> can be accomplished by colorimetric, capnometric, or capnographic means. In colorimetric CO<sub>2</sub> monitoring, a disposable device, for example, Nellcor Easy Cap<sup>®</sup> II (Pleasanton, California, U.S.A.), is connected between the 15-mm airway adapter of the endotracheal tube (ETT) and the ventilator tubing. The presence of CO<sub>2</sub> in the exhaled gas causes a chemical reaction in the indicator device changing the color from a baseline purple to yellow. The Nellcor Easy Cap II is a commonly employed device for secondary confirmation of ETT placement in locations outside of the OR, where capnography may not be available (see Volume 1, Chapters 8 and 9). While colorimetric monitoring provides qualitative information, capnometric and capnographic monitoring devices provide more quantitative information. The numerical value of CO<sub>2</sub> measured is typically reported in mmHg. The end tidal CO<sub>2</sub> (P<sub>ET</sub>CO<sub>2</sub>) value is usually monitored in the OR, as this most closely reflects the PaCO<sub>2</sub>. **The P<sub>ET</sub>CO<sub>2</sub> provides information about four important issues: (i) the correct placement of the ETT, (ii) the ventilation status, (iii) the cardiac output (Q̇), and (iv) the metabolic status of the patient.**

### Metabolic Status of the Patient

As the cellular byproduct of respiration, CO<sub>2</sub> blood levels mirror metabolic rate. When the rate of metabolism increases, the level of CO<sub>2</sub> produced ( $\dot{V}CO_2$ ) also increases. A list of hypermetabolic disease processes commonly encountered in critically ill trauma patients are listed in Table 1. However, the P<sub>ET</sub>CO<sub>2</sub> and the PaCO<sub>2</sub> can vary in response to a variety of conditions (described later).

### Correct Placement of the Endotracheal Tube

Incorrect placement of an ETT leads to catastrophic results if it is not recognized immediately after it occurs. Historically, physical exam findings were used to confirm placement. Auscultation of the lungs is error prone, particularly in noisy environments such as the TRS of the ED, in an ambulance, or in a helicopter. Brunel et al. (1) found that 60% of main-stem intubations occurred despite the reported presence of equal breath sounds on examination. His group also found that cuff ballotement and referencing the markings on the ETT to the incisor line (as a measure of insertion depth) were not completely reliable (1).

Other clinical indicators of endotracheal versus esophageal intubation are likewise error prone. In one study condensation was observed in the ETT in more than 50% of patients intentionally intubated in the esophagus (2). White and Slovis (3) summarize the reliability of the clinical exam when they state that using physical exam alone as confirmation of correct ETT placement represents reliance on a “fool’s gold standard.”

**The American Society of Anesthesiologists Difficult Airway (ASADA) guidelines, along with the Advanced Cardiac Life Support<sup>®</sup> (ACLS<sup>®</sup>) guidelines currently recommend secondary confirmation of ETT placement with exhaled CO<sub>2</sub> measurement or an esophageal detector device (EDD); as it has become increasingly recognized that physical exam alone is error prone.**

Animal studies have indicated that recent ingestion of carbonated beverages may produce a false positive result (4). As a result, the manufacturer’s recommendations for the Nellcor Easy Cap<sup>®</sup> II state that the colorimetric CO<sub>2</sub> detector color should be evaluated “after six full breaths”; the initial breaths being delivered to “wash out” any CO<sub>2</sub> artifact (5).

A concern with this technique is the potential delivery of six full breaths of gas to the esophagus and stomach, increasing the risk of aspiration. Capnometry, or better still capnography allows for more precise confirmation of tube placement, as long as the operator understands the workings and artifacts affecting these devices. If the putative ETT is actually incorrectly placed (e.g., in the esophagus), the exhaled CO<sub>2</sub> would decrease with each subsequent breath.

**Table 1** Causes of Hypermetabolism

Postburn
Post-trauma
Post-CNS injury

Hyperthyroidism
Cocaine use
Methamphetamine use
Neuroleptic malignant syndrome
Malignant hyperthermia

The accuracy of either of these two modalities typically allows for a detection endpoint to occur before six full breaths have been delivered, provided the patient has adequate  $\dot{Q}$ . Silvestri et al. (6) found that in 153 patients, who received out-of-hospital intubation, no unrecognized misplaced intubations occurred in patients for whom paramedics used continuous  $P_{ET}CO_2$  monitoring. Continuous monitoring can also alert the practitioner to accidental extubation of the patient, as ETT dislodgement is common during both out-of-hospital transport and intrahospital transport (7,8).

The major limitation of exhaled  $CO_2$  monitoring is in patients with very low  $\dot{Q}$ , and those in complete cardiac arrest. If the time the patient has been without spontaneous circulation has been prolonged, lack of  $P_{ET}CO_2$  may reflect an absence of pulmonary blood flow rather than incorrect tube placement. In this condition, an EDD is recommended (see Volume 1, Chapters 8 and 9).

### Cardiac Output

The heart and the lungs are the only organs that receive 100% of  $\dot{Q}$ . **In patients with fixed ventilation/perfusion ( $\dot{V}/\dot{Q}$ ) relationships in the lungs, and stable minute ventilation ( $\dot{V}_E$ ), the  $P_{ET}CO_2$  is proportional to  $\dot{Q}$  (9)**  $\curvearrowright$  Gudipati et al. (10) demonstrated that  $P_{ET}CO_2$  during cardiopulmonary resuscitation (CPR) was predictive of animals that survived resuscitative efforts. The  $P_{ET}CO_2$  also serves as a useful indicator of the return of spontaneous circulation after an arrest (11). The same group examined the effects of  $P_{ET}CO_2$  on a controlled hemorrhage model in sheep, and documented a logarithmic relationship between  $\dot{Q}$  and  $P_{ET}CO_2$  (12).

### Ventilation Status

The  $P_{ET}CO_2$  levels usually provide an approximation of  $PaCO_2$  levels. As such, they allow practitioners to rapidly determine if a patient is being hypoventilated, or more commonly hyperventilated. Aufderheide et al. (13) found that paramedics were consistently hyperventilating patients in cardiac arrest after they were intubated and that this was associated with poor outcomes. An important alternate explanation not considered by the authors that would perhaps better explain the increased mortality associated with low  $P_{ET}CO_2$  was gross underresuscitation of intravascular volume. With either explanation, an excessively elevated  $\dot{V}/\dot{Q}$  condition occurred, and this was most readily diagnosed with combined monitoring of capnography and  $PaCO_2$  values.

Excessive and prolonged hyperventilation is also of concern in patients with traumatic brain injury (TBI) (Volume 1, Chapter 23). Although transient hyperventilation is an appropriate temporizing treatment in cases of impending herniation of brain tissue, its routine and prolonged use is no longer endorsed (14). Hyperventilation may cause

cerebral vasoconstriction and hypoxia to regions of the brain. There is evidence that paramedic-induced hyperventilation routinely occurs after head injury. Davis et al. (15,16) found that more than half of the patients studied had a  $P_{ET}CO_2$  level of less than 25 mmHg. **A low  $P_{ET}CO_2$  value in multi-trauma patients usually reflects insufficient  $\dot{Q}$  (i.e., under resuscitation) and a resultant high ( $\dot{V}/\dot{Q}$ ) as mentioned previously.**  $\curvearrowright$  Accordingly, the study by Davis et al. (15) [as in the case of Aufderheide et al. (13)], may not necessarily have provided evidence of absolute hyperventilation (but rather, relative underresuscitation of intravascular volume).

Typically, the  $P_{ET}CO_2$  value is slightly less than the concomitant  $PaCO_2$ . This  $P_{ET}CO_2-PaCO_2$  gradient can be affected by a number of processes as summarized in Table 2. The use of capnometry to assist with tight ventilatory control during transport has been reported (17). However, the  $P_{ET}CO_2-PaCO_2$  gradient needs to be established with an ABG to ensure that the  $P_{ET}CO_2$  is truly reflecting the  $\dot{V}_E$  [as would occur with stable alveolar dead space ( $V_{D\text{ alveolar}}$ ),  $\dot{Q}$ , and  $\dot{V}CO_2$ ]. Otherwise, a decreasing  $P_{ET}CO_2$  value is likely reflecting an increasing  $\dot{V}/\dot{Q}$  condition, as occurs during exsanguination.

### Waveform Analysis

If capnography is applied, analysis of the  $P_{ET}CO_2$  waveform can be a useful tool. Figure 1 shows a normal waveform. Loss of the tracing altogether usually represents a circuit disconnect, kinked tubing, or extubation of the trachea. Gradually increasing levels of  $CO_2$  in the  $P_{ET}CO_2$  waveform may indicate ongoing gradual hypoventilation, hyperthermia, or increased metabolism. In contrast, gradually decreasing  $CO_2$  levels may indicate hemorrhage in a patient with a fixed  $\dot{V}_E$  and  $\dot{V}CO_2$ . Abrupt decreases in  $P_{ET}CO_2$  often indicate cardiopulmonary arrest, pulmonary embolism, or sudden catastrophic blood loss (e.g., ruptured abdominal aortic aneurysm).

**An exaggerated upstroke in segment C–D (also known as the plateau phase), as shown in Figure 2A, indicates an increase in airway resistance with associated  $\dot{V}/\dot{Q}$  spread among the millions of alveoli.**  $\curvearrowright$  Such an exaggerated slope to the plateau phase of the capnographic trace is often created by patients with reactive airways disease and

**Table 2** Factors that Increase the End-Tidal Arterial  $CO_2$  Gradient<sup>a</sup>

Low cardiac output states
Hypovolemia
Blood loss
“Third-space” fluid losses
Excessive diuresis
Excessive GI losses
Impaired contractility
Myocardial ischemia
Dilated cardiomyopathy
Valvular heart disease
Pulmonary embolism
Elevated alveolar pressure
Increased tidal volumes
Increased I:E ratios
Increased PEEP

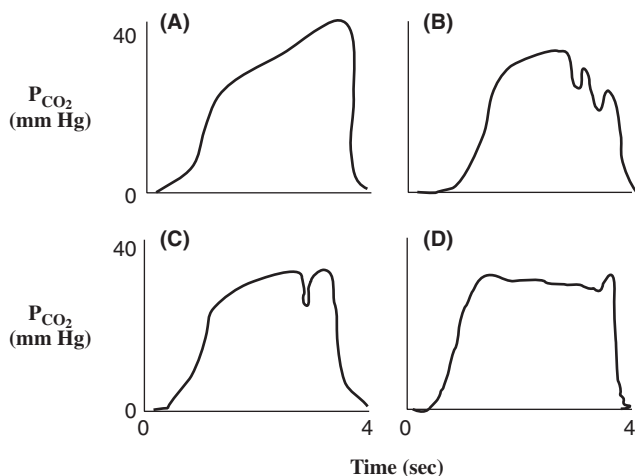

<sup>a</sup>Note that all entities that cause an increase in the  $P_{ET}CO_2-PaCO_2$  gradient are also factors that increase the alveolar dead space.

Abbreviation: PEEP, positive end expiratory pressure.

**Figure 1** The essential elements of a normal capnogram. The left-sided drawing depicts the anatomic components monitored, and the apparatus involved in the capnographic display. The right-sided drawing shows a normal capnographic display. Segment A–B represents the zero baseline during early exhalation of  $CO_2$ -free gas from the anatomic dead space. Segment B–C represents mixed dead space and alveolar gas. The degree of slope in segment B–C represents the unevenness of the exhalation time constants of various lung segments (i.e., if all empty at the same time in a normal fashion, the upstroke is nearly vertical). Segment C–D represents alveolar plateau phase. D represents the end-tidal value. Segment D–E represents inhalation. *Source:* From Ref. 6.

those with chronic obstructive pulmonary disease (COPD). However, an acute change in waveform during monitoring may represent mucous plugging, bronchospasm, or a partially kinked ETT. Changes in the shape of the capnographic waveform typically precede decreases in oxygenation, as would be detected by pulse oximetry monitoring; and thus capnography would potentially allow for earlier warning and intervention.

**Figure 2** Common abnormalities seen in the alveolar plateau phase of the capnogram. (A) Increased slope of alveolar plateau. This waveform is consistent with increased airway resistance. The increasing slope of the plateau phase (segment C–D from Fig. 1) represents a gradient in  $CO_2$  release from various alveoli as is commonly seen with bronchospasms or chronic obstructive pulmonary disease. (B) Cardiogenic oscillations. (C) Inspiratory effort during incomplete muscle relaxation during anesthesia. (D) Side-stream sampling tube leak. *Source:* Adapted from Ref. 60.

## Prediction of Outcome in Trauma Patients

Several studies have examined  $P_{ET}CO_2$  values and tried to extrapolate data on survivability after traumatic injury. As expected, Tyburski et al. (18) found the best survival rates in patients who had higher  $P_{ET}CO_2$  levels and a lower  $P_{ET}CO_2 - PaCO_2$  gradient at the end of emergency surgery. The same group followed these experiments with a study specifically examining the  $P_{ET}CO_2 - PaCO_2$  difference in over 500 patients. The average gradient of  $P_{ET}CO_2 - PaCO_2$  was less than 10 mmHg in all survivors at all times. The average gradient was greater than 10 mmHg in all nonsurvivors at all times (19). This difference also held true in patients who died more than 24 hours after surgery. Deakin et al. looked at prehospital  $P_{ET}CO_2$  values as a predictor of mortality. He found that at 20 minutes after intubation, a  $P_{ET}CO_2 < 3.25$  kPa ( $\sim 24.4$  mmHg) was associated with only a 5% survival rate to discharge rate (20). Aufderheide et al. showed that in cardiac arrest patients, the poor survival in hyperventilated patients may have been due to the decrease in cardiac preload, or may have been due to hypocarbia itself (which, in the authors' opinion, is the far less plausible explanation). As suggested earlier, whether or not the poor survival in trauma patients was a direct result of decreased  $P_{ET}CO_2$ , due to poor  $Q$  cardiac output and/or a decrease in cardiac preload against simple hyperventilation, as posited by the authors, remains unexplored.

Transcutaneous  $CO_2$  ( $T_cCO_2$ ) monitoring is a 20-year-old technology, which is enjoying a resurgence of interest. Heretofore,  $T_cCO_2$  monitoring was largely utilized in the neonatal intensive care units (NICUs). Commercially available versions of  $T_cCO_2$  measuring devices, such as the Novamatrix  $TCO_2M^{\text{®}}$  (Respironics, Inc., Murrysville, Pennsylvania, U.S.A.), combine the continuous measurement of  $T_cCO_2$  and  $O_2$ . Studies are being conducted to determine its reliability of  $T_cCO_2$  monitoring in adult SICU patients, and preliminary results look promising (21).

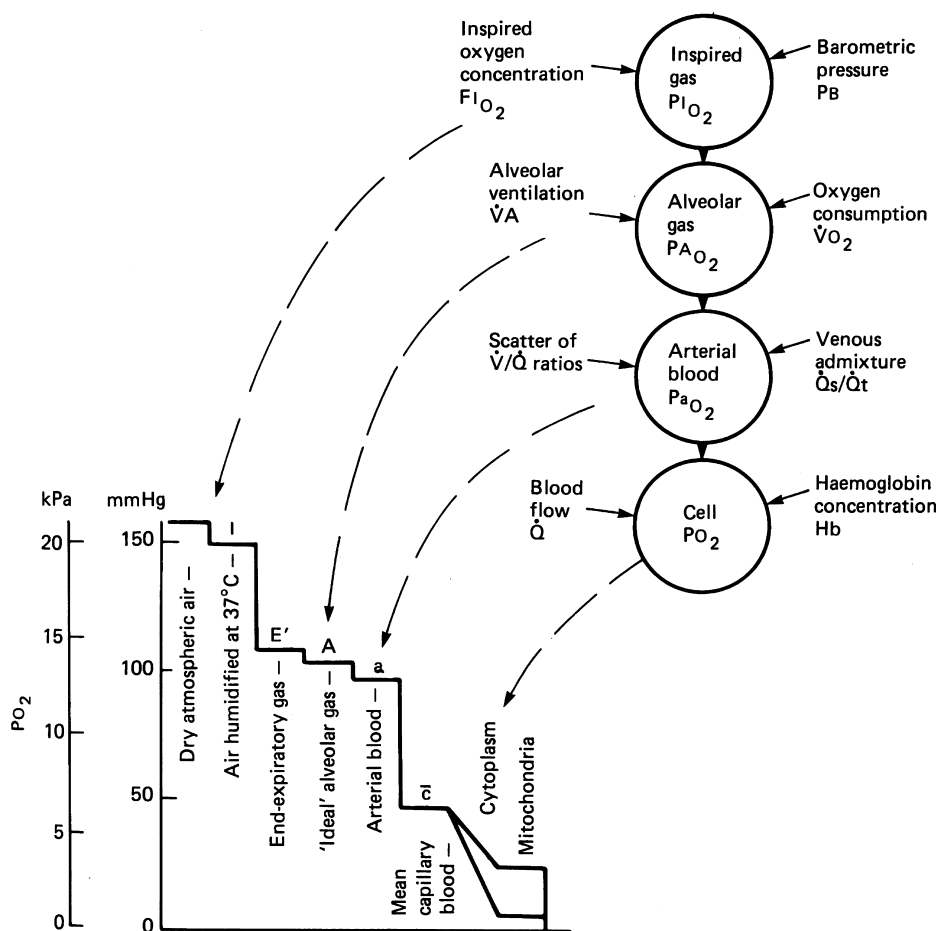

## OXYGEN MONITORING

Oxygen serves as the substrate for aerobic metabolism. After entering the body via the lungs,  $O_2$  travels down a partial pressure gradient from the atmosphere to its final site of action, the electron transport chain of mitochondria (Fig. 3). The  $O_2$  levels can be monitored at key sites along the way, including the inspired gas, the alveolar gas (reflected in the end tidal  $O_2$  concentration), the arterial blood, the mixed venous blood, and with transcutaneous sampling.

### Inspired Gas and Alveolar Gas Monitoring

Monitoring the  $O_2$  concentration of inspired gas is a necessity in anesthesia practice, and in other realms whenever the precise concentration of inhaled  $O_2$  is important (i.e., whenever the potential for delivering a hypoxic gas mixture exists). **All mechanical ventilators in use in the SICU should also have the ability to measure and continuously display the fraction of inspired  $O_2$  ( $F_{I}O_2$ ).** This becomes of increasing importance when gas mixtures such as heliox, nitrous oxide ( $N_2O$ ), and nitric oxide (NO) are administered (22). Monitoring the  $F_{I}O_2$  of patients who are not intubated is problematic, as only an approximation can be made. Because the supplemental  $O_2$  will blend with, and sometimes entrain, room air, the final  $F_{I}O_2$  is related to numerous factors including the flow rate of  $O_2$ , the site of

**Figure 3** The oxygen cascade. The left side (“Y axis”) shows the partial pressure of O<sub>2</sub> (PO<sub>2</sub>) in both KPa and mmHg. Oxygen moves down a partial pressure gradient from dry atmospheric air (±160 mmHg at sea level) to the mitochondria (±3–20 mmHg), which is the site of utilization. On the right/top is a summary of the factors influencing oxygenation at different levels in the cascade. Source: From Ref. 61.

administration (i.e., nasal vs. oral), the devices used (i.e., simple mask vs. a nonrebreather), along with the  $\dot{V}_E$  of the patient. The partial pressure of O<sub>2</sub> at the alveolus (P<sub>A</sub>O<sub>2</sub>) correlates directly with the F<sub>I</sub>O<sub>2</sub>, as shown in the alveolar air equation (Equation 1).

$$P_{A}O_2 = [F_I O_2 \cdot (P_B - P_{H_2O})] - [PaCO_2 / RQ] \quad (1)$$

### Arterial Blood Gas Monitoring

Loading of the oxygen from the alveoli to the red blood cells (RBCs) within the pulmonary circulation is often impaired in critically ill patients. Monitoring this pulmonary transfer of O<sub>2</sub> is a factor that is of interest to many intensivists. The multiple inert gas elimination technique has been cited as the gold standard of oxygen transfer monitoring, but its use is cumbersome and not widely available except in research settings (23). One of the simplest methods of quantifying oxygen transfer is by determining the alveolar arterial partial pressure of O<sub>2</sub> [P(A-a)O<sub>2</sub>] gradient, calculated as shown in Equation 2:

$$P(A - a)O_2 \text{ gradient} = P_A O_2 - PaO_2 \quad (2)$$

The P(A-a)O<sub>2</sub> gradient should be on the order of 7 to 14 mmHg for patients breathing room air. As a person ages, the normal PaO<sub>2</sub> decreases, and the P(A-a)O<sub>2</sub> gradient

conversely will increase. Breathing 100% oxygen (i.e., F<sub>I</sub>O<sub>2</sub> = 1.0) also results in a discrepancy in the calculation of the P(A-a)O<sub>2</sub> gradient. These two factors taken into account, an elderly patient breathing at an F<sub>I</sub>O<sub>2</sub> of 1.0 may have an P(A-a)O<sub>2</sub> gradient approaching 60 mmHg with healthy lungs. This example highlights one drawback to using the P(A-a)O<sub>2</sub> gradient. Following the P(A-a)O<sub>2</sub> gradient is most useful when examining trends. However, the F<sub>I</sub>O<sub>2</sub> must remain approximately the same to accurately reflect the changes. Table 3 reviews common causes for P(A-a)O<sub>2</sub> gradient abnormalities.

Another method of estimating pulmonary oxygen transfer is the PaO<sub>2</sub>/F<sub>I</sub>O<sub>2</sub> (P/F) ratio. The normal P/F ratio is ≥500 mmHg; acute lung injury (ALI) is defined as a P/F ratio ≤300 mmHg, and the acute respiratory distress syndrome (ARDS) is defined as a P/F ratio ≤200 mmHg. Although its attraction is its simplicity, inaccuracies occur under a host of conditions seen in critically ill patients such as low oxygen extraction (24), COPD (25), and large intrapulmonary shunt (26).

⚡ Both right-to-left transpulmonary shunt ( $\dot{Q}_s/\dot{Q}_t$ ) and low  $\dot{V}_A/\dot{Q}$  lung regions will contribute to an increase in the P(A-a)O<sub>2</sub> gradient. ⚡ The P(A-a)O<sub>2</sub> gradient does not readily distinguish between shunt (e.g., basilar atelectasis) and low  $\dot{V}_A/\dot{Q}$  (e.g., COPD) pathophysiology. Due to the sigmoid shape of the oxyhemoglobin dissociation curve, it

**Table 3** Hypoxemia

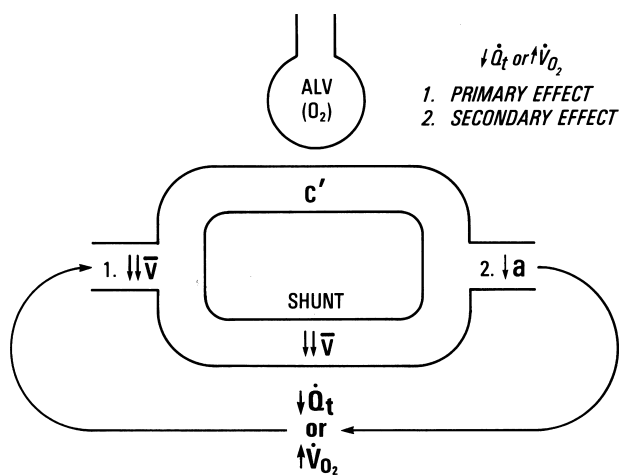

Normal P(A-a)O <sub>2</sub> gradient	Increased P(A-a)O <sub>2</sub> gradient
↓PIO <sub>2</sub>	Right-to-left shunting
↓F <sub>I</sub> O <sub>2</sub>	Transpulmonary
↓P <sub>B</sub>	Intracardiac
Hypoventilation	Diffusion defect
	Interstitial pulmonary fibrosis
	$\dot{V}/\dot{Q}$ mismatch

Abbreviations: (A-a)O<sub>2</sub> gradient, alveolar to arterial O<sub>2</sub> partial pressure gradient; PIO<sub>2</sub>, F<sub>I</sub>O<sub>2</sub> · P<sub>B</sub>; F<sub>I</sub>O<sub>2</sub>, fractional concentration of inhaled O<sub>2</sub>; P<sub>B</sub>, barometric pressure;  $\dot{V}/\dot{Q}$ ; ventilation/perfusion; ↓, low.

is evident that any given P(A-a)O<sub>2</sub> gradient is more significant as the P(A-a)O<sub>2</sub> decreases and hemoglobin begins to desaturate. Accordingly, a more precise measure of oxygenation deficit may be the actual determination of right-to-left transpulmonary shunt or venous admixture.

**Calculation of Right-to-Left Transpulmonary Shunt**

In a simple two-compartment lung model (Fig. 4), consisting of a perfused and oxygen-ventilated lung compartment and a shunt lung compartment that is normally perfused but not ventilated, the pulmonary shunt (QS) fraction can be readily

**Figure 4** Two-compartment lung model. Mixed venous blood ( $\bar{v}$ ) perfuses either ventilated alveolar (ALV O<sub>2</sub>) capillaries and becomes oxygenated end-pulmonary capillary blood (c') or perfuses whatever true shunt pathways exist and remains the same in composition (desaturated). These two pathways must ultimately join together to form mixed arterial (a) blood. If the cardiac output ( $\dot{Q}_T$ ) decreases and/or the O<sub>2</sub> consumption ( $\dot{V}O_2$ ) increases, the tissues must extract more oxygen per unit volume of blood than under normal conditions. Thus, the primary effect of a decrease in  $\dot{Q}_T$  or an increase in  $\dot{V}O_2$  is a decrease in  $\bar{v}O_2$  content. The  $\bar{v}$  blood with a decreased O<sub>2</sub> content must flow through the shunt pathway as before (which may remain constant in size) and lower the arterial content of O<sub>2</sub>. Thus, the secondary effect of a decrease in  $\dot{Q}_T$  or an increase in  $\dot{V}O_2$  is a decrease in arterial oxygen content. Source: From Ref. 62.

derived by using the shunt equation (Equation 3)

$$\dot{Q}S/\dot{Q}T = (Cc'_{O_2} - Ca_{O_2}) / (Cc'_{O_2} - C\bar{v}_{O_2}) \quad (3)$$

where  $\dot{Q}T$  is total cardiac output,  $Cc'_{O_2}$  is the end capillary O<sub>2</sub> content (C<sub>O<sub>2</sub></sub>), which represents the blood leaving the normal lung unit, and is a value that cannot be easily measured. The  $Cc'_{O_2}$  is assumed to be essentially the same as the PAO<sub>2</sub>, and for calculation purposes, its value is derived by using the alveolar air equation (Equation 1), as this represents ideal oxygenation of arterial blood. The  $C\bar{v}_{O_2}$  is the mixed venous C<sub>O<sub>2</sub></sub>, and is measured in the blood aspirated from the distal [pulmonary artery (PA)] port of the Swan-Ganz catheter. The C<sub>O<sub>2</sub></sub> for any sample of blood is calculated by using O<sub>2</sub> content equation (Equation 4).

$$C_{O_2} = [Hb] \times 1.34 \times \text{Sat } O_2 + 0.003 \times PO_2 \quad (4)$$

Intuitively, the numerator of the shunt equation quantifies the oxygenation deficit (ideal oxygenation,  $Cc'_{O_2}$ , minus actual oxygenation,  $Ca_{O_2}$ ), normalized by  $\dot{Q}t$ , which is estimated by the inverse of the denominator, that is,  $1/(Cc'_{O_2} - C\bar{v}_{O_2})$ . The term,  $1/(Cc'_{O_2} - C\bar{v}_{O_2})$ , closely approximates the expression,  $1/(Ca_{O_2} - C\bar{v}_{O_2})$ , which is proportional to  $\dot{Q}T$  during conditions of constant  $\dot{V}O_2$ , as given by rearrangement of the Fick equation (Equation 5).

$$\dot{Q}T = \dot{V}O_2 / (Ca_{O_2} - C\bar{v}_{O_2}) \quad (5)$$

As the  $\dot{Q}S/\dot{Q}T$  increases, the PaO<sub>2</sub> will decrease in a patient breathing the same F<sub>I</sub>O<sub>2</sub>. Thus, the ultimate PaO<sub>2</sub> depends also upon the F<sub>I</sub>O<sub>2</sub> and the  $\dot{Q}S/\dot{Q}T$ , provided the other parameters remain stable. However, the greater the  $\dot{Q}S/\dot{Q}T$  the less important is the F<sub>I</sub>O<sub>2</sub> at determining the final PaO<sub>2</sub> (see Volume 2, Chapter 2). In addition, the Ca<sub>O<sub>2</sub></sub> can be decreased by a decline in the  $\dot{Q}T$  (at a constant  $\dot{V}O_2$ ) and by an increased  $\dot{V}O_2$  (for a constant  $\dot{Q}T$ ). In either case (decreased  $\dot{Q}T$  or increased  $\dot{V}O_2$ ), along with a constant right-to-left shunt, the tissues must extract more O<sub>2</sub> from the blood per unit blood volume. Therefore, the  $C\bar{v}_{O_2}$  must primarily decrease (Fig. 4). When the blood with lower  $C\bar{v}_{O_2}$  passes through whatever shunt that exists in the lung and remains unchanged in its oxygen composition, it must inevitably mix with oxygenated end pulmonary capillary blood (c' flow) and secondarily decrease the Ca<sub>O<sub>2</sub></sub> (Fig. 4). The pulmonary shunt fraction ( $\dot{Q}S/\dot{Q}T$ ) is normally less than 5%. However, many conditions in trauma and critical care increase the  $\dot{Q}S/\dot{Q}T$  including atelectasis, pneumonia, cardiogenic and noncardiogenic pulmonary edema, pneumothorax, hemothorax, and pulmonary contusion to name a few. Atelectasis is one of the most common problems that can dramatically increase  $\dot{Q}S/\dot{Q}T$  in patients with otherwise normal lungs (Fig. 5).

If the lung is ventilated with an F<sub>I</sub>O<sub>2</sub> < 1.0, then the oxygenation defects resulting from low  $\dot{V}A/\dot{Q}$  units are added to it due to shunt regions. In this case, Equation 3 becomes an expression of the so-called venous admixture ( $\dot{Q}V_A$ ). An attempt to discriminate between pulmonary shunt units ( $\dot{V}A/\dot{Q} = 0$ ) and venous admixture units (low  $\dot{V}A/\dot{Q}$ ) can be made by placing the patient on 100% O<sub>2</sub> ventilation. Then, the difference between the venous admixture fraction and the shunt fraction will estimate the amount of low  $\dot{V}A/\dot{Q}$  units. However, this approach is limited because low  $\dot{V}A/\dot{Q}$  lung units may collapse and

**Figure 5** Association between shunt fraction and atelectasis in a normal subject. Atelectasis percentage data is derived from computed tomography scans taken through the caudal lung, just above the diaphragm, and right–left transpulmonary shunt ( $\dot{Q}_s/\dot{Q}_t$ ) is calculated as a percent of the total cardiac output ( $\dot{Q}_t$ ) during anesthesia. In this study, there was a close correlation according to the equation: shunt = atelectasis area + 1.7 ( $r = 0.1$ ,  $P < 0.01$ ). *Source:* From Ref. 63.

convert themselves to shunt units during  $O_2$  breathing (i.e., absorption atelectasis).

Venous admixture can be calculated if a PA catheter is in place, but requires numerous calculations. A simplified version of this equation was developed by Rasanen et al. (27) in 1988. These investigators termed this shunt approximation as the  $\dot{V}/\dot{Q}$  index (Equation 6).

$$\dot{V}/\dot{Q} \text{ index} = \frac{1 - SaO_2}{1 - SvO_2} \quad (6)$$

The  $\dot{V}/\dot{Q}$  index ignores content calculations and substitutes only the saturations (assuming the pulmonary capillary saturation is 100%). Then the pulse oximeter saturation and mixed venous saturations and all that are required. The attractiveness of this equation is the ability to approximate shunt instantly from a continuous cardiac output PA catheter and a pulse oximeter. An example calculation is provided from a patient with a  $SaO_2 = 90\%$  (or 0.9) and  $SvO_2 = 60\%$  (or 0.6) the calculation would be as shown in Equation 7.

$$\dot{V}/\dot{Q} \text{ index} = \frac{1 - 0.9}{1 - 0.6} = \frac{0.1}{0.4} = 0.25 \quad (7)$$

The 25% shunt calculated fails to reflect the severity of respiratory failure. Indeed, a  $\dot{V}/\dot{Q}$  index of 0.25 for a patient breathing  $F_{I}O_2 = 1.0$  is far worse than a  $\dot{V}/\dot{Q}$  index of 0.25 for a patient breathing  $F_{I}O_2 = 0.3$ .

### Complications with Arterial Blood Gas Measurement

An arterial puncture to obtain the sample may cause spasm, clot, hematoma, and distal ischemia, all of which need to be addressed immediately to prevent serious morbidity. The predictive value of the Allen's test in determining collateral flow to the palmar arch has been shown to be poor, and alternatives have been suggested (28). Care must be taken in those patients who are anticoagulated and those who have arterial occlusive diseases, such as Raynaud's disease.

If an arterial line is used, an adequate amount of dead space volume must be removed from the line before an accurate sample can be obtained.

A recent study suggests that discarding twice the dead space volume will ensure accurate blood gases and electrolytes, while preventing unnecessary blood loss (29). Returning the dead space blood to the patient and using pediatric vials further diminishes the blood loss. Blood gases should be analyzed immediately after they are obtained to decrease the effects that metabolism and gas diffusion through the syringe have on the sample. The temperature of the patient may cause erroneous measurements. The solubility of oxygen increases as blood is cooled. By convention, blood gas analyzers are maintained at  $37^\circ\text{C}$ . In a hypothermic patient, the  $PaO_2$  will be artificially elevated. Much debate has occurred over the years whether or not to correct for temperature. If the change in temperature is mild to moderate, it does not appear that temperature correction has any significant effect on therapy (30).

### Complications with Pulse Oximetry Measurement

☞ Pulse oximetry relies on three principles: impedance plethysmography, absorption spectrophotometry, and the Beer-Lambert law. ☞ It distinguishes arterial blood from that of venous and capillary blood by relying on the fact that only arterial blood pulsates. All other sources of fluctuating light absorption are filtered out. Current pulse oximeters measure at two light wavelengths: 660 nm (red) and 940 nm (infrared). The effects of carbon monoxide (CO) on pulse oximetry have been studied in animals (31). Hemoglobin bound to CO (carboxyhemoglobin) absorbs light at 660 nm similarly to oxyhemoglobin, and at 940 nm it is virtually invisible to the photodetector. The result is that carboxyhemoglobin is spuriously detected by the pulse oximeter as oxyhemoglobin and the saturation levels of carboxyhemoglobin are artifactually elevated. Methemoglobin's effect on pulse oximetry has also been studied in animals (32). At both 660 nm and 940 nm, methemoglobin absorbs light equally. This corresponds to a saturation reading of 85% on a typical pulse oximeter calibration algorithm. Other causes of artifacts in pulse oximetry reading are listed in Table 4.

Despite the large number of artifacts affecting the pulse oximetry reading, it is an invaluable tool in reducing the occurrence of hypoxia in the TRS, the trauma OR, and the SICU. Patients with a high likelihood to have significant hemoglobin species other than oxy- and deoxyhemoglobin include inhalation burn victims (elevated carboxyhemoglobin) and those who have received benzocaine or prilocaine local anesthetics (elevated methemoglobin). These patients should have their  $O_2$  saturation evaluated by a cooximeter

**Table 4** Causes of Pulse Oximetry Artifact

with the ABG sample rather than the pulse oximeter, which will be erroneous.

### Mixed Venous Oximetry

Mixed venous oximetry is an extension of pulse oximetry. Specially designed PA catheters emit light, which are reflected off of intact RBCs, down one set of fiberoptic cables. The light is carried by another set of fiberoptic cables to the photodetector. Mixed venous oxygen content is determined by the following formula:

$$SvO_2 = SaO_2 - [\dot{V}O_2 / (\dot{Q} \times 1.36 \times Hgb)]$$

where  $\dot{V}O_2$  is oxygen consumption,  $\dot{Q}$  is cardiac output, and Hgb is hemoglobin concentration. From the formula, it is easy to see that a decrease in mixed venous oxygen saturation is caused by either a decrease in  $\dot{Q}$  or a decrease in hemoglobin concentration, provided the oxygen consumption remains fixed. Causes of increased oxygen consumption that would decrease mixed venous saturation include sepsis, malignant hyperthermia, fever, and thyrotoxicosis. Continuous mixed venous saturation monitoring does not indicate to the practitioner the exact source of the disruption, but it does provide a finite list of them, which can be used in clinical assessment of the critically ill patient. The use of central venous saturation has gained attention as it does not require the placement of a PA catheter, but at least one recent study found lack of equivalence between these two methods (33). At the very least, the trends of central venous saturation and mixed venous saturation are interchangeable, and monitoring the trend may be of more clinical significance (34).

### Tissue Oxygen Monitoring

Monitoring the oxygen at the tissues can either be noninvasive (cerebral oximetry, transcutaneous  $PO_2$ ) or invasive. Transcutaneous  $PO_2$  requires equipment maintenance, warmup time, and can result in skin burns. It has largely been replaced in the clinical setting by pulse oximetry. The data on cerebral oximetry is seemingly equivocal. Invasive tissue monitoring is fraught with complications and this provides information only about the tissue that the probe is located within.

### Near Infrared Spectroscopy

A newer modality for cerebral ischemia monitoring is near infrared spectroscopy (NIRS). **✦ NIRS is a technology designed to measure the adequacy of cerebral blood flow (CBF), but remains controversial because there is no universal agreement about normal values and the permissible degree of change. ✦** The device utilizes infrared light of wavelengths 600–1300 nm to penetrate human tissue to a depth of several centimeters. Within the human brain this light is attenuated by the chromophores oxyhemoglobin, deoxyhemoglobin, and oxidized cytochrome aa3. Positioning a near infrared light source and a photodetector in a side-by-side configuration detects light attenuated and reflected in a parabolic path through the scalp, skull, and brain tissue (35). The standard probe placement of the NIRS devices is on the forehead, thus providing an estimation of tissue  $O_2$  saturation in the vascular bed (primarily the venous component) of frontal lobes.

The most commonly utilized commercially available devices are the INVOS line of devices (Somanetics Corporation, Troy, Michigan, U.S.A.). Although the INVOS-3100

was introduced over a decade ago, and was utilized with minimal outcome data generated, questions arose regarding the validity of normal measurements and the meanings of abnormal numbers. The most notorious was the study by Schwartz et al. (36) who measured NIRS in 18 dead patients. They found that 6 of the 18 dead subjects (with obviously no cerebral blood flow) had values above the lowest values found in the healthy adults (or = 60%). Additionally, Lewis et al. (37) found poor correlation between NIRS and jugular venous saturation readings in head-injured patients. These findings raise serious concerns about the reliability of regional saturation ( $rSO_2$ ) values obtained in adults by current generation NIRS monitoring devices.

The newest version of the INVOS line, the 5100B, provides an onscreen trend (graph) display, and is updated every 30 or 60 seconds (depending upon the settings). The generated data can be stored for one hour to 24 hours, and retrieved via supplied RS-232 port. The other widely used, commercially available device is the NIRO-300® (Hamamatsu Photonics K.K., Hamamatsu City, Japan). Although these devices are based upon the same principle, they both utilize different algorithms; however, studies generated on one device are not directly comparable with the other. Furthermore, currently no specific indications for these devices exist, and studies are still needed to correlate NIRS values with neurologic outcomes for various procedures (see “Eye to the Future” section).

### Monitoring the Splanchnic System: Gastric Tonometry

Gastric tonometry uses the measurement of gastric intramucosal pH (pHim) as a method of determining the adequacy of oxygenation and perfusion of the splanchnic bed. Gastric pHim measurements are made to assess the adequacy of perfusion of the splanchnic circulation. The splanchnic circulation may be particularly prone to injury as a consequence of hypoperfusion. Hypoperfusion-related tissue to the splanchnic circulation may allow intestinal bacteria and endotoxins to gain access to the systemic circulation (38). This so-called translocation of bacteria in hypoperfused patients may trigger the elaboration of several mediators of inflammation (interleukins, tumor necrosis factor, and activated white cells) that, in turn, contributes to the sepsis-like state of circulatory failure, which leads eventually to multiple organ failure (39). In an investigation in adult patients with acute circulatory failure, pHim was a highly predictive correlate of survival/nonsurvival, and its predictive accuracy was better than that of serum lactate determinations and greatly exceeded that of  $\dot{D}CO_2$ ,  $\dot{V}CO_2$ , and cardiac index (39).

Because pHim requires steady-state conditions to establish baseline perfusion, it has been used more as an intensive care unit (ICU) management tool than as a monitor during initial resuscitation. Gastric pHim is calculated, using the Henderson-Hasselbach equation, from measurements of intragastric  $PCO_2$  and arterial bicarbonate concentration. First, the intragastric  $PCO_2$  is obtained via tonometry (using a small, saline-filled intragastric balloon). Next, the serum  $[HCO_3^-]$  is measured, and the machine then calculates the pHim. At least one gastric tonometry device is available commercially (Tonocap; Instrumentarium Corp., Helsinki, Finland; and, Datex-Ohmeda). Gastric tonometry is discussed in greater detail in Volume 2, Chapter 10.

## EYE TO THE FUTURE

As described earlier,  $T_C\text{CO}_2$  and  $\text{O}_2$  measurements are routinely used in pediatric ICUs in order to avoid serial arterial punctures; these technologies should likewise be utilized in adult units. A recent study involving COPD patients showed that  $T_C\text{CO}_2$  values accurately reflected  $\text{PaCO}_2$  values during mechanical ventilation in COPD patients (40). However, the accuracy of these data seem to be restricted to patients with  $\text{PaCO}_2$  values of  $<56$  mmHg (40).

Currently no reliable monitoring modality allows clinicians to assess the efficacy of CPR. As discussed earlier in this chapter,  $P_{\text{ETCO}_2}$  provides an indication of the  $\dot{Q}$  produced by chest compressions and can indicate return of spontaneous circulation. This fact is now also endorsed by the recent American Heart Association Guidelines for Cardiopulmonary Resuscitation (41). However, to accurately assess the  $\dot{Q}$ , one needs to evaluate the  $P_{\text{ETCO}_2}$ - $\text{PaCO}_2$  gradient. In the prehospital setting, ABG analysis may not be available. However, the  $T_C\text{CO}_2$  values closely approximate the  $\text{PaCO}_2$  and can likely be used as a surrogate, but this remains to be validated.

With regard to  $\text{O}_2$  monitoring the future resides in increasing the ability to measure the saturation of various specific tissues, such as splanchnic and renal circulation (Volume 2, Chapter 10), cerebral (Volume 2, Chapter 7), etc. In terms of cerebral oximetry (introduced above), both the INVOS-5100<sup>®</sup> and the NIRO-300<sup>®</sup> are increasingly studied as indicators of CBF and cerebral tissue oxygenation. Although the data in TBI patients are mixed (37,42–47), these instruments have recently been used with some success in patients with cardiopulmonary bypass (CPB) (48–53), subarachnoid hemorrhage (54), and in carotid surgery (55,56).

Investigators are beginning to define threshold values for animals in various settings. Hagino et al. (53) studied pigs undergoing CPB, and were able to define a minimum safe flow rate during CPB in these animals using the NIRO-300<sup>®</sup>. Pigs were placed on CPB and cooled to various levels, and then run on various levels of low flow perfusion. Animals with an average tissue oxygenation index of less than 55% showed cerebral injury, whereas animals with an index of greater than 55% showed minimal or no evidence of injury (53).

The contribution of extracranial blood (57), and other artifacts continues to be a problem in some settings. In addition, comparisons between the various commercially available NIRS devices (e.g., NIRO-300 and the INVOS-5100) are only qualitative currently, as both manufacturers utilize different methodological approaches (including diodes with varying band widths and different algorithms to calculate saturations) (58). Once these concerns are addressed, the authors expect NIRS to become more widely employed in the near future, and ultimately begin to provide clinically useful in certain realms, such as CPB, carotid endarterectomies, and certain neurosurgical procedures. Additional research is required before the role of NIRS in trauma and critical care can be defined.

## SUMMARY

Monitoring gas exchange in patients who have undergone traumatic injury ranges from the simple, noninvasive monitoring to the more invasive and complex modalities. In the acutely decompensating patient, time to place a PA catheter is a luxury that is rarely afforded. Pulse oximetry

has gained acceptance as a universal monitor, since its introduction to the OR in the 1980s. Capnography which is well known to anesthesiologists, has yet to gain such widespread favor in the resuscitation area and the ICU. Despite the benefits of continuous  $P_{\text{ETCO}_2}$  monitoring, one study found that in the centers that did have access to it, more than half “rarely” or “never” used it (59). It is perhaps the simplest and easiest-to-implement monitor that has yet to catch on.  $T_C\text{CO}_2$  monitoring is in clinical use, but it cannot provide all of the useful information that is made available by capnography. Monitoring  $\text{O}_2$  comprises testing the concentration of it at various points on its cascade from the atmosphere to the tissues. Currently, tissue oxygen monitoring is in its preliminary stage, and advances are eagerly anticipated.

## KEY POINTS

- ☞ Exhaled gas  $\text{CO}_2$  concentrations provide physiologic information about both systemic perfusion and pulmonary function.
- ☞ The  $P_{\text{ETCO}_2}$  provides information about four important issues: (i) the correct placement of the ETT, (ii) the ventilation status, (iii) the cardiac output ( $\dot{Q}$ ), and (iv) the metabolic status of the patient.
- ☞ The American Society of Anesthesiologists Difficult Airway (ASADA) guidelines, along with the ACLS<sup>®</sup> guidelines now recommend secondary confirmation of ETT placement with exhaled  $\text{CO}_2$  measurement or an esophageal detector device (EDD) as it has become increasingly recognized that physical exam alone is error prone.
- ☞ In patients with fixed ventilation/perfusion ( $\dot{V}/\dot{Q}$ ) relationships in the lungs, and stable minute ventilation ( $\dot{V}_E$ ), the  $P_{\text{ETCO}_2}$  is proportional to the  $\dot{Q}$  (9).
- ☞ A low  $P_{\text{ETCO}_2}$  value in multitrauma patients usually reflects insufficient  $\dot{Q}$  (i.e., under resuscitation) and a resultant high ( $\dot{V}/\dot{Q}$ ) as mentioned previously.
- ☞ An exaggerated upstroke in segment C–D (also known as the plateau phase), as shown in Figure 2A, indicates an increase in airway resistance with associated  $\dot{V}/\dot{Q}$  spread among the millions of alveoli.
- ☞ All mechanical ventilators in use in the SICU should also have the ability to measure and continuously display the fraction of inspired  $\text{O}_2$  ( $F_{\text{I}\text{O}_2}$ ).
- ☞ Both right-to-left transpulmonary shunt ( $\dot{Q}_s/\dot{Q}_t$ ) and low  $\dot{V}_A/\dot{Q}$  lung regions will contribute to an increase in the  $P(A-a)\text{O}_2$  gradient.
- ☞ Pulse oximetry relies on three principles: impedance plethysmography, absorption spectrophotometry, and the Beer-Lambert law.
- ☞ NIRS is a technology designed to measure the adequacy of CBF, but remains controversial because there is no universal agreement about normal values and the permissible degree of change.

## Cardiovascular Monitoring

William C. Chiu

Department of Surgery, R Adams Cowley Shock-Trauma Center, Baltimore, Maryland, U.S.A.

### INTRODUCTION

The clinical assessment and monitoring of the cardiovascular system is a fundamental necessity in severely injured and critically ill surgical patients to ensure optimal resuscitation and perfusion of organ systems. Traditional methods for cardiovascular evaluation were able to determine heart rate (HR), rhythm, and blood pressure using simple noninvasive means. The application of various invasive intravascular catheters then provided us with continuous pressure and flow measurements and was revolutionary to advanced hemodynamic monitoring. Now, current technological advances are returning to the development and perfection of noninvasive tools, with the hope that they will have the ability to acquire hemodynamic data with similar accuracy and reliability as invasive devices currently provide.

Many situations in critically ill trauma and surgical patients warrant monitoring of the heart and circulation. Guidelines from the American College of Cardiology (ACC)/American Heart Association (AHA) outline certain comorbid conditions that increase cardiac risk in surgical patients (Table 1) (1). Among these clinical predictors are ischemic coronary disease, congestive heart failure, significant dysrhythmias, and valvular heart disease. In the previously healthy patient, traumatic injury to the heart or aorta may require hemodynamic monitoring to ensure tissue oxygen delivery, while minimizing cardiac contractile force (2). Conversely, injuries to the central nervous system may require hemodynamic monitoring to facilitate resuscitation from neurogenic shock, and therapies to maintain cerebral and spinal cord perfusion pressure. Patients with significant blood loss from injury or surgery require monitoring to optimize resuscitation and determine response to therapy. In particular, geriatric blunt-trauma patients may have occult hypoperfusion, and are at risk for untreated shock (3). Finally, those patients developing overwhelming inflammatory response from trauma or sepsis require monitoring to limit organ system failure, and to guide supportive measures.

This chapter will provide a review of the tools in the intensivist's armamentarium to evaluate and monitor hemodynamics in the intensive care unit (ICU). These devices include electrocardiography, arterial pressure monitoring, central venous pressure (CVP) monitoring, pulmonary artery catheter (PAC) monitoring, and cardiac output monitoring. The focus of this chapter will be on the utilization of these devices and interpretation of the acquired data in the ICU. Further discussion on initial assessment of circulation and shock in the emergency room (see Volume 1, Chapter 12), preoperative evaluation and preparation (see Volume 1, Chapter 17), basic cardiovascular physiology

(see Volume 2, Chapter 3), and management of cardiovascular problems in the ICU (see Volume 2, Chapters 17–22) can be found in other chapters of this book.

### ELECTROCARDIOGRAPHY

Monitoring HR and rhythm has become a standard of care for patients admitted to the ICU. Einthoven first noted that the electrical activity of the heart produces electrical currents at the skin, giving rise to the development of surface electrocardiography. The electrocardiogram (ECG) depicts the electrical events of the heart, providing information on cardiac impulse morphology, HR, and abnormalities of these components. While a static 12-lead ECG may be comprehensive for the diagnosis of cardiac electrical abnormalities, continuous monitoring of one or two leads in the ICU allows the early detection of most HR changes, ischemic changes, transient abnormal beats, and dysrhythmias.

### Heart Rate and Pulse Monitoring

Although the terms HR and pulse rate are commonly used interchangeably in clinical situations, there are subtle differences and implications that distinguish the two terms. The term HR, itself, may represent either the frequency of cardiac electrical activity or the frequency of cardiac contractions. The mechanical contraction results in ejection of blood into the aorta, which can be palpated in the arteries as a pulse. Natural coupling of electrical and mechanical cardiac events results in a condition where the pulse is equal to the electrically monitored HR. Certain conditions, such as pulseless electrical activity (PEA), are marked by a dissociation of electrical and mechanical events resulting in an electrical HR unequal to the mechanical HR.

Continuous ECG monitoring displays the electrical activity of the heart and is the best method for determining electrical HR, but does not always accurately reflect the mechanical HR (pulse). Since most modern telemetry monitors continuously display a computer-derived HR, it is critical that the clinician distinguish between cardiac electrical activity and artifacts. Inadequate electrode-skin contact or electrical interference within the monitoring equipment may produce artifacts resulting in an inaccurately derived HR. Patient motion or shivering may produce artifactual activity on the display. High-amplitude P or T waves may be incorrectly counted as QRS complexes by the telemetry computer, resulting in falsely elevated rates. In those patients with pacemakers, telemetry monitors may display the rate of pacemaker spikes. It is incumbent on the clinician

**Table 1** Clinical Predictors of Cardiac Risk*Major clinical predictors*

Unstable coronary syndromes

Recent MI

Unstable angina

Decompensated CHF

Significant dysrhythmias

High-grade AV block

Symptomatic dysrhythmias

SVT

Severe valvular disease

*Intermediate clinical predictors*

Mild angina pectoris

Prior MI

to determine if electrical capture is present, and to evaluate whether there is a resultant mechanical contraction.

Accurate determination of mechanical HR, when necessary, may be assessed several ways: (i) observing the arterial pressure waveform of an intra-arterial catheter, (ii) observing ventricular contractions at echocardiography, or (iii) by observing change in pressures using a pulmonary artery catheter. Auscultation for cardiac sounds alone is often unreliable in the ICU, especially when HR is rapid and when there is excessive ambient noise. The most practical clinical estimate of mechanical HR is the pulse rate palpated at a peripheral arterial site.

The pulse rate typically equals the mechanical HR, except in conditions of irregular ventricular contractions such as ventricular fibrillation, conditions in which the contractile force is especially weak, or in association with perfusion deficit to the peripheral site. Pulse rate and rhythm information adds a valuable adjunct to complete evaluation of cardiac dysrhythmias. Accurate measurement of pulse rate depends on measuring pressure changes with an intra-arterial catheter, but may be estimated if a pulse oximeter is available. While palpation of peripheral pulse has similar shortcomings to auscultation of the heart in the ICU, it may be the most rapid method to assess pulse rate in those patients without other monitoring devices.

ECG lead II, displaying the electrical vector from the right arm electrode to the left leg electrode, is most commonly used for routine continuous monitoring. This lead best parallels the direction of forward electrical conduction, and results in the greatest P wave voltage of any surface lead configuration. The ability to rapidly detect and analyze P wave presence and regularity best facilitates evaluation of an abnormal rhythm. Placement of the limb electrodes is routinely adjusted proximal to the standard positions of the wrists and ankles, by placing arm electrodes over

the shoulders and leg electrodes over the lower torso (Fig. 1). This modification reduces electrical noise from extremity muscle contractions, while preserving the triangular cardiac axes.

**Ischemia Monitoring**

☞ **The precordial leads are the most sensitive for detecting myocardial ischemia in the operating room; this is presumably true in the ICU as well.** ☞ Indeed, London et al. studied a large cohort of patients with known coronary artery disease undergoing noncardiac, mainly vascular surgery and found that V<sub>5</sub> was most sensitive, detecting 75% of ischemic events (4). Simultaneously monitoring both leads, V<sub>4</sub> and V<sub>5</sub>, increased sensitivity to 90%, whereas the standard II and V<sub>5</sub> array was only 80% sensitive. Because lead II is most sensitive for P wave evaluation and detects inferior wall ischemia, simultaneous monitoring of lead II and V<sub>5</sub> is recommended. The V<sub>5</sub> lead is classically placed over the left fifth intercostal space, in the anterior axillary line (also see Volume 2, Chapter 19).

**ST Segment Depression**

ECG changes suggestive of myocardial ischemia may occur with or without any associated clinical symptoms (e.g., chest pain, shortness of breath, dizziness, nausea) or signs (e.g., tachycardia, tachypnea, hypotension, or hypoxia). The recognition of acute ECG changes allows for the early detection and management of myocardial ischemia. ☞ **ST segment depression is the most common manifestation of subendocardial myocardial ischemia.** ☞ ST segment depression is commonly encountered during provocative ischemia studies (e.g., treadmill test), and clinically when perfusion pressure to a stenotic coronary artery drops below a critical threshold value (Fig. 2). The ST segment is that part of the ECG trace that immediately succeeds the QRS. The point at which it “takes off” from the QRS is called the J (junction) point. The position of the ST segment relative to baseline and its slope should be noted and monitored. Changes in the level of the ST segment are measured at the beginning of the ST segment (i.e., the “J” point), and are compared to the level of the isoelectric line, also known as the T-P segment. The standard criterion for diagnosing ischemia is ST segment depression of  $\geq 0.10$  mV or 1 mm (on a standard amplitude signal calibration of 1 mV = 10 mm), with a downsloping depression representing worse ischemia than a horizontal or upsloping segment (5).

**ST Segment Elevation**

☞ **Acute transmural myocardial ischemia, or infarction, results in acute ST segment elevation.** ☞ ST segment elevation of >1 mm from the J point is considered abnormal for women. However, ST segment elevation of 2 mm is the threshold for men. Indeed, 1 mm of ST segment elevation is normal for 90% of males, and the presence of prior myocardial infarction (MI) and other conditions must also be considered (6). In patients with Q waves, ST segment elevation may be related to wall motion abnormalities. In patients without Q waves, leads with ST segment elevation are very specific indicators of the location of ischemia. T wave inversions and new Q waves are suggestive of either recent or evolving MI. For more detailed information on the diagnosis and treatment of myocardial ischemia, the reader is referred to Volume 2, Chapter 19.

**Figure 1** Recommendations for placement of 12-lead electrocardiogram electrodes. Electrodes are routinely adjusted proximal to the standard positions of the wrists and ankles by placing arm electrodes over the shoulders and leg electrodes over the lower torso for patients in the operating room, surgical intensive care unit, and during exercise testing. *Abbreviations:* RA, right arm; LA, left arm; RL, right leg; LL, left leg. *Source:* From Ref. 5.

**Dysrhythmia Monitoring**

Similar to monitoring for myocardial ischemia, continuous ECG monitoring in the ICU allows the early detection of changes in cardiac rhythm, or those dysrhythmias that are transient or episodic. The analysis of a dysrhythmia involves the delineation of three characteristics—*anatomic origin,*

*discharge sequence,* and *conduction sequence* (7). After initially identifying the dysrhythmia as a bradycardia (ventricular rate <60) or a tachycardia (ventricular rate >100), the next priority in the analysis involves determining whether the origin of the electrical impulse is sinoatrial (SA), atrial, atrioventricular (AV), or ventricular. P waves

**Figure 2** Abnormal and borderline ST segment depression criterion. ST depression is specific for ischemia when depressed greater than or equal to 1.0 mm, and flat or downsloping. The ST segment depression is borderline when ranging between 0.5 and 1.0 mm and flat or downsloping, or as much as 2.0 mm depressed but upsloping. *Source:* From Ref. 5.

**Table 2** Common Dysrhythmias in the Intensive Care Unit

<i>Supraventricular</i>	
Sinus tachycardia	
Sinus bradycardia	
Sinus arrest	
Sick sinus syndrome	
Sinus node re-entrant tachycardia	
Atrial fibrillation	
Atrial flutter	
Multifocal atrial tachycardia	
Ectopic atrial tachycardia	
Atrial re-entrant tachycardia	
<i>Atrioventricular</i>	
Atrioventricular junctional rhythm	
Accelerated atrioventricular junctional rhythm	
Atrioventricular nodal re-entrant tachycardia	
Wolff-Parkinson-White syndrome	
<i>Ventricular</i>	
Ventricular tachycardia	
Ventricular flutter	
Ventricular fibrillation	

suggesting SA node origin are best observed in lead II, while leads III, aV<sub>F</sub> and V<sub>1</sub> may be alternates. Lack of P waves or abnormal P wave morphology indicates an origin other than the SA node, and associated QRS complex widening may help localize the source to the AV junction or the ventricles.

A full ECG rhythm strip is critical in the analysis of dysrhythmias. Only with a rhythm strip can an adequate assessment be made, regarding whether the discharge sequence is normal sinus rhythm, atrial flutter, or atrial fibrillation, or whether some other ectopic or multifocal pattern exists. Conduction sequence analysis involves the determination of whether the electrical conduction pattern is normal, delayed, blocked, or aberrant. These identifying points facilitate appropriate treatment selection. Table 2 outlines the most common dysrhythmias encountered in surgical patients, and a more detailed discussion on the diagnosis and therapy of dysrhythmias can be found in Volume 2, Chapter 20.

## ARTERIAL PRESSURE MONITORING

### Physiology of Systemic Arterial Pressure

The function of the systemic arterial system is to distribute oxygenated blood to the capillary beds throughout the body, and to serve as a hydraulic filter and reservoir (8). Measurement of arterial blood pressure provides a quantitative assessment of the status of the hydraulic pressure head supplying the cardiovascular system. The mean arterial pressure (MAP) is the average blood pressure during the cardiac cycle. The MAP can be expressed by a cardiovascular equivalent of Ohm's law ( $E = I \times R$ ; energy potential = current  $\times$  resistance) as follows:

$$\dot{Q} \times \text{SVR} \quad (1)$$

where  $\dot{Q}$  is the cardiac output and SVR is the systemic vascular resistance. Thus, the blood pressure is dependent

**Figure 3** Mean arterial pressure throughout the normal circulation. Normal mean arterial blood pressure throughout the circulation is depicted by the continuous trace beginning in the left heart, and continuing through to the pulmonary veins. The systolic/diastolic pulse pressure is shown for the aorta, large arteries, and small arteries as a solid upright line, the top of which indicates the systolic pressure and the bottom of which indicates the diastolic pressure. *Source:* From Ref. 60.

upon the  $\dot{Q}$  [ $\text{HR} \times \text{stroke volume (SV)}$ ] and the SVR:

$$\dot{Q} = \text{HR} \times \text{SV} \quad (2)$$

The SV is dependent upon the preload, afterload, and contractility of the heart. The SVR is chiefly governed by the level of sympathetic stimulation. If SVR and HR are held constant, then the SV will correlate directly with the blood pressure. Indeed, Cullen found a correlation coefficient of 0.82 between changes in SV and systolic blood pressure (9).

✎ **The MAP is highest in the ascending aorta, and drops minimally until the peripheral arteriolar bed is reached (Fig. 3) (10).** ✎ Accordingly, in normal patients, the MAP measured in the larger arteries (radial, femoral, dorsalis pedis) will be an accurate measure of the MAP at the aorta. The pressure in the arterial system drives the flow of blood toward the arterioles and through the capillary system. Blood flow through the vast majority of the arterial system is fairly continuous (except for the proximal aorta), as only about 20% of the flow wave is pulsatile. The ascending aortic flow is quite pulsatile, with almost no flow occurring during diastole (except to the coronary arteries). Similarly, the arch of the aorta undergoes retrograde flow during diastole, as blood flows out the arch vessels from blood stored in the thoracic aorta. Blood flows out of the distal aorta at a relatively slow 0.5 m/sec during diastole, whereas the pulse pressure wave moves at about 10 m/sec (11). However, it is the arterial pressure wave that can be measured, and will be discussed further.

### Arterial Pressure Waveform Characteristics

The arterial pressure waves are transformed as they proceed from the proximal aorta to the distal arteries (Fig. 4). These waveform changes include augmentation of the systolic component and attenuation of the diastolic component. These changes, along with dynamic response incompatibilities in the catheter-manometer system, are responsible for most disparities encountered between cuff pressures in the brachial artery and the invasively measured pressure in the radial artery (12).

The changing pattern in the arterial pressure waveform is chiefly due to the reflection of waves from the periphery.

**Figure 4** Changing pattern of arterial pressure waveforms from the aorta to the peripheral arteries. The contour of the arterial pressure waveform changes as the pressure wave moves from the proximal aorta to the periphery. The central aortic waveform is more rounded and has a definite dicrotic notch. The dorsalis pedis (and to a lesser degree the femoral) artery shows a delay in pulse transmission, a more rapid upstroke ( $dp/dt$ ), and a slurring of the dicrotic notch. The systolic pressure increases and the diastolic pressure decreases as the pressure wave moves distally. However, the mean pressure remains the same. *Source:* From Ref. 61.

Just as waves are created in a still pool of water after an object is thrown into it, these waves reflect back after hitting the edge of the pool, producing a standing wave that adds to (or subtracts from) the incident wave. The artery-arteriole junction is thought to be the principal site of reflection. Additionally, branching points are sites of arterial waveform reflection and, finally, the tapering of arterial vessels as one proceeds toward the periphery acts to amplify waves, similar to how an ear trumpet amplifies sound waves (13).

### Noninvasive Monitoring of Arterial Pressure

Arterial blood pressure can be measured noninvasively using indirect methods (including palpation, auscultation, and oscillometric technology) or invasively following direct arterial cannulation and pressure transduction. All of the noninvasive techniques of blood pressure determination utilize a Riva-Rocci cuff device. This apparatus involves the inflation of a pneumatic cuff (connected to a sphygmomanometer) that surrounds an extremity and occludes a peripheral artery to the point of no-flow. The physical changes that occur at the time of arterial occlusion and return of flow are sensed and correlated with an arterial blood pressure. Furthermore, the various noninvasive blood pressure measurement techniques actually interrogate different physical events. Thus, the blood pressure obtained is a function of the way in which it is measured. Additionally, there are many artifactual causes for blood pressure measurement problems with a noninvasive technique, which are not factors when monitoring the blood pressure directly (14). ⚡ **In trauma situations and shock, the noninvasive automatic blood pressure devices often fail to work properly. In these situations, an invasive arterial line or manual techniques are preferred.** ⚡

**Table 3** Phases of Korotkoff Sounds

- |      |   |
|------|---|
| I.   | First appearance of clear, repetitive, tapping sounds (systolic pressure) |
| II.  | Sounds are softer and longer, with the quality of an intermittent murmur. |
| III. | Sounds again become crisper and louder.                                   |
| IV.  | Sounds are muffled, less distinct, and softer.                            |
| V.   | Sounds disappear completely (diastolic pressure)                          |

### Manual Intermittent Techniques

A variety of methods for measuring blood pressure are available, ranging from basic manual intermittent techniques, to automated continuous technology. With only the means of a sphygmomanometer, systolic arterial blood pressure can be rapidly estimated by the Riva-Rocci technique, based on measuring the external pressure required to compress the brachial artery. This palpation method may be used when a stethoscope is not available. While palpating the radial arterial pulse, the cuff should be inflated to a level about 30 mmHg above the pressure, at which the pulse disappears. Pressure should then be released from the cuff slowly until the return of a regular palpable pulse, indicating a return of pulsatile blood flow. This pressure is the estimation of systolic arterial pressure.

With the assistance of a stethoscope, the auscultation method not only provides a more accurate systolic pressure, but also allows measurement of a diastolic arterial pressure. As the sphygmomanometer cuff pressure is slowly released, the return of pulsatile blood flow produces Korotkoff sounds. The AHA has published guidelines on the determination of blood pressure by sphygmomanometry, and has characterized five phases of Korotkoff sounds (Table 3) (15). The systolic arterial blood pressure corresponds to the pressure at which the sounds first appear at Phase I. The diastolic blood pressure corresponds to the pressure at which the sounds disappear at Phase V.

### Automated Intermittent Devices

Noninvasive blood pressure monitoring has been automated to provide regular and repeated pressure measurements using oscillometry. This method is derived on the concept that as the occluding cuff is slowly deflated, the return of arterial pulsations results in a counterpressure onto the cuff. With continued cuff deflation and progressive increase in arterial pulsations, the oscillation amplitude increases. The definitions of systolic, diastolic, and mean arterial pressures vary somewhat with different device manufacturers. In general, the systolic pressure is determined to be the point of rapid increase in oscillation amplitude, while the mean pressure is determined to be the point of maximum oscillation amplitude. With some devices, diastolic pressure is taken to be the point of rapid decrease in oscillation amplitude [Dinamap (Critikon)], while with other manufacturers, the diastolic pressure is a derived value based on the systolic and mean pressure measurements.

Although the automated oscillometric blood pressure devices are quite accurate in normal patients, when the patients are hypotensive (systolic blood pressure less than 80 mmHg) they tend to overestimate blood pressure, compared to invasive monitoring (16). Furthermore, a recent study by Davis et al. demonstrated that automatic oscillometric blood pressure measurements were consistently higher in hypotensive patients (potentially providing

a false sense of resuscitation adequacy) (17). Accordingly, automated devices are not recommended for field or hospital triage decisions.

### Continuous Automated Technology

Newer methods of continuous noninvasive blood pressure measurement do exist, but these have not yet gained wide acceptance clinically. Photoplethysmography relies on infrared light transmission to monitor the volume of a finger. An inflatable cuff maintains the finger at a constant volume, and continuous arterial pressure is measured as the counter pressure required to maintain constant finger volume. One study performed in patients undergoing spinal anesthesia reported correlations of only approximately 0.72 to 0.79 between this technique [Finapres (Ohmeda)], and invasive indwelling radial artery catheter measurements, citing frequent unexplained large differences (18). Furthermore, it has been shown that measurements of pressure with this technique are very sensitive to malapplication of the finger cuff, contributing to errors and limiting the reliability of the device (19).

While photoplethysmography utilizes light transmission as the initial trigger to influence cuff counterpressure, the technique of arterial tonometry utilizes a surface pressure transducer applied onto the skin directly over an artery, to measure directly transmitted arterial pressure. This device generates a real-time continuous waveform and pressure measurement. A validation study of one of these devices (JENTOW) was performed, comparing it to intra-arterial catheter blood pressures in normotensive and hypertensive patients (20). The findings showed that tonometric pressures and waveforms correlated closely to the intra-arterial components. This reliability was limited in the conditions of rapid or large changes in blood pressure.

## Invasive Monitoring of Arterial Pressure

### History

The Reverend Stephen Hales became the first person to measure intra-arterial blood pressure when, in 1733, he cannulated the left crural artery of a horse (21). The resulting pressure column rose 8 feet, 3 inches (327 mmHg) and was noted to vary in height with the arterial pulse, and the baseline drifted in correlation to the horse's respiratory rate and level of pain. The first direct invasive blood pressure measurement in a human occurred in 1856, when the French physician Faivre cannulated the superficial femoral artery in the leg of an amputee. After McLean (22) discovered heparin in 1916, and the strain gauge was developed by Lambert and Wood (23) in 1947, the critical components necessary for widespread measurement of intra-arterial blood pressure were available. However, the routine measurement of intra-arterial blood pressure did not occur until the mid-1960s with the wide expansion of cardiothoracic and vascular surgery, and the description of the "catheter over the needle" cannulation technique by Barr in 1961 (24). Today, intra-arterial cannulation with continuous blood pressure transduction is considered the gold standard for arterial blood pressure monitoring by most clinicians. However, some maintain that the intra-arterial cannula must be calibrated with an indirect technique, such as "return to flow," prior to use (25,26).

### Indications

Indications for intra-arterial blood pressure monitoring are listed in Table 4. These include "procedure related" indications (such as large fluid shifts, blood loss, or major vital organ surgery), and "patient related" conditions which require continuous arterial pressure monitoring irrespective of the surgical procedure. One of the most common indications for invasive monitoring of arterial pressure, is the need for continuous blood pressure data in a patient at risk of cardiovascular instability (27). There are indications for arterial cannulation for reasons other than arterial pressure monitoring as well, such as the need for frequent arterial blood gas sampling in patients with respiratory compromise.

### Site Selection

Any peripheral artery can be used for catheterization. Sites commonly used include the radial, femoral, dorsalis pedis, brachial, and axillary arteries. In neonates, the umbilical artery is an excellent source of pressure monitoring and blood sample acquisition. The choice of site for arterial cannulation includes many factors. Typically, the radial artery of the nondominant hand is utilized. When this site is unsuitable, alternate sites are chosen based upon the following four criteria: (i) the artery should be large enough to accurately reflect systemic blood pressure, (ii) the chosen site should be free of cellulitis or nearby infected/devitalized tissue, (iii) there should be sufficient collateral flow to prevent distal ischemia, and (iv) the artery should be proximal to any anatomic aberrations (i.e., use the right arm for patients with aortic coarct or patent ductus arteriosus).

Certain disease states require particular attention to catheter placement site. The dorsalis pedis artery should be avoided in elderly patients, especially those with known peripheral vascular disease or diabetes mellitus.

**Table 4** Indications for Invasive Intra-arterial Blood Pressure Monitoring

#### *Procedure-related indications*

Major procedures involving large fluid shifts and/or blood loss  
Intrathoracic, intracardiac, intracranial procedures  
Anticipated deliberate hypotension, hypothermia, hemodilution  
Procedures with a high risk for spinal cord ischemia (thoracic aneurysm repair, aortic coarctation repair, scoliosis, and other spine surgery)  
Liver, heart, and lung transplantation  
Aortic X-clamp and other major vascular procedures

#### *Patient-related indications*

Significant coronary artery disease (unstable angina, recent MI)  
Myocardial pump dysfunction (CHF, valvular HD, cardiomyopathy)  
Shock (hypovolemic, cardiogenic, septic, neurogenic)  
Significant cerebrovascular disease (internal carotid stenosis)  
Patients with severe ascites  
Significant pulmonary disease, COPD, pulmonary embolism, pulmonary hypertension, ARDS, pneumonia  
Severe renal, acid-base, electrolyte, or metabolic disorders  
Morbid obesity, massive burns, and other conditions where non-invasive monitoring is difficult

*Abbreviations:* ARDS, acute respiratory distress syndrome; CHF, congestive heart failure; COPD, chronic obstructive pulmonary disease; HD, heart disease; MI, myocardial infarction.

The superficial temporal artery, a branch of the external carotid artery, can be used as a vessel of last resort. This artery is tortuous and difficult to cannulate due to its proximity to the internal carotid artery; extreme care must be exercised during flushing. The radial, brachial, and dorsalis pedis arteries are contraindicated in patients with Raynaud's syndrome or Buerger's disease (thromboangiitis obliterans). In both of these conditions, cannulation of the femoral artery is indicated. These guidelines are especially important for Raynaud's syndrome, because environmental hypothermia is a known trigger for vasospasm.

### Complications

The majority of complications after insertion of an arterial pressure-monitoring catheter are either mechanical or infectious. Thrombosis is the most common mechanical complication noted and partial or complete radial artery occlusion occurs in more than 25% of patients. Slogoff et al. (28) found that no ischemic damage or disability developed in any of their patients with catheter-associated radial artery occlusion, and most thromboses recannulate within two to four weeks after catheter removal.

Many investigators still recommend performing the modified Allen's test prior to cannulation of the radial artery, to assess adequacy of perfusion and collateral flow to the extremity (e.g., cold, ischemic digits are an absolute contraindication to cannulation of the vessel that supplies the digits). The modified Allen's test begins with compression of both the radial and ulnar arteries. Next, the patient's fist is clenched until it blanches. The patient's hand is then relaxed, and the pressure on the ulnar artery is released. If the patient's skin promptly becomes hyperemic, collateral ulnar flow is considered adequate for radial artery cannulation. The Allen's test, while recommended, has not been demonstrated to reduce the risk of digit ischemia (29), nor has an abnormal Allen's test been demonstrated to increase the risk of arterial cannulation. Indeed, Slogoff et al. cannulated the radial arteries in 16 patients with suboptimal ulnar flow assessed by the modified Allen's test, and none of these patients (0/16) had evidence of digital ischemia. ⚡ **Although imperfect, if the Allen's test is markedly abnormal, and alternate sites are available, one of these other sites should be used.** ⚡

When the radial artery is not available for cannulation, several other sites are available. One of the main concerns regarding the brachial artery is that few collaterals normally exist around this artery, so that a thrombotic or ischemic event may lead to morbidity. While this concept is valid anatomically, available evidence suggests that brachial artery cannulation is associated with an acceptable risk. Barnes et al. (30) reported their study on indwelling brachial artery cannulae and found no Doppler evidence of obstruction or vascular complications. Even with this information, it is generally recommended to use the axillary artery preferentially to the brachial artery, because of the abundant natural collateral blood supply.

After arterial cannulation, the tissues perfused by the artery should be routinely monitored for evidence of ischemic or thromboembolic events. Although permanent ischemic damage after arterial catheterization is uncommon, there have been rare reports of necrosis requiring amputation. Patients having certain risk factors deserve more careful surveillance for ischemic sequelae following catheterization (Table 5) (31). Any evidence of ischemia, infection, or embolic events should lead to immediate removal of the catheter.

**Table 5** Predictors of Ischemic Risk for Radial Artery Catheterization

---

Proximal embolic source
Increased duration of cannulation
Long or large-caliber catheter
Hyperlipoproteinemia
Peripheral vascular disease
Low cardiac output
Vasoconstrictor agents
Female gender
Small wrist circumference

---

Another mechanical complication occasionally associated with arterial cannulation is pseudoaneurysm. A pseudoaneurysm is a persisting cavity that results from extravasation of blood from an injured vessel that is partially contained by surrounding tissues. It is thought that the technique of catheter insertion may predispose to pseudoaneurysm formation. If the posterior wall of the artery is punctured deliberately or unintentionally, or if multiple passes through the artery are attempted, then the risk of pseudoaneurysm is greater. These same factors increase the risk of arteriovenous fistula formation, where wounds to the artery and an adjacent vein persist. Smaller traumatic AV fistulae tend to close spontaneously, while larger fistulae may persist, because the venous outflow provides a path of least resistance for arterial inflow.

In consideration of femoral arterial cannulation, the clinician must always assess whether the patient may have a femoral arterial prosthesis. Patients with peripheral vascular disease often have previous femoral arterial reconstruction with a vascular graft. Puncture wounds through prosthetic material are at much higher risk for pseudoaneurysm formation. Upon removal of catheters from native arteries, endogenous arterial smooth muscle contraction facilitates closure of the wound, while this factor is absent in wounds to prosthetic grafts. Other predisposing factors for pseudoaneurysm formation seem to be prolonged cannulation and infection.

Embolization is a complication more frequently significant in femoral arterial cannulation. Flushing of catheters may result in thrombus or air emboli to distal regions. Less commonly, vessel instrumentation and catheterization alone may potentially cause atheromatous embolization from diseased femoral vessels. Routine pulse checks by palpation or Doppler sonography should be performed in those patients with indwelling femoral catheters.

Infection is the other main category of complications from arterial catheters. In cases of catheter-associated bacteremia and sepsis, the most common route of bacterial invasion is the insertion site, where organisms colonizing the catheter and skin have a portal of entry into the host. Strict aseptic insertion technique, catheter use, care, and dressing protocols help limit the incidence of infection. Unlike venous catheters, studies have shown that the risk of arterial catheter infections do not increase exponentially over time. Norwood et al. (32) performed a prospective study on prolonged arterial catheterization, and found that infection developed in less than 10% of radial and femoral sites used greater than 96 hours. It appears that arterial catheters may be left as long as skin colonization is well controlled and there is absence of systemic infection.

### Systolic Pressure Variation

It has long been appreciated that large respiratory variation in the arterial pressure waveform correlates with hypovolemia. Perel (33) has developed a technique to better define the relative degree of volume depletion, using the systolic pressure variation (SPV) resulting from the dynamic response of the left ventricle to alterations in preload and afterload induced by mechanical ventilation. The SPV occurring during mechanical ventilation is divided into a delta up and a delta down component. When the delta down component exceeds a SPV of 10 mmHg (in patients ventilated at 10–15 cc/kg tidal volume), patients can generally be thought of as needing additional preload for the conditions (also see discussion on SPV in Volume 2, Chapter 3).

CVP and pulmonary artery wedge pressure (PAWP) are altered by both spontaneous and mechanical ventilation. The changes in these pressures, likewise, affect arterial blood pressure through changes in  $\dot{Q}$ . Increased intrathoracic pressure during mechanical ventilation leads to increased right atrial pressure which decreases venous return to the right heart, while the left atrium and ventricle are being filled by blood which has been squeezed out of the pulmonary vascular system.

Similarly, there is an increase in the afterload on the right side of the heart due to increased airway pressure compressing the pulmonary artery (PA) vessels. In contrast, the left side of the heart has a relative decrease in afterload during positive pressure ventilation. This is because the increased pleural pressure is transmitted to the left ventricle and the thoracic aorta, and their pressure is transiently increased relative to the extrathoracic aorta. As exhalation occurs, these forces reverse. These changes in preload and afterload are most marked in the hypovolemic state and are reflected in the systolic arterial pressure variation (34).

## CENTRAL VENOUS PRESSURE MONITORING

### Indications

The CVP has long been used as an estimator of intravascular volume and a guide to fluid therapy in critically ill patients. The CVP gained popularity as a hemodynamic measure due to relatively simple catheter insertion and ease of interpretation. Some of the various indications for CVP monitoring include patients with the diagnosis of hemorrhage, trauma, sepsis, and cardiovascular dysfunction. Patients may benefit from CVP monitoring during the perioperative period, fluid resuscitation, or blood transfusion.

### Site Selection

The three sites available for central venous catheterization are subclavian, jugular, and femoral. The internal jugular vein is probably the most commonly chosen site for placement of a central venous catheter, when the procedure is performed in the operating room. In this setting, the anesthesiologist typically has easiest access to the patient's head and neck. This site is associated with the least mechanical risk of insertion because inadvertent arterial puncture wounds can easily be compressed externally, and the possibility for pneumothorax is more remote.

Trauma patients having cervical collars, whether from spine injury or from an uncleared spine, pose a particular challenge for internal jugular venous access. Identification of surface landmarks is more difficult without the benefit

of turning the head, and an assistant should immobilize the neck during the procedure. In those patients with tracheostomy, contamination of the catheter site and dressing is more likely with internal jugular vein catheters.

Outside the operating room, the subclavian vein is the favored site for central venous access. In those patients that are awake, an indwelling catheter on the chest wall is more comfortable than one in the relatively mobile neck. Trauma patients who already have a chest tube decompressing a pneumothorax do not have this associated risk factor during catheter insertion.

There are several situations that represent relative contraindications to subclavian venous catheterization. One of these is the coagulopathic or thrombocytopenic patient. Inadvertent arterial puncture wounds are more difficult to suppress with external compression, because the bony clavicle overlies the subclavian artery, and the pliable pleura and lung do not offer effective counterpressure. Patients who will not remain still for the procedure, such as the agitated uncooperative patient or the patient having active chest compressions during cardiopulmonary resuscitation, are poor candidates for subclavian venous catheter attempts because of the high risk for pneumothorax. However, subclavian lines are easier to maintain once in place in ICU patients, and less uncomfortable than neck lines for awake patients who are actively moving around. Accordingly, weighing the relative risks and benefits often results in placement of subclavian lines in patients who have some relative contraindications for the line.

**✎ In the acutely injured, or unstable, critically ill patient requiring central venous access, the femoral vein site is an excellent choice because of its relative ease of insertion.** ✎ For prolonged CVP monitoring purposes, the femoral venous catheter is a less optimum choice than sites located above the waist (subclavian or internal jugular), because of increased risk of lower extremity deep venous thrombosis for femoral vein lines. Furthermore, the ideal catheter tip position for the assessment of preload is the atriocaval junction, near the right atrium. The usual central venous catheter inserted through the femoral vein will be remote from the atriocaval junction. While the pressure from a femoral venous catheter may be used to estimate CVP, it is important to recognize that factors concurrent in the abdomen and periphery may influence this pressure measurement. In those patients with an injured extremity, it is preferable to avoid catheterizing the respective femoral or subclavian vein. These injured extremities, typically, are burdened by hematoma and inflammatory edema and swelling. Optimal venous return from these injured extremities facilitates resolution of swelling and pain, limits the risk of elevated compartment pressures, and improves tissue perfusion and healing.

### Interpretation

The CVP is measured as the pressure in the superior vena cava, an estimate of right atrial pressure. This pressure is an estimator of right atrial volume or cardiac preload. The normal range for CVP in critical care patients is 0–10 mmHg. The typical CVP waveform consists of three waves ("a," "c," and "v") and two descents ("x" and "y") (Fig. 5). While we use CVP to estimate the status of intravascular volume, the state of venous tone has an influence on the CVP. Rapid blood loss or fluid administration results in changes in CVP. A fluid challenge in a hypovolemic patient would result in an increase in CVP. The effect

**Figure 5** The cardiac cycle and the genesis of the a, c, and v waves. The a wave is caused by atrial contraction. The c wave is caused by bulging of the atrioventricular (AV) valve into the atrium during isovolemic ventricular contraction. The v wave is caused by passive venous filling of the atrium. The x descent results from ventricular decompression, following the opening of the ventricular outlet. The y descent results from draining the atrial blood into the ventricle, following the opening of the AV valve. The electrocardiogram trace serves as a useful marker to discern the components of the central venous pressure trace. *Abbreviations:* CVP, central venous pressure; ECG, electrocardiogram. *Source:* From Ref. 62.

may be transient, in that venous compliance responds to these fluctuations in volume by adjusting venous tone. Elevation in CVP may represent hypervolemia, or impaired right ventricular function from congestive heart failure, or tricuspid valve regurgitation. The CVP may also be elevated in disease processes associated with pulmonary hypertension, such as pulmonary embolism, acute respiratory distress syndrome, or chronic obstructive pulmonary disease.

#### **Effect of Mechanical Ventilation and PEEP**

CVP measurements are affected by mechanical ventilation because of its effects on intrathoracic pressure. In the normally spontaneously ventilating patient, inspiration results in a negative intrathoracic pressure and resultant decrease in measured CVP. Expiration results in a positive intrathoracic pressure and a subsequent increase in measured CVP. These changes are considered normal respiratory variation of the CVP waveform. When patients are on positive pressure ventilation from a mechanical ventilator, the reverse effects are noted. Delivery of an inspiratory breath from a mechanical ventilator results in positive intrathoracic pressure and elevation in measured CVP, while the expiratory phase leads to a decrease in measured CVP.

It is recommended that serial CVP measurements be obtained at the same point of the respiratory cycle. In order to avoid the influence of intrathoracic pressure, CVP measurements are taken at end-exhalation in both spontaneously and mechanically ventilated patients. This is the point at which the intrathoracic pressure is most stable and least affected by ambient influences. When positive end-expiratory pressure (PEEP) is being administered, whether by the mechanical ventilator or by noninvasive means, the

**Figure 6** Giant cv waves and cannon (or Giant) a waves. Giant (or Cannon) a waves are caused by atrial contraction against a closed atrioventricular (AV) valve (as occurs with atrial ventricular dyssynchrony). Giant cv waves occur when the Giant c wave persists into the time when the v wave should be occurring, and are due to AV valve regurgitation. *Source:* From Ref. 61.

result is an increased intrathoracic pressure at end-expiration, and subsequent elevation in measured CVP.

#### **Pathologic Central Venous Pressure Waveforms**

Conditions of right heart flow pathology are manifested by changes in the normal CVP waveform (Fig. 5). The "a" wave, indicating the venous pressure during atrial contraction, is magnified in conditions of resistance to right atrial outflow. The classic giant or "cannon a" wave may be seen in situations where the atrium is contracting against a closed tricuspid valve (i.e., AV dyssynchrony or nodal rhythm) (Fig. 6). Less prominent "cannon a" waves are seen in situations with increased resistance to right atrial emptying (e.g., tricuspid stenosis). Other conditions in which the "a" wave is accentuated are right ventricular failure, pulmonary stenosis, and pulmonary hypertension. The "a" wave is absent during atrial fibrillation. In the condition of tricuspid regurgitation, the "c" and "v" waves are combined to form a large regurgitant CV wave, obliterating the normal "x" descent (Fig. 6).

#### **PULMONARY ARTERY CATHETER MONITORING**

Despite the controversy regarding its use, the PAC remains the ultimate invasive monitoring tool in the intensivist's armamentarium. Introduced into clinical practice in 1970, and initially used to diagnose patients with acute cardiac disease, the PAC allows us to directly measure three key parameters not available with any other invasive monitoring device: PAWP,  $\dot{Q}$ , and mixed venous oxygen saturation. Acquisition and utilization of these measurements formulate the most fundamental indications for use of the PAC.

## Indications

Previous studies have documented the unreliability of the CVP and right atrial pressure to accurately estimate left atrial pressure or left ventricular preload. Patients with isolated right- or left-sided heart failure, and those patients with altered systemic or pulmonary vascular resistance from shock or respiratory failure, may have discrepant right and left heart pressures. ⚡ **The following clinical situations may benefit from monitoring with a PAC: cardiovascular dysfunction, MI, congestive heart failure, pulmonary hypertension, shock, geriatric patients, traumatic injury, sepsis, and respiratory failure.** ⚡

Among the most common indications for PAC use is the hemodynamically unstable patient not responding predictably to conventional fluid resuscitation. The PAC may provide valuable hemodynamic data that will help evaluate the pathophysiology of the abnormality. Measurement of  $\dot{Q}$  and calculation of SVR will help differentiate hypotension into hypovolemic shock, cardiogenic shock, or a form of distributive shock. The patient with respiratory failure requiring advancing ventilator support may benefit from a PAC. Measurement of the PAWP will allow the differentiation between cardiogenic and noncardiogenic pulmonary edema.

In addition to its diagnostic uses, the PAC is a valuable tool in guiding therapy in the critically ill. The PAWP may be used as a guide for fluid resuscitation as an estimate of left ventricular preload. Monitoring  $\dot{Q}$  theoretically improves the appropriateness of inotropic therapy. Similarly, calculation of SVR using the PAC allows for improved titration of vasoactive agents. In those patients at risk for systemic inflammatory response syndrome, or sepsis and organ dysfunction, measurement of mixed venous oxygen saturation and calculation of oxygen transport variables may help determine presence of tissue ischemia, and guide resuscitation efforts.

There has been recent controversy regarding the utility and safety of PAC use. In 1996 Connors et al. (35) reported a multicenter observational study, showing that PAC use was associated with increased mortality and utilization of resources. This study stimulated intense debate, that even reached a point in which a moratorium on PAC use was recommended by the Food and Drug Administration (FDA), until a multicenter randomized clinical trial (RCT) could be performed. It was later realized that a study such as this would be too difficult to enroll patients and to practically complete, and the Connors study had several experimental design flaws.

The American Society of Anesthesiologists (ASA) established the Task Force on PACs in 1991 to determine the risk/benefits ratio for PAC use in settings encountered by anesthesiologists. The ASA guidelines (36) were adopted in 1992 and published in 1993. The ASA guidelines stated that the PAC should not be used routinely, but is likely beneficial when three high-risk variables intersected (patient, procedure, and clinical setting). The ASA guidelines also stated that the PAC will only prove beneficial when insertion and data interpretation are performed by competent individuals, and called for additional research.

Subsequently, in 1996, the Council of the Society of Critical Care Medicine (SCCM) hosted a consensus conference to examine important issues related to the PAC with representatives from the American Association of Critical-Care Nurses, the American College of Chest Physicians, the American College of Critical Care Medicine, the American Thoracic Society, the European Society of Intensive Care Medicine, and the SCCM in attendance (37). Among the consensus recommendations were that there was no basis for an FDA

**Table 6** Indications for Pulmonary Artery Catheter Use in the Trauma Patient

---

To ascertain the status of underlying cardiovascular performance.
To direct therapy when noninvasive monitoring is inadequate or misleading.
To assess response to resuscitation.
To potentially decrease secondary injury when severe closed-head or acute spinal cord injuries are components of multisystem trauma.
To augment clinical decision making when major trauma is complicated by severe acute respiratory distress syndrome, progressive oliguria/anuria, myocardial injury, congestive heart failure, or major thermal injury.
To establish futility of care.

---

moratorium of PAC use and instead, that clinician knowledge about the use of the PAC and its complications should be improved (38).

In October 2003, the revised ASA guidelines were published, and the recommendations were essentially unchanged from those published a decade earlier (39). Also, in 2003, two large multicenter RCTs were completed with conflicting results. The first showed a slightly higher complication rate, and markedly higher incidence of pulmonary embolism in the group assigned to PACs (40). The other study by Richard et al. (41) demonstrated that PAC use is not associated with increased mortality or morbidity, as did a similar study by Rhodes et al. (42).

Accordingly, clinical decision making is still guiding the indications for PAC use. Table 6 lists the indications for PAC use in trauma patients, recommended by the SCCM consensus conference (albeit only supported by Level IV or V evidence).

## Measurement of Cardiac Output

### Thermomodification Technique

One of the most important capabilities of the PAC is the measurement of  $\dot{Q}$ . The PAC uses a thermodilution method for measuring  $\dot{Q}$ , with the injection of a bolus of cold solution. The technique is performed with the manual injection of 10 mL of a room temperature solution of 5% dextrose in water, into the right atrial port. The rate of blood flow determines the resultant temperature change, sensed by a thermistor at the tip of the catheter in the pulmonary artery. The device then calculates a  $\dot{Q}$  by the integration of the change in temperature over time, where the area under the temperature-time curve is inversely proportional to the  $\dot{Q}$ .

Variability in  $\dot{Q}$  measurement with the thermodilution technique may be either due to technical factors, or from physiologic causes (43). With repeated measurements, the injectate volume must be accurate and the injection administration speed must be consistent. The amount of fluid loaded into the syringe may vary simply from human error, or the volume may be altered when air becomes trapped within the catheter tubing. Any factors that may alter the injectate temperature may also affect the  $\dot{Q}$  measurement. If the injection solution bag is changed between measurements, a significant difference in temperature may potentially occur between measurements.

Patients with tricuspid valve regurgitation have increased variability of  $\dot{Q}$  measurement using the thermodilution technique. Some reports suggest an overestimation

of  $\dot{Q}$ , based upon the concept that regurgitant blood flow warms the injectate more rapidly, resulting in a more rapid washout of temperature. Other reports point to the potential for a delay in flow of the injectate to the distal thermistor, resulting in an underestimation of  $\dot{Q}$ . Another physiologic source of  $\dot{Q}$  variability arises in patients with dysrhythmias. One example is atrial fibrillation, where the actual  $\dot{Q}$  may vary from beat to beat. Due to the great potential for variability, the possibility of artifactual signals and noise is also greater.

### Fick Principle (Conservation of Mass)

While the PAC has allowed routine thermodilution  $\dot{Q}$  measurement to be performed in the ICU, the Fick principle method remains the gold standard by which these methods are assessed. In the 1880s, Adolph Fick applied the law of conservation of mass to estimate  $\dot{Q}$ . The fundamental concept of Fick's principle is that the amount of oxygen exiting the heart equals the amount of oxygen entering the heart, plus or minus the amounts of oxygen added or removed from the heart, respectively. Thus, the  $\dot{Q}$  equals the oxygen consumption ( $\dot{V}O_2$ ) divided by the difference between arterial and venous oxygen concentrations ( $CaO_2 - CvO_2$ ).

$$\dot{Q} = \frac{VO_2}{CaO_2 - CvO_2} \quad (3)$$

$CaO_2$  may be calculated by measuring hemoglobin concentration in blood and the oxygen saturation in arterial blood, and applying it to the following equation:

$$CaO_2(L/min) = Hb(g/dL) * SaO_2 * 1.36 \\ (mL O_2/100 mL blood) \quad (4)$$

$CvO_2$  must be calculated from the oxygen saturation in mixed venous blood ( $SvO_2$ ). The only practical site to obtain a sample with complete venous mixing of blood from throughout the body, is in the pulmonary artery. This sample is withdrawn from the pulmonary artery port at the tip of the PAC, and  $CvO_2$  is calculated similarly to  $CaO_2$ :

$$CvO_2(L/min) = Hb (g/dL) * SvO_2 * 1.36 \\ (mL O_2/100 mL blood) \quad (5)$$

With the Fick principle,  $\dot{V}O_2$  is calculated using indirect calorimetry results with a metabolic cart, measuring the differences in oxygen concentration between expired and inspired gas.

Measurement of  $\dot{Q}$  further allows the assessment of the derived oxygen transport variables that are believed to estimate the body's overall state of tissue perfusion and oxidative metabolism (Table 7). Oxygen delivery ( $\dot{D}O_2$ ) is calculated by the product of  $\dot{Q}$  and  $CaO_2$ , while oxygen extraction is the ratio of  $\dot{V}O_2$  to  $\dot{D}O_2$ :

$$\dot{D}O_2 = \dot{Q} * CaO_2 \quad (6)$$

$$O_2 \text{ extraction} = \frac{\dot{V}O_2}{\dot{D}O_2} \quad (7)$$

Low  $\dot{D}O_2$  most often suggests inadequate  $\dot{Q}$ . Methods of improving  $\dot{D}O_2$  include blood transfusion to increase [Hb] or inotropic support to increase  $\dot{Q}$ .  $SaO_2$  is typically

**Table 7** Derived Hemodynamic Variables from Pulmonary Artery Catheter Data

Cardiac index	$CI = \dot{Q}/BSA$
Stroke volume	$SV = \dot{Q} / HR$
Systemic vascular resistance	$SVR = (MAP - CVP) * 80/\dot{Q}$
Pulmonary vascular resistance	$PVR = (MPAP - PAWP) * 80/\dot{Q}$
Arterial oxygen content	$CaO_2 = Hb * SaO_2 * 1.36 + (PaO_2 * 0.003)$
Mixed venous oxygen content	$CvO_2 = Hb * SvO_2 * 1.36 + (PaO_2 * 0.003)$
Oxygen delivery	$\dot{D}O_2 = \dot{Q} * CaO_2$
Oxygen consumption	$\dot{V}O_2 = \dot{Q} * (CaO_2 - CvO_2)$
Oxygen extraction	$O_{2ext} = \dot{V}O_2/\dot{D}O_2$

*Abbreviations:* BSA, body surface area; CVP, central venous pressure; Hb, hemoglobin; HR, heart rate; MAP, mean arterial pressure; MPAP, mean pulmonary artery pressure;  $O_{2ext}$  =  $O_2$  extraction;  $PaO_2$ , partial pressure of  $O_2$  in arterial blood; PAWP, pulmonary artery wedge pressure;  $SaO_2$ ,  $O_2$  saturation in blood;  $SvO_2$  =  $O_2$ , saturation in mixed venous blood; SVR, systemic vascular resistance;  $\dot{Q}$ , cardiac output.

near its maximum, where an increase would not result in significant change in  $\dot{D}O_2$ . Low  $\dot{V}O_2$  may suggest inadequate tissue perfusion or oxygen metabolism. Tissue ischemia may result from inadequate supply of oxygen, or a maldistribution of microcirculatory perfusion to certain tissue regions. Decreased metabolism in critically ill patients may result from severe uncompensated shock states.

In those patients without a PAC, mixed venous blood is not available to assess oxygen transport dynamics. In an animal study of hypotensive hemorrhage, Scalea et al. (44) found that central venous oxygen saturation mirrored mixed venous oxygen saturation. In a subsequent study of trauma patients with evidence of hemorrhage, Scalea et al. (45) reported that central venous oxygen saturation, or the oxygen saturation of blood obtained from a central venous catheter, was a reliable and sensitive correlate of blood loss. They discovered that despite stable vital signs, the 39% of patients that had saturations under 65% had more serious injuries and required more transfusions.

## Insertion Technique

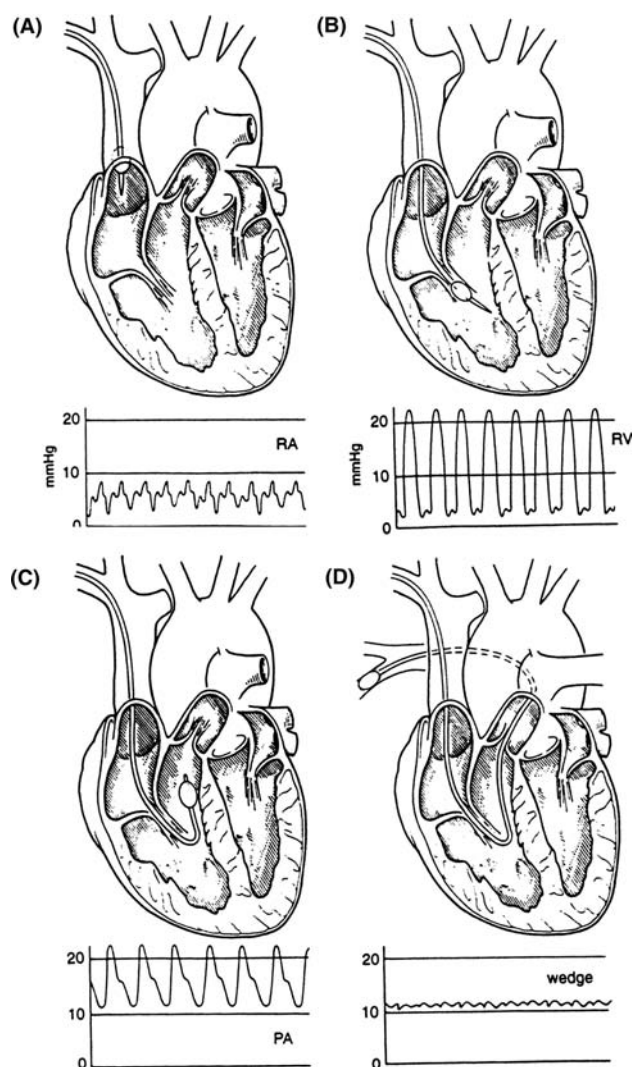

### Site Selection

The major sites for PAC insertion are similar to those of central venous access, with some special considerations. Ease of passage of the PAC into the pulmonary artery is influenced by the convolutions required for the catheter to reach its destination. The following sites are described in increasing level of technical difficulty. The most direct insertion route for the PAC is via the right internal jugular vein, where the PAC only requires one gentle curve to reach the right pulmonary artery. Access via the left subclavian vein also follows a generally smooth curve, but must traverse the left innominate vein to reach the superior vena cava. Access via the right subclavian vein requires the catheter to initially traverse the right innominate vein to reach the superior vena cava, then alter its curvature to enter the right atrium, in an S-shaped configuration. Finally, entry through the left internal jugular vein also requires an S-shaped configuration, with a greater travel distance.

Maneuvering through the left internal jugular vein to innominate vein curve is required, followed by an altered curve through the superior vena cava and right atrium. Femoral vein sites are acceptable alternatives, but are often more difficult to traverse into the right atrium. Fluoroscopic guidance may be necessary for those patients with unusual difficulty in placing the PAC.

### Pulmonary Artery Catheter Advancement Considerations

After gaining central venous access via one of the above insertion points, the flushed and zeroed PAC is advanced, with the balloon deflated, to a distance of 12–15 cm (just past the introduction tip). At this point the flotation balloon is inflated, and the PAC is carefully advanced while simultaneously observing the pressure waveforms (Fig. 7), measured at the tip of the PAC. The initial CVP waveform leads to the right atrial pressure waveform,

**Figure 7** Advancement of the pulmonary artery catheter through the cardiac chambers and respective waveforms. (A) Pulmonary artery catheter (PAC) in right atrium. (B) PAC passing through tricuspid valve into the right ventricle. (C) PAC in the pulmonary artery (PA). (D) PAC in the distal PA in a wedge position. *Abbreviations:* RA, right atrium; RV, right ventricle. *Source:* From Ref. 63.

which is not always easy to distinguish, depending on the sensitivity of the monitor settings. Upon reaching the right ventricle, there is an abrupt and obvious high spiking pressure waveform of 20–30 mmHg, representing the systolic right ventricular pressure, with a diastolic pressure that is unchanged from the CVP. This waveform leads to the pulmonary artery waveform with its characteristic step-up in diastolic pressure and a clear dicrotic notch. Finally, as the inflated balloon reaches a pulmonary arterial wedge, the waveform flattens as it loses its systolic and diastolic variation. After briefly observing the wedge waveform, the balloon should be deflated to confirm the reappearance of the pulmonary artery waveform.

✎ **Appropriate positioning of the PAC tip is critical to minimize risk for complications, and to achieve reliable data.** ✎ When the tip is in an appropriate position, a wedge waveform will be obtained with balloon inflation of 1.5 mL of air. If the wedge waveform does not appear, the catheter tip may need a slight advancement of several centimeters, with the balloon inflated, until the wedge reappears. If the wedge waveform is obtained with less than 1.5 mL, the catheter tip is probably in a small branch and should be withdrawn several centimeters, with the balloon deflated, followed by reinflation of the balloon and advancement back into a wedge position. After registering a wedge pressure, it is safest to pull the catheter back a few centimeters (with the balloon down), each time between readings to minimize the natural distal migration of the catheter.

### Interpretation of PAC Waveforms and Pressures

#### Effect of Mechanical Ventilation

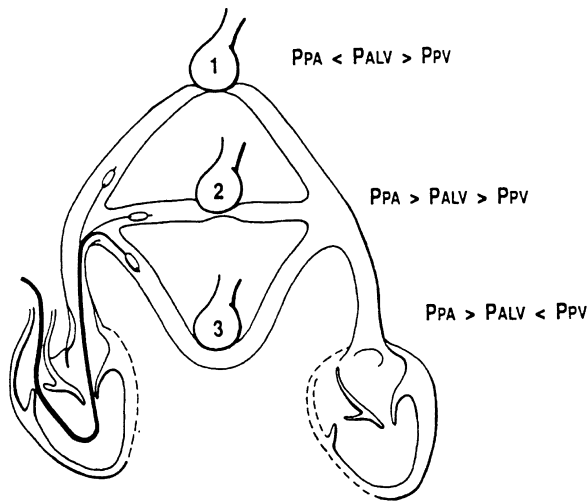

The PAWP, like the CVP, is best measured when there is the least influence from external transmural pressures, juxtacardiac pressures, and intrathoracic pressures (46). This situation seems most closely approximated when the lungs return to their relaxed volume and state at end-expiration. In the spontaneously breathing patient, inspiration involves the development of a negative intrathoracic pressure that is transmitted through the pleura, lungs, alveoli, heart, and great vessels. In the mechanically ventilated patient, an increased intrathoracic pressure occurs with the positive pressure delivery of a breath. Still, in both spontaneously and mechanically ventilated patients, the chest returns to its most normal pressure configurations at end-expiration, and this is the most reliable for repeated measurements of intravascular pressure.

#### Effect of PEEP

PEEP may also influence the measurement of the PAWP. There are three physiologic lung zones, based upon the relationship between the pulmonary vascular and alveolar pressures (Fig. 8). In lung zones 1 and 2, the extent of alveolar pressure affects the pressure read by the PAC. The ideal position for the catheter tip is in lung zone 3, where the intravascular pressure always exceeds the alveolar pressure. In nonzone 3 situations, alveolar pressure may exceed intravascular pressure. The level of alveolar pressure and PEEP then affects measurement of PAWP.

#### Hemodynamic Profiles

Rational use of all the available data obtained from the PAC requires careful assessment of how individual data points fit into clinical scenarios. Hemodynamic profiles align several individual hemodynamic variables to fit into specified clinical patterns (Table 8). These specific patterns

**Figure 8** Physiologic lung “Zones of West.” The zones are based upon alveolar–vascular pressure relationships. In either zone 1 or zone 2,  $P_{ALV}$  exceeds  $P_{PV}$ . During balloon occlusion of the pulmonary artery, wedge pressure reflects  $P_{PV}$  and left atrial pressure accurately only in zone 3. *Abbreviations:*  $P_{ALV}$ , alveolar pressure;  $P_{PA}$ , pulmonary arterial pressure;  $P_{PV}$ , pulmonary venous. *Source:* From Ref. 64.

are associated with certain appropriate therapeutic responses and subsequent prognoses (47). For example, a basic profile for acute hypovolemia would include low PAWP, low  $\dot{Q}$ , and high SVR.

**CONTINUOUS CARDIAC OUTPUT MONITORING  
Modified Pulmonary Artery Catheters**

In response to increased monitoring needs in the ICU, technological advances have improved the utility of the PAC. Special catheters are now available that continuously monitor mixed venous oxygen saturation and/or cardiac output (48). In some ICUs, these modified catheters have become preferred.

Patients in whom oxygen transport variables are regularly followed require repeated blood draws for mixed venous oxygen analysis with the traditional PAC. In the Fick equation, the mixed venous oxygen saturation reflects the overall oxygen extraction, whereby a reduction in mixed venous oxygen saturation may suggest an uncompensated increase in oxygen consumption. Continuous mixed

venous oximetry has given us the benefit of decreasing the labor of blood drawing required to measure mixed venous oxygen saturation, but an even greater advantage is that monitoring and therapeutic decisions can occur in real time, without the delay of laboratory processing of bloodwork. The technology of continuous mixed venous oximetry uses fiberoptic bundles and an optical transducer in the tip of the catheter. As red blood cells flow past the catheter tip, a measurement of oxyhemoglobin relative to total hemoglobin is determined.

Another modification of the PAC that has gained some popularity in use is the continuous cardiac output ( $\dot{Q}$  cont.) devices. The  $\dot{Q}$  cont. PAC takes advantage of the thermodilution technique for measurement of  $\dot{Q}$ , but rather than injections of cold solution, it uses a heating filament on the catheter to deliver thermal pulses. The thermistor at the catheter tip senses the temperature change, and a computer-derived  $\dot{Q}$  measurement is made. The  $\dot{Q}$  displayed on the monitor is not truly continuous. Three- to six-minute periods of blood flow are analyzed to generate average  $\dot{Q}$ . Every 30 seconds, the  $\dot{Q}$  is updated with these averages, thereby limiting extreme fluctuations that may occur with real-time measurements. **Several studies have since evaluated this  $\dot{Q}$  cont. PAC was compared to bolus  $\dot{Q}$  measurements in ICU patients, with the results showing that the  $\dot{Q}$  cont. measurements compared favorably (49–51).**

The technological advance in catheter capability is also associated with its own inherent drawbacks. Calibration of the measurements and troubleshooting dysfunctional catheters are occasional problems. Another potential pitfall lies in the reliability of the displayed measurements. Poor signal quality of the device may lead to inaccurate readings. Response to fluctuating readings may result in inappropriate therapy. Finally, the added cost of the modified catheters may be up to twice the cost of traditional PACs. While there is certainly time and labor saving with these options, the cost-efficiency of the devices must be assessed by the individual institutions using them.

One other PAC modification provides measurement of a hemodynamic variable that has yet to gain widespread acceptance in use. The right ventricular function catheter calculates the right ventricular end-diastolic volume index (RVEDVI) as the estimator of preload, and right ventricular ejection fraction as the estimator of contractility. The technology uses a thermodilution method, whereby the temperature changes between baseline and residual temperatures in successive heartbeats are computer analyzed to generate the ejection fraction. The SV and end-diastolic volume can be solved for (using an equation with a constant related to the specific gravity and heat capacity of blood) (52). A number of studies have attempted to assess the correlation between these measures and  $\dot{Q}$ . Martyn et al. (53) performed a study in acutely burned patients and reported that the RVEDVI is a better measure of right ventricular preload than CVP and PAWP. Subsequently, Chang et al. (54) reported a consecutive series of 46 trauma patients, who received volumetric PACs and required greater than 10 L of fluid in 24 hours. This study also concluded that the RVEDVI is a better predictor of preload than the PAWP in trauma patients during large-volume shock resuscitation, and promoted the idea that when the RVEDVI is 130 mL/m<sup>2</sup> or less, volume administration would increase the cardiac index. It still remains to be seen whether knowledge of right ventricular volumes and function and use of the volumetric PAC actually improve outcome.

**Table 8** Hemodynamic Profiles Based on Three Variables

	PAWP	$\dot{Q}$	SVR
Hypovolemia	Low	Low	High
Fluid overload	High	High	Low
Septic shock	Low	High	Low
Left heart failure	High	Low	High
Pulmonary hypertension	Low	Low	Normal

*Abbreviations:* PAWP, pulmonary artery wedge pressure;  $\dot{Q}$ , cardiac output; SVR, systemic vascular resistance.

### Noninvasive Cardiac Output Monitoring Devices

☞ The esophageal Doppler monitor (EDM) is a relatively new advance in continuous  $\dot{Q}$  monitoring, and represents the most promising of noninvasive techniques (55). ☞ The Doppler method is based on the analysis of ultrasound waves to measure the velocity of blood flow. Doppler waveforms are analyzed to assess preload, afterload, and contractility. The EDM probe must be positioned to best visualize adjacent descending aortic blood flow through the esophageal wall. One of the drawbacks of this technique is that proper positioning is critical to achieving accurate results, and subsequent probe movement out of position is difficult to prevent. Studies have shown that this technique may better predict preload than either PAWP or CVP (56).

Thoracic electrical bioimpedance techniques are based on the concept that intrathoracic volume changes with each SV. An alternating current is applied by electrodes, whereby increased aortic flow during systole decreases the thoracic impedance.  $\dot{Q}$  is subsequently determined by computerized analysis of peak aortic flow, SV, and HR. Several different commercial devices are available, and at least one prospective study in 134 blunt-trauma patients concluded that bioimpedance  $\dot{Q}$  monitoring, as part of a multicomponent noninvasive system, approximated those of thermodilution methods shortly after admission (57). Conversely, a recent meta-analysis of 42 clinical studies instead found a wide variation of correlations between bioimpedance  $\dot{Q}$  and different invasive reference methods (58). Therefore, more work needs to be done on impedance cardiography before this technique can be recommended for clinical use in critically ill patients.

### EYE TO THE FUTURE

The advent of invasive monitoring technology has been a significant factor in defining the role of the ICU and the intensivist in the care of critically ill patients, and the bulk of this chapter is devoted to the current invasive devices. We have recently seen that the minimally invasive movement is changing the approach to medical care. In critical care, there is a parallel movement to develop and refine noninvasive means to acquire cardiovascular and hemodynamic data. Some of the technologies discussed in this chapter are examples of this effort, applied clinically today.

Esophageal Doppler monitoring of continuous  $\dot{Q}$  is rapidly gaining interest, and clinical trials are actively investigating feasibility. Further improvement of probes is needed to limit the artifactual information and to more easily maintain proper positioning. Continued advances in ultrasonic probe technology and computer processing will provide higher level analytical information regarding ventricular volume and function. Contrast echocardiography and three-dimensional technology will certainly add additional anatomic and physiologic data (59). Photoplethysmography for continuous automated noninvasive arterial blood pressure monitoring using infrared light transmission, and arterial tonometry utilizing surface pressure transducers are undergoing clinical study and refinement, and may be applicable to clinical trials in the near future.

### SUMMARY

Cardiovascular monitoring needs, in trauma and the critically ill, range from those patients needing just basic

electrocardiography, to those patients that would benefit from intensive continuous assessment and oxygen transport evaluation. The level and extent of monitoring is dependent on the patient's injuries, comorbid diseases, current physiologic condition, and response to resuscitation and therapy. Arterial blood pressure, CVP, pulmonary artery pressures, CO, mixed venous oxygen saturation may now all be continuously monitored in those patients requiring advanced levels of care. The successful intensivist is one who clearly understands the technologies available, can appropriately analyze the data for accuracy and utility, and can integrate the findings with all the other relevant conditions and events in the patient, to formulate effective therapeutic strategies.

### KEY POINTS

- ☞ The precordial leads are the most sensitive for detecting myocardial ischemia in the operating room; this is presumably true in the ICU as well.
- ☞ ST segment depression is the most common manifestation of subendocardial myocardial ischemia.
- ☞ Acute transmural myocardial ischemia, or infarction, results in acute ST segment elevation.
- ☞ The MAP is highest in the ascending aorta, and drops minimally until the peripheral arteriolar bed is reached.
- ☞ In trauma situations, and shock, the noninvasive automatic blood pressure devices often fail to work properly. In these situations, an invasive arterial line or manual techniques are preferred.
- ☞ Although imperfect, if the Allen's test is markedly abnormal, and alternate sites are available, one of these other sites should be used.
- ☞ In the acutely injured, or unstable, critically ill patient requiring central venous access, the femoral vein site is an excellent choice because of its relative ease of insertion.
- ☞ The following clinical situations may benefit from monitoring with a PAC: cardiovascular dysfunction, MI, congestive heart failure, pulmonary hypertension, shock, geriatric patients, traumatic injury, sepsis, and respiratory failure.
- ☞ Appropriate positioning of the PAC tip is critical to minimize risk for complications, and to achieve reliable data.
- ☞ Several studies have since evaluated this  $\dot{Q}$  cont. PAC compared to bolus  $\dot{Q}$  measurements in ICU patients, with the results showing that the  $\dot{Q}$  cont. measurements compared favorably.
- ☞ The esophageal Doppler monitor (EDM) is a relatively new advance in continuous  $\dot{Q}$  monitoring, and represents the most promising of noninvasive techniques.

### INTRODUCTION

Methods for monitoring resuscitation of patients in overt shock, as well as those with less obvious occult hypoperfused states, continues to be actively pursued. Along with research into shock states, increased standardization in definitions has been required. To this end, the American College of Surgeons Committee on Trauma (ACS-COT) defined shock as “an abnormality of the circulatory system that results in inadequate organ perfusion and tissue oxygenation” (1). The American College of Chest Physicians (ACCP) and the Society of Critical Care Medicine (SCCM) similarly established a Consensus Conference Committee, which defined shock associated with sepsis as “. . . hypotension [systolic blood pressure (SBP) <90 mmHg or reduction  $\geq$ 40 mmHg from baseline] despite adequate fluid resuscitation, along with the perfusion abnormalities that may include, but are not limited to: (i) lactic acidosis, (ii) oliguria, or (iii) an acute alteration in mental status” (2).

These definitions and the inferred resuscitation end-points are clinically relevant to goal-directed therapy for trauma (3,4) and sepsis respectively (5,6). Traditional end-points of resuscitation include blood pressure (BP), pulse, urine output, and mentation. Invasive monitors of hemodynamic status include central venous pressure (CVP), indwelling arterial catheter and mean arterial pressure (MAP), and pulmonary artery occlusion pressure (PAOP). Invasively measured and derived variables, such as cardiac output ( $\dot{Q}$ ), mixed venous oxygen saturation, and central venous oxygen saturation, have also been widely utilized in the critical care settings as part of goal-directed therapy. Other markers of hypoperfusion include measuring serum lactate, base deficit (BD), and arterial pH.

The aforementioned global measures of resuscitation can be inaccurate and slow to change in the young or well-compensated patient (see Volume 1, Chapters 12 and 18) (7,8). In addition, these are nonspecific markers that reflect the overall patient status, and do not necessarily correlate with the specific well being of any particular vascular bed. Indeed, all of these parameters are incomplete predictors of resuscitation status (9).

Critically ill patients that are underresuscitated require prompt treatment to prevent further damage to their vital organs (see Volume 1, Chapter 12). Surrogate markers have been used for decades, in an attempt to assess the adequacy of circulation to end-organs and the end-points to resuscitation (see Volume 1, Chapter 18).

✎ **The two organ systems most often initially impacted in**

**the underresuscitated trauma patient are the kidneys and the gastrointestinal (GI) organs.** ✎ Significant research efforts have been focused on developing techniques for measuring renal and splanchnic perfusion. Direct measurement is normally not available clinically, so surrogate markers have been studied as measures of resuscitation success.

This chapter will primarily focus on the intricacies and utility of the various monitoring modalities that reflect the adequacy of splanchnic and renal blood flow. In addition, some newer monitoring systems that correlate with splanchnic perfusion will be introduced.

### SPLANCHNIC MONITORING

Due to the current limitations of global resuscitation markers, end-organ and tissue-specific markers of hypoperfusion continue to be sought. Splanchnic monitoring is one such area—examples include gastric tonometry and pH monitoring. Other measures that correlate, but are not direct measurements, include sublingual capnography, buccal tissue CO<sub>2</sub> monitoring, as well as biochemical markers of insult (e.g., abnormal increases in lactic acid), and other surrogates of splanchnic well-being (e.g., tolerance to enteral nutrition).

#### Anatomy and Pathophysiology

##### Splanchnic Circulation

The distribution of splanchnic blood flow is determined by well-known embryologic relationships (Table 1) (10). The abdominal foregut structures include the stomach, duodenum proximal to Wirsung's duct, liver, biliary drainage system, and pancreas. These structures are supplied by the celiac trunk via the common hepatic, left gastric, right gastric, and splenic arteries. Midgut structures encompass the bowel from the distal duodenum to the proximal two-thirds of the transverse colon, and are supplied by the superior mesenteric artery (SMA). The hindgut is composed of the remaining colon, rectum, and proximal anal canal. The inferior mesenteric artery (IMA) supplies these structures.

The renal blood supply is separate (individual right and left renal arteries, arising off the aorta between the SMA and IMA), but these vessels respond similarly to hypovolemia and hypotension (with relative hypoperfusion). Monitoring of renal perfusion and function is discussed below.

**Table 1** Splanchnic and Renal Blood Supply

Artery (from aorta)	Major branch	Feeding artery	Organ perfused
Celiac	Common hepatic	Right and left hepatic	Liver (25% of flow, 50% O <sub>2</sub> ) The portal vein provides 75% of the hepatic inflow and 50% of the O <sub>2</sub>
		Right hepatic	Gall bladder via cystic artery (branch of right hepatic)
		Gastrooduodenal	First, second, and third part of duodenum, head of the pancreas
	Left gastric Superior pancreatic		Gastroesophageal junction
			Midsection and tail of pancreas
Superior mesenteric	Splenic	Superior and inferior pancreatic	Midsection and tail of pancreas
		Short gastrics	Fundus of stomach
		Left gastroepiploic	Greater curvature of stomach (joins right gastroepiploic, which is the distal continuation of the gastroduodenal artery)
		Splenic	Spleen
Inferior mesenteric	Inferior pancreaticoduodenal		Head of pancreas, and first and third part of duodenum
	Inferior pancreatic Superior mesenteric		Middle and tail of pancreas Small intestine (including the fourth part of duodenum usually) to the proximal two-third of the transverse colon
Right and left renal arteries			Right and left kidneys
Inferior mesenteric	Left colic		Distal transverse and descending colon
	Sigmoid branches of IMA		Sigmoid colon
	Superior rectal branches of IMA		Rectum

Abbreviation: IMA, inferior mesenteric artery.

✎ In the resting normovolemic patient, approximately 20% to 35% of the cardiac output is directed to the splanchnic circulation. ✎ The tissues supplied by the splanchnic circulation have large metabolic compensatory abilities, in response to either increased or decreased demand, and these tissues can increase oxygen extraction upwards of 90%. During a sympathetic circulatory response to hypovolemic shock, blood is shunted to tissue beds most needed—heart, lungs, brain—and away from nonvital circulatory systems, such as the splanchnic circulation, via release of catecholamines and subsequent vasoconstriction (11,12). Nitric oxide (NO) is likely the most important regulator of splanchnic vascular tone at rest (11). The gut is susceptible to periods of hypoxemia, but due to the abundant collateralization of blood flow, and partly due to the countercurrent exchange of the vascular supply of the intestinal villi, ischemia is usually averted when hypotension periods are brief (11).

### Pathological Consequences of Splanchnic Hypoperfusion

The splanchnic circulation is susceptible to episodes of hypoperfusion during shock. Due to the relatively low metabolic rate of the splanchnic organs (compared to heart and brain), these low perfusion states are generally well tolerated for brief periods. When periods of splanchnic hypoperfusion become prolonged ischemia and ultimately sepsis, the multiple organ dysfunction syndrome (MODS) can occur. The risk factors associated with splanchnic ischemia are listed in Table 2.

If splanchnic oxygen consumption is increased, as occurs in sepsis or other shock states, splanchnic hypoxemia can be exacerbated even if blood flow returns (13–16). ✎ The pathogenesis of sepsis and MODS is multifactorial. The concept of a “leaky” gut barrier and translocation of bacteria (and cytokines) are likely the integral component. ✎

During ischemic or low flow states in the viscera, proinflammatory cytokines are released. Tumor necrosis factor- $\alpha$  (TNF- $\alpha$ ), interleukin-1, 6, 8, and interferon- $\gamma$  lead to release of secondary inflammatory mediators such as NO and complement, all resulting in the upregulation of immune cell production and stimulation. Once activated, neutrophils adhere to endothelial cells, promoting cell permeability and occasionally injury. Endothelial and junctional damage leads to reductions in gut barrier function, and subsequent translocation of enteric bacteria, lipopolysaccharide, and endotoxin. This is thought to lead to the development of the systemic inflammatory response syndrome (SIRS), sepsis, and eventually MODS (Fig. 1) (16).

### Gastric pH Monitoring

#### Physiological Tenets of Gastric pH Monitoring

Tonometry is the measurement of the partial pressure of a gas in a fluid or intravascular medium. ✎ Gastric tonometry measures luminal CO<sub>2</sub> and mucosal CO<sub>2</sub> partial pressures (PCO<sub>2</sub>), as they become equalized across a semipermeable membrane. ✎

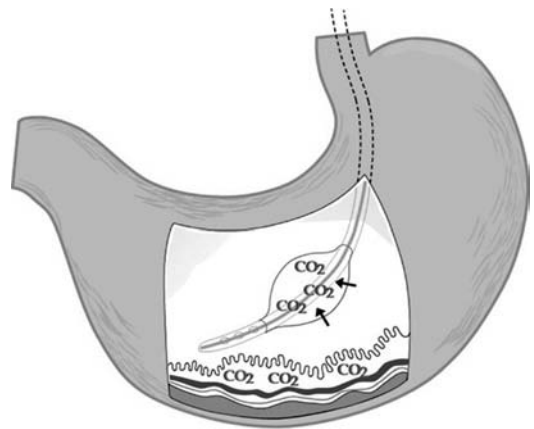

Most gastric tonometers utilize a saline-filled latex balloon (Fig. 2). CO<sub>2</sub> freely diffuses across the membrane,

**Table 2** Risk Factors for Mesenteric Ischemia

Preexisting mesenteric disease	Chronic mesenteric ischemia
Systemic diseases associated with mesenteric disease	Coronary artery disease
	Acute or chronic heart failure
	Diabetes
	Hypertension
	Peripheral vascular disease
	Previous reconstruction for occlusive-stenotic arterial lesions
	Episodes of arterial embolism
	Congenital or acquired hemostatic disorders
	Oral contraceptives
	DVT or PE
Procedures associated with mesenteric ischemia	Trauma
	Abdominal surgery
	Cardiac surgery/CPB
Trauma-related risk factors	Hypotension/hypoperfusion
	SIRS/sepsis
	Vasopressor therapy
	Abdominal trauma
	Abdominal compartment syndrome
	Mechanical ventilation (with high PIP/PEEP)

*Abbreviations:* CPB, cardiopulmonary bypass; DVT, deep venous thrombosis; PE, pulmonary embolism; PEEP, positive end expiratory pressure; PIP, peak inspiratory pressure; SIRS, systemic inflammatory response syndrome.

leading to equilibrium between the saline  $PCO_2$  and the gastric mucosal  $PCO_2$ . The  $PCO_2$  within the saline-filled balloon is used as a proxy for gastric mucosal  $CO_2$ , and is measured using a blood gas analyzer. Utilizing the Henderson-Hasselbach equation, and assuming that the partial pressure of stomach mucosa and arterial bicarbonate are equal, the intramucosal pH (pHi) can be calculated

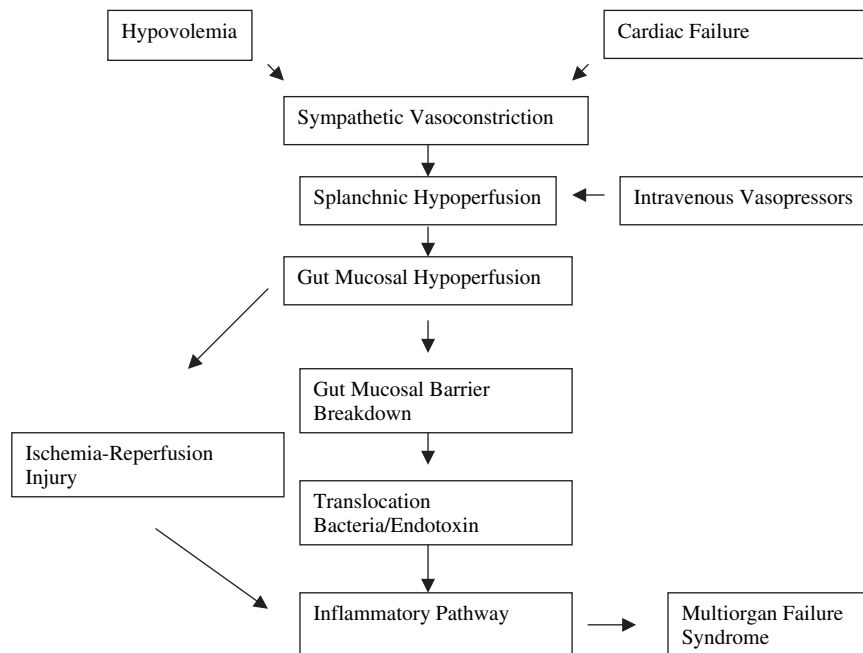

**Figure 2** Gastric tonometry. Gastric mucosal  $CO_2$  diffuses into the gastric tonometer balloon, and is measured using a blood gas analyzer. *Source:* Adapted from Ref. 16.

(Table 3) (15). A decreased pHi is thought to reflect either an increased anaerobic metabolism or a low flow state, and thus ischemic states (15,16).

Two major assumptions enter into the calculation of pHi (15). First, the  $PCO_2$  measured via gastric tonometry approximates the intramucosal  $PCO_2$ , because  $CO_2$  freely diffuses in tissue. In animal studies, no difference has been found between luminal and mucosal  $CO_2$  measurements (17). Second, intramucosal and arterial  $HCO_3^-$  measurements are the same. However, arterial  $HCO_3^-$  measurements are likely an overestimation of the mucosal  $HCO_3^-$  in decreased splanchnic flow states, due to the release of  $H^+$  ions and subsequent buffering via bicarbonate (15). This may lead to altered measurements of pHi.

In the stomach and proximal duodenum, the assumption that mucosal and luminal  $PCO_2$  equilibrates, may fail (15). Unlike the majority of the small and large bowel, the stomach actively secretes  $H^+$  and the proximal duodenum

**Figure 1** The gut hypothesis of sepsis and multiple organ dysfunction syndrome. *Source:* Adapted from Ref. 16.

**Table 3** Physical Principles and Equations Used in Gastric Tonometry

Physical principle	Equation or relationship
Henderson-Hasselbach equation (adapted for pHi)	$pHi = 6.1 + \log_{10} [HCO_3^-] / [\alpha \cdot PCO_2]$ $\alpha = 0.03$ (solubility factor of $CO_2$ in plasma)
Bicarbonate buffer	$HCO_3^- + H^+ \leftrightarrow H_2CO_3 \leftrightarrow CO_2 + H_2O$

Abbreviation: pHi, intramucosal pH.

secretes  $HCO_3^-$ . Although the mucosal barrier in the stomach largely protects against the back diffusion of  $H^+$ , it does not completely do so. This back-diffused  $H^+$  is buffered by bicarbonate in the mucosa, leading to the production of  $CO_2$ , and the reading of a falsely low pHi. Similarly, bicarbonate secreted by the duodenum may reflux into the stomach, buffering  $H^+$ , and artificially lowering the tonometrically measured  $PCO_2$ . Studies in animals have found that back diffusion of  $H^+$  is not much of a confounding factor, whereas increased luminal  $CO_2$  production is (18). It has been proposed that gastric  $H_2$  blockers be utilized to decrease luminal  $H^+$  and thus decrease error in tonometric  $PCO_2$  measurements. In stable subjects, the measured variance between luminal  $PCO_2$ , luminal pH, and pHi were decreased when given an  $H_2$  blocker, whereas when the same values were measured in a small study of critically ill patients on an  $H_2$  blocker, no difference was found versus placebo (19,20).

Other physiological differences may affect the measured pHi (21). Differences in gastric mucosal temperature and arterial blood temperature may change the amount of gas dissolved in tissue or blood respectively. Also, the Haldane effect can increase the measured  $PCO_2$  in the setting of increased oxygen consumption ( $\dot{V}O_2$ ), without increased perfusion (16). Finally, the measured  $PCO_2$  may be confounded by gastric  $H^+$  secretion.

It has been suggested that the difference between gastric and arterial  $PCO_2$  (the "PCO<sub>2</sub> gap") be utilized in order to eliminate the variables and confounding factors of gastric  $H^+$  secretion. This idea of measuring this  $PCO_2$  gap, and not the absolute marker pHi, is utilized in both resuscitation endpoints and in sublingual capnography. Recent expert consensus asserts that the  $PCO_2$  gap is a more accurate reflection of gastric dysoxia (22). A normal  $PCO_2$  gap is approximately less than 8 mmHg, whereas a normal intramucosal  $PCO_2$  is less than 48 mmHg (22). Additional randomized controlled trials (RCTs) will be needed to settle this question.

### Techniques of Gastric Tonometry

#### Conventional Gastric Tonometry

In most commercially available gastric tonometers, a saline solution is infused into a semipermeable balloon (composed of silicone or latex polymers) at the end of a nasogastric tube. Fundamental to the above physiology of tonometry, silicone is permeable to  $CO_2$ . The luminal and mucosal  $PCO_2$  generally equilibrate in approximately 30 minutes, although equilibration times up to 90 minutes have been reported (13). The saline is drawn anaerobically from the saline-filled balloon, and  $PCO_2$  is measured via standard blood-gas analysis. Once the  $PCO_2$  equilibrates, this is used with an arterial bicarbonate measurement to determine pHi. Standard

values for pHi fall within two standard deviations of the norm as found in studies of  $H_2$  blockers on stable subjects. Thus, it is generally accepted that a pHi < 7.32 represents mucosal acidosis (23). However, the type of saline solution and buffer composition used in the blood-gas analysis can skew results (24,25). Strict anaerobic conditions must be maintained, and saline is the preferred media over phosphate bicarbonate or succinylated gelatin solutions due to long equilibrium times (25).

#### Air-Semicontinuous Gastric Tonometry

In an effort to increase the reproducibility and accuracy of gastric tonometry and pHi monitoring, other methods such as air-semicontinuous tonometry are utilized to measure luminal  $PCO_2$  (26,27). Air tonometry uses an air-filled  $CO_2$  permeable balloon that rapidly equilibrates with luminal and mucosal  $PCO_2$ . This is directly measured in a semicontinuous manner, by an infrared sensor. While this too may under- or overestimate the  $PCO_2$  depending on the blood gas machine and assumed equilibrium times, it has been found in animal studies to correlate well with gastric pHi monitoring and be more accurate in the in vitro laboratory (27,28,29). However, outcome data utilizing gastric air-semicontinuous tonometry is similar to traditional saline-filled balloon tonometry and, in fact, both are ubiquitous in research (30).

#### Outcome Studies

Numerous indications exist for gastric tonometry and pHi monitoring. It can be used in all critically ill patients in order to guide resuscitation and improve outcome in sepsis, cardiogenic, and hypovolemic shock (23). Most critically ill patients in the intensive care unit (ICU) have some method to monitor global monitors of ischemia. Gastric tonometry can be utilized as a regional corollary.

☞ **One of the earliest associations identified by gastric tonometry was that MODS rates are correlated with decreased pHi (31).** ☞ Failure of the gut, liver, pancreas, lungs, and generalized sepsis have all been postulated to correlate with decreasing pHi (31). Outcome-driven critical care studies have found a correlation between optimization times for pHi guided resuscitation and survival; as a prognostic marker and independent predictor for mortality; as an independent predictor of MODS; and an association between decreased pHi and increased length of ICU stay (9,32–36). However, other studies have found that guiding resuscitation with pHi versus traditional resuscitation techniques does not yield improved outcomes in either overall survival or rates of MODS (37,38).

Other applications exist for gastric tonometry. In the preoperative setting, gastric pHi monitoring can be used to predict postoperative morbidity and mortality (39). Further, gastric pHi monitoring can guide vasoactive drug administration, particularly when norepinephrine or dopamine is used in conjunction with vasopressin for refractory shock (40,41). Physiologic doses of vasopressin (0.01–0.04 U/min) does not cause significant severe splanchnic vasoconstriction. However, higher doses can threaten gut perfusion. ☞ **Gastric tonometry might evolve into a commonly employed monitor for preventing mesenteric ischemia during prolonged vasopressin use in the setting of refractory shock.** ☞ However, due to the need for stable conditions in order to obtain baseline values and to monitor ongoing resuscitation efforts, gastric tonometry (in its current technological state) is not useful during the initial

resuscitation efforts for the seriously injured trauma patient. With current technology, gastric tonometry is unlikely to provide additional useful information during the initial phase. However, technological advancements in stability calibration and equilibration time could result in early benefits to use.

### Sublingual Capnography

#### **Physiological Tenets of Sublingual Capnography**

Due to the numerous limitations to gastric pHi monitoring utilizing  $PCO_2$  as a surrogate marker, sublingual capnography surfaced as an alternative to directly monitoring tissue-perfusion. Although gastric tonometry measures tissue specific hypercapnia, other tissue, such as renal or brain tissue, have been suggested as sentinel markers for tissue hypoperfusion and shock states.

Unlike gastric monitoring, sublingual capnography is applied to a readily accessible site (42). This facilitates data gathered during initial resuscitation efforts in the trauma resuscitation suite (TRS) or in the trauma operating room (OR). In a fashion similar to gastric  $PCO_2$  monitoring, the sublingual  $PCO_2$  ( $P_{SL}CO_2$ ) is measured against the arterial  $PCO_2$  to define a  $P_{SL}CO_2$  gap. Sublingual capnography does not necessarily reflect perfusion to the splanchnic circulation. Indeed, the sublingual mucosa is not perfused by the splanchnic circulation. However, the sublingual mucosal vascular bed shares similar characteristics with the splanchnic circulation, including a rich vascular supply and stimulatory parasympathetic innervation. Most importantly, several investigations have demonstrated that the  $P_{SL}CO_2$  correlates closely with those values obtained in the stomach during low flow states (43–45).

#### **Technique of Sublingual Capnography**

Several sublingual capnographic measuring devices are commercially available. Studies reviewed here utilize either the MI-720  $CO_2$  electrode (Microelectrodes; Londonderry, New Hampshire, U.S.A.) or the Capnoprobe SL Monitoring System (Nellcor; Pleasanton, California, U.S.A.). The most popular device, the Capnoprobe SL, utilizes a specific  $CO_2$ -sensing optode consisting of a  $CO_2$ -permeable silicone bag with known buffer solution and a fluorescent dye solvent. This bag is attached to a light source that senses the wavelength changes of the fluorescent dye as it is acted upon by the pH of the solution. This is converted into a measurement of  $P_{SL}CO_2$ . It is imperative for measurement that the subject's mouth be closed around the monitor (42).

#### **Outcome Studies**

Studies on sublingual capnography were first conducted in animals, which found plausible reason to study sublingual  $CO_2$  in humans due to correlations between rising  $P_{SL}CO_2$  and systemic markers such as arterial lactate (43). Further, a head-to-head animal study comparing sublingual monitoring with gastric tonometry found similar monitoring characteristics and increases measured in both gastric intramucosal  $PCO_2$  and  $P_{SL}CO_2$  gap (44). Subsequently, the same investigators found that  $P_{SL}CO_2$  values greater than 70 mmHg were predictive of hospital survival, and that  $P_{SL}CO_2$  corrected in a more rapid manner than serum lactate (45). The  $P_{SL}CO_2$  gap has also been found to correlate with gastric  $PCO_2$  gap and lactate levels in critical care patients in circulatory or septic shock, and a small study has found that sublingual  $P_{SL}CO_2$  gap is a better predictor of survival than lactic acid (46–48).

✎ A recent study has also found correlation between hemorrhage in penetrating trauma and rise in sublingual  $P_{SL}CO_2$ , coinciding with increasing in BD and lactate levels (49). ✎

### Surrogate Measures of Splanchnic Well-Being

#### **Lactic Acidosis**

Lactic acidosis is a global marker of tissue hypoxia and is produced anaerobically from the substrate pyruvate. A normal plasma lactate level is less than 2.0–2.2 mmol/L; elevated levels correlate with oxygen delivery  $\dot{D}O_2$  deficit and global under-resuscitation. Anaerobically produced lactate is generally independent of other metabolic processes (in comparison to other global hypoxia markers such as base deficit), although severe liver dysfunction can artificially prolong lactic acid levels (50). Outcome data has shown a correlation to lactate level normalization and mortality; development of acute respiratory distress syndrome; the SIRS and severe sepsis; and an increase in infection rates (51–55).

For the purposes of splanchnic monitoring, lactic acidosis is felt to be a generalized marker. Studies are mixed as to whether direct splanchnic monitoring (gastric tonometry), indirect splanchnic monitoring (sublingual capnography), or global markers of hypoperfusion are more sensitive guides to resuscitation. Early studies found gastric tonometry and pHi to better predict mortality and multiorgan system failure than traditional markers such as lactate levels and BD (9,35). The  $P_{SL}CO_2$  was found, in one small study, to be a better predictor of mortality and a more sensitive marker than lactate levels (48). However, few RCTs exist comparing traditional endpoints with focused splanchnic monitoring. A recent small study, which randomized resuscitation in trauma patients to either “traditional” pHi markers (such as lactate) or gastric pHi directed therapy, found no difference in outcomes (38).

#### **Tolerance of Enteral Nutrition**

✎ Tolerance of early enteral feeding has been shown to correlate with numerous markers, including decreasing bacterial translocation and morbidity from sepsis, overall mortality, the length of ICU stay, and cost of ICU admission (56). ✎ Although a majority of physicians begin enteral feeds within 48 hours of admission, less than half of patients started on enteral nutrition achieve tolerance to the feedings (56,57). Historically, tolerance of enteric feeding has been based on the concept of gastric residual volumes (GRVs). High GRVs are traditionally thought to correlate with poor outcomes, such as aspiration and pneumonia, or as a marker for intolerance of enteral nutrition (58). However, the definition of “high” by some (>150 mL in a 70-kg patient) is felt to be too low a threshold by most experienced intensivists. GRVs in this (150–200 mL) range are of little value in directing feedings due to: (i) lack of correlation with the measured value and adverse outcomes; and (ii) absence of standardization of GRV values. Using such low “acceptable” GRVs likely impedes the progression of feedings (58). The use of higher threshold GRVs (~450 mL in a 70-kg patient), along with the administration of promotility agents, and distal duodenum- or jejunal-placed feeding tubes, all correlate with increased tolerance of enteral nutrition (also see Volume 2, Chapter 32) (59,60). Due to conflicting opinions on the utilization of GVRs in the clinical setting, other methods for monitoring tolerance of enteral nutrition have been sought.

A few small studies have looked at tolerance of enteral nutrition and measuring Brix values, a measurement of the total amount of soluble solids in a solution. The Brix value is designed to help account for the amount of enteral formula versus gastric secretions and saliva contained in the GRV (61,62). The Brix value is obtained using a refractometer to assay the GRV aspirated from the patient. At best, these studies show the Brix value measurements as a clinical adjunct with GRV values, but have little clinical correlation to tolerance of enteral feedings or outcome.

Splanchnic monitoring via gastric tonometry or sublingual capnography may also serve as markers for tolerance to enteral nutrition. In theory, intolerance of enteral feedings can result from splanchnic hypoperfusion and, conversely, prolonged starvation could decrease splanchnic hypoperfusion. In cardiothoracic surgery patients, early enteral feedings did not show any effect on gastric tonometry measurements, potentially indicating tolerance of enteric feedings (although this was not an endpoint in the study) (63). Enteral feeding in burn patients has been shown via gastric tonometry to have beneficial effects on splanchnic circulation (64). In a small case study, a gastric pH less than 7.30 was found in all patients with nonocclusive bowel necrosis, one of the dreaded, but rare, complications of enteral feeds in the critically ill (65).

### Stress Gastritis

Stress gastritis is associated with gastric mucosal ischemia (Volume 2, Chapter 30). A recurring paradigm of ischemia and reperfusion injury not only provides a plausible explanation for the development of stress gastritis (66,67), but also highlights the physiology and importance for other methods of splanchnic monitoring.

Mucosal ischemia (from various etiologies including occult hypoperfusion) interrupts gastric mucus production and has an overall negative effect on the gastroprotective prostaglandin (PG) and bicarbonate production. Further exacerbating the breakdown of the protective gastric mucus is reflux of bile salts into the gastric lumen in critically ill patients (67). The breakdown of gastric mucosa leads to subendothelial petechiae and small erosions from the acidic gastric contents. Ultimately, this may lead to frank ulceration (67).

Numerous risk factors, such as mechanical ventilation, coagulopathy, hypotension, sepsis, hepatic failure, renal failure, burns, and major trauma, may contribute to the development of mucosal ischemia and stress gastritis (67). All of these factors have specific physiological mechanisms, although two are particularly pertinent. Patients with critical illness often exhibit associated respiratory failure, and consequently require mechanical ventilation. The institution of mechanical ventilation can directly impair the splanchnic blood flow. Increased intrathoracic pressure and positive end expiratory pressures can decrease venous return and, thus, splanchnic perfusion (68).

The GI tract is susceptible to prolonged periods of decreased perfusion pressures. In addition to the increased risk of bacterial and cytokine translocation, the end result of gastric mucosal ischemia is stress gastritis. Medications that limit splanchnic perfusion also have the potential to cause mucosal ischemia and stress gastritis (67). Vasoactive agents, such as norepinephrine and vasopressin, can cause a decrease in splanchnic circulation, although correlations between these agents and stress gastritis are not as clear (69,70).

Prophylaxis against stress gastritis is recommended (Volume 2, Chapter 30), although the best choice is not readily apparent (71–73). Mechanical barriers, such as sucralfate, and pharmaceutical agents, such as H<sub>2</sub> blockers and proton pump inhibitors, are utilized. These agents have been shown to decrease the incidence of stress gastritis in the critical care setting, and subsequently decrease the utility of monitoring for stress gastritis as a marker for splanchnic ischemia and occult hypoperfusion—leading to the utility of gastric tonometry or sublingual capnography.

## RENAL MONITORING

### Introduction

Renal dysfunction and renal failure (Table 4) remain a serious complication in the critically ill trauma or postoperative patient (see Volume 2, Chapters 40–42). The trauma, burn, and the postoperative surgical patient have numerous risk factors that make them at high risk for the development of renal dysfunction (Table 5). Renal failure complicates the perioperative management of these patients. The onset of acute renal failure (ARF) portends a poor prognosis and a high association with mortality, sepsis, and MODS. The prevention of ARF lies in ensuring adequate resuscitation, preventing continued damage, minimizing the impact of coexisting disease, and minimizing the number of nephrotoxic drugs (Table 6).

As with other organ systems, renal function is intimately related to blood flow supplied by its arteries (renal artery). The detection of altered or diminished renal blood flow (RBF) is clinically difficult due to the limited available monitoring technologies. ⚡ **Surrogate markers [urine output, serum creatinine, and glomerular filtration rates (GFRs—which is most commonly calculated from creatinine clearance (CL<sub>CR</sub>)] are routinely used to assess for clinically detectable alterations in RBF.** ⚡ The most commonly employed tests and imaging studies used to evaluate renal perfusion and function are listed in Tables 7 and 8.

### Anatomy and Physiology

#### Renal Circulation

Each kidney is supplied by a single renal artery arising from the aorta at the level of the intervertebral disc between L1 and L2 vertebrae. Each renal artery divides at the renal pelvis into 5 to 6 segmental arteries, which give rise to the interlobar arteries. At the division between the renal cortex and medulla, the interlobar arteries divide again into the arcuate arteries. Arcuate arteries then give rise to the interlobular arteries and the capsular perforating branches. Interlobular arteries directly supply each nephron through a

**Table 4** Causes of Perioperative Renal Failure

Category	Description
Prerenal	Reversible increase in serum creatinine and blood urea. Results from a decreased renal perfusion, which leads to a decreased GFR
Postrenal	Caused by an obstruction of the urinary collection system by either intrinsic or extrinsic causes
Renal	The structures of the glomerulus, tubules, vessels, or interstitium are affected

Abbreviation: GFR, glomerular filtration rate.

**Table 5** Risk Factors for Perioperative Acute Renal Failure

Risk factor category	Examples/comments
Preexisting renal insufficiency	The worse the preexisting renal insufficiency, the greater the risk
Systemic diseases associated with chronic renal failure	Coronary artery disease Congestive heart failure Diabetes Hypertension Liver failure, hepato-renal syndrome Peripheral vascular disease Polycystic kidney disease Scleroderma Systemic lupus erythematosus Rheumatoid arthritis Wegner’s granulomatosis
Procedures associated with acute renal failure	Biliary surgery Burns Cardiac surgery Genitourinary surgery/obstetric surgery Transplant Trauma CAT scan
Trauma-related risk factors	Hypotension Hypovolemia Hypoperfusion Medication/antibiotics IV contrast Blood transfusion Rhabdomyolysis SIRS/sepsis Vasopressor therapy

*Abbreviations:* CAT, computerized axial tomography; IV, intravenous; SIRS, systemic inflammatory response syndrome.

single afferent arteriole (74). The microcirculation of the kidney is arranged into three separate blood flow zones, including that perfusing the cortex, the outer medulla, and the inner medulla (74).

**Table 6** Medications Associated with Renal Failure

Nephrotoxic drug type	Examples/comments
IV radiocontrast	Nonionic less toxic than ionic
H <sub>2</sub> receptor antagonists	Cimetidine, rantidine, fomotidine
NSAIDs	Ibuprofen, Cox2 inhibitors, aspirin
Immunosuppressive drugs	Cyclosporin A, tacrolimus
Antibacterial drugs	Aminoglycosides, penicillins, sulfonamides, cephalosporins, vancomycin
Antifungal agents	Amphotericin B
Malignant chemotherapy drugs	Methotrexate, nitrosureas, cisplatin, asparaginase,
Others	Acetaminophen, ACE inhibitors, allopurinol, IVIG, hydroxyethyl starch, antivirals, metoclopramide

*Abbreviations:* ACE, angiotensin-converting enzyme; Cox2, cyclooxygenase 2; IV, intravenous; IVIG, intravenous immunoglobulin; NSAIDs, nonsteroidal anti-inflammatory drugs.

**Table 7** Commonly Used Tests and Studies in the Diagnosis of Acute Renal Failure

Category	Examples
Radiographic imaging	Ultrasound CT scan RUG Plain radiographs (KUB) IVP Angiography
Urine evaluation	Urine electrolytes Urine eosinophiles Urine analysis Urine culture
Tests of cardiac function	Cardiac echocardiography CVP Pulmonary capillary wedge pressure Left atrial pressure
Histological	Renal biopsy Autopsy

*Abbreviations:* CT, computed tomography; CVP, central venous pressure; IVP, intravenous pyelogram; KUB, kidneys, ureters, and bladder; RUG, retrograde urethrogram.

The blood flow through both kidneys constitutes approximately 20% to 25% of the total Q̇, but can dramatically drop in patients that are hypovolemic or hypotensive. Approximately 80% of RBF supplies the cortical nephrons, whereas 10% to 15% supplies the juxtamedullary nephrons. Redistribution of RBF away from cortical nephrons, with short loops of Henle, to larger juxtamedullary nephrons with long loops, occurs during periods of stress and other times that are clinically relevant. Vasoactive hormones that regulate intrarenal blood flow originate from outside the kidney (vasopressin, norepinephrine, epinephrine), areas adjacent to the kidney (kinins, endothelins, adenosine), and from within the endothelium (NO, prostacyclin, endothelins) (74). Sympathetic nerve activation (75), angiotensin II (76), norepinephrine (76), and heart failure (77) have all been found to cause a redistribution of RBF away from the renal cortex and to the renal medulla. However,

**Table 8** Physiologic Tests of Renal Tubular Function

Test	Prerenal	Renal (intrinsic)
U:P osmolality	> 1.4:1	1:1
Urine osmolality	>500	<400
U:P creatinine	>50:1	<20:1
Urine Na level, mEq/L	<20	>40
FE <sub>Na</sub>	<1	>3
CL <sub>CR</sub>	15–20	<10
FE <sub>UA</sub>	<35	>35
FE <sub>Li</sub>	<15	>25
Urinary sediment	Normal, occasional hyaline, or finely granular casts	Renal tubular epithelial cells, granulars, and muddy brown granular casts

*Abbreviations:* CL<sub>CR</sub>, creatinine clearance; FE<sub>Li</sub>, fractional excretion of lithium; FE<sub>Na</sub>, fractional excretion of sodium; FE<sub>UA</sub>, fractional excretion of urea; P, plasma; U, urine.

not all vasopressors preferentially reduce cortical blood flow; vasopressin was recently found to preferentially reduce medullary blood flow in an animal model (76).

Contrast media is a major cause of hospital-acquired renal insufficiency. It has a heterogeneous effect on regional RBF, affecting outer medulla greater than the inner medulla or cortical blood flow (78). Iso-osmolar and high-osmolar contrast media, at normal and high doses, decrease outer medullary blood flow and place patients at significant risk for renal dysfunction (79).

The clinical significance of the redistribution of blood flow within the kidney can vary from situation to situation and patient to patient. Regardless of the stressor causing redistribution of RBF, it has been shown to be associated with sodium retention in both hypertensive and nonhypertensive patients. Initially, the redistribution of RBF serves to conserve sodium and free water. Prolonged periods of ischemia unleash a cascade of intrarenal mediators that potentially could lead to renal insufficiency and MODS. The role of NO and prostaglandin E<sub>2</sub> (PGE<sub>2</sub>) in the prevention of this alteration in RBF is an ongoing area of research, but has shown promise in angiotensin II and norepinephrine dependent cortical constriction (80,81).

The kidney is the only organ in which oxygen consumption ( $\dot{V}O_2$ ) is determined by RBF, this relationship seems to be maintained during periods of extreme stress (82–84). The rate of active transport of Na<sup>+</sup> best correlates with the  $\dot{V}O_2$  (85,86). The simple relationship between  $\dot{V}O_2$  and sodium transport best explains why the active transport of sodium decreases when RBF is diminished. **Renal physiology and pathophysiology are described by the relationships between RBF, renal  $\dot{V}O_2$ , O<sub>2</sub> extraction, and CL<sub>CR</sub> in patients with normal and abnormal renal function (87).**

### Pathology of Renal Hypoperfusion

Trauma patients have multiple reasons for increased perioperative risk of renal failure (Table 5), including hypovolemia, hypotension, rhabdomyolysis, use of nephrotoxic agents (e.g., contrast, aminoglycosides, etc.). The risk increases further if they have associated intra-abdominal or renal trauma (e.g., renal contusion, lacerations, etc.). Trauma patients who are severely injured and have associated renal injury, have a much higher incidence of renal insufficiency and twice the mortality of those without renal injuries (88). In addition to direct renal trauma, secondary injury from conditions causing abdominal compartment syndrome (Volume 2, Chapter 34) are also important.

The renal circulation is extremely susceptible to periods of hypoperfusion. Prerenal causes account for 75% to 80% of the cases of perioperative dysfunction. Intrinsic causes account for 20% to 25% of the cases. The balance between renal  $\dot{V}O_2$  and RBF tends to be maintained in states of shock or other shock states. However, with prolonged periods of renal hypoperfusion, ischemia and ultimately MODS can occur.

The role of the kidney in the propagation of SIRS and sepsis to MODS is incompletely understood. However, we do know that prolonged periods of reduced  $\dot{D}O_2$  can lead to renal insufficiency. During periods of ischemia, the kidneys develop an O<sub>2</sub> debt and increase the release of vasoactive hormones, to include PGs, interleukins, and endothelin. Renal failure might supply a "second hit" in the development of sepsis, SIRS, and MODS in certain conditions (89).

## Urine Output

### Monitoring Urine Output

Serial measurements of urine output constitute the simplest form of RBF monitoring and assessment of renal function (see Volume 2, Chapter 40). Urine output is also one of the most commonly measured variables in the critically ill patient (90). However, resuscitation state, perioperative medications, and other interventions can alter the validity of this surrogate measure for RBF and renal function.

**When evaluating a patient for alterations in urine output, the patient's medical history, medication use, type of surgery (or trauma), and relevant perioperative interventions must all be considered.**

Urine output is an imperfect measure of renal function. Renal failure can occur in the setting of normal, elevated, or low urine output when confounders are present. That being said, urine formation is a sensitive marker of low flow states and prerenal causes of ARF. In the SICU, and especially in postsurgical and trauma patients, low urine output should be assumed to be prerenal until proven otherwise. Oliguria or low urine output, regardless of the setting, should prompt an evaluation of the patient and the correction of prerenal causes of renal dysfunction. Acute anuria suggests a mechanical or obstructive cause of renal failure, and the evaluation should be focused on the obstructive causes of renal failure in otherwise stable patients (e.g., kinked indwelling urine catheter).

However, in the setting of massive hemorrhage, oliguria and anuria reflect inadequate RBF due to insufficient intravascular volume repletion and/or inadequate renal perfusion pressure.

Oliguria is defined as urine output of 400 mL/day in a patient with previously normal kidneys. However, it is preferable to monitor urine output in the terms of hourly output, because prolonged periods of prerenal causes could lead to renal ischemia and acute tubular necrosis. Hence, oliguria has been traditionally defined as less than 0.5 mL/kg/hr. In critically ill, postoperative, or trauma patients, it should be expected that their trends of urine output should be greater than this value.

### 24-Hour Urine Output and Outcomes

Monitoring 24-hour urine output is useful in monitoring resuscitation, predicting the need for dialysis, and predicting mortality. Low urine output has been shown to be predictive of those patients requiring dialysis after cardiac surgery (91). It is predictive of those patients having higher mortality after myocardial infarction (92). Oliguric ARF was found to be an independent predictor for overall mortality in a subgroup of 348 patients with renal failure in the ICU (93).

## Tubular Function

### Creatinine and Creatinine Clearance

Creatinine is an end-product of skeletal muscle catabolism. Creatinine production is proportional to skeletal muscle mass, and is excreted solely by the kidneys. CL<sub>CR</sub> measures the ability of the glomerulus to filter creatinine, and is the most reliable and widely used marker of GFR. Normal serum creatinine values range from 0.7 to 1.2 mg/dL. The formulas used to assess tubular function are listed in Table 9.

The most widely utilized formula to standardize GFR and renal function, according to age, is the Cockcroft-Gault equation: CL<sub>CR</sub> = [140 - age (yrs)] × wt (kg) × 0.85 (if

**Table 9** Formulas Used to Assess Tubular Function

$$CL_{CR} = (\text{creatinine})_U \times \text{urinary flow rate} / (\text{creatinine})_P$$

$$GFR = (140 - \text{age})(\text{body weight in kg}) / (\text{serum creatinine} \times 72)$$

$$FE_{Na} = (\text{urine sodium} / \text{serum sodium}) / (\text{urine creatinine} / \text{serum creatinine}) \times 100\%$$

$$FE_{UA} = (\text{urine urea} / \text{serum urea}) / (\text{urine creatinine} / \text{serum creatinine})$$

*Abbreviations:*  $CL_{CR}$ , creatinine clearance;  $FE_{Na}$ , fractional excretion of sodium;  $FE_{UA}$ , fractional excretion of urea; GFR, glomerular filtration rate; P, plasma; U, urine.

female)/72  $\times$  [serum creatinine (mg/dL)] (94). Normal values range from 110 to 150 mL/min. Mild, moderate, and severe renal impairment have corresponding values of 40 to 60 mL/min, 20 to 40 mL/min, and less than 20 mL/min. Serial measurement of GFR is important for the early detection of renal dysfunction, determining the severity of renal impairment, and the need for further evaluation.

The  $CL_{CR}$  as a measure of GFR is commonly employed in the SICU for monitoring proper drug dosing and for the early detection of ARF. However, there is ongoing debate regarding the accuracy of these formulas for predicting  $CL_{CR}$  in critically ill patients. Wells et al. retrospectively evaluated 18 critically ill patients, nine without renal dysfunction, and nine with ARF. The investigators found statistically significant differences between measured  $CL_{CR}$  and the predicted values using the Cockcroft-Gault equation (94). Robert et al. assessed renal function utilizing inulin clearance, 30-minute  $CL_{CR}$ , 24-hour  $CL_{CR}$ , and the values estimated by the Cockcroft-Gault equation. They found that Cockcroft-Gault equation, using ideal body weight and the corrected serum creatinine concentration, was the best predictor of inulin clearance (95).

Furthermore, they found good correlation existed between inulin clearance and the Cockcroft-Gault equation, if the actual or ideal body weight and the actual or corrected serum creatinine were used in the calculation (95). Studies in trauma patients have shown that  $CL_{CR}$  can be used in those with stable renal function (96), and for the early detection of renal failure (97).

### Fractional Excretion of Sodium

Fractional excretion of sodium ( $FE_{Na}$ ) reflects tubular sodium reabsorption.  $FE_{Na}$  describes sodium clearance as a percentage of  $CL_{CR}$ .  $FE_{Na}$  less than 1% is seen in normal or hypovolemic patients.  $FE_{Na}$  above 3% indicates tubular damage or intrinsic causes of renal failure. Care must be taken when using  $FE_{Na}$  to evaluate for renal failure; medications are known to both raise and lower the  $FE_{Na}$ . Diuretics are the class of medications most notoriously known to alter the value and the usability of  $FE_{Na}$ . Both hydrochlorothiazide and furosemide have been shown to increase the fraction of sodium excreted (98).

### Fractional Excretion of Urea

Fractional excretion of urea ( $FE_{UA}$ ) reflects the tubular reabsorption of urea. As with  $FE_{Na}$ ,  $FE_{UA}$  describes urea clearance as a percentage of  $CL_{CR}$ .  $FE_{UA}$  less than 35% is seen in patients that are hypovolemic or prerenal.  $FE_{UA}$  above 35% indicates a normal, tubular damage or intrinsic causes of renal failure. In well-hydrated patients, the  $FE_{UA}$  is between 50% and 65% (99). Patients that have acute tubular necrosis (ATN) routinely have a  $FE_{UA}$  above 40%.

$FE_{UA}$  may be a more sensitive and specific index than  $FE_{Na}$  in differentiating between prerenal-associated oliguria and ATN. ⚡ **The  $FE_{UA}$  has a much higher positive predictive value in separating prerenal from ATN, 98% versus 89%.** ⚡ It is especially useful in differentiating prerenal from intrinsic renal failure, after diuretics are used (100).

### Urine-Concentrating Ability

The human body's ability to concentrate urine and maintain a normal serum osmolality is imperative. This is assessed by measuring urine osmolality, and comparing this value to the serum osmolality. Normal urine osmolality ( $U_{osm}$ ) is 300 mOsm/kg (range 50–1200 mOsm/kg). Serum osmolality (278–298 mOsm/kg) should be measured in conjunction with urine osmolality. As serum tonicity increases, the release of antidiuretic hormone (ADH) increases, causing an increase in the reabsorption of free water and in the osmolality of urine. The opposite is true with a decrease in the serum tonicity; the decrease in ADH causes a decrease in the reabsorption of free water and in the osmolality of urine.

The most common times that clinicians will utilize these studies ( $S_{osm}$  and  $U_{osm}$ ) is immediately postoperatively, ARF, and in the neurosurgical patient where diabetes insipidus (DI) results in a large quantity of dilute urine with increasing serum sodium and osmolality. The syndrome of inappropriate antidiuretic hormone (SIADH) can also occur in neurosurgical patients, and presents with a low quantity of concentrated urine, along with a concomitantly decreased serum sodium and osmolality (see Volume 2, Chapter 44).

## Imaging in Genitourinary Conditions

### Renal Ultrasound

The evaluation and workup of patients in acute, or acute on chronic, renal failure has traditionally focused on identifying the underlying etiology; prerenal, renal, or postrenal causes. Imaging techniques, especially ultrasound, can give an effective assistance in the differential diagnosis of ARF. ⚡ **Imaging techniques can be used to exclude postrenal (obstruction) and prerenal (renal artery stenosis, low RBF) renal failure and confirm the diagnosis of intrinsic causes of renal failure.** ⚡

Color and pulse Doppler ultrasound are noninvasive tests that can be performed quickly and safely at the bedside. Color Doppler ultrasound has been utilized in diagnosing pyelonephritis (101), assessing RBF post-transplant (102,103), and differentiating between the causes of renal failure (104). However, many of the studies utilizing Doppler to assess for RBF have focused on renal transplant recipients.

Color Doppler (or duplex) ultrasound is commonly utilized in assessing patients with renal insufficiency and clearly has a role in the diagnosis of obstructive renal failure. Color Doppler has been increasingly utilized to assess for prerenal and renal causes of ATN as well. Izumi et al. evaluated 42 patients with ARF by Doppler ultrasound. Not only did they find that it was an effective tool to evaluate ARF caused by ATN, but also found it predictive of the recovery from ATN. However, its overuse in the initial diagnosis and management of ARF, especially in patients at low risk for obstructive renal failure, has been questioned (105).

Power Doppler ultrasound is a technique that has been in use since the mid-1990s, and is capable of detecting small-vessel, low-velocity flow (106,107). It has the ability to differentiate a wide spectrum of hypovascular renal pathologies. Renal hypoperfusion measured by power Doppler

ultrasound has the ability to detect focal, multifocal, global, and cortical lesions (108). A recent animal study has found that image intensity of power Doppler ultrasound correlated well with invasively measured renal cortical blood flow (109). This technology has the greatest possibility to provide real-time measurement of renal perfusion during resuscitation of the injured and critically ill patient.

### Computed Tomography

Computed tomography (CT) has primarily been used to evaluate renal injury following intra-abdominal and retroperitoneal injuries sustained after blunt and penetrating trauma (110) (see Volume 1, Chapters 16, 27, and 28). Intrarenal blood flow derived from CT has been utilized in patients with renovascular disease (111), living kidney donors (112), and as an assessment prior to abdominal aortic aneurysm (113). In these studies, it was predominately utilized as a single occasion evaluation tool. Given the limitations of this technique and the advent of newer technologies that can be utilized continuously at the bedside, the role of CT in renal monitoring is obviously limited.

### EYE TO THE FUTURE

The advent of newer technologies and biomarkers will allow for closer and more accurate monitoring of splanchnic and RBF. Many of the modalities described above represent techniques that require RCTs to better determine utility. Further, each of the techniques discussed is undergoing rapid technological improvements. Thus, the current notions of utility for various monitoring devices may change in the near future.

A relatively new perfusion monitoring tool that is on the clinical horizon is the buccal tissue  $\text{CO}_2$  monitoring device (Fig. 3) (114). Increases in sublingual and buccal tissue  $\text{PCO}_2$  ( $\text{PCO}_2$  BU) have been shown to approximate those in the stomach and gut during low-flow states (115). At each of these sites, tissue  $\text{PCO}_2$  was closely correlated with decreases in tissue blood flows (115–117).

Recently, Cammarata et al. (114) measured the  $\text{PCO}_2$  BU in a rodent model of hemorrhagic shock. Rats were

**Figure 3** Buccal capnometry device (including positioning doughnut). A miniature  $\text{CO}_2$  electrode (MI-720  $\text{CO}_2$  electrode; Microelectrodes, Londonderry, New Hampshire, U.S.A.), is positioned with the aid of a foam “doughnut.” The doughnut helps maintain continuous contact with the mucosa without compromising local blood flow. Source: From Ref. 114.

bled over an interval of 30 minutes, in amounts estimated to be 25, 30, 35, or 40% of total blood volume. The  $\text{PCO}_2$  BU was predictive of outcomes. Neither noninvasive end-tidal  $\text{PCO}_2$ , nor invasive aortic pressure measurements achieved such discrimination (114).

### SUMMARY

Trauma patients commonly present hypotensive and hypovolemic. Optimal resuscitation requires early goal-directed therapy to prevent damage to organ systems and propagation of systemic inflammation. In addition to global measures, assessing perfusion adequacy for specific vascular beds (e.g., splanchnic and renal) are increasingly pursued, and newer technologies are becoming increasingly useful.

The splanchnic circulation is susceptible to prolonged periods of hypoperfusion. Markers used to assess adequacy of  $\text{DO}_2$  include gastric pH monitoring, sublingual capnography, lactic acidosis, tolerance of gastric feeds, and stress gastritis. The benefits and drawbacks of each of these methods for monitoring splanchnic circulation have been discussed.

The renal circulation has been established to preferentially shunt blood away from the cortex and supply the medulla. This places the kidney at high risk for ischemia and ATN, during periods of hypoperfusion as well. Markers used to assess RBF and renal dysfunction were described, including urine output,  $\text{FE}_{\text{Na}}$ ,  $\text{FE}_{\text{UA}}$ , urine-concentrating ability, and imaging modalities.

Injuries to the splanchnic and renal systems likely play key roles in the propagation of SIRS to sepsis, septic shock, and ultimately MODS in the trauma patient. As we better understand the pathophysiology of trauma, SIRS, and MODS, the better we will understand the role played by splanchnic and renal hypoperfusion in the development of these conditions. By improving the circulation to these two organ systems and providing better ways to gauge and monitor that perfusion, we hope to improve the outcomes of patients who experience trauma.

### KEY POINTS

- ☞ The two organ systems most often initially impacted in the underresuscitated trauma patient are the kidneys and GI organs.
- ☞ In the resting normovolemic patient, approximately 20% to 35% of the cardiac output is directed to the splanchnic circulation.
- ☞ The pathogenesis of sepsis and MODS is multifactorial. The concept of a “leaky” gut barrier and translocation of bacteria (and cytokines) are likely the integral component.
- ☞ Gastric tonometry measures luminal  $\text{CO}_2$  and mucosal  $\text{CO}_2$  partial pressures ( $\text{PCO}_2$ ), as they become equalized across a semipermeable membrane.
- ☞ One of the earliest associations identified by gastric tonometry was that MODS rates are correlated with decreased  $\text{pHi}$  (31).
- ☞ Gastric tonometry might evolve into a commonly employed monitor for preventing mesenteric ischemia during prolonged vasopressin use in the setting of refractory shock.

- 9 A recent study has also found correlation between hemorrhage in penetrating trauma and rise in sublingual  $P_{SL}CO_2$ , coinciding with increasing BD and lactate levels (49).
- 9 Tolerance of early enteral feeding has been shown to correlate with numerous markers, including decreasing bacterial translocation and morbidity from sepsis, overall mortality, the length of ICU stay, and cost of ICU admission (56).
- 9 The onset of acute renal failure (ARF) portends a poor prognosis and a high association with mortality, sepsis, and MODS.
- 9 Surrogate markers [urine output, serum creatinine, and glomerular filtration rates (GFRs)—which is most commonly calculated from creatinine clearance ( $CL_{CR}$ )] are routinely used to assess for clinically detectable alterations in RBF.
- 9 Renal physiology and pathophysiology are described by the relationships between RBF, renal  $\dot{V}O_2$ ,  $O_2$  extraction, and  $CL_{CR}$  in patients with normal and abnormal renal function (87).
- 9 Renal failure might supply a “second hit” in the development of sepsis, SIRS, and MODS in certain conditions (89).
- 9 When evaluating a patient for alterations in urine output, the patient’s medical history, medication use, type of surgery (or trauma), and relevant perioperative interventions must all be considered.
- 9 Studies in trauma patients have shown that  $CL_{CR}$  can be used in those with stable renal function (96), and for the early detection of renal failure (97).
- 9 The  $FE_{UA}$  has a much higher positive predictive value in separating prerenal from ATN, 98% versus 89%.
- 9 Imaging techniques can be used to exclude postrenal (obstruction) and prerenal (renal artery stenosis, low RBF) renal failure and confirm the diagnosis of intrinsic causes of renal failure.

## Temperature Monitoring

Abdallah Kabbara

Department of Anesthesia, MetroHealth Medical Center, Cleveland, Ohio, U.S.A.

Charles E. Smith

Department of Anesthesiology, MetroHealth Medical Center, Case Western Reserve University, Cleveland, Ohio, U.S.A.

### INTRODUCTION

Although fever has been recognized since antiquity as an accompaniment of illness (1), the ability to measure temperature clinically was developed only over the last 300 years (2–4). Temperature measurement continues to serve as a simple and direct method of tracking a patient's progress and recovery from disease (particularly infectious). Body temperature was not routinely measured during anesthesia until malignant hyperthermia was described in the mid-1960s (5). Over the years, the art of temperature measurement has evolved to incorporate new advances in technology. Like so many other areas of care, measuring a patient's temperature has become increasingly precise and efficient. Similarly, there is far better understanding of the ramifications and management of hypothermia and heat-related illnesses (Volume 1, Chapter 40), as well as the evaluation of fever (Volume 2, Chapter 46) following trauma and critical illness.

This chapter briefly reviews the history of thermometry extending back to the early Greeks, the rediscovery of their writings in the 1600s by Galileo, Sanctorio, et al., and subsequent developments. The "normal" temperature range was not established until 1868, by Wunderlich and his cadre of medical students (6,7); the major findings of this early research, along with the subsequent work on establishing the "normal temperature" is clearly presented. The mechanism of thermoregulation, heat loss, and the normal response to cold and heat are also reviewed. The importance of measuring temperature in trauma and critically ill patients is emphasized with examples of related complications. The pathophysiology of heat- and cold-related conditions is only briefly summarized here, as it is thoroughly covered in Volume 1, Chapter 40. The currently employed temperature measurement instrumentation, as well as the advantages and disadvantages of these devices for measuring temperature at various anatomic sites is thoroughly reviewed. In the "Eye to the Future" section, newer modes of temperature measurement are introduced. The evaluation of fever is the subject of Volume 2, Chapter 46 and not covered here.

### HISTORY OF THERMOMETRY

The term "thermometer" is a compound word derived from the Greek *therme* (heat) and the Latin *metrum* (to measure). Early versions of this device were known as thermoscopes; the word scope is derived from the Greek *skopos*, (target, aim, or see).

The ancient Greeks knew that air could be expanded by heat, and in the second century BC, Philo of Byzantium (260–180 BC), a Greek engineer, constructed a crude thermoscope, as did Heron of Alexandria (250–150 BC) (2). A simple air-thermoscope traps air in a bulb so that applied heat expands and cold contracts it; the temperature variations are reflected in a rising or falling column of water in the tube connected to the bulb (Fig. 1) (3).

Galileo Galilei (1564–1642) has been credited with inventing the air/water thermoscope in 1593. However, he never claimed to have invented the device himself. Galileo most likely learned of the thermoscope from colleagues (described subsequently) and from reading Latin translations of Arabic documents that contained records of the aforementioned Greek engineer scholars Philo of Byzantium or Heron of Alexandria. It is likely that Giambattista della Porta (1535–1615), a wealthy Italian scholar, was the purveyor of such information. Della Porta, 31 years Galileo's senior, translated some of the Arabic records of Greek works into Latin, and initiated a scholarly society and convened meetings at his estate until these were closed down by the Inquisition. His book, "Natural Magic," (1558) described a Greek thermoscope (this was published 35 years prior to the time some claim that Galileo invented it).

The Italian physician-scientist Sanctorio Sanctorio of Padua (1561–1636), a colleague of both Galileo and della Porta, was the first to put a numerical scale on the instrument, thereby converting the thermoscope into the first thermometer (4). In his publication depicting medicine from Galen (Venice, 1612), Sanctorio acknowledges that he adapted his thermometer from one described by Heron of Alexandria.

In 1714, Daniel Gabriel Fahrenheit (1686–1736), a German physicist, invented the first mercury thermometer, which has now been in use for nearly 300 years. Fahrenheit discovered that mercury exhibits a more constant rate of expansion and a wider temperature range compared to the alcohol thermometer that he had invented a decade earlier (3).

Fahrenheit also devised a temperature scale to accompany his instrument. The coldest temperature he could reproducibly generate in his laboratory was an ice/salt mixture that Fahrenheit called "0°F"; on this scale the freezing point of pure water occurs at 32°F, and the boiling point is at 212°F (3).

In 1742, the Swedish astronomer and scientist, Anders Celsius (1701–1744), devised a centigrade scale using the mercury (Fahrenheit) thermometer. Initially he used 0° and 100° for the boiling point of water and the melting point of snow respectively (3). Later he reversed the numerical

**Figure 1** Simple air thermometer. The initial design for the thermometer was described by both Philo of Byzantium (260–180 B.C.) and Heron of Alexandria (250–150 B.C.). The illustration provided represents a modern-day depiction of the thermometer described by these Greek inventors. A simple glass or thin metallic flask is partially filled with water and air, with an occluding stopper pierced by a glass tube. The heat derived from warming hands placed upon the sides of the flask warms the air and water, causing expansion of the gas forcing water up the thermometer tube. This qualitative example of heat energy transfer was not useful for measuring temperatures until it became calibrated, as accomplished by Sanctorio (Fig. 2).

assignment so that 0°C represented the freezing point, and 100°C the boiling point. This revised centigrade scale gained widespread use. It was initially known simply as the centigrade scale until the term “Celsius” was adopted in 1948 by an international conference on weights and measures. The Celsius temperature scale is now part of the metric system of measurement (SI).

In 1848, the British physicist Lord William Thomson Kelvin (1824–1907) further developed the science of thermodynamics, but in order to do so, developed a new scale (in essence an expansion of the Celsius scale to a far more negative range) (3). Kelvin developed the concept of absolute zero, the temperature at which molecular energy stops (–273.15°C). Conversion factors have since been established to simplify calculations of temperature equivalences between the three commonly employed scales of Fahrenheit, Celsius and Kelvin (Table 1).

The early thermometers were at least a foot long and required 20 minutes to register a patient’s temperature (3,7). In 1866, an English physician Sir Thomas Clifford

**Table 1** Temperature Conversion Factors

From	To Fahrenheit	To Celsius	To Kelvin
°F	°F	$(°F - 32) \times 5/9$	$(°F - 32) \times 5/9 + 273.15$
°C	$(°C \times 9/5) + 32$	°C	°C + 273.15
°K	$(°K - 273.15) \times 9/5 + 32$	°K – 273.15	°K

Abbreviations: °C, Celsius; °F, Fahrenheit; °K, Kelvin.

**Figure 2** First thermometer—calibrated thermometer. The first calibrated thermometer (or thermometer) is credited to Sanctorio (1561–1636), who was driven to calibrate and measure all of the natural phenomena he observed. (A) is a wood cutting from the era, representing a stylistic depiction of the early Sanctorian thermometer. The hatch marks on the tube represent calibration lines. In (B) a modern-day mercury thermometer is shown.

Allbutt developed the shorter, modern mercury thermometer. Even the most recently developed glass mercury thermometers (Fig. 2) take time (2–3 minutes) to equilibrate with the patient’s temperature; and prior to use, these thermometers need to be shaken so that the mercury is sequestered in the bulb at the start of temperature measurement.

In the 1980s, a series of newer technologies were developed for measuring temperature including electronic thermometers utilizing thermistors, for example, Diatec 500® (Diatec Inc., San Diego, California, U.S.A.). In 1984, David Phillips invented the infrared ear thermometer, for example, Braun Thermoscan® (Braun GmbH, Kronberg, Germany), or the ZT (ZyTemp, Hsin-Chu, Taiwan, China). These newer devices are described below in the section on current instrumentation.

## ESTABLISHMENT OF NORMAL TEMPERATURE

The normal core temperature of 37°C was established by Professor Carl Reinhold August Wunderlich, the “father of

**Figure 3** Frequency distribution of 700 baseline oral temperatures obtained during two consecutive days of observation in 148 healthy young male and female volunteers. Arrow indicates location of 37.0°C (98.6°F). Source: From Ref. 7.

prerounds,” in the 1800s (6). Dr. Wunderlich instructed his medical students to measure the axillary temperature of the patients evaluated in the wards of St. James University Hospital, a large teaching hospital in Leipzig, Germany, until over one million temperature measurements were registered. Dr. Wunderlich was an early teacher of the pathologic basis of disease, and of empirical observation of patients. He was one of the first to write that fever is a symptom of disease, rather than a disease itself.

Macowiak (7), in 1996 repeated the study with a far smaller sample size, taking oral temperatures and essentially found the same results. In their sampling of 700 baseline oral temperatures from 148 young male and female volunteers, the mean temperature recorded was 36.8°C (Fig. 3). Macowiak et al. (7) claimed that their smaller, but more recent sampling demonstrated that the 37°C standard set by Wunderlich “should be abandoned.” Perhaps a more enlightened interpretation of the Macowiak data is that oral temperatures are often slightly lower than true centrally obtained temperatures (e.g., via Swan-Ganz catheter); and that all individuals have their own thermoregulatory set point (TRSP) that is generally very near to 37°C.

**Normal core temperature ranges between 36.5°C and 37.5°C, but may vary because of circadian rhythms and other factors.** The oral body temperature in a healthy

individual ranges between 35.6° and 38.2°C on average, which are slightly lower than core temperatures with a mean of 36.8°C [per Macowiak (7)]. Normal temperature also tends to increase slightly during the day from a nadir of 6:00 a.m. to a zenith at 4:00 to 6:00 p.m. (Fig. 4). Diurnal variation depends on activity throughout the day. Both gender and race are reflected in temperature difference with women having slightly higher normal temperatures than men, and black individuals having a trend toward higher temperatures compared to white subjects (7).

Persons working at night and sleeping during the day do not have the same changes in diurnal variation. When fever occurs, diurnal variation can also play a role accentuating or limiting fever, which generally reaches its peak in the evening. Accordingly, a very sick patient can have their temperature dip toward normal in the morning.

Young persons will have generally higher and more intense body temperature changes than older individuals. Body temperature may slightly or temporarily increase in a hot environment. Physical activity plays a role in increasing body temperature. During extreme effort, the increase may be very high. A marathon runner may have a core temperature increase to the 39–41°C range. Vasodilatation, hyperventilation and other compensatory mechanisms can slightly alter temperature.

**Figure 4** Diurnal variation of oral temperatures in 148 healthy young male and female volunteers. Mean (solid squares) oral temperatures and temperature ranges according to time of day. The four temperatures shown at each sample time are the 99th percentile (top), 95th percentile (second from top), mean (second from bottom), and 5th percentile (bottom) for each sample set. ## THERMOREGULATION

### Hypothalamus

☞ **The hypothalamus is the center of thermoregulatory control.** ☞ Located at the base of the brain, the hypothalamus functions as the body's thermostat, and helps keep the core temperature constant at about 37°C by using physiological adjustments under its control (8). The hypothalamus monitors input from the central and peripheral heat sensors located throughout the body and relays information to various areas to raise or lower temperature by numerous mechanisms (vasodilation, vasoconstriction, and thermogenesis), to maintain the core temperature at the patient's TRSP, which is usually calibrated to a core temperature near 37°C. Close regulation of core temperature has evolved in organisms as a mechanism for optimizing enzymatic activities at the temperature of their best effect.

### Mechanisms of Thermoregulation

The specific location of the thermoregulatory center within the hypothalamus is the preoptic area (anterior portion). This area receives input from peripheral thermoreceptors in the skin and mucous membranes and from central thermoreceptors, located in bone, spinal cord and brain, as well as the hypothalamus itself (Fig. 5) (8). The central core temperature is compared with the reference TRSP, which is the "normal" temperature for that individual. The hypothalamic thermostat works in conjunction with other hypothalamic, autonomic and higher nervous system thermoregulatory centers to maintain a constant core temperature by regulation of heat production and expenditure. When the hypothalamus senses a change in the core temperature, behavioral and physiologic mechanisms occur to oppose any deviation from the TRSP.

☞ **There are three components of the thermoregulatory system: (i) afferent input of temperature information; (ii) central processing of the information by the anterior**

**Figure 5** Thermoregulatory control system of the hypothalamus. The illustration shows the thermoregulatory control mechanisms utilized by the hypothalamic thermoregulatory control center. The left side of the image depicts the afferent input into the hypothalamus (including information from the hypothalamus itself, skin, deep tissues, spinal cord, and nonhypothalamic portions of the brain). The right side shows the temperature scale at which certain mechanisms of heat loss (e.g., sweating) and heat conservation (e.g., vasoconstriction and shivering) occur. No thermoregulatory responses are initiated when the core temperature is between these thresholds; these temperatures identify the inter-threshold range, which in humans is usually only about 0.2°C. *Source:* From Refs. 71 and 72.

**hypothalamus; and (iii) efferent responses to control heat production and heat loss.** ☞

Numerous medications will alter the TRSP, and thus the ability to mount a normal thermoregulatory response. For example, nearly all sedatives and analgesics used in trauma, anesthesia, and critical care will alter the TRSP. This alteration in TRSP results in the requirement of a higher than normal core temperature to be registered before vasodilation occurs, and a lower than normal temperature to occur before vasoconstriction, shivering, and non-shivering thermogenesis mechanisms are invoked. Additional thermoregulatory dysfunction results following the administration of neuromuscular blockade (NMB) drugs and meperidine, which both inhibit shivering, whereas anticholinergics inhibit sweating.

### Heat Production

Heat is produced by increasing the metabolic process in which energy is released in the form of heat. ☞ **The liver, heart, and skeletal muscle are the major heat generators, whereas the skin and respiratory system are the major organs responsible for heat loss.** ☞ Skeletal muscle, liver, splanchnic organs and the brain are the largest heat producers (8). Because of its weight, skeletal muscle plays an important role in heat production. Muscles are able to produce large amounts of heat in a short time period via several mechanisms including shivering and increased physical activity. During digestion, increased production of heat occurs in the gastrointestinal tract. Central nervous system regulation (chiefly at the hypothalamus) maintains optimal intensity of metabolism and regulates heat loss.

Nonshivering thermogenesis is mediated by brown fat and has an important function in increasing heat production in newborns and children. Brown fat is found between scapulas, on the neck, in the axilla, around the aorta, and the kidneys in children. It is a highly vascularized tissue, and has large mitochondria within its cells. Increased firing of the cold receptors leads to the release of norepinephrine from adrenergic nerve terminals, which in turn activates the enzyme lipase. Activated lipase splits the brown fat to glycerol and free fatty acids, and heat is released. Adults have very little brown fat.

### Heat Loss

☞ **Heat is lost by radiation, conduction, evaporation, and convection (Table 2).** ☞ Radiation is the emission of electromagnetic energy in the infrared wavelengths (8–10). Conduction is the flow of heat energy from regions in contact between two objects: the warmer object transfers heat to the cooler object based upon the area in contact and the thermal conductivity of the objects. Air, sheets, and clothing have low thermal conductivity; water conducts heat 32× faster than air.

Evaporation is the heat loss to the atmosphere that occurs when water undergoes a change of phase (liquid to gaseous) following the discharge of aqueous fluid from an object by transfer of heat from skin (sweat), respiratory track (exhaled moist air), and exposed viscera in the operating room (OR). Each gram of water that vaporizes consumes 0.58 Kcal of heat (11). Sweating is mediated by postganglionic, cholinergic nerves. During intensive sweating, up to 1 L/hr of sweat can be formed with a heat elimination of 0.58 Kcal/g of evaporated sweat (or nearly 600 Kcal/hr).

When the humidity of the environment is higher, heat loss by sweating becomes less efficient. Yet, evaporation

**Table 2** Heat Loss Mechanisms

Mechanism of heat loss	Description (caloric loss example)
Radiation	Transmission of heat from exposed skin to surrounding objects (exposed patient: 50 Kcal/hr; draped and covered: 10 Kcal/hr)
Conduction	Transfer of heat due to direct contact of skin and viscera with colder objects Operating room table Spine backboard Skin-antiseptic solution Surrounding air Transfer of heat from patient's blood to colder intravenous fluids Crystalloid, 20°C, 16 Kcal/L Blood, 4°C, 30 Kcal/L
Convection	Removal of air warmed by skin or viscera Increases conductive heat loss by 10 Kcal/L
Evaporation	Transfer of heat from skin, respiratory tract, and viscera Skin and respiratory system: 12–16 Kcal/hr Exposed viscera and body cavities: up to 400 Kcal/hr Skin-antiseptic solutions: 6–8 Kcal/m
Redistribution	With redistribution of warm core blood to the periphery, heat is lost much faster via one of the above four mechanisms. Alcohol, as well as nearly all sedatives and analgesics used in anesthesia and critical care cause redistribution by altering the thermoregulatory set point. (e.g., first hour of anesthesia: 46 Kcal, next 2 hrs of anesthesia: 34 Kcal)

*Note:* It is estimated that for every 60–75 Kcal/hr heat loss in excess of heat production, a 1°C decrease in core temperature may occur (assumes 70-kg adult at 37°C). Note that the normal 60–75 Kcal/hr heat loss in an adult 70-kg patient is offset by 60–75 Kcal/hr metabolic heat production to maintain thermal steady state. If heat production is decreased (e.g., anesthesia, severe injury, medical diseases, extremes of age) greater decreases in core temperature may occur. All values are estimates only.

*Source:* Modified from Ref. 10.

(sweat and exhaled vapor) is an important mechanism, and the only one by which humans can eliminate heat into an environment exceeding core temperature (8). In addition to sweat, water vapor is lost during respiration. The volume of air, which is inhaled with each breath, is immediately humidified by the nasopharynx and lungs to full saturation. Some of this vapor is then exhaled, resulting in evaporative loss. At high altitudes, evaporative heat loss via the respiratory tract can rival sweat as a cooling factor.

Convection is the removal of air (warmed by the body) when blown away by a breeze or wind (i.e., the transfer of heat to an air current). Convection also describes the heat loss or gain when fluids are administered, or during cardiopulmonary bypass (CPB).

### Countercurrent Heat Exchange (Vasoconstriction/Vasodilation)

Humans use a simple mechanism of countercurrent heat exchange to regulate blood flow through the skin and subcutaneous tissues. Distribution of heat occurs by blood

circulation. Heat goes from each cell to the surrounding liquid and afterwards to the circulated blood. The modulating factor of heat loss is the amount of blood that circulates through the body surface. The large blood flow through the subcutaneous area and the skin allows heat loss to the surrounding environment. When it is necessary to conserve heat, adrenergic stimuli cause reduction of blood flow through the skin, and the skin becomes an insulator (8,12).

Vasoconstriction allows the increased accumulation of central core heat, and vasodilation secures its quick loss. When vasodilation occurs in a cool environment (not normal, but does occur in sedated or anesthetized patients) a large flow of warm core blood will rapidly cool the core temperature. When vasodilation occurs in a warm environment heat loss is increased through the four aforementioned heat transfer mechanisms.

### Pathophysiology of Temperature Change

Human life is only compatible within a narrow range of temperatures. If the core body temperature is increased above 42.2°C, irreversible damage occurs to the brain. Death occurs at core temperatures of  $\geq 44^\circ\text{C}$  due to protein denaturation. In humans, the temperature does not usually increase to levels above 41.1°C. Decreases in temperature to below 32.8°C is accompanied by confusion, and gradual loss of consciousness. If the decrease continues below 30°C, ventricular dysrhythmias may occur. At 28°C, there is a 50% decrease in cerebral metabolic requirement for oxygen (Table 3) (13).

### Heat Balance

To maintain a constant body temperature, an individual must maintain a balance between the heat generated and the heat lost. Thus for temperature to be held constant and achieve thermal homeostasis, an individual must constantly vary many physiological and behavioral systems to maintain balance (14). This is achieved through integration of multiple systems (Table 4).

## TEMPERATURE MONITORING RATIONALE

Humans require a nearly constant internal body temperature and when temperature deviates significantly from normal, metabolic function deteriorates and ultimately death can result. Trauma is a major condition where hypothermia (core temperature below 35°C) is common. The very young do not have fully developed thermoregulatory systems (14), and the elderly often have dysfunctional thermoregulation (15), hence both groups are more prone to hypothermia. Temperature should be monitored in all critically ill patients, particularly those with trauma and at the extremes of age.

### Incidence and Risk Factors for Hypothermia in Trauma

In a study by Luna et al. (16), 23% of severely injured patients had core temperature  $<34^\circ\text{C}$  with a range of 27–33.8°C. In a study of 71 patients with severe truncal injury and injury severity score (ISS)  $>25$ , 42% had core temperature  $<34^\circ\text{C}$ , 23%  $<33^\circ\text{C}$ , and 13%  $<32^\circ\text{C}$  (17).

Multisystem trauma is the most common cause of hypothermia in patients requiring admission to the surgical intensive care unit (SICU) (18), and as many as 46% of injured patients leave the OR hypothermic (19). Fifty-seven percentage of trauma patients became hypothermic in the

**Table 3** Physiologic Characteristics of the Three Stages of Hypothermia (Nonanesthetized, Nonintoxicated Patients)

Core temperature		
°C	°F	Characteristics
<i>Mild</i>		
37.6	99.6	Normal rectal temperature
37	98.6	Normal oral temperature
36	96.8	Increase in metabolic rate
35	95	Maximum shivering thermogenesis
34	93.2	Amnesia and dysarthria develop; maximum respiratory stimulation
33	91.4	Ataxia and apathy develop
<i>Moderate</i>		
32	89.6	Stupor; 25% ↓ in $\dot{V}O_2$ , Osborne waves seen
31	87.8	Shivering thermogenesis extinguished
30	86	A-fib common, ↓HR and $\dot{Q}$ ; insulin ineffective
29	85.2	Progressive ↓ consciousness, pulse, and breathing; pupils dilated
28	82.4	V-fib susceptibility; 50% ↓ in $\dot{V}O_2$ and HR
<i>Severe</i>		
27	80.6	Losing reflexes and voluntary motion
26	78.8	Major acid–base disturbances; no reflexes or response to pain
25	77	CBF 1/3 normal; $\dot{Q}$ 45% normal; pulmonary edema may develop
24	75.2	Significant hypotension
23	73.4	No corneal or oculocephalic reflexes
22	71.6	Maximum risk of V-fib; 75% ↓ in $\dot{V}O_2$
20	68	Lowest resumption of cardiac electro-mechanical activity
19	66.2	Flat electroencephalogram
18	64.4	Nerve and cardiac muscle silence
16	60.8	Lowest accidental hypothermia survival in an adult
15	59.2	Lowest accidental hypothermia survival in an infant
9	48.2	Lowest therapeutic hypothermia survival

*Abbreviations:* ↓, decrease; A-fib, atrial fibrillation; CBF, cerebral blood flow; HR, heart rate;  $\dot{Q}$ , cardiac output; V-fib, ventricular fibrillation;  $\dot{V}O_2$ , oxygen consumption.

*Source:* Modified from Ref. 13.

time interval between injury and completion of the initial surgical procedure.

✎ **Although hypothermia decreases the metabolic function of the body, and is neuroprotective, in traumatized individuals hypothermia most often results in deleterious effects such as coagulopathy, metabolic acidosis, and impaired immune response (8).** ✎ Injured patients in whom hypothermia develops have a higher mortality than do patients with a similar ISS who remain normothermic (17). Core rewarming increases the likelihood of successful trauma resuscitation (19). Hypothermia (<35°C) and acidosis (base deficit >12 mEq/L) were strong predictors of death in a retrospective review of exsanguinating trauma patients undergoing surgery (20).

Older data suggested that trauma alters thermoregulation, decreases heat production, and impairs shivering

**Table 4** Integration of Behavioral and Autonomic Systems for Thermoregulation

System	Example
Behavioral	This is accomplished by adjusting clothing, modifying environmental temperature, assuming positions that oppose skin surfaces, voluntary movements, and timing of activities.
Autonomic	Vasodilation increases cutaneous blood flow and promotes either heat loss or heat gain depending on the environmental conditions. Vasoconstriction reduces peripheral flow. Cutaneous blood flow decreases to near zero in cold temperatures. Heart rate is often higher for any given core temperature during heating than during cooling, thus increasing heat transfer via the blood, decreasing rate of cooling and achieving optimal core temperature quicker. Piloerection increases insulation and slows heat exchange. Increased body fat. Fat conducts heat only one-third as fast as other tissues. Shivering is under central and peripheral control. Shivering increases heat production when the skin and/or body is cold. “Nonshivering” thermogenesis increases heat production without muscular activity. The principal heat producers are the liver, kidney, and brain via brown adipose tissue whose sole function is to produce heat in neonates. Evaporation, by increasing the amount of sweating.

(21,22). Impaired thermoregulation may transiently result from reduced cerebral and hypothalamic blood flow, constriction of hypothalamic blood vessels from release of endogenous substances such as norepinephrine, whereas, the major loss of hypothalamic thermoregulation results from alcohol and drug intoxication, and from direct traumatic brain injury (TBI) (8,10,13).

✎ **Risk factors that contribute to hypothermia include environmental exposure, alcohol and drug intoxication, intravenous (IV) infusion of room temperature fluid, transfusion of cold blood without warming, spinal cord injuries, head injury, shock, and associated medical conditions such as hypothyroidism and hypoglycemia (Table 5) (8,10,13).** ✎ Individuals at extremes of age are at greatest risk for accidental hypothermia (5,23). Exertional fatigue, sleep deprivation, and negative energy balance can also increase susceptibility to hypothermia (24).

### Hypothermia-Associated Increased Mortality and Morbidity

Jurkovich et al. (17) demonstrated that survival, independent of injury severity, was dependent upon patient temperatures, such that core temperatures of 34°C, 33°C, and 32°C, correlated with mortality rates of 40%, 69% and 100%, respectively. In a retrospective review of 7045 patients admitted to a SICU, 661 (9.4%) had hypothermia with a mortality rate of 53% (18). ✎ **Trauma-associated hypothermia increases morbidity because of impaired cardiorespiratory**

**Table 5** Risk Factors for Hypothermia

Mechanism	Examples
Impaired thermoregulation and decreased heat production	Alcohol
	Drugs: anesthetics, tricyclic antidepressants, phenothiazines, antipyretics, neuromuscular relaxants
	Head injury
	Spinal cord injury
	Severe injury and shock
	Extremes of age
	Autonomic nervous system dysfunction
	Medical disease: thyroid, adrenal, diabetes, malnutrition
	Bacterial toxins
	Neonates
Increased heat loss	Low ambient room temperature
	Burns
	Large blood loss
	Exposed abdominal and/or thoracic contents
	Combined general and neuraxial anesthesia
	Geriatrics
	Thin body type
	Low surface temperature of patient prior to trauma, intoxication, or anesthesia

Source: Modified from Ref. 10.

**function, peripheral vasoconstriction, bleeding diathesis, metabolic acidosis, diminished hepatorenal function, and altered immune response (Table 6).** ⚡

### Cardiac Effects

Hypothermia exerts a negative inotropic effect on the myocardium, resulting in decreased left ventricular contractility (25), increased left ventricular ejection time, reduced early diastolic filling and total diastolic inflow time, and impaired peak velocity of left ventricular wall movement during systole and diastole (Table 6) (26). Hypothermia also impairs the inotropic effects of dopamine and norepinephrine.

Hypothermia is also associated with dysrhythmias. As the core temperature decreases, progressive bradycardia ensues. Below core temperatures of 30°C, ectopic atrial rhythms, atrial flutter, and atrial fibrillation commonly occur. Once the temperature decreases to 28°C, ventricular tachycardia and ventricular fibrillation are seen. Cardiac and neural tissues cease firing at a core temperature <15°C to 18°C (13). Even mild hypothermia can dramatically increase the incidence of morbid cardiac outcomes such as unstable angina, myocardial ischemia, and ventricular tachycardia in perioperative patients (27).

### Vascular

Effects of hypothermia on the vasculature consists of peripheral vasoconstriction, increased blood viscosity (due to direct effect of hypothermia and cold-induced hemoconcentration), and the accumulation of metabolic acids in poorly perfused tissues (10). During rewarming, shivering can occur which will increase O<sub>2</sub> consumption (V̇O<sub>2</sub>), and potentially trigger myocardial ischemia in susceptible patients. In addition, the release of sequestered cold blood and acid metabolites from peripheral vascular beds following

**Table 6** Morbidity of Hypothermia in Trauma and Critical Care

System affected	Examples
Impaired cardiorespiratory function	Cardiac dysfunction
	Myocardial ischemia
	Cardiac dysrhythmias
	Peripheral vasoconstriction
	Decreased tissue oxygen delivery
Coagulopathy	Increased oxygen consumption during rewarming
	Blunted response to catecholamines
	Increased blood viscosity
	Leftward shift of hemoglobin-oxygen dissociation curve
	Decreased function of coagulation factors
Impaired hepatorenal function and decreased drug clearance	Decreased platelet function
	Decreased hepatic blood flow
	Decreased clearance of lactic acid
	Decreased hepatic metabolism of drugs
	Decreased renal blood flow
Altered immune response	Cold-induced diuresis
	Increased incidence of wound infection

Source: Modified from Ref. 56.

re-warming can result in myocardial instability, even in patients without coronary artery disease.

### Coagulopathy

Hypothermia leads to a bleeding diathesis due to impaired platelet function, inhibition of clotting enzymes, and altered kinetics of plasminogen activator inhibitors (e.g., alpha-2-antiplasmin). Mild hypothermia increases surgical blood loss and the need for blood transfusions (28,29). Core temperatures should be kept above 35°C because coagulopathy in trauma patients who required massive transfusion was predicted by temperature <34°C and progressive metabolic acidosis (30).

### Respiratory

Moderate hypothermia decreases respiratory drive, and is associated with hypoventilation and the loss of protective airway reflexes (13). Hypothermia also inhibits hypoxic pulmonary vasoconstriction (HPV), increasing right-to-left transpulmonary shunt, and shifts the oxygen-hemoglobin saturation curve to the left. Pulmonary edema can occur at temperatures ≤28°C. Hypothermia also increases alveolar dead space.

### Cellular Immune Response and Infection

Mild hypothermia increases the incidence of wound infection (31). It also impairs immune function, suppresses mitogen-induced activation of lymphocytes, and decreases production of interleukins-1β and interleukin-2. In addition, low tissue oxygen levels due to thermoregulatory vasoconstriction may be associated with impaired resistance to infection. Hypothermia tripled the incidence of surgical wound infection in one study (31), and had a relative risk of 6.3 in

another (32). Hypothermia also increases the risk of pneumonia in patients with closed head injuries (33).

### Glucose and Electrolytes

Hypothermia can cause hypokalemia that can contribute to dysrhythmias and respiratory and cardiac insufficiency. Hyperglycemia commonly occurs at temperatures below 32°C due to decreased insulin production and utilization. Hyperglycemia can significantly aggravate neuronal ischemia.

### Splanchnic and Renal Effects

Hepatic blood flow is decreased with hypothermia as is hepatocellular function. High-energy phosphates such as adenosine triphosphate are depleted in hypothermia, which may lead to organ failure (34). Hypothermia reduces the metabolism and activity of many anesthetics and other drugs, and also increases the solubility of many drugs in tissues. These effects all tend to result in delayed awakening and diminished organ function.

Due to the initial increased cardiac output ( $\dot{Q}$ ) and the mean arterial pressure, the renal perfusion pressures are increased. Accordingly, renal blood flow is increased leading to a "cold-induced" diuresis. However, glomerular filtration rates (GFR) are decreased and there is impaired renal tubular function. There is increased urinary loss of sodium, potassium, and water and a "cold-induced" diuresis. Despite increased urine output, renal clearance of water-soluble drugs is diminished as temperature drops further. Eventually, the  $\dot{Q}$  begins to fall due to decreased heart rate and contractility. However, the "cold-induced" diuresis persists as long as the heart continues to pump due to the persistent effect of these other factors.

### General Anesthesia

☞ Hypothermia is common during general anesthesia because of impaired thermoregulation (Fig. 6), decreased heat production, and internal redistribution of body heat from the warmer core to the cooler peripheral tissue in the exposed patient (35,36).☞

This is due to the alteration in the TRSP, which results from all anesthetic and sedative drugs. Most anesthetized patients will experience a drop in their core temperature of 1°C to 1.5°C in the absence of active warming measures. Patients may suffer additional hypothermic insults due to infusion of cold or inadequately warmed IV fluids as described during initial resuscitation (Fig. 6) (10,37).

Although malignant hyperthermia is a rare condition, the high mortality rate associated with this syndrome mandates routine core temperature monitoring in all anesthetic

$$\Delta \text{MBT} = (T_{\text{fluid}} - T_{\text{patient}}) \text{Sp}_{\text{fluid}} / \text{Weight} \times \text{Sp}_{\text{patient}}$$

where

$T_{\text{fluid}}$  = Outlet temperature of fluid delivered to the patient

$T_{\text{patient}}$  = Temperature of the patient, assumed to be 37°C

$\text{Sp}_{\text{fluid}}$  = Specific heat of infused fluid, 1 Kcal/L/°C

$\text{Sp}_{\text{patient}}$  = Specific heat of the patient, 0.83 Kcal/L/°C

**Figure 6** Change ( $\Delta$ ) in mean body temperature (MBT) as a function of administered intravenous fluid. Change in MBT is calculated in the figure. *Note:* Improvements in fluid warmer design together with set points of 42°C now allow the clinician to maintain thermal neutrality with respect to fluid management over a wide range of flow rates.

cases  $\geq 30$  minutes in duration. The use of effective warming technologies has now made it possible to overheat patients.

### Regional Anesthesia

Core hypothermia can be nearly as common and severe during epidural and spinal anesthesia as during general anesthesia (38). With neuroaxial blockade, vasodilation below the level of the block can result in a core temperature drop due to both heat loss and redistribution. ☞ Epidural and spinal anesthesia block afferent and efferent thermoregulatory responses and cause similar degrees of hypothermia as general anesthesia. ☞

During regional anesthesia for trauma, core temperature should therefore be closely measured, especially in patients at highest risk to become hypothermic such as patients undergoing long extensive procedures in cold environments. Temperature monitoring is not usually required in otherwise healthy patients undergoing minor peripheral procedures <30 minutes in duration with local anesthetics (e.g., suture of finger laceration), because these drugs do not trigger malignant hyperthermia.

### Deliberate Use of Hypothermia: In Cardiac and Neuro-anesthesia

A mainstay of neuroprotective therapy has been moderate systemic hypothermia (26). Mild to moderate hypothermia confers protection against tissue ischemia, especially during cardiac surgery and potentially during certain types of neurosurgery. Beneficial effects of hypothermia are thought to result from reduced metabolism and inhibition of deleterious effects of hypoxia such as free-radical reactions, excitotoxicity, and altered membrane permeability. Hypothermia increases the tolerance time for circulatory arrest and diminished blood flow during cardiopulmonary resuscitation. Improved neurologic outcome has been observed in cardiac surgery patients and in survivors of cardiac arrest treated with mild hypothermia (39). Hypothermia may prevent the initiation of some elements in the cascade of events that lead to cell death following trauma (13).

☞ Mild hypothermia (1–2°C below normal) is neuroprotective, whereas mild hyperthermia (1–2°C above normal) may exacerbate cerebral ischemia. ☞ Although hypothermia clearly has been shown to be neuroprotective, use of hypothermic CPB necessitates rewarming before discontinuation. Because most emboli occur during clamp removal and resumption of pulsatile flow when brain temperature may actually exceed 37°C, the brain may be even more susceptible to injury. Postoperative hyperthermia (37.2–39.3°C) is associated with worsened cognitive outcome after coronary surgery (40). Mild hyperthermia (1–2°C above normal) exacerbates the severity of cerebral ischemia (histopathological consequences, stroke severity, and mortality) by the following purported mechanisms: increased excitotoxic neurotransmitter release, increased free-radical production, increased intracellular acidosis, increased blood-brain barrier permeability, destabilized cytoskeleton, and abnormal modulation of protein kinase.

Hypothermia has long been touted as potentially beneficial for spinal cord ischemia and TBI (41,42). However, the clinical data is unclear. Two large prospective multicenter trials have failed to show improved neurologic outcome after therapeutic hypothermia for isolated TBI patients (43,44). Whereas, two others did show improvements for

those having Glasgow Coma Scale (GCS) values in the 5–8 range (see Volume 1, Chapter 40) (45,46). Accordingly, additional research is required.

### External Factors Affecting Temperature Measurement

Body temperature can be altered by external factors, such as extremes of hot and cold weather, and by internal factors, such as circadian rhythms, infectious processes, and hormonal changes (Volume 1, Chapter 40). In addition, during extracorporeal circulation for cardiac and other surgeries, or as a result of malignant hyperthermia or damage to the hypothalamus, regulatory mechanisms may become ineffective in maintaining normal temperature, which causes hyperthermia or hypothermia.

The two most common factors influencing body temperature are age and gender. For example, when taken orally, adults' normal temperature ranges from 35.8°C to 37.4°C; elderly patients' temperatures will tend to be at the lower end of normal overall if taken correctly, lower still at the oral and axillary sites if tissue contact is inadequate. Children's temperatures normally range slightly higher (36.1–38°C) than adults. Women's temperatures can reach as high as 37.9°C during ovulation; men's generally stay in the range of 36.1–37.2°C (7).

### THERMOMETER INSTRUMENTATION AVAILABLE

Electronic thermometers have largely replaced traditional mercury-in-glass thermometers; although these low-tech devices are still utilized in remote locations. The most common electronic thermometers utilize thermistors and thermocouples. Both devices are accurate for clinical use and sufficiently inexpensive to be widely available. Infrared tympanic membrane thermometers are also sufficiently accurate for clinical use.

A thermometer incorporated into an esophageal stethoscope is a simple and reliable method of measuring core temperature in tracheally intubated patients providing it is inserted deep enough (at least 5–10 cm past the carina).

During regional anesthesia or when patients are mask-ventilated, measurement of axillary, oral, or tympanic membrane temperatures at 15-minute intervals can be substituted for esophageal temperature monitoring.

### TEMPERATURE MONITORING SITES

The core thermal compartment is composed of highly perfused tissues whose temperature is uniform and high compared with the rest of the body (Table 7). Core temperature is the most reliable thermal indicator of the body's condition.

☞ **The preferred technique of temperature monitoring is one that reflects core temperature such as distal esophageal, nasopharynx, pulmonary artery (PA), and tympanic membrane. Intermediate sites such as rectum, bladder, and mouth usually reflect core temperature.** ☞ Core temperature can be determined by measuring a single temperature adjacent to the distal esophagus, nasopharynx, PA, or tympanic membrane (8). Even during rapid thermal perturbations (e.g., CPB), these temperature monitoring sites remain reliable (47). Core temperature can be estimated with reasonable accuracy using oral, rectal, axillary, and

**Table 7** Temperature Monitoring Sites

Core <sup>a</sup>	Intermediate
Pulmonary artery	Bladder
Distal esophagus	Rectal
Nasopharynx	Sublingual (mouth)
Tympanic membrane (ear)	Axilla
Jugular bulb	Skin surface (forehead better than extremity) <sup>b</sup>

<sup>a</sup>Core temperature monitoring sites are recommended.

<sup>b</sup>Skin surface temperature monitoring is the least reliable site.

bladder temperatures except during extreme thermal perturbations (48–50). Temperatures taken at more accessible sites such as the mouth, axilla, and rectum are clinically significant only in terms of how closely they correlate to core temperature. It should be noted that jugular bulb or cerebral temperatures may be higher than temperatures measured at other sites. In the SICU, patients' temperatures are monitored with PA catheters (if in place), or intermittently using tympanic membrane or electronic thermometers placed orally or rectally.

Temperature can be measured at numerous sites in the body. Consideration should be given to both reliability and accessibility. For example, the rectal site should not be used in patients undergoing hemorrhoidectomy. Some sites, primarily the mouth and axilla, are affected by environmental factors; less affected are the rectum and bladder, though they, too, can produce unreliable readings (51). ☞ **The most reliable core monitoring sites are the PA, distal esophagus, nasopharynx, and tympanic membrane (Table 7) (52).** ☞ These sites come closest to reflecting core temperature, which provides about 80% of thermal input to the hypothalamus, and are the best indicators of a deviation from homeostasis.

### Core Sites

#### Esophagus

Distal esophageal thermometry is a highly accurate measure of core temperature. The distal esophagus is a useful site for core temperature measurement, especially in tracheally intubated patients (8). The esophageal stethoscope contains a thermistor and is also useful for monitoring heart and lung sounds (Fig. 7). Temperature readings are displayed on an electronic monitor (Fig. 8). Because of its proximity to the heart, a primary core temperature organ, the thermistor reacts quickly to changes, providing a fast and highly accurate reading (53). Placement is critical; if the probe containing the thermistor is not directly in front of the heart, readings are less reliable.

Esophageal probes should not be placed in patients with mediastinal traversing injuries due to the risk of esophageal trauma. Suction applied to a nasogastric tube will falsely lower the esophageal temperature. If the probe is not placed distally, temperature readings may be inaccurate. Temperature probes incorporated into esophageal stethoscopes must be positioned at the point of maximal heart sounds, or even more distally, to provide accurate readings.

#### Nasopharyngeal

Nasopharyngeal temperature probes usually correlate well with other centrally measured temperatures. Nasopharyngeal temperature exceeded tympanic temperature during

**Figure 7** Distal esophageal (core) temperature is easily measured in tracheally intubated patients using an adult, 18 Fr (A), or pediatric, 9 Fr (B) esophageal stethoscope with thermocouple sensor. The esophageal stethoscope is positioned at the point of maximal heart sounds and temperature is continuously displayed on an electronic monitor. The temperature sensor in this device has an accuracy of  $\pm 0.2^{\circ}\text{C}$  over the range of  $25\text{--}45^{\circ}\text{C}$  (Series 400, Vitals Signs, Inc., Totowa, New Jersey, U.S.A.).

rewarming on CPB, which suggests that this site better reflects the brain temperature (54). When deep hypothermia is rapidly induced and reversed, temperature measurements made at standard monitoring sites may not reflect cerebral

**Figure 8** Two-channel electronic temperature monitor (Bi-Temp, Model TM-200D, Respiratory Support Products, Inc. SIMS, Irvine, California, U.S.A.). Core temperature is displayed on the left ( $34.7^{\circ}\text{C}$ ), and room temperature is displayed on the right ( $18.9^{\circ}\text{C}$ ). Low ambient operating room temperature, as seen in this example, is an important risk factor for intraoperative hypothermia in surgical patients.

temperature. Measurements from the nasopharynx, distal esophagus, tympanic membrane, and PA tend to match brain temperature best (8).

Problems with this site include the risk of nasopharyngeal bleeding. Temperatures may vary between different probe positions. This site is relatively contraindicated in patients with severe midface or basilar skull fractures with cribiform plate disruption.

#### **Pulmonary Artery**

To measure temperature in the PA, a catheter with a thermistor is placed in the PA during surgery or in critical care situations to monitor cardiac output and other hemodynamic parameters. ⚡ **Because temperatures taken at the PA closely correlate with core temperature, many clinicians view this as the most accurate site for measuring body temperature in critical care; this site is far too invasive to use for temperature alone.** ⚡ In any case, readings can be adversely affected by the temperature of the CPB fluids during cooling and re-warming, and by administration of cold or warm fluid directly into the right atrium, right ventricle or PA. The effect of cardiac output flush solution is generally transient and inconsequential.

#### **Tympanic Membrane (Ear)**

The ear canal—more specifically, the tympanic membrane—is just 1.4 inches (3.5 cm) from the hypothalamus, and can be readily monitored using an ear probe (Fig. 9). The temperature of the tympanic membrane is relatively well protected from the influence of ambient temperatures and is unaffected by respiration, eating, drinking, or smoking. Plus, of course, the ear has an equally usable twin on the other side of the head. ⚡ **For these reasons, the tympanic membrane is a good noninvasive site to measure core body temperature in SICU and OR patients, but the probes are easily dislodged during patient movement and transport.** ⚡

Although the tympanic membrane is perfused by the internal carotid artery, studies demonstrate that fanning the face decreases the temperature of the tympanic membrane but not the brain (55). Thus, tympanic membrane probes are not the best choice during initial resuscitation of a patient from the field. Sensor probes do not always abut the tympanum, and cerumen or dried blood in the auditory canal can result in a delayed response time. Tympanic membrane probes are contraindicated in patients with

**Figure 9** Tympanic membrane (TTS-400) temperature sensor. (Level-1, Rockland, Massachusetts, U.S.A.). The temperature probe is placed in close proximity to the tympanic membrane, and the external auditory meatus is covered with gauze and a piece of tape.

cerebrospinal fluid otorrhea and are easily dislodged during patient movement and transport. Measures may be inaccurate if the ears are cold or in the presence of otologic disease.

### Intermediate Sites

☞ When body temperature is constant, intermediate sites such as sublingual, rectal, and urinary bladder are good estimates of core temperature (Figs. 10 and 11). When body temperature is rapidly changing (e.g., CPB, invasive rewarming, surgery), intermediate temperature sites are slower to change compared to core sites. ☞ Core temperature can be estimated with reasonable accuracy using oral, axillary, rectal, or bladder temperatures, except during extreme thermal perturbations. Rectal temperature is considered an intermediate temperature in deliberately cooled patients, and may not prove reliable during malignant hyperthermia episodes. During cardiac surgery, bladder temperature is similar or close to rectal temperature (and therefore intermediate) when urine flow is low, but similar or close to PA temperature (and thus core) when flow is high. Since bladder temperature is strongly influenced by urine flow, it may be difficult to interpret in these patients.

### Mouth

Previously, the most common site for measuring temperature was the sublingual pocket under the tongue on either side of the frenulum. Normally, oral temperature is lower than core temperature by about 0.5°C. Correct placement of the thermometer is essential; dwell time is 15 to 45 seconds for electronic thermometers in the predictive mode, and three to five minutes for glass-mercury thermometers. The advantages of oral thermometry include accessibility, familiarity, and noninvasiveness. The disadvantages are chiefly related to inaccurate readings if the patient eats, drinks, smokes, or chews gum prior to the reading, fails to keep the thermometer properly placed under the tongue, breathes too fast (especially through the mouth), or talks.

### Rectum

Rectal temperatures were long considered the “gold standard” for measuring core temperature, especially in children. Despite possible discomfort and embarrassment, the site has obvious advantages: It’s easily accessible, requires an inexpensive thermometer, and provides an accurate reading when taken properly. What’s more, it’s usually quite close to core temperature—on average, it runs about 0.1°C higher.

Rectal thermometry does have some drawbacks (56). Because the rectum is a cavity, it can retain heat longer than other temperature sites. Rectal temperature normally correlates well with core temperature, but fails to increase rapidly during malignant hyperthermia crises and under other documented situations (51,56). When a patient’s temperature is rising or falling rapidly, the temperature in the rectum can lag behind by as much as an hour. This may be because the rectum contains no thermoreceptors and thus is heated or cooled as an effect of hypothalamic control, rather than in response to it. Other possible causes of inaccurate rectal readings include heavy exercise of the large muscles in the buttocks and thighs, the insulating effect of fecal matter in the rectum, and heat produced by coliform bacteria.

**Figure 10** (A) and (B). An electronic thermometer can be used to accurately measure sublingual (*black probe*) or rectal (*gray probe*) temperatures (IVAC Temp Plus II, Model 2080, Alaris Medical, San Diego, California, U.S.A.).

To measure rectal temperature accurately—whether by electronic, glass-mercury, or single-use chemical thermometer—proper depth and dwell time are necessary. The proper depth for a rectal thermometer varies with the patient’s age: for adults, it is 2 to 3 inches (5–7.5 cm); for children, 0.5 to 1.5 inches (1.25–3.75 cm); for neonates, 0.75 inch (1.9 cm). Proper dwell time is the same for all patients: 15 to 45 seconds for electronic thermometers in the predictive mode; three to five minutes otherwise.

**Figure 11** Bardex® Temperature-Sensing (400-Series) Foley catheter (C.R. Bard, Inc., Covington, Georgia, U.S.A.). This device is accurate to  $\pm 0.2^{\circ}\text{C}$ .

Without proper depth and dwell time, rectal temperature readings will be inaccurate. Rectal probes can become lodged in fecal matter, which insulates them from the surrounding tissues.

**Bladder**

Bladder temperature is measured by an indwelling urinary catheter containing a thermistor (Fig. 11). High correlation exists between bladder and PA temperature. Drawbacks to bladder temperature monitoring include bladder irrigation, which, whether manual or continuous, will cause the thermistor to measure the temperature of the irrigant rather than of the urine. If the patient’s urinary catheter does not have a thermistor attached, and most indwelling urinary catheters do not, it has to be changed to one that does. Finally, patients with hypothermia will show a slight lag in bladder temperature during rewarming.

Although bladder temperature sensors are convenient, they are influenced by urinary flow and consequently, may not provide a reliable measure of core temperature during shock with diminished urinary output or renal failure. Patients with urethral disruption require suprapubic placement of the urinary catheter (57). Open pelvic and lower abdominal trauma may falsely lower temperature readings

**Figure 12** Skin surface temperature sensor with 400 series thermistor.

**Table 8** Methods to Prevent and/or Treat Hypothermia

Method	Examples
Passive	<ul style="list-style-type: none"> <li>a. Warm the room (e.g., 27–30°C)</li> <li>b. Warm blankets, insulating blankets, dry off wet skin</li> </ul>

from this site. Urinary flow may be negligible in the setting of shock or renal failure.

**Axilla and Groin**

When oral and rectal sites are inaccessible or inappropriate, the axilla or the groin may be used. Glass-mercury, electronic, or single-use chemical thermometers can be used in children at the axilla, but this site may not be reliable or accurate enough to use with adults. And, for both populations, it has

**Table 9** Temperature Measuring Devices

Device	Pros	Cons
Glass mercury (oral, rectal, axillary)	Easy accessibility Familiarity Noninvasive	Long dwell time Inaccurate readings possible if patient is not cooperative Temperature read is lower than core temperature Breakable Requires disinfection between patients, or disposable covers
Infrared (tympanic membrane)	Noninvasive Close to the hypothalamus Can be used in either ear TM (but not ear canal) is protected from ambient temperatures Quick temperature acquisition	Current devices not continuous Measurement can be inaccurate in trauma due to blood, CSF, foreign body in ear canal Excessive cerumen interferes with temperature measurement
Thermister tipped ear probe (tympanic membrane)	Noninvasive Close to the hypothalamus Can be used in either ear TM (but not ear canal) is protected from ambient temperatures (positioning critical to reflect TM with this device)	Easily dislodged during movement or transport In setting of CSF otorrhea, other ear trauma, relatively contraindicated
Electronic thermocouple (oral, rectal, axillary)	Easy accessibility Familiarity Noninvasive Short dwell time compared to glass mercury	Inaccurate readings possible if patient is not cooperative Temperature read is usually lower than core temperature Requires disposable cover
Esophageal stethoscope—thermister (esophageal, nasopharyngeal)	Reflects core temperature Reacts quickly to changes Matches brain temperature (nasopharyngeal placement)	Critical placement Esophageal: must be distal to tracheal carina Nasopharyngeal: risk of nasal bleeding
PA catheter—thermister (CVP or PA locations)	Reflects core temperature Continuous measurement	Invasive Expensive
Indwelling urinary catheter—thermister	Convenient if requires catheter In stable patients, reflects core temperature	Influenced by urinary flow

*Abbreviations:* CSF, cerebrospinal fluid; CVP, central venous pressure; PA, pulmonary artery; TM, tympanic membrane.

inherent drawbacks: (i) skin contact with the thermometer must be maintained at the apex of the axilla for 8 to 11 minutes (using a glass-mercury thermometer); (ii) the resulting temperature reading must be adjusted because it can be 0.5°C to 1.2°C lower than core temperature; (iii) the temperature is less accurate in shock due to peripheral vasoconstriction.

Thermoregulatory vasoconstriction shunts blood away from the skin's surface, including the axilla (though less so than with distal extremities) during moderate hypothermia and prolongs thermal response times. During profound hypothermia, intense vasoconstriction redirects blood flow primarily to a very diminished central compartment. Thermal response time is altered by the volume of connective tissue and fat separating peripheral compartments from perfused vasculature.

For these reasons, axillary or groin temperatures are, at best, estimates and not always reliable enough to provide the basis for clinical intervention—except with neonates. Indeed, since neonates have a high rate of heat loss through their skin, the axilla and the groin are often preferred sites; in fact, for most neonates, the axillary site is standard. Because of the risk of perforation, the rectum is not used in neonates.

### Peripheral Skin Sites

Adult temperature is rarely measured on the skin's surface, though this quick technique may help track a trend. At best, it provides a peripheral body temperature with measurements that can vary widely because of vasomotor activity and ambient temperatures (55). These drawbacks particularly apply when using single-use chemical thermometers to measure temperature at the forehead, a site constantly exposed to ambient temperatures. The skin provides approximately 20% of thermal input to the hypothalamus. A valid use of skin temperature is with incubated newborns. Electronic sensing elements (Fig. 12) attached to the skin provide a digital readout showing the trend of neonates' temperature and automatically maintain optimal environmental temperature in the incubator. Skin surface temperature is used in thermoregulatory research to determine mean body temperature, forearm to fingertip gradients and the degree of peripheral vasoconstriction or vasodilation.

Skin-surface temperatures are usually considerably lower than core temperature. However, in direct sun, the exposed skin temperature can be higher than core temperature. Skin-surface temperatures, when adjusted with an appropriate offset, can reflect core temperature reasonably well in stable patients located in protected environments

(53). However, skin temperatures do not reflect core temperature in resuscitation situations, and fail to reliably confirm the clinical signs of malignant hyperthermia (tachycardia and hypercarbia) in swine (58).

In a prospective comparison of esophageal, tympanic membrane, and forehead skin temperatures in adult surgical patients, there was a lack of precision between skin and distal esophageal temperatures with wide limits of agreement (55). Moreover, there was no relation between change in skin temperature and change in esophageal temperature. Accordingly forehead skin temperature should not be considered reliable, and sole reliance on this measurement can adversely affect patient care.

## EYE TO THE FUTURE

Nonintended hypothermia in trauma victims is becoming a less common problem because of early recognition, accurate noninvasive body temperature monitoring, and thermally efficient devices that rapidly achieve desired body temperature (59). The lethal triad of hypothermia, acidosis, and coagulopathy will be easily controlled with interventions that restore organ perfusion, hemostasis, and tissue perfusion.

The role of therapeutic hypothermia in TBI patients will be further delineated in the next decade with increased focus upon the hypothermic intervention, duration of therapeutic hypothermia, and application of therapeutic hypothermia in carefully selected patients together with strict protocols and close monitoring to avoid complications such as hypovolemia, hypotension, and hyperglycemia (60–64).

A clear consensus will emerge as to which temperature monitoring site is best for trauma patients. Site of temperature monitoring will assume increased importance after head, spinal cord, and other injuries since central nervous system temperature may exhibit variability and discordance with respect to traditionally accepted core temperature measures.

## SUMMARY

Body temperature is a vital sign which remains within a narrow range in normal patients. Body temperature is controlled by the hypothalamus, which integrates thermal information and coordinates increases in heat production such as shivering and nonshivering thermogenesis, heat loss (sweating), and/or decreases in heat loss (vasoconstriction) in order to maintain thermal homeostasis (8).

Risk factors that contribute to hypothermia include environmental exposure, especially in the presence of impaired thermoregulation, extremes of age, spinal cord injury, TBI, shock, and administration of sedatives, analgesic, or anesthetic agents (65,66). Acute trauma patients should be warmed to maintain core temperatures  $>35.5^{\circ}\text{C}$  (Table 8) (66). Standard methods available include warming the room to  $>28^{\circ}\text{C}$ , forced air, inhalational gas warming (67,68), warming of IV fluids, and radiant heat (69,70).

Core temperature should be monitored in order to detect thermal disturbances and to maintain appropriate body temperature. Deliberate use of hypothermia is associated with improved neurologic outcome in cardiac and some forms of neuro-anesthesia, but has not been proven for isolated TBI with GCS 3–4, but may be useful in the young with GCS in the 5–8 range and elevated intracranial pressures. Hypothermia is associated with major morbidity

because of impaired cardiorespiratory function, peripheral vasoconstriction, bleeding diathesis, metabolic acidosis, diminished hepatorenal function, and altered immune response.

The preferred technique of temperature monitoring is one that reflects core temperature such as distal esophageal, nasopharynx, PA, and tympanic membrane (Table 9). Intermediate sites such as rectum, bladder, and mouth usually reflect core temperature. Brain temperature may exceed temperature measured elsewhere during hypothermia and subsequent rewarming.

## KEY POINTS

- ☞ Normal core temperature ranges between  $36.5^{\circ}\text{C}$  and  $37.5^{\circ}\text{C}$ , but may vary because of circadian rhythms and other factors.
- ☞ The hypothalamus is the center of thermoregulatory control.
- ☞ There are three components of the thermoregulatory system: (i) afferent input of temperature information; (ii) central processing of the information by the anterior hypothalamus; and (iii) efferent responses to control heat production and heat loss.
- ☞ The liver, heart, and skeletal muscle are the major heat generators, whereas the skin and respiratory system are the major organs responsible for heat loss.
- ☞ Heat is lost by radiation, conduction, evaporation, and convection (Table 2).
- ☞ Although hypothermia decreases the metabolic function of the body, and is neuroprotective, in traumatized individuals hypothermia most often results in deleterious effects such as coagulopathy, metabolic acidosis, and impaired immune response (8).
- ☞ Risk factors that contribute to hypothermia include environmental exposure, alcohol and drug intoxication, IV infusion of room temperature fluid, transfusion of cold blood without warming, spinal cord injuries, head injury, shock, and associated medical conditions such as hypothyroidism and hypoglycemia (Table 5).
- ☞ Trauma-associated hypothermia increases morbidity because of impaired cardiorespiratory function, peripheral vasoconstriction, bleeding diathesis, metabolic acidosis, diminished hepatorenal function, and altered immune response (Table 6).
- ☞ Hypothermia is common during general anesthesia because of impaired thermoregulation (Fig. 6), decreased heat production, and internal redistribution of body heat from the warmer core to the cooler peripheral tissue in the exposed patient (35,36).
- ☞ Epidural and spinal anesthesia block afferent and efferent thermoregulatory responses and cause similar degrees of hypothermia as general anesthesia.
- ☞ Mild hypothermia ( $1\text{--}2^{\circ}\text{C}$  below normal) is neuroprotective, whereas mild hyperthermia ( $1\text{--}2^{\circ}\text{C}$  above normal) may exacerbate cerebral ischemia.
- ☞ A thermometer incorporated into an esophageal stethoscope is a simple and reliable method of measuring core temperature in tracheally intubated patients providing it is inserted deep enough (at least 5–10 cm past the carina).
- ☞ The preferred technique of temperature monitoring is one that reflects core temperature such as distal esophageal, nasopharynx, PA, and tympanic membrane.

Intermediate sites such as rectum, bladder, and mouth usually reflect core temperature.

☞ The most reliable core monitoring sites are the PA, distal esophagus, nasopharynx, and tympanic membrane.

☞ Because temperatures taken at the PA closely correlate with core temperature, many clinicians view this as the most accurate site for measuring body temperature in critical care; this site is far too invasive to use for temperature alone.

☞ For these reasons, the tympanic membrane is a good noninvasive site to measure core body temperature in SICU and OR patients, but the probes are easily dislodged during patient movement and transport.

☞ When body temperature is constant, intermediate sites such as sublingual, rectal, and urinary bladder are good estimates of core temperature (Figs. 10 and 11). When body temperature is rapidly changing (e.g., CPB, invasive rewarming, surgery), intermediate temperature sites are slower to change compared to core sites.

## Traumatic Brain Injury: Critical Care Management

Anne J. Sutcliffe

Department of Anesthesia and Critical Care, Alexandra Hospital, Redditch, U.K.

### INTRODUCTION

In the United States, the annual incidence of traumatic brain injury (TBI) is 1 per 1000 persons. Higher incidences are found in the age groups 15–24 years and 75 years or older (1). However, these data underestimate the true incidence of TBI because only patients dying before admission to the hospital and those admitted to the hospital are included. Prevalence estimates range from 2.5 to 6.5 million individuals living with the consequences of TBI.

Males are twice as likely to be affected as females, and there is a strong association of alcohol with TBI (1). Approximately half of TBIs are caused by motor vehicle, bicycle, and pedestrian-vehicle accidents. A further 10% of TBIs are caused by firearms and the incidence is increasing, 10% by nonfirearm assaults and 3% of total assaults are associated with sporting and recreational activities (1,2). TBIs are particularly associated with falls in the elderly and in the very young. Twenty-five percent of TBIs are due to nonaccidental mechanisms (1).

Mortality from TBI is falling and in 1992 was 19.3 per 1000 population per year (2). The decrease is accounted for by a decrease in deaths associated with blunt trauma. The incidence of deaths from penetrating injury due to firearms is increasing. This is important because most medical interventions for TBI are based on experimental evidence using a blunt trauma model. A different management approach may be more appropriate for penetrating injuries.

Acute care for TBI patients in the United States costs between \$9 and \$10 billion per year. The lifetime cost of care for a single person with severe TBI has recently been estimated at \$1,857,000. This does not include loss of earnings or the cost of social services (1).

✎ **The function of certain portions of damaged brain can be taken over by other areas, for example, the damaged brain is thought to exhibit a certain degree of neural plasticity.** ✎ However, at present, little can be done to reverse the effects of primary brain injury. In the intensive care unit (ICU), management strategies are directed towards preventing and/or minimizing the damaging effects of secondary injury.

This chapter aims to describe the basics of primary brain injury and then address the critical care strategies employed to minimize secondary brain injury. The primary emphasis is on pharmacological interventions and maintenance of homeostasis in the intensive care setting. ✎ **The goal of treatment for TBI is to reduce morbidity and improve outcome.** ✎ New therapies are being actively investigated using animal models and some may prove successful in humans.

### THE GOAL: TO FACILITATE A GOOD OUTCOME

Hospital-based research into outcome after TBI nearly always uses the Glasgow Outcome Scale (GOS) (3). However, TBI is a heterogeneous condition and the GOS conceals a huge variation in disabilities, consequently rehabilitation therapists often use alternative assessment tools that are more sensitive to these variations. Unfortunately, hospital outcome data are not routinely linked to rehabilitation outcome data. Copes et al. (4) have studied 375 patients linking the Major Trauma Outcome Study database and a national rehabilitation outcome database. These authors demonstrated correlations between the two databases' outcome measures, and, although the task of linking the databases is arduous, they recommend that hospital-based trauma registries should routinely include rehabilitation outcome data.

### Defining a Good Neurological Outcome

For many patients, a good outcome appears to have been achieved but a follow-up study has shown that most patients have minimal physical disability at three months after mild or moderate TBI. However, 33% remain cognitively impaired at six months and 60% remain unemployed (5). High rates of depression, loneliness and psychomotor slowness can be demonstrated for up to 20 years after severe TBI (6). The consequences of TBI are summarized in Table 1.

Outcome measurement can be uni-dimensional or multifaceted: a specific function or functions are measured. Alternatively, surrogates such as employment status can be used. Sometimes, the patient's perception of the quality of a given outcome differs from that of his caretakers (7).

### Duration Endpoints and Other Complexities of Outcome Measurements

✎ **The full effects of the ICU management of head injury may not be apparent until years after rehabilitation is complete.** ✎ Motor function improves to its best level relatively quickly, but cognitive function can improve for up to five years (8,9).

Table 2 compares the GOS and the Disability Rating Scale (DRS). These are two of the many outcome scales available. Different outcome scales survey different information, and thus predict different outcomes.

### Glasgow Outcome Scale

The GOS is a simple classification. Possible outcomes are dead, vegetative, severely disabled, moderately disabled, or good recovery (3). The latter three categories depend on

**Table 1** Consequences of Traumatic Brain Injury

Neurological consequence	Example-comments
Cognitive	Memory impairment Poor concentration Language difficulty Abnormal visual perception Difficulty with problem solving and abstract thought Impaired judgment and information processing
Functional	Hemiparesis Foot drop
Neuro-electrical	Seizures Sleep disorders
Behavioral	Verbal and physical aggression Altered sexual functioning Social disinhibition Depression
Social	Suicide Divorce Unemployment Economic strain Substance abuse

the patient's ability to live independently and their ability to return to work or school. The GOS is the most widely used outcome measure in head injury research. However, it is a global and relatively insensitive measure, precluding any description of the types of impairments that lead to the disability. The Glasgow Outcome Scale Extended (GOSE) was devised as a new outcome measure that retains the advantages of the existing GOS but allows comparison of patterns of recovery in different areas of function: behavioral, cognitive, and physical. Using a series of functional outcome measures, assessment of affective status, and neuropsychological tests as criteria, the validity of the GOSE generally exceeded the GOS, and the GOSE was more sensitive to change than the GOS (10).

**Table 2** Comparison of Glasgow Outcome Scale and Disability Rating Scale as Outcome Scores

GOS score	Interpretation	DRS score	Interpretation
5	Good recovery	0	No TBI
		1	Mild TBI
		2–3	Partial TBI
4	Moderately disabled	4–6	Moderate TBI
		7–11	Moderately severe TBI
3	Severely disabled	12–16	Severe TBI
		17–21	Extremely severe TBI
2	Vegetative state	22–24	Vegetative state
		25–29	Extreme vegetative state
1	Dead		

*Abbreviations:* DRS, Disability Rating Scale; GOS, Glasgow Outcome Scale; TBI, traumatic brain injury.

### Disability Rating Scale

The DRS was developed to describe the continuum of recovery and can be used by both acute and rehabilitation clinicians (11). Eye opening, communication ability, and motor response are measured in the same way as the Glasgow Coma Score. Feeding ability, toileting ability, grooming ability, level of functionality (physical and cognitive), and employability are also scored giving a total range of 0–29. Compared to the GOS with a range of 1–5, the DRS better describes the level of functioning from basic to complex.

### Implications for Intensivists

#### Assessing the Evidence Base

Most studies of acute interventions for TBI measure mortality and gross morbidity either in ICU or in the hospital. Long-term improvements in outcome are not reported because insensitive measurement tools are used and recovery is often far from complete at the time of hospital discharge. This may explain why it has been impossible to prove that certain therapies that work in animals are helpful in humans.

#### Participating in a Multidisciplinary Approach to Care

Clinicians working in the ICU are aware that what they do has a significant impact on the patient's eventual outcome. However, there are therapies used by the rehabilitation team that are more effective if the TBI patient is discharged from an acute hospital without complications that restrict rehabilitative efforts. Earlier use of some rehabilitation therapies might speed up or improve the quality of recovery and are discussed in the section "Rehabilitation Begins in ICU."

#### Discussions with Relatives

Failure to appreciate that even minor TBI can cause significant morbidity can lead to misplaced optimism amongst patients and their families. It is important that relatives of those with severe TBI are given a realistic assessment of what the future might hold bearing in mind that it is impossible, even using magnetic resonance imaging (MRI), to predict with any certainty the outcome for an individual patient (12). However, families should be made aware that significant improvement can occur even after acute hospital discharge.

### Mortality and Morbidity After Discharge Following TBI

♣ **Rehospitalization occurs in 23% of TBI patients in the first year after injury and declines to 17% at five years after injury (13).** ♣ During the first year most readmissions are for elective reasons such as reconstructive surgery. By five years after injury, most admissions are related to seizures or psychiatric conditions. Mortality is also increased in the first five years after TBI. Most deaths are related to decreased mobility. The exception is death secondary to seizures (14).

### PRIMARY BRAIN INJURY

Primary brain injury is caused directly by the initial impact, and this damage is generally referred to the pathological state existing immediately following the trauma, whereas "secondary injury" refers to the destructive changes that evolve over time (hours to days) following the primary event. Direct injury can occur to the brain parenchyma, as well as to the skull, meninges, dura, or various blood

**Figure 1** Computed tomograph of the brain showing an acute traumatic right frontal intracerebral contusion.

vessels, which result in space-occupying contusions or hematomas and consequent cell injury or death.

**Parenchymal Tissue Damage**  
**White and Grey Matter Injuries**

Grey matter injury causes functional failure of neuronal cell bodies and synapses, whereas white matter injury causes abnormal axonal conduction. Head impact sets up pressure waves in the brain that can cause contusions on the crests of gyri that may extend into white matter (Fig. 1) (15). Shearing caused by angular acceleration of the head results in diffuse axonal injury (DAI). DAI is not always visible on early computed tomography (CT) scan but depending on its severity, the immediate effect can range from minimal cognitive changes to death. DAI can cause hemorrhage in the corpus callosum, diffuse cerebral swelling, subarachnoid hemorrhage (SAH), and hemorrhage around the third ventricle (16).

**Anatomical Locations of Injury and Implications**

Cortical contusion occurs under the site of impact but, because the brain is mobile within the skull, may also occur opposite the site of impact (contracoup injury). The majority of TBIs requiring ICU admission will be comatose, and a CT scan will have demonstrated areas of contusion and other abnormal features. Knowledge of the functions of various parts of the brain (Table 3) can enable an educated guess to be made on clinical evidence about the areas of likely damage. Furthermore, an understanding of the clinical signs associated with tentorial and or tonsillar herniation allows rapid intervention before radiological confirmation of the herniation (Table 4). For further information, readers are referred to a detailed text on correlative neuroanatomy (17).

**Epidural Hematoma**

Epidural hematomas (EDH) occur outside the dura and are also referred to as extradural hematomas. The incidence of EDH is between 5% and 15% (15). An EDH usually occurs

**Table 3** Location-Based Guide to Brain Function

Location	Description	Function
Cortex	Dominant hemisphere	Speaking
		Reading
	Nondominant hemisphere	Writing
		Calculating
	Frontal lobes	Memory

	Control of temperature	

after a skull fracture tears the middle meningeal artery. The hemorrhage, which has a smooth outline when visualized on CT scan, is usually located in the temporal or temporal-parietal region. Rupture of the sagittal or lateral sinus may also cause an EDH (Fig. 2).

**Subdural Hematoma**

The incidence of subdural hematoma (SDH) is 20% to 63% (15). An SDH occurs in isolation following rupture of

**Table 4** Clinical Signs of Brainstem Herniation Based upon Type

Herniation type	Clinical signs of herniation
Sub-falcine	Usually none
Lateral tentorial	Pupil dilatation on ipsilateral side
	Loss of light reflex
	Ptosis
	Deterioration in conscious level
Central tentorial	Limb weakness on the contralateral side
	Pupils small, then moderately dilated
	Loss of light reflex
	Deterioration in conscious level
Tonsillar	Loss of upward gaze
	Diabetes insipidus
	Depression of conscious level
	Abnormal respiratory pattern, then apnea
	Neck stiffness

**Figure 2** Computerized tomograph of the brain showing a left frontal epidural hematoma and mild left-to-right midline shift.

bridging veins (connecting the cortical surface to a venous sinus) (Figs. 3–5). Cerebral damage occurs because pressure from the clot causes ischemia. Frequently, there is underlying cerebral contusion particularly if the impact occurs over the frontal or temporal lobe. If the contusion is hemorrhagic, necrotic brain and blood escapes into the subdural space. This association of intracerebral and subdural hemorrhage is sometimes called a “burst lobe.”

**Intracerebral Hemorrhage**

Closed head injury may also result in intraparenchymal hemorrhage, often referred to as hemorrhagic contusion (18). Seen as hyperdense areas within brain matter on

**Figure 3** Computerized tomograph of the brain showing an acute left frontoparietal subdural hematoma with significant left-to-right midline shift.

**Figure 4** Computerized tomograph of the brain showing a right subacute subdural hematoma with significant right-to-left shift and effacement of the right ventricle (occipital horn). Note that the subacute hematoma (1–2 weeks) is nearly isodense with the density of the cerebral hemisphere.

CT imaging during the workup of head injury, these lesions most commonly occur in areas where sudden deceleration of the head causes the brain to impact bony intracranial surfaces in a coup or countercoup fashion.

**Figure 5** Computerized tomograph of the brain showing a left chronic subdural with significant left-to-right midline shift.

Surgical decompression is warranted if the mass effect threatens herniation and the temporal lobes in particular are housed in a region where uncus herniation can occur with smaller contusions (19). Chapter 14 more fully discusses the topics of intracerebral hemorrhage.

### Subarachnoid Hemorrhage

SAH following head trauma is common and is associated with a poorer outcome (Fig. 6) (20). Animal experiments suggest that SAH causes an increase in intracranial pressure (ICP) and decrease in cerebral blood flow (CBF) independent of the effects of TBI (22). SAH also compromises the integrity of the blood-brain barrier. In some patients, SAH may be the primary cause of coma, secondarily leading to a motor vehicle accident or a fall which results in TBI. If this is suspected, following stabilization in the ICU, additional investigation is required to diagnose a possible cerebral aneurysm or arteriovenous malformation (also see Volume 2, Chapter 14).

### Vascular Injury

Injury to the middle meningeal artery causing EDH is most common. Penetrating skull injuries can damage almost any vessel. Damage to the carotid artery by a blunt neck injury can mimic a severe head injury. The history and mechanism of the injury should alert the clinician to the possibility of this rare injury. Vertebral artery injuries also result from blunt neck trauma. These are diagnosed by CT angiography.

## SECONDARY BRAIN INJURY

Secondary injury can result from pressure increases caused by hematomas and contusions, as they expand, as well as from the resultant edema, hyperemia, or release of inflammatory and cytotoxic mediators (as described below).

**Figure 6** Computerized tomograph of the brain showing severe posttraumatic subarachnoid hemorrhage. Acute blood appears radiodense (white) on CT. The subarachnoid blood is seen in the suprasellar cistern (arrow 1), the interhemispheric cistern (arrow 2), temporal horn of the lateral ventricle (one of the radiological stigmata of hydrocephalus—arrow 3), and in the ambient cisterns around the midbrain (arrow 4).

**Table 5** Causes of Secondary Brain Injury

Hypotension
Hypoxia
Herniation
Pyrexia
Seizures
Hyperglycemia
Hydrocephalus
Vasospasm
Cerebral infection
Reperfusion injury
Cytotoxic cellular edema
Vasogenic and hydrostatic interstitial edema

Edema can occur within the cell itself, as well as within the interstitial space (due to vasogenic and hydrostatic factors). Hypotension, hypoxia, and other non-physiologic conditions (e.g., hyperglycemia, hyperthermia, etc.), can cause or exacerbate secondary injury. ⚡ **Secondary brain injuries (Table 5) are of particular interest because they are potentially preventable.** ⚡

### Cytotoxic Cellular Edema

Injured and dying neurons have disturbed ionic gradients that lead to swelling. Following mitochondrial swelling and failure of membranous ionic pumps, toxic factors are released that can cause further neuronal damage. These effects may be specific with respect to brain region and time (22). The mechanisms are complex and our understanding is far from complete. The cellular effects of TBI are commonly studied using rodents. A recent article shows that the method by which the animals are anesthetized can have an independent effect on mortality and calls into question the results of many earlier studies (23). Furthermore, it is not yet certain that different types of cellular injury, for example, DAI, contusion, hypoxic, are damaged by the same metabolic and biochemical mechanisms which include: anaerobic metabolism (producing lactate) glutamate toxicity, intracellular calcium influx, nitric oxide synthesis, and apoptosis (24–28).

These have been studied using specific antagonists of intracellular and cell membrane metabolic processes in cell culture and animal models. Unfortunately, although some experimental results are promising, they have not yet been successfully translated into neuroprotection in the clinical setting partly because most benefit occurs when the drug is applied prior to the initiation of trauma.

### Interstitial Edema: Vasogenic and Hydrostatic

TBI causes an inflammatory response that involves cytokine production, chemokine release, inflammatory adhesion molecule upregulation and neutrophil recruitment (22). Macrophages from the circulation and microglia accumulate at the site of injury and release inflammatory mediators including tumor necrosis factor alpha (TNF $\alpha$ ), and interleukin-6 (IL-6). These and other inflammatory mediators disrupt the tight junctions that normally exist between the cerebral capillary endothelial cells that form the blood-brain barrier. Leakage of protein-rich serous fluid from the capillaries causes vasogenic interstitial edema.

Hydrostatic interstitial edema occurs when there is a sudden increase in capillary transmural pressure. It may

follow decompression of a mass lesion or occur in the presence of defective autoregulation. The fluid, which escapes into the interstitial space, unlike vasogenic edema, is low in protein.

**Hyperemia**

Animal experiments show that CBF increases immediately after injury, then decreases by up to 40% within a few minutes and returns to normal after approximately 24 hours (29). Hyperemia, defined as CBF in excess of metabolic demands, has been demonstrated in the hippocampus, and in the areas of brain close to the ischemic penumbra of injury (30). Usually hyperemia follows a period of increased ICP and/or reduced CBF. Its etiology is unexplained, but metabolic derangement, loss of vasomotor tone, or severe tissue acidosis are possible explanations.

**Hypotension**

☞ **A systolic blood pressure of less than 90 mmHg occurring between the time of TBI and completion of resuscitation is associated with a 33% increase mortality (31).** ☞ During the first 24 hours in ICU, the lowest recorded blood pressure is correlated with mortality (Fig. 7) (32). Systemic hypotension is particularly damaging in the setting of increased ICP and/or concomitant decreased systemic oxygenation (discussed subsequently).

**Hypoxia**

☞ **An arterial oxygen tension (PaO<sub>2</sub>) of less than 60 mmHg (8 kPa) occurring between the time of TBI and completion of resuscitation is also associated with an increase in morbidity and mortality but to a lesser extent than the effect of hypotension (31).** ☞ An early hypoxic episode increases mortality by 6%. Hypoxia can be caused by airway obstruction or chest injury. Reduced cerebral blood flow, systemic hypotension or hypocapnic vasoconstriction may also cause cerebral hypoxia (Fig. 7). The effect of combined hypoxia and hypotension is synergistic and must be avoided (31).

**Herniation**

Brain herniation may be tentorial, subfalcine, or tonsillar. In general, the effect of herniation is compression of the adjacent brain, stretching or tearing of the blood vessels and ischemic damage (Table 4; Volume 2, Chapters 1 and 7).

**Figure 7** Bar graph demonstrating the relationship between hypoxia or hypotension or both hypoxia and hypotension and outcome following traumatic brain injury.

**Figure 8** Bar graph demonstrating the relationship between highest measured blood glucose (mg/dL) in the first 24 hours in ICU and mortality. There is a 20% mortality for blood glucose in the normal range of 75–146 mg/dL (4.1–8 mmol/L). Moderately elevated glucose 147–218 mg/dL (8.1–12 mmol/L) is associated with more than twice the mortality. Blood glucose in the 219–291 mg/dL (12.1–16 mmol/L) range approaches 60% mortality. Patients with a blood glucose in the 292–364 mg/dL (16.1–20 mmol/L) range had slightly higher mortality than 60%. However, those patients with serum glucose measurements greater than 364 mg/dL (>20 mmol/L) had the highest mortality of all (approaching 100%).

**Hyperglycemia**

☞ **The highest blood sugar occurring in the first 24 hours of ICU care is linearly correlated with mortality (Fig. 8) (32).** ☞ It is not clear whether hyperglycemia is merely a manifestation of the stress response to injury or another secondary insult (also see Volume 2, Chapter 60) (33,34). It is interesting to observe that the correlation of blood glucose with mortality is closer than the inverse correlation between mean arterial pressure (MAP) with mortality (32). Furthermore, a high blood sugar combined with a MAP of 60 to 80 mmHg is associated with a poorer outcome than a low blood sugar and a MAP of less than 60 mmHg (Fig. 9) (32). In the cortical extracellular space, microdialysis has been used to

**Figure 9** Bar graph demonstrating the relationship between highest blood glucose, lowest mean arterial pressure in the first 24 hours in ICU and mortality. Key: 75–146 mg/dL (4.1–8 mmol/L) = clear columns, 147–182 mg/dL (8.1–10 mmol/L) = grey columns, >182 mg/dL (>10 mmol/L) = solid columns.

show that lactate concentration is increased and glucose decreased indicating increased anaerobic glycolysis, which is associated with a poor outcome (24). The effects of delivering more glucose in the blood are debated. On the one hand, anaerobic metabolism is inefficient so additional glucose might provide fuel for more energy. On the other, increased energy production produces more lactate as a by-product, and lactate causes cellular damage.

### Fever

The brain's metabolic rate alters in direct proportion to core temperature. Thus, a fever occurring in a patient with TBI will increase the oxygen requirement of cells that are already in an ischemic environment. Abundant animal data show moderate hypothermia to be protective (35). Conversely, hyperthermia increases mortality and morbidity by aggravating axonal and microvascular damage (36). ⚡ **Although human outcome data is controversial, fever should be prevented in TBI patients.** ⚡

### Seizures

Within the first week after TBI, continuous electroencephalographic monitoring has shown that seizures occur in 20% of patients (37). Seizures cause intense local metabolic activity and can aggravate ischemic damage in affected areas of brain. Diagnosis can be difficult in the ventilated patient. Sedative drugs can mask typical tonic-clonic limb movements but twitching of the corner of the mouth is sometimes seen. An unprovoked episode of hypertension, tachycardia, increased ICP, and a small rise in core temperature is highly suggestive of undiagnosed seizures.

### Hydrocephalus

Hydrocephalus is usually a late complication of TBI. The published incidence varies depending on whether the diagnosis is made on CT findings alone or whether combined clinical, physiologic, and imaging data are used (38). Distortion of the ventricular system by edema or intracerebral hemorrhage can obstruct cerebrospinal fluid (CSF) circulation. Alternatively a localized obstruction due to clot is common following SAH. In either event, the ventricles enlarge and ICP rises.

### Vasospasm

Vasospasm occurs in 19% to 40% of patients following traumatic SAH and can contribute to brain ischemia from other causes (15). The pathogenesis of vasospasm is unclear, but it could be caused by blood or oxyhemoglobin binding with endothelial nitric oxide (the endogenous relaxant factor). Free radicals and inflammatory mediators have also been implicated. Transcranial Doppler ultrasonography is used for diagnosis. Reduced middle cerebral artery blood flow and increased pulsatility index are usual findings after severe TBI (39). These global changes must be differentiated from the more local increases in flow velocity associated with vasospasm.

### Cerebral Infection

Meningitis may follow basal skull fractures, vault fractures, prolonged external ventricular drainage (EVD) or craniotomy. Meningitis can also cause hydrocephalus and a late deterioration in consciousness level. Post-traumatic brain abscess is rare and usually follows a penetrating injury, especially gunshot or shrapnel wounds.

### Reperfusion Injury

Free-radical generation during reperfusion is facilitated by fresh oxygen carried by the recovering circulation and free iron derived from the breakdown of extravascular hemoglobin. Under normal circumstances, intracellular enzyme systems metabolize free radicals so that they do not cause damage. It is speculated that the influx of calcium that follows TBI inactivates these enzymes and allows an excess of free-radical species to cause significant endothelial damage. Although direct measurement of free radicals is impossible, indirect evidence suggests that there is an increase following TBI (40).

## UNIFYING THE EFFECTS OF SECONDARY (AND SOME PRIMARY) INSULTS

### Cerebral Metabolic Rate for Oxygen

Under normal conditions, the brain requires 3.5 mL oxygen per 100 g of brain tissue per minute. This accounts for 20% of total body oxygen consumption. Oxygen requirements increase if the patient is febrile or suffering seizures. In patients with severe TBI, global cerebral metabolic rate for oxygen (CMRO<sub>2</sub>) may be decreased by one-third to one-half. It is thought that this reduction occurs in the energy expenditure component that governs cellular activation and that the brain's basal metabolic requirements are unchanged (41).

### Cerebral Blood Flow, Cerebral Perfusion Pressure, and Autoregulation

Fifteen percent of the cardiac output is required to deliver the brain's oxygen requirements. In addition to a high basal oxygen utilization requirement, the brain has limited reserves of glucose, which must also be delivered by the cerebral circulation. Aerobic oxidation of glucose via the glycolytic and tricarboxylic acid pathways is essential for the production of high-energy phosphates. Most of the energy generated is used to maintain ionic gradients. In the intact brain, CBF closely matches CMRO<sub>2</sub>. Anything that reduces CMRO<sub>2</sub>, such as hypothermia or barbiturates, also reduces CBF. CBF is determined by the pressure difference across the cerebral circulation, known as cerebral perfusion pressure (CPP), and vascular resistance. MAP is easily measured but the measurement of mean cerebral venous pressure is more difficult. For convenience, mean cerebral venous pressure is usually equated to ICP. Hence:

$$CPP = MAP - ICP$$

The normal brain requires a constant blood flow, which is achieved by CBF autoregulation. Between a CPP of 50 and 150 mmHg, blood flow is controlled by alterations in the resistance of the arterioles and precapillary segments. Above and below these values, CBF is pressure dependent. In the injured brain, autoregulation is sometimes lost and CBF becomes pressure dependent over the entire CPP range. In this situation, the relationship between CMRO<sub>2</sub> and CBF can become uncoupled. ⚡ **For the patient with TBI, a CPP of >60–70 mmHg is generally sufficient to maintain cerebral oxygenation (42).** ⚡

Arterial carbon dioxide tension (PaCO<sub>2</sub>) has a significant effect on CBF (3–6% change in CBF per mmHg change in PaCO<sub>2</sub>) in the normal brain. Hypercarbia increases CBF and hypocarbia decreases it. This phenomenon is

known as carbon dioxide reactivity and is caused by CO<sub>2</sub>-mediated changes in hydrogen ion concentration. ⚡ **Excessive hyperventilation of patients with TBI may cause ischemia if CO<sub>2</sub> reactivity is preserved.** ⚡ However, those patients with moderate to severe TBI often have diminished or absent CO<sub>2</sub> reactivity.

### **Intracranial Pressure**

Essentially, the skull is a semiclosed box of fixed volume (1600 mL). The contents of the skull are the brain representing 80% of the total intracranial volume, blood 12% and CSF 8%. Blood and CSF can be shifted away from the skull. This provides the total cerebral contents with some ICP buffering capacity. Reduced compliance implies increasing stiffness. Elasticity is the converse of compliance. Small, slow increases in the volume of the brain can be compensated for by a reduction in CSF volume and cerebral blood volume. Thus, normal ICP is maintained until elasticity is exhausted at which point pressure within the skull rises.

⚡ **The interpretation of a given ICP measurement must be made in the light of the underlying pathology and the speed with which that pathology has occurred.** ⚡ Cytotoxic cellular edema is initially compensated for by movement of CSF out of the skull into the subarachnoid space around the spinal cord. If, however, SAH has caused a blockage in the interventricular canals or the basal cisterns, CSF movement out of the skull is restricted, the total contents of the skull are less elastic and for the same amount of cerebral swelling, the rise in ICP will be greater. Although this description may be useful in clinical practice, it is important to realize that the relationships between intracranial blood, CSF, and brain volume with ICP are extremely complex and that greater understanding of these relationships may lead to improvements in the management of TBI (43). ⚡ **Current evidence suggests that 20–25 mmHg is the upper threshold above which treatment to lower ICP should be started (42).** ⚡

### **THE ROLE OF MONITORING IN THE MANAGEMENT OF TRAUMATIC BRAIN INJURY**

Multimodal monitoring of the patient with TBI is discussed in detail in Volume 2, Chapter 7. The importance of adequate monitoring cannot be overemphasized. Many of the current treatments for TBI have never been proven in prospective, randomized trials. Furthermore, many of the monitoring techniques employed in the ICU setting are subject to inaccuracies and doubts about their benefit. However, their utilities in detecting the trends of therapy are valuable. A Canadian study has shown that although 98.1% of surgeons use ICP monitors for patients with severe TBI, only 20.4% have confidence that ICP monitoring improves outcome (44). If a treatment is administered with the expectation that it will cause a specific effect, monitoring is required to detect that effect. If the treatment is ineffective for the specific result required or fails to produce a reduction in mortality or morbidity, attention should be directed to inappropriate treatment not necessarily inappropriate monitoring. Vasopressor drugs may have a limited effect in the presence of hypovolemia, and mannitol may not reduce ICP in the presence of hyperemia. Monitoring should be used in conjunction with knowledge of the injury process, clinical examination, laboratory measurements, and imaging.

### **MANAGEMENT OF TBI IN THE INTENSIVE CARE UNIT**

#### **The Evolution of Intensive Care Unit Management for Traumatic Brain Injury**

Much of the management of TBI is intuitive and preferred therapy varies between institutions and countries. Guidelines have been issued in the United States using published studies to make evidence-based recommendations and in Europe, based on consensus statements by experienced senior physicians (42,45). There is no doubt that neurosurgical ICU practice has changed in recent years (46,47). Whether this change has been brought about by the publication of guidelines, or in spite of them, is unclear. What is certain is that practice is not 100% uniform. However, overall, there are more common points of management in centers around the globe than divergent. In addition, the science behind our therapies is still in its infancy. Current specific management considerations for TBI are reviewed in the following section.

#### **Specific Therapies of Importance in the Management of Traumatic Brain Injury**

##### **Oxygen**

Postmortem studies of head-injured patients often show a high proportion of patients with secondary ischemia. It is hardly surprising, therefore, that most treatises on the management of TBI advise that oxygen be given to prevent hypoxia. ⚡ **During the resuscitation phase it is recommended that PaO<sub>2</sub> be maintained above 60 mmHg (8 kPa) (42).** ⚡ Hypoxic insults during intensive care also increase mortality (48). Nowhere is an upper limit of PaO<sub>2</sub> recommended. Consequently, it is not unusual to find ICU patients with TBI being managed with PaO<sub>2</sub> values well above the normal range.

This approach may not be as safe as is commonly supposed. High concentrations of oxygen are toxic to the lungs and can cause the acute respiratory distress syndrome (ARDS) (49). The role of oxygen free radicals in causing secondary brain damage has been described above. It seems sensible to suggest that sufficient supplemental oxygen be given to maintain PaO<sub>2</sub> within the normal range and that the dose should be titrated in the same way as for all other drugs and fluids.

##### **Intravascular Repletion for Hypotension**

During the early period after injury, hypotension is strongly associated with an increase in mortality suggesting that poor perfusion leads to reduced oxygen delivery to the brain with significant ischemic consequences. Hypotension in the ICU may be equally devastating. For patients whose only hypotensive episode occurred in ICU, 66% either died or remained in a vegetative state compared to 17% for those patients who never suffer a hypotensive episode (48). The target systolic blood pressure appears to be 90 mmHg or more (42).

In a small group of patients with severe TBI and significant extracranial injuries, aggressive fluid resuscitation is associated with remarkably good outcomes suggesting that archaic practices of fluid restriction (to reduce edema) is not only unnecessary but potentially harmful (51,52). A fluid deficit of only 594 mL has an adverse effect on outcome after isolated TBI (53). Animal studies suggest that resuscitation can be successfully completed using physiological saline, hypertonic saline, hetastarch or whole blood provided that adequate volumes are given. Hypertonic saline, however, appears to have the additional advantage of reducing ICP (53). It is important to remember that all

hypertonic solutions exert their effect by increasing plasma osmotic pressure. Water is drawn first from the interstitial space and then from the cells. However, excessive use of hypertonic solutions can cause dangerous intracellular dehydration and increase mortality (54). Hypertonic saline should not be used for prolonged periods unless additional water is given in the form of other fluids.

Hypotension has many causes including vasodilator sedatives, ventilation, incomplete resuscitation prior to ICU admission, and continued blood loss from a known injury. The ICU doctor should always be alert to the possibility that there are other undiagnosed injuries causing occult bleeding. The chest and abdomen are common sites for such injuries. ✎ **The management of hypotension must include not only fluid replacement but also identification of the cause.** ✎

### **Ventilation, PaCO<sub>2</sub>, and Effects of Intrathoracic Pressure**

The patient with severe TBI requiring admission to ICU is typically comatose and at high risk of airway obstruction and pulmonary aspiration because airway reflexes are obtunded. Consequently, endotracheal intubation and mechanical ventilation will already have started or will be indicated shortly after ICU admission. At this time, ICP monitoring is very helpful. As expected venous return will be maximized if mean intrathoracic pressure is kept to the minimum required for adequate oxygenation and carbon dioxide removal. In theory, improving cerebral venous drainage will assist in the control of ICP by minimizing cerebral venous engorgement. This implies the use of head elevation, smaller tidal volumes, and proportionately increased respiratory rates. If TBI is associated with pulmonary contusion, positive end expiratory pressure (PEEP) may be used to aid alveolar recruitment. Also, postural drainage facilitates removal of secretions. The amount of PEEP or reversal of head elevation that can safely be used is variable. Their use should be guided by their effect on ICP. In theory, both of these interventions may raise ICP. In practice, their effect is very much dependant on individual patient variables. Accordingly, ICP monitoring is an invaluable aid to optimizing respiratory management. Positive pressure ventilation is often cited as a cause of hypotension. Hypotension is unlikely in euvolemic patients, when physiological (7–15 mL/kg) tidal volumes are used, and its occurrence should provoke further thought concerning the adequacy of fluid resuscitation.

For the patient with TBI, another important benefit of ventilation is the ability to control PaCO<sub>2</sub>. For the majority of patients, PaCO<sub>2</sub> should be maintained in the low normal range. A PaCO<sub>2</sub> of between 30 and 35 mmHg (4–4.5 kPa) is recommended in the United Kingdom and between 35 and 40 mmHg (4.5–5 kPa) in the United States. Improved survival has been demonstrated for patients in whom PaCO<sub>2</sub> is maintained at 35 rather than 25 mmHg and local reductions in cerebral perfusion have been demonstrated when PaCO<sub>2</sub> is between 27 and 32 mmHg (55,56). Chronic hyperventilation should be avoided particularly in the early days after TBI (42). However, a brief period of hyperventilation is an appropriate option if there is an acute deterioration in neurological status (42). This allows time for other therapies such as increased sedation and mannitol to become effective and also allows time for diagnostic CT scanning and if appropriate, urgent surgical intervention to control raised ICP.

Monitoring of jugular bulb venous oxygen saturation (SjO<sub>2</sub>) and arteriojugular venous oxygen content differences (AVdO<sub>2</sub>) will facilitate the identification of hyperemia as a

cause of raised ICP. An SjO<sub>2</sub> of more than 80% indicates that the brain is receiving more oxygen than it can extract. This may be because of high CBF and increased oxygen delivery, but can also occur if the brain has died and metabolic processes have ceased. In the presence of preserved CO<sub>2</sub> reactivity and hyperemia, temporary hyperventilation will reduce ICP and is generally considered safe provided that the SjO<sub>2</sub> does not fall below 55% and the AVdO<sub>2</sub> does not exceed 9%. Hyperventilation in excess of these values may cause cerebral ischemia. Recent research, however, shows that even in the presence of acceptable SjO<sub>2</sub>, localized areas of ischemia are often present (56).

### **Sedation, Analgesia, Neuromuscular Blockade**

Sedation and analgesia are essential components to the management of ventilated patients. They permit the patient to be comfortably settled on the ventilator. During unpleasant interventions, boluses obtund the hypertensive response. For the patient with TBI, the effects of sedatives and analgesics on ICP, CPP, CBF, CO<sub>2</sub> vasoreactivity and seizure activity must be considered and the beneficial effects balanced against detrimental effects. The choice of agent also depends upon whether it can be administered by infusion and its duration of action when the infusion is discontinued. Even opioids such as Morphine, when administered as a low dose infusion, will have minimal respiratory depression, sedation, pupillary constriction or unwanted cardiovascular effects (57). Short-acting drugs are preferred for patients where the ventilation period is expected to be brief or when brain death tests may need to be performed. In some centers, cost may also dictate the choice of drug, although it is important to remember that the cost of an expensive drug may be offset by reduced ICU costs brought about by a reduction in time to extubation. Minimal data exists upon which to base a recommendation that any particular drug is more or less beneficial to use in the TBI patient (58). Propofol (0.1–0.5 mg/hr) and midazolam (1–6 mg/hr) are equally successful for long-term sedation of critically ill patients (59). Propofol may, or may not, have a cost advantage because weaning is more rapid (59,60). Lorazepam (0.05 mg/kg, then 0.007 mg/kg/hr) has also been advocated as a safe, cost-effective sedative for critically ill trauma patients (61). Dexmedetomidine, a new  $\alpha_2$ -agonist, is increasingly used in critically ill patients, and may become an ideal drug for patients recovering from TBI (62). If possible, evidence-based sedation guidelines should be followed (63).

In the past, nondepolarizing neuromuscular blockade (NMB) drugs were routinely given to prevent rises in ICP secondary to coughing on the endotracheal tube. With the advent of ICP monitoring, use of NMB has decreased and is now reserved for patients in whom persistently elevated ICP is difficult to control. NMB drugs are also frequently used during transport when movement may provoke coughing on the endotracheal tube and increases in ICP, or accidental extubation. The choice of NMB drug depends on the side effects and the anticipated clinical duration of use, just as with sedatives and analgesics. Pancuronium, vecuronium, and cisatracurium are commonly used (58). Pancuronium can cause tachycardia and minimal hypertension that may or may not be desirable depending on the ICP, CPP, and CO<sub>2</sub> reactivity. Its main advantage is its long duration of action and low cost. A disadvantage is that excretion is dependant on normal renal function. Atracurium can cause histamine release and hence hypotension when administered as a bolus but cardiovascular stability is the rule when it is given by infusion. Cisatracurium does not cause

histamine release (thus more stable hemodynamically), and does not depend upon renal or hepatic function for clearance. Cisatracurium is degraded spontaneously via Hoffman degradation, and is thus useful in patients with multiple organ dysfunction syndrome (MODS). Vecuronium causes minimal hemodynamic disturbances and is inexpensive, but its duration of action will be slightly prolonged in patients with liver disease. Guidelines are available for the prolonged use of NMB drugs in the general ICU population (also see Volume 2, Chapter 6) (64).

### **Head Elevation and Extracerebral Venous Drainage**

It is traditional to nurse the head-injured patient with a 30° head up tilt. This usually reduces ICP by 1 or 2 mmHg. Hypovolemic patients may, however, become hypotensive causing a greater reduction in CPP. If CPP falls, the horizontal position should be used until blood pressure is restored by volume resuscitation or vasopressors.

There is no evidence that catheters sited in the internal jugular veins have an important effect on venous drainage. Placement of internal jugular catheters, however, can cause raised ICP, particularly if the head is turned and the patient is tilted head down. At many institutions, the placement of a subclavian catheter without causing a pneumothorax is the preferred method for skilled practitioners. In addition, tape used to secure the endotracheal tube should be sufficiently loose that engorgement of the jugular veins does not occur.

### **Surgery for Evacuation of Hematomas**

The decision to evacuate hematomas is made by the neurosurgical team. Small hematomas may be observed but require regular CT assessment because they can enlarge. Any hematoma causing greater than 5 mm of midline shift or persistently raised ICP is usually removed urgently to minimize ischemic damage.

### **Ventriculostomy for External Ventricular Drainage**

ICP can be reduced by the intermittent or continuous drainage of small volumes of CSF through a ventriculostomy. A ventriculostomy is a catheter inserted into one of the lateral ventricles (Fig. 10). Uncontrolled continuous drainage of CSF can lead to the complete collapse of the ventricles. A closed external ventricular drainage (EVD) system should always be used to reduce the risk of infection.

### **Osmotic Diuretics for Control of Cytotoxic and Vasogenic Edema**

Used in single doses, all osmotic diuretics are reasonably safe. Potential risks of repeated doses are hypokalemia, hyperosmolarity possibly causing renal failure, subdural hematoma, congestive cardiac failure, and coagulopathy.

1. Mannitol is the most commonly used osmotic diuretic, and has been used for decades without randomized trials documenting its efficacy. However, a recent randomized trial has demonstrated clear benefit for the use of bolus doses of mannitol for patients with localizing signs in the emergency room (65). In the ICU, trials are needed to demonstrate benefit and an optimal dosing regime. Contrary to common belief, the osmotic effect of mannitol on the cells is probably the least important of its mechanisms of action. Its ability to reduce blood viscosity, increase the deformability of erythrocytes, and induce constriction of pial arterioles is most likely more important (66,67).

**Figure 10** Computed tomograph of the brain showing the proper position and appearance of a ventriculostomy. The catheter is located in the frontal portion of the right lateral ventricle.

2. Hypertonic saline, from 3% to 23.4% has been used for ICP management; 7.5% saline as a single dose of 100 to 150 mL is commonly used for prehospital small volume resuscitation in Europe. Its use remains experimental in the United States. It reduces ICP but CBF is unaffected. This suggests that it works by an osmotic mechanism (68).
3. 23.4% saline has been used successfully for patients with refractory raised ICP who have failed to respond to mannitol (69). A single bolus of 30 mL given over 15 to 20 minutes through a central line did not alter the serum sodium concentration.

### **Loop Diuretics**

Furosemide and other loop diuretics cause a diuresis and may reduce CSF formation. They may help to reduce ICP when used in conjunction with mannitol but are ineffective when used alone. Furthermore, both furosemide and mannitol may lead to hypotension, which requires volume repletion with physiological saline or colloid.

### **Steroids**

The American standard is that steroids should not be used in the treatment of TBI (42). A more recent systematic review of randomized controlled trials concluded that "there remains considerable uncertainty over their effect" but this view has been challenged because exclusion of one of the trials changes the results to suggest that steroids do not have any benefit (70,71). Statistically, the systematic review could not rule out moderate harm from steroids (70). However, a significant increase in the incidence and severity of infectious complications has been noted in an observational study (72). Furthermore, dexamethasone can cause femoral and humeral head necrosis, and the non-steroid part of the methylprednisolone molecule causes anaphylaxis (73,74).

### **Vasopressors to Increase Cerebral Perfusion Pressure**

Currently, a target CPP of >60 mmHg is recommended but some evidence suggests that this CPP may not be appropriate for all patients, particularly those who have preexisting hypertension (75,76). Vasopressors are used to increase CPP in euvoletic patients; adrenaline, noradrenaline, and dopamine are frequent choices. None have been specifically investigated with regard to outcome after TBI. The choice is typically made because of the personal preferences and/or biases of the ICU team. A more logical approach might be to monitor the circulation with a pulmonary artery flotation catheter and to choose a vasopressor after reviewing the findings. Pulmonary artery catheters can cause some morbidity and should not be used without an assessment of the risks and benefits.

### **Barbiturates**

Barbiturates are thought to have several potentially useful mechanisms of action. These are altered vascular tone, suppression of metabolism, and free-radical scavenging. Regardless, the use of barbiturates is controversial. They may be helpful in reducing refractory raised ICP in salvageable, hemodynamically stable patients although there is no evidence that outcome is improved (42,77). Anaerobic metabolism is not always prevented even when electroencephalographic burst suppression is achieved (78).

### **Temperature Control Including Hypothermia**

Pyrexia is associated with seizures, infection, an inflammatory response and thalamic injury. Depending on the cause, it is generally agreed that definitive treatment should be started and core temperature reduced to as near normal as possible. Paracetamol (acetaminophen) and surface cooling are simple, nonspecific methods that are easy to use.

Hypothermia reduces ICP but whether its use for the treatment of refractory raised ICP improves outcome is unproven (79). In the general population of blunt-trauma victims, hypothermia is an independent predictor of increased mortality (80). Despite numerous animal experiments suggesting that early hypothermia is protective in TBI, it has proved ineffective in the largest and most recent randomized human trial (81). The reasons for this disappointing finding are probably multifactorial but it has been shown that hypothermia below 35°C impairs cerebral oxygenation possibly because of a leftward shift of the oxygen dissociation curve (82). Other possible factors include prolonged time from injury to achieving hypothermia, the methods of cooling used, the difficulty of maintaining a constant temperature, and the duration of cooling (83).

### **Seizure Control**

☞ There is minimal evidence for the routine use of anti-convulsants to prevent seizures (84). ☞ Phenytoin and sodium valproate are equally effective at treating seizures that do occur (85). Lamotrigine has not been tested for the prevention of early seizures but is of interest because it may also increase the speed of recovery from TBI (86). If anticonvulsants are used, they should be limited to the first week after head injury.

### **Decompressive Craniectomy**

Decompressive craniectomy soon after TBI does not improve outcome (87). Some centers use decompressive craniectomy for refractory raised ICP but its benefit has not been tested in a controlled trial. Anecdotal evidence suggests that this pro-

cedure is useful when high doses of vasopressors are causing side effects and adequate perfusion pressure is becoming difficult to maintain (88). Until the bone flap is replaced, the brain is at greater than normal risk of injury particularly if the patient is confused or unstable while ambulatory. Furthermore, replacement of the bone flap is associated with the risks of postoperative EDH and significant infection. In the absence of clear evidence of benefit, the decision to proceed to decompressive craniectomy should be made after careful assessment of the risks and benefits for the individual patient.

### **Chest Physiotherapy and Endotracheal Suctioning**

ICP and CPP increase with both these procedures. In the majority of patients, ICP falls to baseline values rapidly (89). If the patient has significant secretions, failure to provide physiotherapy and suction can result in consolidation and hypoxia, which may lead to ARDS. In order to reduce the intracerebral effects of suction and physiotherapy, many clinicians use preoxygenation and a bolus of sedative prior to the intervention.

### **Nimodipine to Control Vasospasm**

Following nontraumatic SAH, the routine use of nimodipine has dramatically reduced the incidence of secondary ischemic damage due to vasospasm. Some favorable results have been obtained using nimodipine following traumatic SAH, yet its routine use in traumatic SAH is not indicated (90). Also see Volume 2, Chapter 14 for extensive discussion of nimodipine and other treatments for cerebral vasospasm following SAH.

### **Management of Hyperglycemia**

In a study of 1548 surgical patients including 68 suffering from trauma or burns, intensive insulin therapy to control hyperglycemia reduced mortality by almost one-half (91). Patients with MODs and sepsis derived most benefit with significant reductions in the incidence of blood infections, acute renal failure, and polyneuropathy (also see Volume 2, Chapter 60). A reduction in red cell transfusion requirement and duration of mechanical ventilation were also observed. It is tempting to suggest that blood glucose should be maintained within the normal range because of the association of hyperglycemia with increased mortality following TBI particularly if the brain is ischemic. Although there are minimal standards for the management of hyperglycemia in TBI, it is clearly unacceptable to allow severe hyperglycemia to persist untreated. In the past, blood glucose was usually maintained between 125 and 175 mg/dL. However, with the newly recognized benefits of tight blood glucose with intensive insulin therapy, most units are now keeping the glucose in tighter range (e.g., 90–120 mg/dL).

### **Management by Standardized Protocol**

☞ A standardized protocol for the management of ICP appears to provide more consistent control (92). ☞ Similarly, a standardized protocol for CPP management of patients admitted with a Glasgow Coma Scale (GCS) of less than 8 claimed a mortality rate better than any described previously. Only 31% of patients died or remained in a vegetative state (93). Another protocol designed to control both ICP and CPP also achieved a dead or vegetative rate of 30% but even better results were obtained when the

therapy goal was cerebral extraction of oxygen. Use of this parameter permitted hyperventilation to be used for the treatment of hyperemia (94). A randomized study comparing a CBF targeted protocol against an ICP targeted protocol failed to show a significant difference in mortality between the groups. The most significant finding of the study was that both protocols prevented secondary ischemic insults (95).

In practice, equally good results are obtained by strict adherence to local protocols that may differ from each other in several ways. It has been suggested that this is because the use of a protocol implies exemplary critical care. The subtleties of management may be less important than the prevention of hypotension (96).

### The Lund Protocol

There is evidence to support the belief that as much as 75% of brain swelling is due to cytotoxic edema and only 25% of increased brain bulk is due to vasogenic edema and hyperemia (97). The protocols discussed above share a common approach: treatment is designed to control cytotoxic and vasogenic edema with the primary intention of reducing ICP and increasing CPP, CBF, and hence cerebral oxygenation.

A completely different approach is used in Lund, Sweden. The two goals of therapy are prevention of cerebral hypoxia (by maintaining euolemia) and control of vasogenic edema (by maintaining colloid osmotic pressure, reducing MAP, and constricting precapillary resistance vessels). The specifics of the Lund Management Protocol are summarized in Table 6. Of the 53 patients with severe TBI and ICP greater than 25 mmHg treated using the new Lund protocol, 8% died and 13% were left in a vegetative state or severely disabled (98). Like many other aspects of TBI management, the Lund protocol has not been tested in a randomized controlled trial. At present, all that can be concluded is that the results are impressive and have been replicated outside Lund (99). It may be that the Lund team has identified a key area where targeted intervention improves outcome. Alternatively, the Lund protocol may be yet another example of how exemplary ICU care combined with aggressive treatment of hypovolemia improves outcome.

## ASSOCIATED ORGAN SYSTEM COMPLICATIONS FOLLOWING TRAUMATIC BRAIN INJURY

### Neurogenic Pulmonary Edema

Neurogenic pulmonary edema is thought to be due to massive alpha-adrenergic discharge at the time of injury (100). A transient surge in left atrial and pulmonary artery occlusion pressure disrupts the alveolar-capillary membrane leading to massive fluid leakage into the lungs and airways. The clinical picture is similar to severe ARDS, and ideal respiratory management includes oxygen, ventilation with low tidal volumes of approximately 6 mL/kg, maximum peak airway pressures of 35 mmHg, PEEP of 5 to 10 mmHg, and an inverse inspiratory/expiratory ratio. The prone position also improves oxygenation in some patients. Clearly, some of these interventions may increase ICP or decrease CPP. Management should be individualized to each patient and compromises in the optimum management of both brain and lungs are often necessary. At its worst neurogenic pulmonary edema is so severe that the patient drowns in edema fluid. Even in the best institutions, adequate oxygenation cannot always be achieved. Accurate fluid management is crucial and a pulmonary artery flotation catheter can be very helpful to optimize cardiovascular parameters. Obviously fluid overload must be avoided but many of these patients become volume depleted as a result of the huge loss of proteinaceous fluid from the lungs.

### Hypertremia

Hypertremia associated with TBI is usually a result of water depletion. Commonly, it is caused by the use of mannitol or diabetes insipidus.

Mannitol-induced hypertremia is associated with excessive volumes of dilute urine that coincide with doses of mannitol. Treatment includes water replacement given via the enteral route or 5% dextrose given intravenously. Mannitol may also contribute to hypomagnesaemia and hypophosphatemia (101).

Diabetes insipidus should be suspected when the urine output is over 200 mL/hr for two consecutive hours and the serum sodium is rising. The diagnosis is confirmed if the urine osmolality is lower than plasma osmolality (also see Chapter 44). Desmopressin, 1–2 µg subcutaneously or intravenously, as single or repeated doses is the treatment of choice.

**Table 6** The Lund Management Protocol

Goal	Target	Intervention
Reduce capillary hydrostatic pressure	CPP 60–70 mmHg (but 50 mmHg acceptable)	Metoprolol Clonidine Dihydroergotamine
Reduce cerebral blood volume	ICP < 25 mmHg	Thiopental Dihydroergotamine
Reduce stress response and cerebral energy metabolism	Adequate sedation and analgesia	Benzodiazepines Fentanyl Low-dose thiopental
Fluid balance and maintenance of colloid osmotic pressure	Hemoglobin 125–140 g/L Albumin 40 g/L Equal of slightly negative fluid balance	Albumin infusion Frusemide Blood Enteral nutrition
Intermittent CSF drainage	ICP < 25 mmHg	EVD

Abbreviation: EVD, external ventricular drainage.

### Hyponatremia: SIADH vs. Cerebral Salt Wasting Syndrome

Hyponatremia is common in neurosurgical patients, and is often attributed to the syndrome of inappropriate secretion of antidiuretic hormone (SIADH). This syndrome is characterized by a urine osmolality which is greater than serum osmolality, and an elevated urinary sodium concentration (typically  $>20$  mmol/L). Additionally, SIADH patients have normal or slightly elevated intravascular volume. Aggressive fluid restriction may be all that is needed to correct this syndrome.

It is important to distinguish between SIADH from the cerebral salt wasting syndrome, which also occurs commonly following TBI, because their treatments are divergent (102). Cerebral salt wasting syndrome occurs with concurrent water loss, and these patients are volume depleted. Careful assessment of trends in fluid and sodium balance combined with urine and serum osmolality measurements usually provide the clues to the correct diagnosis. In cerebral salt wasting syndrome, there is an excess loss of sodium compared to changes in other parameters (osmolality may be increased with cerebral salt wasting syndrome). Treatment for SIADH is dramatically different from that for cerebral salt wasting syndrome. SIADH requires only fluid restriction, whereas cerebral salt wasting syndrome requires repletion of intravascular fluid as well as salt. Accordingly 3% saline is often administered for patients with cerebral salt wasting syndrome.

Hyponatremia when severe causes cerebral edema and seizures, thus treatment is required. However, hypertonic saline should be given slowly once the serum sodium is greater than 120 mmol/L. The reason for raising the serum sodium slowly is the association between rapid correction and central pontine myelinolysis (103). Accordingly, 3% saline is often given in addition to larger quantities of normal saline or albumin, until intravascular volume is replenished in the setting of cerebral salt wasting syndrome.

## OTHER ASPECTS OF CRITICAL CARE FOR TRAUMATIC BRAIN INJURY PATIENTS

### Enteral Nutrition

Patients with severe TBI are hypercatabolic and have reduced immune function (104). Early enteral feeding is essential to prevent malnutrition with attendant muscle wasting. Traditional wisdom had maintained that it is difficult to establish enteral nutrition early in head-injured patients because they have gastric stasis and/or intestinal ileus. However, early enteral feeding is successful in most patients. The benefits of jejunal versus gastric feeding have been studied, with the results showing that gastric feeding is successful in 97% of patients (105). Gastric feeding using a percutaneous endoscopic gastrostomy (PEG) starting on day 3 is also successful in 97% of patients (106). During the recovery phase, a PEG is helpful if the patient has dysphagia or diminished protective airway reflexes. Many centers believe that feeding via the gastric route using a nasogastric tube can and should be started shortly after admission, and is successful in the majority of patients. When enteral feeding is problematic, maxolon or low-dose erythromycin is used to encourage gastric emptying (107,108).

### Acute Respiratory Distress Syndrome and Sepsis

ARDS is the most severe form of a spectrum of lung injury that occurs after injury and sepsis. In its less severe form, it is referred to as acute lung injury (ALI). ALI occurs in

20% of comatose TBI patients and is associated with the global severity of TBI rather than specific injury patterns (109). **TBI patients with ALI are almost three times more likely to die than patients with similar head injury severity but no ALI.**

ARDS causes more severe hypoxia than ALI. Numerous strategies have been suggested for the treatment of ALI/ARDS but although most of them increase  $\text{PaO}_2$ , none confer survival benefit (110,111). Over the years, however, mortality from ARDS has declined. The decline is probably due to better attention to fluid balance combined with lung-protective strategies. The patient with TBI and ARDS presents a particular challenge. Current treatment of ARDS includes reducing inspired oxygen concentration so that  $\text{PaO}_2$  is maintained at around 60 mmHg (8 kPa) and adjustments to the ventilator so that tidal volumes and airway pressures are limited. These ventilator adjustments commonly cause hypercapnia. For the patient with TBI, relative hypoxia and absolute hypercapnia are undesirable with respect to brain recovery. Herein lies the challenge. Interventions must be tailored to each individual patient's physiological state, which will vary over time. It is helpful to maintain the  $\text{PaO}_2$  at about 75 mmHg (10 kPa) and to manage  $\text{PaCO}_2$  according to the ICP response.

Sepsis and multiorgan failure are common in critically ill patients, and patients with TBI are no exception. The use of prophylactic antibiotics is controversial except in the case of penetrating head injuries (112). Meticulous attention to infection control techniques will reduce the risk of infection.

### Weaning and Extubation

There is little consensus regarding the best method of weaning patients with TBI from the ventilator. In addition to the normal respiratory parameters, the clinician should also be aware of the impact of weaning on ICP and CPP. For patients with uncomplicated TBI one method is to first reduce the respiratory rate so that  $\text{PaCO}_2$  rises to at least 5 kPa. If ICP does not increase, paralysis is discontinued (if it is still being used). Lastly, sedation is reduced stepwise until either ICP rises or breathing commences. Assuming that ICP does not rise, the patient is weaned as rapidly as tolerated from synchronized intermittent mandatory ventilation to spontaneous ventilation with pressure support. As sedation is withdrawn, many relatively alert patients become hypertensive and ICP sometimes rises. At this point it is necessary for the clinician to decide whether hypertension and raised ICP will settle after extubation and whether the patient has sufficient airway control to manage following extubation. If it is thought that the patient will cope after extubation, weaning to independent breathing and extubation should proceed as quickly as possible watching for signs of clinical deterioration in the GCS. Commonly, the patient's GCS does not deteriorate despite the rise in ICP and extubation can be achieved uneventfully. In the event that the patient does not have adequate airway control and/or protective reflexes, a tracheostomy is indicated prior to a second attempt at weaning. TBI patients recovering from lower respiratory tract infection or ARDS usually require a tracheostomy to facilitate the weaning process.

### Indications for Tracheostomy

In general tracheostomy is indicated to protect the lower airway, to aid weaning in the presence of copious secretions

or muscle weakness, and as an aid to patient comfort. Predisposing factors indicating potential need for tracheostomy in patients with TBI include admission GCS of less than 8, injury severity score greater than 25 or ventilator days of more than 7 (113). Tracheostomy, whether performed percutaneously or by traditional surgical techniques, carries the risk of hypercarbia and sometimes hypoxia. For this reason, it is better to delay performing a tracheostomy until ICP is under control and the condition of the lungs has improved to a point where weaning is likely to be successful.

### The Diagnosis and Treatment of Agitation Following Extubation

Agitation is a common problem following extubation of patients who have suffered a severe TBI. ⚡ **It is essential to distinguish between agitation that results from the primary brain injury and agitation due to hypoxia, hypercarbia, or cerebral swelling; the latter are easily diagnosed by arterial blood gas analysis and the former by CT scan.** ⚡

Whichever cause is identified, sedation and reintubation and ventilation for 24 hours are often the safest and most appropriate treatments. Sedatives such as benzodiazepines or haloperidol can be given but may reduce GCS to the point where there is a risk of airway compromise. Consequently, sedatives should be used with caution and frequent monitoring of GCS and airway status. Many head-injured patients suffer prolonged headache and simple analgesics sometimes reduce agitation. Physical restraint is an option but should only be used if this is believed to be in the patient's best interests and after discussion with members of the family.

### REHABILITATION BEGINS IN THE INTENSIVE CARE UNIT

Most patients with severe TBI face a prolonged period of rehabilitation following discharge from acute hospital care. In the ICU, some rehabilitation techniques are appropriate. Even though dramatic improvements may not be achieved this early in the patient's care, an awareness of rehabilitation techniques and prevention of pressure sores and limb contractures can be important in facilitating eventual successful rehabilitation (see Volume 2, Chapter 66).

#### Appropriate Sensory Stimulation

Given that some aspects of recovery appear to be due to the recruitment of alternative neural pathways, sensory stimulation is commonly practiced in the ICU setting. Favorite music and frequent touching are encouraged. The evidence that these interventions make a real difference is sparse but involvement of family members comforts them at a time when they feel most helpless.

#### Spasticity and Contractures

Increased muscle tone is a common feature of severe TBI. Not only is this condition painful but also it can lead to permanent deformities of the limbs that can make subsequent mobilization difficult. Benzodiazepines, baclofen, dantrolene, and tinzandine (a clonidine analogue) have been recommended for the treatment of spasticity (114). All can cause sedation as a side effect. Consequently some specialized centers prefer to use botulinum toxin type A injected locally into affected muscles (114). Sometimes splints are

used in addition or as an alternative to drug therapy. As with so many other aspects of head injury management, the long-term consequences of spasticity must be balanced against short-term side effects of drugs.

#### Heterotopic Ossification of Joints

Heterotopic ossification of joints occurs after severe head injury and can limit joint mobility. The diagnosis is likely if a joint becomes warm and swollen or the range of movement diminishes and is confirmed using plain radiography. Management is difficult and includes antiinflammatory drugs such as indomethacin, surgical removal of ectopic bone, physical therapy, and radiation treatment (115).

#### Management of Long Bone Fractures

Outcome following TBI with associated long bone fractures depends mainly on the severity of the TBI. Fracture management should be a secondary consideration in the immediate aftermath of injury. However, initial planning should anticipate full neurological recovery of the patient. Adequate resuscitation and control of ICP and CPP during anesthesia and surgery are of paramount importance (116). The treatment of fractures should be planned to facilitate nursing care and in the longer term, to ensure that mobilization is not hindered by limb deformities or nonunion of fractures.

### DYING IN THE INTENSIVE CARE UNIT FROM A HEAD INJURY

All deaths following trauma are stressful for families and staff alike. Death from head injury can be particularly difficult because the external signs of injury may be minimal and the severity of the underlying injury may be difficult to comprehend (see Chapters 16 and 67–69).

#### Brain Death and Brainstem Death

Cultural, social, religious, and legal differences mean that the definition of death and hence the diagnosis of death differ between countries. Judaism, for example, requires that the patient's heartbeat and breathing cease before death can be certified. Some countries, such as the United Kingdom, require that the brainstem is dead for death to be legally diagnosed. Yet others require that the whole brain is dead before death can be declared. Consequently each country and/or state has its own criteria for the diagnosis of death after head injury, which is discussed in detail in Volume 2, Chapter 16.

#### Organ Donation After Traumatic Brain Injury

The diagnosis of brain death or brainstem death permits removal of organs for the purposes of transplantation while the heart is still beating and oxygenation of the tissues is maintained by means of mechanical ventilation. Although the grief of family members will be acute at the time of death, many relatives eventually take comfort from the knowledge that organ donation has taken place. One organ donor can save more than nine lives and improve the quality of life for many others. A complete review of the determination of brain death and management of the brain dead organ donor is proved in Volume 2, Chapter 16.

### Communication with Family Members

The importance of sensitive and realistic communication with family members cannot be overemphasized. It is essential too that all members of the team communicate with one another so that confusing and contradictory information is not given. Death is much easier to accept if information is staged. Constant discussion with the family will ensure that deteriorations are communicated as they occur until the time that death becomes inevitable and the diagnosis is made. Preparation of the family for the death of the loved one is not only considerate but also facilitates the decision to proceed with organ donation (117,118).

### Withhold or Withdrawal of Treatment

Not all head-injured patients die quickly as a result of brain death. Nevertheless, many injuries are ultimately not survivable, but death is delayed by the intensive support provided in an ICU. Current wisdom is that early intensive intervention is provided to all injured patients. When stabilization in the ICU has been achieved, the consequence of this approach is that ICU clinicians must, in conjunction with their neurosurgical colleagues, reassess the patient's potential for survival. For a few patients, the decision to withhold or withdraw active treatment is the inevitable consequence because further intervention is futile. The decision to withdraw treatment is based on experience and opinion and is emotionally difficult. Despite the risk of potential criticism from relatives, we owe it to our patients to ensure that inevitable death occurs in as dignified a manner as possible and with the minimum of medical intervention. This does not mean that routine nursing care and comfort sedation and analgesia should not be given. It does mean that prolonged ventilation and vasopressor support are inappropriate and should be discontinued.

### UNCERTAINTIES IN THE MANAGEMENT OF TRAUMATIC BRAIN INJURY

The need for prolonged rehabilitation after TBI has already been alluded to and the consequences of TBI of all severities discussed. TBI also shortens the time to onset of Alzheimer's disease and increases the risk of suicide (119,120). No association has been found between TBI and the subsequent risk of primary brain tumors (121).

ICU management of TBI is targeted towards reducing secondary brain injury. In the future, antagonist cocktails that prevent the molecular cascades that occur shortly after injury will undoubtedly be developed. Because the molecular mechanisms of TBI are so complex and a balance between the protective and damaging effects of some of the cascades must be maintained, hopes that this will be an option in the near future are not realistic.

Many of the changes seen in the brain following TBI have been described in localized areas only. Currently, however, TBI management is restricted to global techniques in the hope that the damaged part of the brain will benefit. Some global therapies have the potential to damage normal brain. Hyperventilation, for example, is more effective in areas of brain that maintain the ability to autoregulate. Thus, excessive vasoconstriction will occur preferentially in areas of undamaged brain that could be rendered ischemic. Furthermore, blood flow may take the path of lesser resistance and be preferentially directed to damaged brain, thus

causing local hyperemia. ⚡ **All those who care for head-injured patients need to remember that the evidence for their management is strictly limited and that therapies considered acceptable today may be obsolete in the near future.** ⚡ Not that many years ago, strict fluid restriction was recommended to reduce cerebral edema. It is now accepted that this treatment method may compromise circulating blood volume, increase viscosity, and reduce cerebral perfusion and blood flow (51).

There is a dearth of high quality evidence from randomized trials that the practitioner can refer to for guidance in the management of TBI. Clearly, there is a need to maintain CBF at a level sufficient to maintain the injured brain's global oxygen and glucose requirements. How this might be achieved is still debated.

### EYE TO THE FUTURE

In the future, brain repair facilitated by nerve growth factors, tissue transplantation, and gene therapy may become available and would become the treatment of choice for TBI. Before that, it is likely that pharmacological interventions will be developed that either enhance natural protective mechanisms or that mitigate the damaging effects of the cascades activated by the release of toxic substances from dead and dying brain tissue. For example, intact female rats have a survival advantage over males and ovariectomized females (122). Progesterone given to male rats significantly reduces cerebral edema (123). Melatonin, a free-radical scavenger, is neuroprotective in mice (124). Cyclosporin A, which reduces mitochondrial membrane permeability and limits necrosis of cortical tissue, is neuroprotective in rats (125). These medications are already used and their safety profile is known, so with appropriate randomized controlled trials, they could be tested in humans relatively easily and rapidly. Also encouraging is the discovery of CNS 2103 in viper venom, which may lead to the development of brain-specific calcium antagonists (126). Ischemic preconditioning also significantly reduces contusion volume in rats, however, it is difficult to imagine how this might be used to protect humans (127).

Although there are many exciting developments that could become available in the next few years, we should not forget current possibilities. Hypothermia may yet prove to be helpful and despite evidence-based guidelines being available, clinical practice is still inconsistent (128). Although the search for new and better therapies must continue, it is probable that we could make further inroads into TBI mortality and morbidity if only we used existing therapies properly.

### SUMMARY

⚡ **The effects of a head injury are for life.** ⚡ At present exemplary basic care is the best that can be offered. Adequate oxygenation and blood pressure are essential. Control of ICP by surgical means, gentle ventilation, control of PaCO<sub>2</sub>, and the use of diuretics are standard therapies. Adequate sedation and analgesia are helpful in controlling ICP as well as a basic human right. Paralysis is sometimes needed. CPP should be maintained between 60 and 70 mmHg to facilitate cerebral oxygenation. Interventions to prevent secondary injury due to chemical mediators have been unsuccessful so

far. Good nutrition is important. Prevention of fever, seizures, infection, and contractures can all contribute to an improved outcome. In the future, it may be possible to prevent secondary damage due to chemical mediators. An even more exciting development will be the facilitation of neuronal repair. In the meantime, it behooves us all to minimize secondary insults and to manage our patients guided by the best evidence available.

## KEY POINTS

- ✦ The function of certain portions of damaged brain can be taken over by other areas, for example, the damaged brain is thought to exhibit a certain degree of neural plasticity.
- ✦ The goal of treatment for TBI is to reduce morbidity and improve outcome.
- ✦ The full effects of the ICU management of head injury may not be apparent until years after rehabilitation is complete.
- ✦ Rehospitalization occurs in 23% of TBI patients in the first year after injury and declines to 17% at five years after injury.
- ✦ Secondary brain injuries (Table 5) are of particular interest because they are potentially preventable.
- ✦ A systolic blood pressure of less than 90 mmHg occurring between the time of TBI and completion of resuscitation is associated with a 33% increase in mortality.
- ✦ An arterial oxygen tension (PaO<sub>2</sub>) of less than 60 mmHg (8 kPa) occurring between the time of TBI and completion of resuscitation is also associated with an increase in morbidity and mortality but to a lesser extent than the effect of hypotension.
- ✦ The highest blood sugar occurring in the first 24 hours of ICU care is linearly correlated with mortality (Fig. 8).
- ✦ Although human outcome data is controversial, fever should be prevented in TBI patients.
- ✦ For the patient with TBI, a CPP of >60–70 mmHg is generally sufficient to maintain cerebral oxygenation.
- ✦ Excessive hyperventilation of patients with TBI may cause ischemia if CO<sub>2</sub> reactivity is preserved.
- ✦ The interpretation of a given ICP measurement must be made in the light of the underlying pathology and the speed with which that pathology has occurred.
- ✦ Current evidence suggests that 20–25 mmHg is the upper threshold above which treatment to lower ICP should be started.
- ✦ During the resuscitation phase it is recommended that PaO<sub>2</sub> be maintained above 60 mmHg (8 kPa).
- ✦ The management of hypotension must include not only fluid replacement but also identification of the cause.
- ✦ There is minimal evidence for the routine use of anti-convulsants to prevent seizures.
- ✦ A standardized protocol for the management of ICP appears to provide more consistent control.
- ✦ TBI patients with ALI are almost three times more likely to die than patients with similar head injury severity but no ALI.
- ✦ It is essential to distinguish between agitation that results from the primary brain injury and agitation due to hypoxia, hypercarbia, or cerebral swelling; the latter are easily diagnosed by arterial blood gas analysis and the former by CT scan.
- ✦ All those who care for head-injured patients need to remember that the evidence for their management is

strictly limited and that therapies considered acceptable today may be obsolete in the near future.

✦ The effects of a head injury are for life.

## Spinal Cord Injury: Critical Care Management

Christopher Junker and Lucia Palladino

Department of Anesthesiology and Critical Care Medicine, George Washington University Hospital, Washington, D.C., U.S.A.

### INTRODUCTION

Spinal cord injury (SCI) continues to be a devastating problem worldwide. In the United States alone, with more than 11,000 cases per year, SCI is a major cause of morbidity and mortality, especially in otherwise healthy young men (age 15–40) (1,2). The major causes of SCI are motor vehicle collisions accounting for 40% to 50%, falls (16%), and sports injuries (10–15%) (2). The cervical spine (C-spine) is involved in 55% of all SCIs (2–4).

Over the last decade, numerous major advances in our understanding of SCI pathophysiology have occurred. The possibility of beneficial treatment of acute injury with recovery of lost function and our improved ability to limit damage beyond the initial insult have begun to change the historically pessimistic attitude of physicians towards SCI (5,6).

The common assumption that patients who suffer SCI are inevitably unhappy following their injury is untrue. In one study of 128 patients with injuries at the C4 level or above, 64% of those who were ventilator dependent, 54% of those not dependent on a ventilator rated the quality of their lives as good or excellent, and more than 90% reported that they were glad to be alive (6). Old-fashioned approaches are characterized by words from the ancient Edwin Smith papyrus which declared: SCIs are “ailments not to be treated” (7). However, as new therapies promote neural regeneration in areas of the central nervous system (CNS) previously thought to be impossible, including the spinal cord, *these opinions will acquire* their appropriate status as merely historical footnotes. As new therapies promote neural regeneration in areas of the CNS previously thought to be impossible, including the spinal cord.

In this chapter, anatomic considerations and pathophysiology of SCI are reviewed. Only a brief mention is made of initial assessment and management considerations, as these topics are extensively covered in Volume 1, Chapters 15 and 26. This chapter reviews the critical care management and focuses upon the elimination of medical complications of SCI. By anticipating potential problems, the surgical intensive care unit (SICU) length of stay can be decreased, and emphasis can then be turned to rehabilitation.

### ANATOMICAL CONSIDERATIONS

#### Skeletal Structure

The human vertebral column consists of 30 vertebrae: seven cervical, 12 thoracic, five lumbar, five sacral (fused), and the coccygeal bone. The cervical canal is typically wider at C1–C2 and tapers caudally through the thoracic vertebrae,

widening again in the lumbar region. The impact on neurological function after trauma differs between cervical and thoracolumbar injuries, and is related to the change in spinal canal shape and diameter (8). The greatest degree of flexion and extension occurs at the atlanto-occipital junction, and the greatest rotatory capability takes place at the atlantoaxial joint. The bony elements of the spinal column articulate by intervertebral disks. Joint capsules and strong, elastic ligaments give the spine its unique combination of stability and flexibility.

#### Vascular Anatomy

The blood supply to the spinal cord is provided through paired anterior spinal arteries (branches off the vertebral arteries) that join to become the single anterior median spinal artery and supply the anterior two-thirds of the full length of the spinal cord. Paired posterior spinal arteries lie medial to the dorsal roots and supply the posterior one-third of the spinal cord. Collateral flow from radicular arteries emanating from the thoracic and abdominal aorta provides vital additional perfusion. The T4 to T8 region is most vulnerable to low flow because it is supplied mainly by a single thoracic radicular artery that branches off of the thoracic aorta at T7. The distribution from T9 to the sacrum is supplied mainly by a single left radicular artery at T11 called the artery of Adamkiewicz. ✎ **Because of the variable vascular anatomic distribution of the artery of Adamkiewicz, the upper thoracic portion of the spine has watershed zones that are extremely sensitive to ischemic and hypoxic insults.** ✎

### PATHOPHYSIOLOGY OF SPINAL CORD INJURY AND THE BASIS OF PHARMACOLOGICAL INTERVENTION

#### Pathophysiology

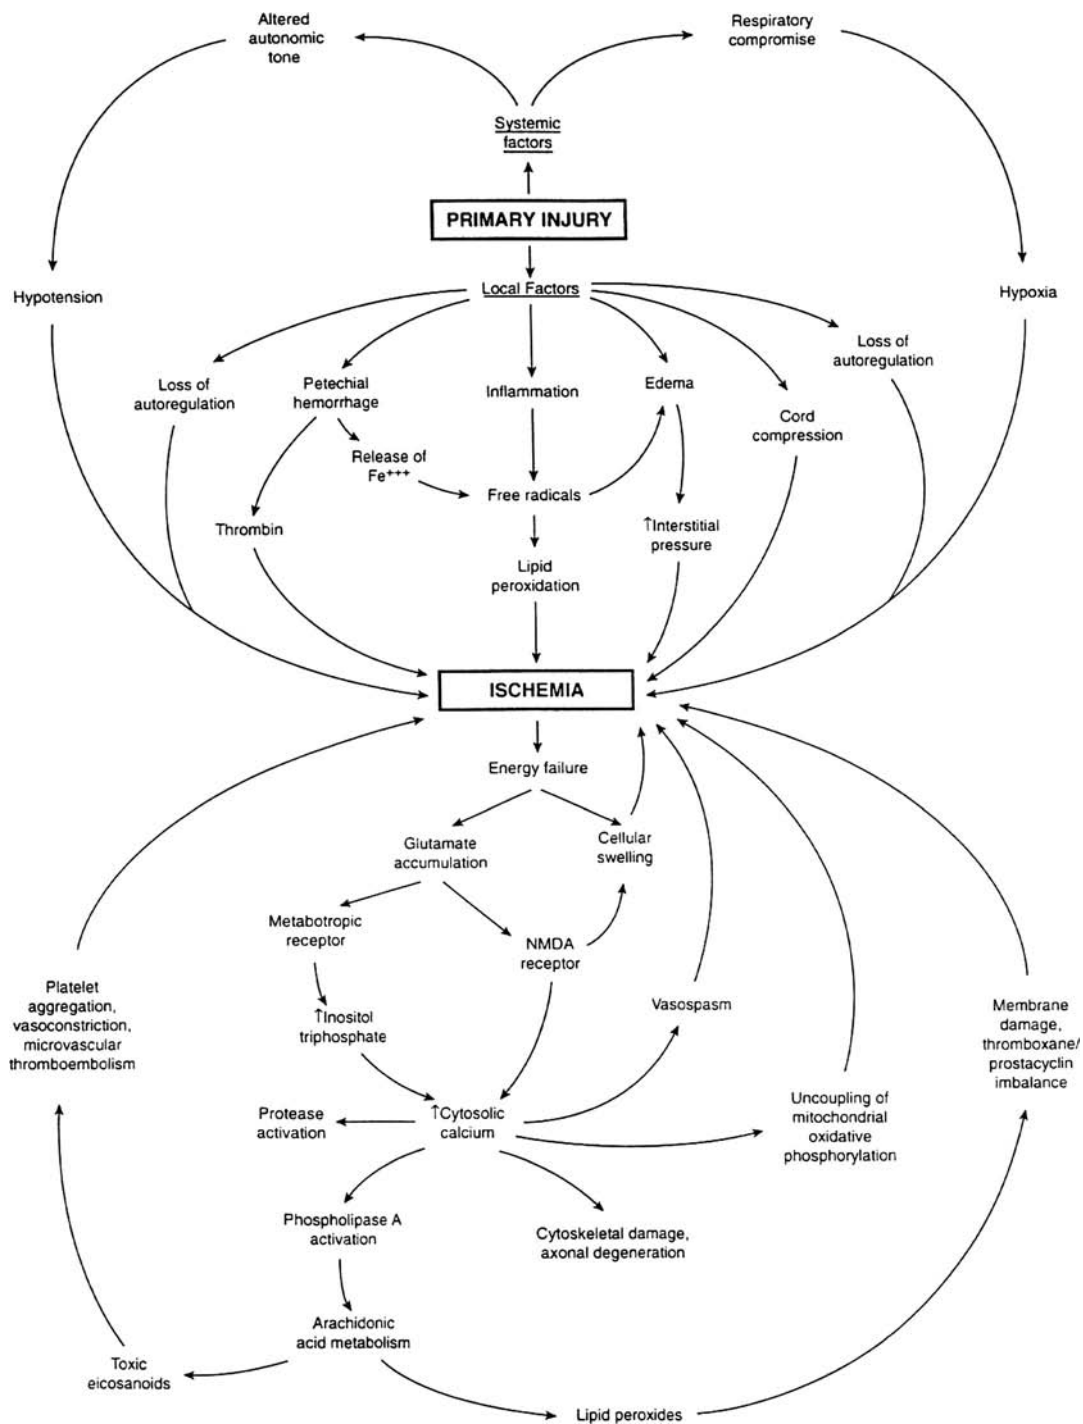

Both experimental models and clinical observations reveal two overlapping phases of SCI regarded as primary and secondary injury (2,5,9–13). The primary injury is the direct, immediate, and irreversible mechanical injury of the spinal cord. Secondary injury is the subsequent destruction of neural elements caused by edema, ischemia, and compression from unstable fractures or bony elements impinging on the cord. SCI is the result of force applied directly to the cord or surrounding tissue.

The type of force applied influences the way in which the cord is injured. Traumatic distraction forces (flexion, extension, dislocation, rotation) cause stretching or shearing of the neural elements or the spinal vascular system. Compressive forces (edema, hematoma, or bone fragments

within the spinal canal) cause crush injury and ischemia. Long-term mechanical instability leads to structural deformation (kyphosis, subluxation) and further neurological sequelae (10). The size of the spinal canal, the vascular distribution at the level of injury and its location relative to the conus medullaris are all important prognostic factors (8,10,14–16). Figure 1 gives a diagrammatic representation of the cascade of primary and secondary injury mechanisms.

### Basis of Pharmacological Intervention

Current treatment of primary injury to the cord and supporting structures is limited to structural stabilization, maintaining mean arterial pressure (MAP), and limiting progression of the primary injury. Although recovery of function from primary injury to the cord through regeneration or grafting is still experimental, therapeutic interventions for secondary injury have a demonstrable, though limited, impact on

**Figure 1** Schematic representation of key mechanisms, molecular species, and interrelations underlying the pathogenesis of acute spinal cord injury. Principal pathways of secondary injury that converge upon ischemia are emphasized and others have been omitted for simplicity. These pathogenetic determinants represent the logical targets for therapeutic modulation. *Abbreviation:* NMDA, N-methyl-D-aspartate. *Source:* From Ref. 5.

outcome (5,11). The primary insult to the spinal cord initiates the major determinants of secondary injury: vasospasm (13,17), axonal degeneration and demyelination, activation of the inflammatory response, intramedullary hemorrhage secondary to postcapillary venular rupture (18), disruption of the blood-cerebrospinal fluid barrier with edema formation as response to filtration of larger molecules, and water into the extracellular and interstitial space (18,19). Any of these secondary events can be exacerbated by hypotension, fever (20), and hypoxia. Hyperglycemia worsens neurological outcome in traumatic brain injury. Although its effect in SCI is less clear (21), meticulous control of glucose levels appears to be beneficial in other critically ill patients (22,23) and an insulin infusion protocol is recommended for any patient not easily controlled with a sliding scale insulin regimen.

### Pharmacology for Specific Treatment of Spinal Cord Injury

The only agent supported by large human studies [i.e., National Acute Spinal Cord Injury Study (NASCIS) trials] and presently in widespread use is high-dose methylprednisolone (24–26) (Table 1). However, the results are controversial, and if therapy is not initiated within eight hours postinjury, the complications of treatment clearly outweigh the benefits. ✎ **The NASCIS trials supporting the use of methylprednisolone have been viewed as methodologically flawed, with the most encouraging results emerging only in posthoc analyses. Some prominent authors in the field of SCI have argued that 24-hour methylprednisolone should not be routinely used in SCI, and then only on a compassionate use basis (27).** ✎ The Spine Focus Panel offered this summary opinion, “Given the devastating impact of SCI and the evidence of a modest, beneficial effect of methylprednisolone, clinicians should consciously consider using this drug despite the well founded criticisms that have been directed against the NASCIS II and NASCIS III trials” (28). Despite the controversy, methylprednisolone remains a common treatment of SCI in the United States, and, if used, should be started as soon as a diagnosis is established.

Spinal cord ischemia results in lactic acid production due to anaerobic glycolysis, depletion of ATP, loss of cellular homeostasis and, finally, disruption of membrane function. The disruption of the ion pump compromises the membrane potentials and synaptic transmission. The pathological terminal membrane depolarization causes the release of excitatory amino acid (EAA) neurotransmitters, such as aspartate and glutamate, a phenomenon called excitotoxicity (5,11,29,30).

In experimental models of SCI, high extracellular levels of EAA appear within 15 minutes after the cord injury (5). These excitotoxins activate the *N*-methyl-D-aspartate (NMDA), nonNMDA receptors, and voltage-dependent  $Ca^{++}$  and  $Na^{+}$  channels (2,5,11,31,32). As the energy-dependent ion pump loses the ability to maintain

the concentration gradient between the intra- and extracellular space, the large influx of sodium and calcium into the cytosol leads to cellular swelling (2,31–33).

Increased calcium flux into the cells activates many  $Ca^{++}$ -dependent catabolic reactions that culminate in cellular necrosis and apoptosis (11,34–37). Phospholipase  $A_2$  with generation of free fatty acid, synthesis of toxic eicosanoids, generation of free radicals (38), impairment of mitochondrial oxidative phosphorylation, and lytic enzymes activation (proteases, endonucleases) have all been linked to secondary neuronal injury.

Many of these observations suggest possible pharmacologic interventions to block or mitigate some of these effects, and in both animal models and human trials have shown promise, but none has yet proven a definitive convincing clinical success (Table 2).

### INITIAL ASSESSMENT AND MANAGEMENT

✎ **All patients sustaining major trauma, a fall from greater than ten feet, MVC, or noticeable injuries to the head or neck should be thoroughly evaluated for evidence of SCI (12).** ✎ At the scene, the first goal is to protect the patient from further injury and provide resuscitation (39). Early stabilization of an SCI is imperative to prevent movement of the injured spine that can further neurological damage. The most effective way to stabilize the spine is with a rigid spine backboard and a cervical collar in combination with bilateral sandbags and supporting tape fixed across the forehead and secured to the spine board. If necessary, intubation in the field may be performed with manual inline traction and oral intubation (12,39,40). Airway management is discussed in Volume 1, Chapter 9. During the primary survey of the trauma patient, after airway, breathing, and circulation are assessed and stabilized, a brief neurological exam is performed. Once life-threatening problems are addressed, full neurological examination must be performed during the secondary survey. If, at any time during the primary or secondary survey, the neurological exam is suggestive of SCI, and high-dose methylprednisolone is part of the local treatment protocol, it should be started immediately for maximum potential benefit, even if the radiological examination is not complete (26,27,41–43).

There are several different systems for grading SCIs. These include: spinal cord injury severity scale (44,45), Sunnybrook cord injury scale (45), American Spinal Injury Association classification (46) (Fig. 2), and the Frankel classification (16), described in 1969 and still widely used. Grading systems facilitate the initial assessment, subsequent follow-up, and prognosis.

### RADIOLOGIC DIAGNOSIS

Radiologic evaluation in SCI is used to assess alignment, detect ligamentous injuries or fractures, and visualize any compression of neural structures by soft tissue or bone fragments. The initial studies can be either plain radiographs or increasingly computed tomography (CT) scan. For cervical injury, the classic films include a lateral view of the C-spine followed by the anteroposterior, odontoid, and occasionally oblique views. A complete lateral view radiograph of the C-spine should include C7–T1 junction

**Table 1** High-Dose Methylprednisolone Dosing for Acute Spinal Cord Injury

Time from injury	Loading dose	Infusion dose	Duration of infusion
1–3 hrs	30 mg/kg	5.4 mg/kg/hr	23 hrs
3–8 hrs	30 mg/kg	5.4 mg/kg/hr	48 hrs

**Table 2** Agents Used to Block or Mitigate Secondary Neuronal Injury

Agent	Rationale	State of development	Note
Corticosteroids	Suppression of vasogenic edema Enhancement of spinal cord blood flow Stabilization of lysosomal membranes Inhibition of pituitary endorphin release Alteration of electrolyte concentrations in injured tissue Attenuation of the inflammatory response	Yes, some improvement in functional recovery, no change in level of care posthospital Multiple complications (especially with prolonged use) Additional studied needed	If started <3 hrs following injury should continue for 24 hrs If started between 4 and 8 hrs, must continue for 48 hrs If not started ≤8 hrs postinjury complications outweigh benefits
Gangliosides	Improve neuronal outgrowth, neural development and plasticity Increase synaptic transmission	Phase I trial showing motor improvement in lower extremities, Phase II in progress	May limit some effects of corticosteroids
Opiate antagonists	Antagonizes endogenous opioid peptides, which diminish micro-circulatory blood flow acting through the kappa subtype opioid receptor	Ineffective in NASCIS II by primary endpoints, reanalysis suggested functional improvement if given within 8 hrs	Dosing in NASCIS II was likely subtherapeutic
EAA receptor antagonists	NMDA receptor mediating excitotoxic neuronal damage have been found to be effective in both in vitro and in vivo models of cerebral ischemia, hypoglycemia, and trauma	A Phase III clinical trial of the NMDA receptor antagonist GK11 for acute SCI is currently under way	Most experimental models suggest that for brain lesions, window of effectiveness is narrow. In animal models of SCI within 15 min
Calcium channel blockers	Attenuation of vasospasm	Conflicting studies	No role at this time
Antioxidants and free-radical scavengers	Limit secondary damage after various types of CNS insults	Animal models	Primary protective effect only when administered before injury; possible role in surgical situations in which risk of injury exists

*Abbreviations:* CNS, central nervous system; EAA, excitatory amino acid; NASCIS, National Acute Spinal Cord Injury Study; NMDA, *N*-methyl-D-aspartate; SCI, spinal cord injury.

(12,47). Plain films of the spine are evaluated following the contour of four lines (Fig. 3) formed by the anterior margins of the vertebral body, the posterior vertebral margins, the anterior cortical margins of spinous process, and the tips of spinous process (47). The instability criteria include: widening of the interspinous process distance, translation of more than 3.5 mm, and segmental angulation more than 11° when compared to contiguous segments (48,49). Particularly important is the assessment of the posterior ligaments since three-column injury might necessitate an anterior and posterior stabilization procedure (16).

If the patient is conscious, without neurological deficit, has negative static images, yet complains of neck pain, flexion and extension views may be read to evaluate instability. Alternatively, the patient can be asked to rotate the head or the neck 45° in each direction (as per the Canadian C-spine Rule) (50). If the patient is able to do this, the chance of significant injury is exceedingly rare (50).

The stepwise approach to dynamic flexion and extension views exam includes the first film with the neck in extension position followed by the neutral position. If on comparison of the two views the alignment of the spine does not change, the flexion film may be taken. Ultimately,

if the alignment remains the same on flexion and extension, the spine is considered stable. If the patient exhibits any neurological deficit, dynamic images are contraindicated due to risk of causing further injury.

If the patient is unconscious and there is concern for SCI, further evaluation with CT (51) and/or magnetic resonance imaging (MRI) is indicated. Midsagittal T<sub>1</sub>- and T<sub>2</sub>-weighted images are considered the most reliable to assess spinal cord compression and/or contusion (Fig. 4) (49). MRI is particularly useful in situations where there is a discrepancy between the radiological images and the clinical neurological abnormalities or deterioration in the patient's neurological function. MRI is superior to CT in detecting cord hemorrhage or edema, hematoma, ligamentous disruption, and disc pathology. When MRI is unavailable or not feasible, CT myelography and two-dimensional reconstruction of the spinal CT are still useful.

Although angiography remains the standard for evaluation of vertebral artery injuries, noninvasive MR angiography is gaining acceptance (52). In addition, helical CT angiography is becoming increasingly capable of evaluating vascular injuries in the neck. CT scan, with threedimensional reconstructions, remains superior to MRI in the evaluation of bony injuries (Figs. 5 and 6). Because of restrictions regarding ferrous materials in the area of the MRI

scanner, many MRI suites are minimally equipped to monitor unstable or mechanically ventilated trauma patients, which is often a consideration in the early phases of critical care management.

### NONSURGICAL STABILIZATION

The goals of nonsurgical treatment are improvement or restoration of spinal alignment and decompression of neural elements with prevention of further injury. Stability is clinically confirmed by the ability of the spine to tolerate physiologic loads without additional neurological deficits, deformity, or pain. Spine fractures can be complicated, requiring evaluation of neurological status, biomechanical instability, and comorbidities, all of which influence the ultimate approach to management (12). However, many fractures are stable and require only limited restrictions, such as unilateral facet and small compression fractures.

An unstable fracture does not always necessitate operative reduction and fixation with hardware; it is important to

remember that some unstable fractures may be treated with external immobilization and close clinical and radiographic follow-up. When a fracture warrants nonoperative stabilization, a vest or cuirass is fitted to the patient to limit movement of the spine and support the thorax and abdomen. However, if nonoperative therapy means prolonged bed rest, then operative intervention is almost always a better option when linked to early postoperative mobilization. The timing of intervention, surgical or nonsurgical, and its relation to neurological recovery remains controversial, and there is considerable variation in practice in the choice of surgical and nonsurgical methods of stabilization (12).

Currently, if indicated, traction to achieve realignment is applied as soon as possible after visualization of the injury on the imaging studies. Some experimental studies have reported reversal of neurological deficits if decompression is performed in six to eight hours from the time of injury (53), and clinical improvement of neurological deficits after cervical traction has been applied (54,55). The many traction devices fall into two basic design categories composed either of metal tongs or a halo ring apparatus attached to the head with screws and to a pulley system attached to a set of weights (47). The two essential components in cervical traction are the amount of weight and the direction of the applied force. The amount of applied weight depends on the location, type of injury, and the extent of subluxation (47). Excessive weight may cause overdistraction, exacerbating the injury directly or injuring vertebral arteries (12).

### SPECIFIC SPINAL CORD INJURY SYNDROMES

☞ Lesions in the spinal cord produce sensory and motor disturbances corresponding to the functions of the tracts that have been injured or transected. ☞ Depending on the clinical exam, they are further categorized as incomplete or complete SCI (Table 3).

The segmental level of a lesion is indicated by the affected dermatomes and myotomes. The major descending motor tract is the crossed lateral corticospinal tract. This tract

**Table 3** Neurological Conditions Associated with Partial or Complete Spinal Cord Injuries

Severity of injury	Associated neurological conditions
Complete spinal cord injury	Complete loss of voluntary movement, sphincter control, and sensation below the level of the injury No preservation of motor and sensory function more than three segments below the level of the injury The persistence of a complete spinal cord injury beyond 24 hrs indicates that no distal function will recover Hypotension, bradycardia, and priapism may also be present
Incomplete spinal cord injury	Central cord syndrome Anterior cord syndrome Brown-Sequard syndrome Posterior cord syndrome (very rare)

originates in the opposite hemisphere, crosses in the medulla, and ultimately descends in the lateral aspect of the spinal cord. Ascending sensory tracts include the uncrossed gracile and cuneate fasciculi (dorsal columns) and the crossed spinothalamic tract. The dorsal columns test provides proprioception/joint position sense as well as vibratory sensation; and the ascending crossed spinothalamic tract provides pain and temperature sensation.

There are several SCI syndromes with characteristic neurological deficits. Unilateral SCI causes Brown-Sequard syndrome that presents with ipsilateral loss of joint position sense, motor function deficits, contralateral pain, and temperature sensation deficits. The syndrome, rare in patients sustaining blunt trauma, was first described in victims with penetrating SCI (Table 4) (47,56).

The central spinal cord syndrome presents with severe upper extremity weakness with relative sparing of lower extremities. The degree of sensory deficit and the severity of bowel and bladder dysfunction are variable. This syndrome is often secondary to hyperextension of the neck and, most often, seen in the elderly population, in whom cervical spinal stenosis secondary to spondylosis is more common (47,57). The conus medullaris syndrome is secondary to lesions involving the thoraco-lumbar junction (T11–L1). Usually, the prognosis is more favorable if the lesion involves only the cauda equina. Patients affected by conus injury present with sexual and sphincter function loss.

The Wallenberg syndrome usually results from damage to a vertebral artery, often associated with forced flexion of the C-spine, but can also occur with cervical hyperextension and rotation. Typical findings are deficits of the ipsilateral cranial nerves (V, IX, X, XI), ipsilateral Horner syndrome, cerebellar ataxia, and contralateral impairment of pain and temperature perception. Atlanto-occipital injury should be considered in trauma patients with posterior occipital neck pain and a suboccipital hematoma upon physical exam (16).

**Table 4** Syndromes Associated with Incomplete Spinal Cord Injuries

Syndrome	Definition and comments
Central cord syndrome	Most common type of incomplete spinal cord syndrome Disproportionately greater motor deficit in the upper extremities than lower, worst in hands Usually due to hyperextension injury Blunt trauma to forehead common Surgery often performed on a nonurgent basis
Anterior cord syndrome	Spinal artery syndrome Anterior cord compression causes cord infarct in the territory supplied by the anterior spinal artery Motor deficit and loss of pain and temperature sensation Preservation of proprioception and two-point discrimination (dissociated sensory loss)
Brown-Sequard syndrome	Spinal cord hemisection Usually due to penetrating trauma Ipsilateral loss of proprioception and motor function Contralateral loss of pain and temperature sensation

## SYSTEMIC MANIFESTATIONS OF SPINAL CORD INJURY AND RELATED MANAGEMENT

Medical complications of SCI arise both from systemic effects of the cord injury itself and from prolonged immobilization secondary to paresis or paralysis. We will review the manifestations of each organ system and briefly discuss specific cord injury syndromes at the end of this section.

### Cardiovascular

#### Spinal Shock

Spinal shock was first described by Hall more than 150 years ago, to distinguish it from arterial hypotension caused by hemorrhage or other cardiovascular problems. Spinal shock is defined as insufficient perfusion pressure to tissues, to maintain cellular function in concert with all phenomena surrounding physiologic or anatomic transection of the spinal cord that result in temporary loss or permanent depression of spinal reflex activity, below the level of the lesion (58). In animal models of SCI, spinal shock occurring in the acute setting differs from the one occurring with gradual compression of the spine, and the response varies with species (58,59). ⚡ **Clinically, the term spinal shock refers to systemic hypotension due to a decrease in sympathetic fiber-mediated arterial and venous vascular resistance, along with venous pooling and loss of preload, with or without bradycardia.** ⚡ Loss of the peripheral sympathetic vasomotor control occurs when SCI involves segments between T1 and L1 sympathetic innervations of the peripheral vasculature. Since the sympathetic innervation of the heart arises from T1 to T5, lesions involving the spine above T5, unopposed vagal stimulation especially from visceral stretch receptors can lead to severe bradycardia or asystole. With high thoracic lesions, hypotension can be especially severe and difficult to treat if the loss of chronotropic reflex inhibits the normal tachycardic response to decreased preload or peripheral vasodilation. Usually, symptoms resolve within days or weeks (58), but the patient may require intermittent doses of glycopyrrolate or atropine, external or temporary transvenous pacing, and invasive arterial pressure monitoring. Later, compression stockings and abdominal binders are useful to mitigate against orthostatic hypotension during rehabilitation.

#### Early Cardiovascular Resuscitation Following Spinal Cord Injury

The immediate end points for resuscitation in SCI are the same as with other major trauma: restoration of vital organ perfusion as evidenced by end organ function with adequate urine output, resolution of acidosis, and normal mental status off sedation.

#### Choice of Vasopressor Drugs

With impairment of normal cardiovascular reflexes, the selection of agents for blood pressure support should have both  $\alpha$ - and  $\beta$ -adrenergic properties to cover both cardiac function and peripheral vascular tone. ⚡ **Although phenylephrine, a nearly pure  $\alpha$ -agonist, is commonly used in conjunction with volume in trauma resuscitation, for SCI we favor norepinephrine as a first choice, and if more  $\beta$ -adrenergic support is needed, epinephrine.** ⚡

#### Invasive Monitoring

⚡ **Cord perfusion is crucial in the first 72 hours following injury, and even short periods of hypotension may have**

**severe consequences; all patients should receive an arterial line in the intensive care unit (ICU), and MAPs should not be allowed to fall below 60 to 70 mmHg.** ⚡ There is no outcome data to support the use of pulmonary artery catheterization in SCI, but recent studies of early goal-directed therapy in sepsis (60) and a meta-analysis supporting goal-directed hemodynamic management in acute critically ill patients (61) appear to support an aggressive approach to resuscitation using parameters beyond simple restoration of a normal blood pressure.

It appears likely that much of the benefit of resuscitation for limiting secondary damage to the spinal cord will occur early in the patient's course, including the first several hours of ICU management. Maintaining adequate perfusion to the injured cord is very important, and the combination of trauma and SCI can make assessment of volume status, arterial tone, and cardiac performance difficult, especially in elderly patients and those with coronary artery disease. Pulmonary artery catheterization can be helpful in guiding therapy in this setting (12,47,62).

With the combination of major trauma and the potentially confusing cardiovascular effects of SCI itself, we frequently place pulmonary artery catheters early in the resuscitation phase if cardiovascular stability without the use of vasopressors is not achieved quickly on admission to the ICU. Spinal cord perfusion pressure is defined as the difference between MAP and cerebrospinal fluid pressure. However, cerebrospinal fluid pressure is difficult to measure in the clinical setting, and spinal cord edema may increase flow resistance to tissues at risk, which makes the optimal MAP in the setting of SCI unknown. In one nonrandomized trial of goal-directed resuscitation and hemodynamic management by protocol, SCI patients were maintained at a MAP of 85 mmHg. The authors concluded, "Early and aggressive medical management (volume resuscitation and blood pressure augmentation) of patients with acute spinal cord injuries optimizes the potential for neurological recovery after sustaining trauma" (63). The selection of a MAP of 85 mmHg was essentially arbitrary. But some elevation of hemodynamic parameters above normal values is likely to prove useful, even if maintaining elevated parameters only decreases the incidence of hypotension by creating a margin of safety for the abrupt changes in blood pressure that is often seen in critical care settings.

#### *Fluid Therapy for Spinal Cord Injury*

The debate concerning fluids of choice for SCI resuscitation has produced a large volume of inconclusive literature. Hypotonic and glucose containing solutions have potential risks and offer no benefit during the initial resuscitation period. There is a trend toward improved outcomes using low-volume resuscitations with hypertonic saline and dextran for resuscitation in traumatic brain injury (64,65). Currently, the data is insufficient to recommend the routine use of hypertonic saline for resuscitation in SCI, however, its use should be considered in the setting of resuscitation when CNS edema amenable to osmotic therapy is present. Unlike mannitol, hypertonic saline does not need to be eliminated from the body to preserve its effect, thus it can serve both as an osmotic agent and a resuscitation fluid.

#### *Autonomic Hyperreflexia*

Spinally mediated sympathetic reflexes in segments distal to the injury typically start to reappear as early as three to six weeks after the injury, and these nerves are involved in autonomic dysreflexia. In the normal state, descending inhibitory

tracts that travel in the spinal cord moderate these reflexes, but in SCI patients with lesions above T6 the inhibitory pathways are disrupted leading to unopposed sympathetic discharge. These patients consequently experience episodes of massive, uncontrolled sympathetic discharge.

Often these responses are triggered by relatively minor autonomic stimuli, such as bladder distension 75% to 85% and fecal impaction 13% to 15% (66). Autonomic dysreflexia events can cause strokes, pulmonary edema, myocardial ischemia, and are occasionally fatal. ⚡ **Somewhere between 19% to 70% of SCI patients have at least one episode of autonomic dysreflexia in their lifetime (67), and should always be anticipated when patients are scheduled for even small procedures, such as cystoscopy (68).** ⚡

As SCI patients often have normal blood pressures in the 90/60 range, a rise to 150/95 mmHg, not necessarily alarming in another patient population, may represent an emergency in the SCI patient. Therefore, a heightened awareness of this phenomenon among nurses and physicians working with SCI patients is important. Treatment consists of sitting the patient up, if possible, to induce an orthostatic drop in blood pressure, removing the stimulus, and administration of rapid onset antihypertensives, primarily afterload reducers. Discontinuing any ongoing procedure, relieving bladder distension, or manually disimpacting stool will address the majority of cases. For blood pressure control hydralazine IV is an effective initial choice, moving to nitroprusside if blood pressure is not brought rapidly under control.

#### **Pulmonary**

⚡ **Pulmonary complications, after the primary injury, are the largest cause of morbidity and mortality in SCI.** ⚡ Pneumonia, aspiration, pulmonary embolism, airway complications, and neurogenic pulmonary edema are common in patients with SCI. Preexisting pulmonary conditions are exacerbated by SCI and most SCI patients will require mechanical ventilation at some time in their course.

#### **Early Pulmonary Complications of Spinal Cord Injury**

##### *Aspiration and Ventilator-Associated Pneumonia*

Ventilator-associated pneumonia (VAP) carries a high mortality rate (69), and the incidence increases by 1% to 3% per day of mechanical ventilation (70). Early mobilization, aggressive pulmonary toilet, and institution of the cough and breathing support are crucial in reducing the incidence of this complication. Accurate diagnosis and treatment of pneumonia is often difficult to make because the presence of fever, leukocytosis, pulmonary secretions, and an abnormal chest film are not uncommon findings in SCI patients without pneumonia. Initial, empiric therapy for VAP is based on the severity, the presence of coexisting illness, and length of hospital stay. Community-acquired *Streptococcus pneumoniae* and *Hemophilus influenzae* are the most common early pathogens. After a week, *Pseudomonas aeruginosa* or *Staphylococcus aureus* are more likely (62), and local antibiotic resistance patterns should be taken into consideration with increasing appearance of nosocomial organisms. Although some authors recommend the use of prophylactic antibiotics (71), most centers have not adopted this approach.

When aspiration of tube feeding or oral secretions is suspected, the use of antibiotics is controversial (72). We recommend antibiotic therapy for aspiration pneumonia for patients with persistent infiltrates >48 hours, suspicion of

aspiration of bowel contents, or those who appear septic and are at risk for hemodynamic compromise. Supine body position has been identified as an independent risk factor for VAP (73), and SCI patients should be kept out of the supine position as soon as the stability of their injuries allows. Placement of the feeding tube past the pylorus or even past the ligament of Treitz has been advocated for aspiration prevention, however, current literature is equivocal regarding this approach and repeated attempts at post-pyloric placement often delay nutritional support (74).

**Neurogenic Pulmonary Edema**

Neurogenic pulmonary edema is an important complication occurring in some patients with SCI. Although there is some cardiac dysfunction associated with high cord level injuries, myocardial failure is not a significant component. In addition, there is no evidence for any direct nerve-mediated reflex. Rather, the mechanism appears to involve massive sympathetic activation triggered by the insult with associated marked systemic and pulmonary hypertension, leading to diffuse pulmonary capillary damage (62). Supportive care with close attention to fluid management to limit excessive hydrostatic pressures in the pulmonary circulation is the primary treatment.

**Thromboembolic Complications**

♣ **Acute SCI victims have the highest risk of developing deep venous thrombosis (DVT) among all hospitalized patients (75,76).** ♣ Venous stasis due to immobility and platelet and coagulation abnormalities occurring during the acute phase of injury are major factors contributing to DVT risk in SCI patients. Development of DVT and PE during the acute phase of SCI is both a cause of acute morbidity and mortality, and also contributes to long-term disability (77). The incidence of DVT is highest during the first three months postinjury (69,75,78–80), declining thereafter due to increased mobility during rehabilitation and resolution of the hypercoagulable state associated with acute injury (75,81). However, patients with SCI remain at risk for DVT and fatal PE in the rehabilitation phase as well (82). Accordingly, it is imperative that DVT prophylaxis should be instituted as soon as possible. Also see Volume 2, Chapter 56.

The ACCP consensus guidelines for antithrombotic therapy are based on several small, randomized trials of DVT prophylaxis in SCI patients (Table 5) (75). Low-molecular weight heparin (LMWH) is more effective than the combination of low-dose-unfractionated heparin, elastic stockings, and intermittent pneumatic compression. If there is evidence of perispinal hematoma, therapy with LMWH must be delayed for 24 to 72 hours and conversion to warfarin should be postponed at least for two weeks from the time of injury. Inferior vena cava (IVC) filter placement is recommended for protection against PE in patients with diagnosis of DVT who are not candidates for anticoagulation, documented failure of anticoagulation therapy, and patients in whom a PE would likely be fatal (83–85). However, despite the theoretical benefit, there are few controlled trials demonstrating the impact of IVC filters on recurrence rates and mortality from PE (86,87), and a large, retrospective study of over 8000 trauma patients (88) found no evidence to support prophylactic use of IVC filters. Only one randomized trial (89) suggested that the addition of IVC filter to standard anticoagulation showed short-term benefit in terms of decreased incidence of PE, but in the long term demonstrated a higher recurrence rate of DVT. Unfortunately, this study did

**Table 5** American College of Chest Physicians Recommendations for Deep Venous Thrombus and Pulmonary Embolus Prophylaxis<sup>a</sup>

Risk group	Recommended prophylaxis
Intracranial neurosurgery	IPC device, with or without ES (grade 1A) LDUH or postoperative LMWH may be accepted alternatives (grade 2A) High-risk patients: ES or IPC device with LDUH or postoperative LMWH may be more effective than either prophylactic modality alone (grade 1B)
Trauma, with identifiable risk factor for thromboembolism	Prophylaxis with LMWH, as soon as considered safe (grade 1A); if delayed, or contraindicated because of bleeding concerns: initial use of ES or IPC device or both (grade 1C). If prophylaxis is suboptimal, offer screening of high-risk patients with duplex ultrasound (grade 1C). If proximal DVT is demonstrated and anticoagulation is contraindicated, IVC filter insertion (grade 1C+), but we do not recommend IVC filter insertion as primary prophylaxis (grade 1C)
Acute spinal cord injury	Prophylaxis with LMWH (grade 1B). We do not recommend LDUH, ES, and IPC as sole prophylaxis (grade 1C). ES and IPC may be offered in combination with LMWH or LDUH, or if early use of anticoagulants is contraindicated (grade 2B). In the rehabilitation phase, we recommend continued LMWH therapy or full-dose oral anticoagulation (both grade 1C).

<sup>a</sup>The Sixth Consensus Conference on Antithrombotic Therapy from the American College of Chest Physicians.

not compare the efficacy of standard anticoagulation with IVC filter placement alone without any anticoagulation therapy. Morbidity and mortality from IVC filter placement are low (86), the most common complications being venous thrombosis at the insertion site and IVC obstruction. Filter migration and filter erosion through the IVC wall are rare, but can be catastrophic.

**Chronic Pulmonary Complications of Spinal Cord Injury (Ventilator Weaning, Diaphragmatic Pacing, Chronic Ventilator Dependence)**

The degree to which respiratory mechanics are affected depends on the level of the spinal injury and whether it is complete. Patients with injuries to lower thoracic cord or below typically have minimal changes in pulmonary function. Pulmonary mechanical dysfunction from SCI arises from decreased tidal volumes and minute ventilation and impaired cough with retained secretions (Table 6) (90).

Normal inhalation requires outward movement of the rib cage through contraction of the intercostal muscles with

**Table 6** Comparison of Pulmonary Function in Patients with Cervical and Thoracic Spinal Cord Injury

Variable	C4 to C7	T3 to T12
FVC	52	69

Source: From Ref. 90.

expansion of the lower rib cage. The intercostal muscles are required for chest expansion during inhalation (91). Paralysis of the intercostals and abdominal musculature impairs both expansion of the lungs and diaphragmatic stabilization, dramatically compromising vital capacity, deep breathing, and cough strength.

If the lesion is high enough to impair intercostal function, the diaphragm becomes the principal muscle of ventilation. In this setting, the rib cage often moves paradoxically inward during inhalation. On pulmonary function testing, SCI patients typically have decreased total lung, vital inspiratory capacities, and expiratory reserve volume, with increased residual volume. Patients with intact diaphragm function can maintain adequate minute ventilation through increased stimulation of their diaphragm. Table 7 shows the innervation of the respiratory muscles with the corresponding spinal cord level (92). **Diaphragmatic breathing is affected by body position. When supine, abdominal contents push the diaphragm up increasing excursion and tidal volume, but at the expense of functional residual capacity (FRC). When**

**Table 7** Innervation of the Respiratory Muscles

Muscle group	Spinal cord level	Nerve(s)
<i>Inspiratory muscles</i>		
Diaphragm	C3 to C5	Phrenic
Parasternal intercostals	T1 to T7	Intercostal
Lateral external intercostals	T1 to T12	Intercostal
Intercostal	C4 to C8

**the patient is upright, FRC is preserved, but diaphragmatic “doming” and, thus, excursion is diminished.** Patients with SCI below C5 often benefit from the use of an abdominal binder, which increases intra-abdominal pressure and thus helps the diaphragm start contraction in a more domed position. If the diaphragm is significantly weakened (i.e., injury level above C6), minute ventilation declines markedly when the patient is upright (93,94).

The phrenic nerve arises from the third to fifth cervical roots, so a complete C3 level or higher will cause near complete ventilatory muscle paralysis. High cervical injuries have the highest incidence of ventilation complications, are difficult to wean from mechanical ventilation (Volume 2, Chapter 28), and have the highest mortality when compared with other SCI injury levels (95–97). Injuries above C3 are at high risk for nosocomial pneumonia, and without recovery of some function, will require diaphragmatic pacing or chronic ventilatory support.

A diaphragmatic pacer delivers an electrical stimulus to the phrenic nerve, allowing some of these patients, who might otherwise require chronic mechanical support, to maintain adequate gas exchange. However, if the lesion affects the anterior horn cells of C3 to C4, Wallerian degeneration will impair propagation of electrical impulses in the phrenic nerves. Intercostal to phrenic nerve transfers with diaphragmatic pacing have shown promising improvements, and other surgical remedies are currently being developed in animal models.

Patients with SCI at levels C3 to C5 have variable loss of diaphragmatic strength, and often require mechanical ventilation during acute hospitalization, but permanent ventilatory support is usually unnecessary (98–100). Occasionally, the initial level of motor loss can be due to inflammation and edema of neural tissue that is not permanently injured and, in a high cervical lesion, even a small improvement of function as this resolves, allows recruitment of accessory ventilatory muscles. Retraining muscles that are deconditioned during the acute illness and the evolution from flaccid to spastic paralysis can also lead to improvement in respiratory function (98–103). **The use of abdominal thrusts or quad coughing, postural drainage, chest percussion, and effective pain management lower the incidence of pneumonia in these patients.**

Lesions from levels C5 through C8 leave an intact diaphragm and the use of accessory muscles in the neck for inhalation, with exhalation primarily through the passive recoil of the chest wall and lungs. Injuries to the thoracic spinal cord have less impact on ventilatory muscle function, but have a higher incidence of associated chest trauma with pneumothorax, hemothorax, flail chest, and lung contusion, as well as damage to other thoracic structures (96,97).

### Tracheostomy Decision Making in Spinal Cord Injury Patients

Decisions regarding chronic airway management are made based on the patient's overall condition, estimated duration of mechanical ventilation, type of injury, and any plans for surgical stabilization. For example, after anterior surgical stabilization for cervical SCI, a period of two weeks is usually required prior to tracheostomy to allow healing of tissue planes (62).

Tracheostomy results in greater comfort for the patient and diminished sedation requirements. Tracheostomy facilitates ventilator weaning, simplifies pulmonary toilet, decreases dead space (especially useful in patients with compromised minute ventilation), and may decrease the rate

of pneumonia in trauma patients (104,105). The current consensus is to allow at least ten days for weaning attempts and performing the tracheostomies on patients who have been on the ventilator for more than 14 to 21 days (106,107).

However, these recommendations are for the general ventilated population, and if the likelihood of long-term mechanical ventilatory support is known with some degree of certainty based on the level of cord injury, the decision timing should be modified accordingly (108). The introduction of percutaneous tracheostomy in 1985 (109) has shortened the time to placing a chronic airway in some centers, and this technique has been used safely in patients with SCI, including patients with known cervical injury who cannot have their neck placed in extension (110).

## Gastrointestinal System

### Enteral Nutrition

☞ **Severe CNS injury causes a hypermetabolic response that peaks 5 to 12 days after injury and decreases to a level below pre-injury needs, depending on residual level of motor function.** ☞ Nutritional needs should be monitored and regularly reassessed because of the vulnerability of injured neural tissue to hyperglycemia and because over-feeding can impede weaning from mechanical ventilation, especially when pulmonary function is marginal. Most of the patients affected by SCI suffer from ileus due to autonomic dysfunction. A nasogastric or orogastric tube should be placed to avoid abdominal distension, and enteral feeding should be started as soon as it can be tolerated (see Volume 2, Chapter 32), which is often immediately.

Although the best enteral formulation for SCI patients is debatable, enteral feedings are preferred over parenteral nutrition to preserve intestinal function, minimize bacterial translocation, decrease complications of central venous catheters, and decrease ICU length of stay (111–121). In patients who are difficult to wean from the ventilator due to limited minute ventilation, a relatively high fat pulmonary formula can be used for nutrition which limits CO<sub>2</sub> production. The role of immunonutrition formulae, with arginine and omega3 polyunsaturated fatty acid versus the isocaloric isonitrogenous formulas in this ICU population is not established (122–124). Although gastric versus pyloric tube placement remains controversial, jejunal placement does reduce the incidence of abdominal distension, high gastric residuals, and vomiting compared with gastric placement (117). However, there is no increase in caloric administration or decrease in the incidence of nosocomial pneumonia (125–127).

### Ulcer Prophylaxis

Stress ulcer prophylaxis should be instituted on admission (62,118,128), and some overlap between discontinuation of prophylaxis and successful enteral feeding are recommended, as the role of feeding in stress ulceration prevention is unclear in SCI patients (see Volume 2, Chapter 30) (125). The incidence of gastrointestinal (GI) bleeding in SCI patients peaks between postinjury days 4 to 10 (112,113). The pathogenesis of stress ulcer is not completely understood, increased destructive factors such as elevated levels of gastrin, bile, pepsin, acid, and diminished protective factors including prostaglandin production, mucous bicarbonate layer, and epithelial cell renewal have all been observed (125,129). Some authors (111,112) have postulated that unopposed vagal activity might predispose SCI victims to GI ulceration or hemorrhage.

A correlation exists between the level of injury and incidence of GI bleeding with cervical injuries that are at

highest risk. Patients with cervical and thoracic cord injury also have a higher incidence of pancreatitis, likely due to the predominant visceral parasympathetic tone. Accordingly, we check pancreatic enzymes as a part of nutritional monitoring. Simple antacids, H<sub>2</sub>-antagonists, proton pump inhibitors (PPI), and sucralfate are all effective prophylactic agents for stress-related ulcer (114,115,129).

Some studies have shown that continuous infusion of a PPI or an H<sub>2</sub>-antagonist is superior to both intermittent equivalent dosing or antacid and sucralfate (130,131), but whether this is true in the setting of CNS injury is unclear (132). Although early studies suggested that the use of pH-altering therapy increases the incidence of nosocomial pneumonia (130), a relatively recent large trial showed no significant difference (133). Currently, most centers use intermittent dosing of either an H<sub>2</sub>-antagonist or a PPI as prophylaxis against stress gastritis (see Volume 2, Chapter 30).

## Genitourinary System

Acutely, all SCI patients should be managed with a Foley catheter. As the patient enters the recovery phase, the indwelling Foley is replaced with an intermittent straight catheter regimen every four hours, provided that daily urine output is less than 2500 cc. If the use of a catheter is necessary, intermittent catheterization reduces the risk of infections [urinary tract infections (UTI), orchitis, epididymitis, urethritis, and periurethral abscess or fistula], as well as long-term complications such as calculi and bladder carcinoma (134,135). Condom catheters seem to carry the least risk of complicated UTI. In addition, recurrent UTI in patients using condom catheters should prompt examination for voiding problems (134,136). The incidence of UTI in catheterized patients can be reduced through education of patients and staff to use the appropriate technique, hand hygiene, use of closed drainage system (134,137), and use of silver alloy catheters (134,138). Topical antiseptic agents to the perineal area and the use of antiseptic solutions in drainage bags and bladder washout are not effective (134,136,137).

The clinical presentation of UTI in SCI patients is often problematic. Pyuria is commonly an irritative effect of the catheter on the urinary tract, and culture results are often polymicrobial. Bacteriuria in patients with indwelling catheter should be treated only if symptomatic (134,139), and treatment should be continued for 5 days, or 7 to 14 days for cases of reinfections and complicated UTI (134,136,140). Prophylactic antibiotics should not be used in patients with indwelling catheters, and the evidence is not clear enough to make a recommendation for patients using intermittent catheterization (3,141).

☞ **Chronic urinary tract dysfunction requiring catheter drainage and recurrent UTIs are a serious problem for patients with SCI.** ☞ In the past, urologic complications played a major role in SCI mortality (142,143), and renal insufficiency from ascending UTI is still one of the leading causes of morbidity in SCI patients (134,141). Incomplete voiding with large postvoiding residual (141,144), and outlet obstruction such as detrusor sphincter dyssynergia, high-pressure voiding, and vesicoureteral reflux are the well-recognized predisposing factors for UTI in patients with SCI (134).

Careful attention to bladder management also decreases the incidence of autonomic dysreflexia, often associated with UTI, bladder distention, and urogenital diagnostic testing (68,145,146). The diagnosis of possible structural and functional abnormalities is essential in order

**Table 8** Neurosurgery, Trauma, and Acute Spinal Cord Injury

Risk group	Recommended prophylaxis
Intracranial neurosurgery	IPC device, with or without ES (grade 1A) LDUH or postoperative LMWH may be acceptable alternatives (grade 2A) High-risk patients: ES or IPC device with LDUH or postoperative LMWH may be more effective than either prophylactic modality alone (grade 1B)
Trauma, with identifiable risk factor for thromboembolism	Prophylaxis with LMWH, as soon as considered safe (grade 1A); if delayed, or contraindicated because of bleeding concerns: initial use of ES, or IPC device, or both (grade 1C) If prophylaxis is suboptimal, offer screening of high-risk patients with duplex ultrasound (grade 1C) If proximal DVT is demonstrated and anticoagulation is contraindicated, we recommend inferior vena cava (IVC) filter insertion (grade 1C+), but we do not recommend IVC filter insertion as primary prophylaxis (grade 1C)
Acute spinal cord injury	Prophylaxis with LMWH (grade 1B) We do not recommend LDUH, ES, and IPC as sole prophylaxis (grade 1C) ES and IPC may be offered in combination with LMWH or LDUH, or if early use of anticoagulants is contraindicated (grade 2B) In the rehabilitation phase, we recommend continued LMWH therapy, or full-dose oral anticoagulation (both grade 1C)

*Abbreviations:* DVT, deep venous thrombosis; ES, elastic stockings; IPC, intermittent pneumatic compression; LDUH, low-dose unfractionated heparin; LMWH, low-molecular-weight heparin.

to provide adequate care to SCI patients affected by UTI. Prior to transfer to rehabilitation phase, appropriate baseline urodynamic evaluation is recommended (141).

## Cutaneous and Musculoskeletal Systems

### Pressure Sores

Patients with SCI are particularly prone to develop pressure sores (decubitus ulcers). Pressure sores are potentially serious, putting patients at risk for osteomyelitis and septicemia, especially if they occur near the area of surgical intervention for spinal stabilization (147). Risk factors for pressure sores are immobility, nutritional status, fecal and urinary incontinence, and decreased sensory perception, all conditions commonly found in SCI patients. Table 8 summarizes the Braden scoring system for estimating risk of developing pressure sores.

Although pressure sores (decubitus ulcers) are often considered primarily a problem in long-term facilities, Figure 7 illustrates the findings of early development of pressure sores (Stage II or greater) in 18 of 183 SCI patients in a neuro-ICU over a three-month period (148). Establishing

**Figure 7** Maximum days to decubitus ulcer detection. This figure demonstrates the number of days that elapsed prior to decubitus ulcer formation in a group of spinal cord injured patients. *Source:* From Ref. 148.

a turning schedule with a recommended maximum duration time of two hours for any single position (as soon as conditions permit) is essential. Although still immobile, patients should be supported with pressure-reducing mattress materials, such as foam, static air, alternating air, gel, water, low air loss, or air-fluidized support surfaces (147), with proper alignment of extremities and cushioning devices between legs and ankles. Trapezes, transfer boards, and lift sheets should be employed to prevent mechanical injuries from friction and shearing forces during repositioning and transfer activities.

### Contractures and Spasticity

Contractures and spasticity are problems that occur over time in SCI patients, but prevention begins in the ICU. Some patients may be able to undertake a partial active exercise regimen. But most will require either active assisted or passive movements to maintain full joint range, muscle length and extensibility and improve venous return. Shoulders, hands, hips, and ankles are at particular risk of contractures. Resting splints for the hands and feet should be employed in appropriate patients to maintain these joints in a neutral position. Spasticity is also a common cause of pressure sores. Spastic syndrome is characterized by exaggerated muscle tendon tap reflexes, increased muscle tone, and involuntary muscle contractions. Commonly used agents for spasticity include baclofen and diazepam with CNS action and dantrolene, which acts directly on skeletal muscles.

## EYE TO THE FUTURE

For the short term, the most dramatic changes in the critical care of SCI will be in the improvements in critical care across the board. New developments in therapies for septic shock, protective ventilator strategies, reduced use of red cell transfusions, early renal replacement therapy, tight glucose control, to name a few examples, will dominate the improved care for all critically ill patients.

Longer term, ICU physicians will begin to introduce agents that reduce secondary SCI in incomplete lesions. Agents that either block endotoxicity or enhance cellular antiexcitotoxic activity may soon be available (149). There

is a very large research effort underway to understand apoptotic pathways and create medications targeted at interrupting or suppressing them (150). Control of apoptosis appears to be of central importance, and may be a precondition of regenerative strategies (151). Several other nonantioxidant approaches are under investigation for application with steroids: these include COX-2 inhibitors, inhibitors of calpain, and thyrotropine releasing hormone analogs (which act as opioid receptor antagonists).

When acute injury cannot be minimized and cell death occurs, the horizon of axonal regeneration research is increasingly showing promise. Regeneration avenues include neural growth factors (152); neural stem cell research (Fig. 8) (153,154); and the use of grafts, electrical stimulation, and physical therapy to induce neural plasticity (155).

Recently, human fetal spinal cord tissue has been cultured for neural stem cells and subsequently implanted into spinal cord injured primates (156). Eight weeks after transplantation, all animals were sacrificed and histological analysis revealed that not only did the human neural stem

**Figure 8** Process of transplanting neural stem cells (or their progeny mature cell types) into the spinal cord of injured patients. Multipotential neural stem cells have the ability to self-renew (curved arrows) and to generate all the mature cell types of the central nervous system—neurons, oligodendrocytes, and astrocytes. Neuronal-restricted precursor cells and glial-restricted precursor cells are more limited in their potential and ability to self-renew. These cells alone or in combination with ex vivo gene therapy are being evaluated for their potential to promote axon regeneration, rescue injured cells, and enhance functional recovery after spinal cord injury. *Source:* From Ref. 153.

cells survive, but they also differentiated into neurons, astrocytes, and oligodendrocytes. On a functional level, power and the spontaneous motor activity of the transplanted animals were significantly higher than those of sham-operated control animals (156). An important caveat for all of this research as it comes into human trials is the need for improvement in diagnostic testing to improve reliability of treatment protocol results (157).

## SUMMARY

SCI represents a catastrophic event for the patient and his/her loved ones. The last decade has witnessed numerous significant improvements. Within the next five to ten years, further improvements are on the horizon. Pharmacological therapies are being developed to limit the extent of secondary injury, and soon thereafter we will likely see effective therapies for restoration of neurological function lost to primary spinal cord damage.

Recent research has shown that transplanted neural stem cells can repopulate damaged areas in the spinal cord. In addition, it is likely that the appropriate trophic factors will be discovered that will render the native spinal cord to transform into a growth permissive environment following SCI and allow regeneration of damaged neurons. In an effort to streamline research efforts and improve collaboration, a recent report from the Institute of Medicine states that the United States National Institutes of Health (NIH) and its subsidiary, the National Institute of Neurological Disorders and Stroke, should develop a centralized network to lead and organize diverse SCI research across the country (158).

In the meantime, meticulous critical care practices are proven to decrease morbidity and mortality in SCI patients and to hasten their readiness to enter rehabilitation. Aggressive rehabilitation should begin in the SICU (Volume 2, Chapter 66) and proceed on the ward, as well as following discharge. New techniques in early mobilization and training of transfers, self-cleansing, feeding, and dressing are also desperately needed. Significant additional funds need to be allocated in this arena as well in order to maximize the full potential for recovery, and return to productive lives following SCI.

## KEY POINTS

- ☞ Because of the variable vascular anatomic distribution of the artery of Adamkiewicz, the upper thoracic portion of the spine has watershed zones that are extremely sensitive to ischemic and hypoxic insults.
- ☞ The NASCIS trials supporting the use of methylprednisolone have been viewed as methodologically flawed, with the most encouraging results emerging only in posthoc analyses. Some prominent authors in the field of SCI have argued that 24-hour methylprednisolone should not be routinely used in SCI, and then only on a compassionate use basis (27).
- ☞ All patients sustaining major trauma, a fall from greater than ten feet, MVC, or noticeable injuries to the head or neck should be thoroughly evaluated for evidence of SCI.
- ☞ Some experimental studies have reported reversal of neurological deficits if decompression is performed in six to eight hours from the time of injury (53), and

clinical improvement of neurological deficits after cervical traction has been applied (54,55).

- ✎ Lesions in the spinal cord produce sensory and motor disturbances corresponding to the functions of the tracts that have been injured or transected.
- ✎ Clinically, the term spinal shock refers to systemic hypotension due to a decrease in sympathetic fiber-mediated arterial and venous vascular resistance, along with venous pooling and loss of preload, with or without bradycardia.
- ✎ Although phenylephrine, a nearly pure  $\alpha$ -agonist, is commonly used in conjunction with volume in trauma resuscitation, for SCI we favor norepinephrine as a first choice, and if more  $\beta$ -adrenergic support is needed, epinephrine.
- ✎ Cord perfusion is crucial in the first 72 hours following injury, and even short periods of hypotension may have severe consequences; all patients should receive an arterial line in the ICU, and MAPs should not be allowed to fall below 60 to 70 mmHg.
- ✎ Currently, the data is insufficient to recommend the routine use of hypertonic saline for resuscitation in SCI, however, its use should be considered in the setting of resuscitation when CNS edema amenable to osmotic therapy is present.
- ✎ Somewhere between 19% to 70% of SCI patients have at least one episode of autonomic dysreflexia in their lifetime (67), and should always be anticipated when patients are scheduled for even small procedures, such as cystoscopy (68).
- ✎ Pulmonary complications, after the primary injury, are the cause of morbidity and mortality in SCI.
- ✎ Acute SCI victims have the highest risk of developing DVT among all hospitalized patients (75,76).
- ✎ Diaphragmatic breathing is affected by body position. When supine, abdominal contents push the diaphragm up increasing excursion and tidal volume, but at the expense of FRC. When the patient is upright, FRC is preserved, but diaphragmatic "doming" and, thus, excursion is diminished.
- ✎ The use of abdominal thrusts or quad coughing, postural drainage, chest percussion, and effective pain management lower the incidence of pneumonia in SCI patients.
- ✎ Severe CNS injury causes a hypermetabolic response that peaks 5 to 12 days after injury, and decreases to a level below preinjury needs depending on residual level of motor function.
- ✎ Chronic urinary tract dysfunction requiring catheter drainage and recurrent UTIs are a serious problem for patients with SCI.

### INTRODUCTION

The management of vascular catastrophes in the brain requires both prompt diagnosis and treatment. It also requires a fundamental knowledge of the medical and surgical principles of neurological intensive care management of both operative and nonoperative cases. Often, the pathology comprising this arena is associated with high morbidity and mortality, underscoring the need for diligence and insight into the particulars of the neurological milieu.

Most neurological emergencies involve hemorrhage within the brain and/or other intracranial spaces, or ischemic insults to the central nervous system (CNS). Among intracranial hemorrhages, management of aneurysmal subarachnoid hemorrhage (SAH) is particularly demanding. Aside from operative or endovascular interventions, significant intensive care management is needed to treat the underlying pathologies and the associated complications. The principles of therapy aim to maintain adequate CNS blood flow to prevent cerebral ischemia, which threatens cell survival. In addition, treatment is focused upon preventing brain shift and herniation as a result of brain swelling. Intracerebral hemorrhage and ischemic cerebrovascular disease remain additional major sources of morbidity and mortality. Because of emerging therapies rapid evaluation is increasingly critical to their appropriate management. This chapter will focus on the pathophysiology, clinical presentation, and management of the aforementioned disease entities, as well as a brief discussion of traumatic cerebral aneurysms, venous sinus thrombosis, and carotid cavernous sinus fistulae.

### SUBARACHNOID HEMORRHAGE

The major cause of nontraumatic SAH is aneurysmal rupture, which occurs in approximately 30,000 persons per year in the United States (1). ⚡ **The mortality associated with the initial hemorrhage is around 20%.** ⚡ Subsequently, the mortality is 30% within the first two weeks, and 45%

within the first month following the initial bleed. Among the survivors, as many as 50% suffer from significant neurological impairment (2,3). Most morbidity subsequent to SAH is due to complications from cerebral ischemia. This results from increased intracranial (ICP) pressure following the initial hemorrhage, and is exacerbated by rebleeding, vasospasm, and hydrocephalus. Nevertheless, outcomes following SAH have improved over the past 10 years as a result of improvements in the medical and surgical management of this disease (4).

### Pathogenesis

⚡ **Saccular aneurysms must be differentiated from traumatic, dissecting, mycotic, and/or tumor-associated aneurysms because the classification dictates management.** ⚡ Saccular aneurysms arise at the sites in a blood vessel where the elastic component is either absent from birth or damaged by arteriosclerotic changes. A saccular outpouching eventually forms into an aneurysmal sac due to the constant impact of the blood stream (5). Aneurysms are also associated with systemic and familial diseases such as Marfan's syndrome, Ehlers-Danlos syndrome, fibromuscular dysplasia, polycystic disease, and coarctation of the aorta (6).

### Presentation

The classical presentation of SAH is a sudden, severe headache, typically the worst in the life of the patient (often termed a thunder clap). This is often accompanied by neck pain, nausea and vomiting, photophobia, varying degrees of altered mental status, and even profound coma (7). The associated acute rise in intracranial pressure (ICP) may also produce subhyaloid hemorrhages. Up to 20% of patients experience a warning leak or sentinel hemorrhage prior to aneurysmal SAH. This is characterized by nuchal rigidity and/or meningismus lasting 24 to 48 hours. Unfortunately, a sentinel hemorrhage is misdiagnosed 20% to 40% of the time as another more benign disease such as migraine, cervical disease, or sinusitis (8,9). In order to minimize this, maintaining a high degree of suspicion for aneurysmal expansion or sentinel hemorrhage is imperative.

**Figure 1** Head computed tomography (CT), noncontrast, with interhemispheric subarachnoid hemorrhage (between the frontal lobes along the left sylvian fissure). Also dilatation of the right temporal horn of the ventricle (one of the radiological hallmarks of hydrocephalus).

In addition to hemorrhage, aneurysmal expansion can cause neurological changes, allowing for the possibility of diagnosis prior to rupture. Depending on the location, the patient may have facial pain, papillary dilatation, ptosis, and/or visual field defects.

### Diagnostic Evaluation

The diagnosis of SAH rests with identification of its classical clinical presentation. This should be confirmed with an emergent noncontrast computerized tomographic (CT) scan. The CT scan aids in detecting, localizing, and quantifying the SAH. It is successful 95% of the time in identifying SAH, when performed on the same day as the onset of symptoms (10) (Fig. 1). Additional information about cerebral edema and hydrocephalus is also provided by CT scan. In the setting of a sentinel hemorrhage from an aneurysm, a CT scan may be negative in up to 35% of patients (11). Patients presenting with a

**Figure 2** Cerebral angiogram, anterior–posterior projection, with anterior communicating artery aneurysm.

**Figure 3** Cerebral angiogram, lateral projection, posterior circulation arterial venous malformation.

history which is suggestive of SAH, yet possessing a normal CT scan, warrant a lumbar puncture (first exclude intracranial mass lesion). This would consistently reveal elevated red blood cell counts in all tubes if SAH had indeed occurred. Lastly, a CT scan also reveals causes of SAH other than an aneurysm rupture. This includes pituitary apoplexy, which can mimic an aneurysm rupture clinically. The identification of a hemorrhagic pituitary adenoma can lead to prompt treatment with steroids to prevent a potentially lethal Addisonian crisis.

☞ **Immediately following the documentation of SAH, attention is directed toward the identification of the responsible vascular abnormality, most commonly a ruptured aneurysm.** ☞ The gold standard diagnostic examination is digital subtraction four-vessel cerebral angiography. This will identify an aneurysm in 95% of cases, and occasionally an arteriovenous malformation (AVM) (12) (Figs. 2 and 3). In addition, an angiogram will show details of the location, size and orientation of the aneurysm as well as demonstrate the presence or absence of vasospasm (Fig. 4). However, in 5% to 15% of the cases, the angiogram is negative. In this situation, the study should be repeated in two to three weeks and again in a few months, because an acute intraluminal thrombus may interfere with angiographic visualization (12,13).

**Figure 4** Cerebral angiogram, oblique projection, demonstrating the significant narrowing of vasculature beginning at the internal carotid artery and extending past the bifurcation in the middle cerebral vasculature, consistent with the angiographic diagnosis of vasospasm.

**Figure 5** Magnetic resonance angiogram of the cerebral vasculature.

In addition to cerebral angiography for visualization of the cerebral vasculature, other noninvasive imaging modalities are available as well. Aneurysms can be demonstrated using magnetic resonance angiography (MRA); however, MRA has limited sensitivity in the detection of small (<5 mm) aneurysms (Fig. 5). On the other hand, CT angiography (CTA) is increasingly being employed for the assessment of the cerebral vasculature in the setting of SAH. This technique obtains images by contrast-enhanced, high-speed spiral CT. The axially acquired data are then reconstructed into three-dimensional angiographic images (14). The advantages of CTA include the rapidity with which images are obtained, its noninvasive nature, and its relative high sensitivity and specificity (15). However, aneurysms less than 3 mm still may escape detection. Additionally, extensive SAH may hinder the clear demonstration of an aneurysm. Finally, postoperative use of CTA is limited by scanning artifacts introduced by an aneurysm clip.

### Clinical Grading

The clinical state of a patient presenting with SAH is highly predictive of the therapeutic outcome. A grading system has therefore been developed to document the severity of the patient's disease in order to guide therapy and prognosis. In 1968, Hunt and Hess developed a scale which has been useful in correlating the patient's clinical status and prognosis (Table 1) (16). Vasospasm, which is thought

**Table 1** Hunt and Hess Grading Scale

Grade	Symptoms
I	Asymptomatic or minimal headache and slight nuchal rigidity
II	Moderate to severe headache, nuchal rigidity, no neurologic deficit other than a CN III palsy
III	Drowsiness, confusion, or mild focal deficit (e.g., any cranial nerve palsy other than CN III)
IV	Stupor, hemiparesis, possible early decerebrate rigidity
V	Deep coma, decerebrate rigidity, moribund appearance
Plus one	Serious systemic diseases, such as hypertension, diabetes, severe arteriosclerosis, chronic obstructive pulmonary disease, and severe vasospasm, result in placement of the patient in the next less-favorable category

Abbreviation: CN III, third cranial nerve.

Source: From Ref. 16.

**Table 2** Fisher Grade

Grade	Blood on CT
1	No blood detected
2	Diffuse or vertical layers <1 mm thick
3	Localized clot and/or vertical layer greater than or equal to 1 mm
4	Intracerebral or intraventricular clot with diffuse or no subarachnoid blood

Abbreviation: CT, computed tomograph.

Source: From Ref. 17.

to be caused by subarachnoid blood and its breakdown products, is also responsible for marked morbidity and mortality. As a result, the Fisher grading system was developed to correlate the amount and distribution of subarachnoid blood on CT with the subsequent development of vasospasm (Table 2) (17). In both grading systems, a lower grade (smaller number) is correlated with a better prognosis.

### Therapy

The initial goal in SAH management is stabilization of the neurologic and cardiopulmonary condition of the patient. Once this is accomplished, the necessary steps are taken to diagnose and treat the cause of the SAH. In the case of a ruptured aneurysm, the stabilization, workup, and operative therapy must be instituted expeditiously since rerupture usually occurs within the first 72 hours following SAH. The development of vasospasm may also occur within the first few days following SAH and tends to peak seven to eight days following the initial ictus. Depending on the grade of the SAH (Hunt/Hess and Fisher), the patient may need to be intubated for pulmonary support as well as to facilitate sedation. External ventricular drainage for the treatment of hydrocephalus may be needed. Once the diagnosis of a ruptured aneurysm is established by angiography, definitive treatment of the aneurysm may occur through surgical clipping or endovascular coiling. The algorithm for definitive treatment of aneurysmal SAH is changing rapidly (particularly the criteria for endovascular management).

### Surgical Therapy

☞ Patients with a lower Hunt and Hess grade (Hunt and Hess grade I–III) should undergo an urgent craniotomy and surgical clipping of anatomically accessible aneurysms. ☞ The surgical treatment of higher-grade SAH patients (Hunt and Hess IV & V), who are less favorable operative candidates with a poorer prognosis, remains controversial.

☞ The goal of treatment is to secure the neck of the aneurysm by clipping, so that the common complications of SAH, such as rebleeding, vasospasm, and hydrocephalus can be eliminated or maximally treated (18,19). ☞ This is accomplished by a craniotomy through which the neck of the aneurysm is identified and excluded from the parent circulation by a clip (Fig. 6). The operative techniques may include temporary proximal arterial occlusion (20). Sometimes, aneurysms which are relatively inaccessible may need to be treated with proximal arterial ligation. In some of these cases, blood flow may need to be augmented with the aid of an extracranial to intracranial (carotid/vertebral) arterial bypass.

### Endovascular Therapy

With the development of better fluoroscopy and catheters, endovascular techniques have become increasingly

**Figure 6** Cerebral angiogram, anterior–posterior projection, with anterior communicating artery aneurysm successfully clipped and excluded from the cerebral blood flow.

safe and effective in accessing the cerebral vasculature. Interventional neuroradiology has also become an indispensable adjunct in the management of cerebrovascular disease. A recent randomized International Subarachnoid Aneurysm Trial (ISAT) conducted in Europe, North America, and Australia, demonstrated better overall outcomes for those treated endovascularly. A total of 2143 patients were enrolled in 43 centers; the relative risk of death or significant disability at one year for patients treated with coils was 22.6% lower than those treated with surgical clipping (21).

✎ **Coil occlusion is indicated for the treatment of aneurysms which: (i) are difficult to clip surgically, (ii) occur in patients who are unsuitable for early surgery due to a poor SAH grade, and (iii) occur in patients who are medically unstable (22).** ✎ Detachable platinum-alloy microcoils are deployed through microcatheters into the aneurysm sac (23). The guidewire transmits a low positive direct electric current that detaches the coil from the stainless steel microcatheter. Coils “packed” into the aneurysm sac promote intra-aneurysmal electrothrombosis by attracting local blood components (Figs. 7 and 8) (22). In aneurysms which are treated with proximal parent artery ligation, endovascular balloon occlusion is also used. These include internal

**Figure 7** Cerebral angiogram with microcatheter seen in the internal carotid artery and entering the posterior communicating artery aneurysm.

**Figure 8** Cerebral angiogram with coils deployed within aneurysm.

carotid artery aneurysms in the cavernous sinus or selective vertebrobasilar aneurysms (24). Treatment of nonruptured aneurysms has not been studied prospectively. However, retrospective data tend to favor endovascular management at this time (25).

Vasospasm, diagnosed with angiography, can also be treated by endovascular interventions. Angioplasty can be used to increase luminal diameter and is indicated when calcium antagonist prophylaxis fails or when hypervolemic, hemodilutional, and hypertensive (“triple H”) therapy is ineffective, or unsafe, in treating clinical vasospasm. A soft silicon balloon-tipped catheter is navigated into the affected cerebral vasculature and is inflated with 0.10 mL of saline to deliver 1–3 atm of pressure. This technique should not be employed when there is cerebral infarction or an unsecured aneurysm distal to the stenotic zone intended for angioplasty, as the postangioplasty increase in cerebral blood flow could precipitate a hemorrhage (26). Treatment of vasospasm also includes the perfusion of the stenotic segment with vasoactive drugs (e.g., papaverine). Repeated treatment is frequently necessary and effective.

## Management of Subarachnoid Hemorrhage and Its Complications

### Initial Management

Patients with SAH require intensive care management. All need to be closely monitored for potential medical, neurological, and surgical complications. Upon admission to the intensive care unit (ICU), patients are placed at bed rest with the head elevated to facilitate cerebral venous return. Measures are taken to prevent thrombophlebitis (with sequential pneumatic compression stockings), atelectasis and pneumonia (with good pulmonary toilet), and gastrointestinal ulceration (with the prophylactic use of H<sub>2</sub> antagonists and/or sulcralfate). External ventricular drainage of cerebrospinal fluid (CSF) may be necessary to treat acute hydrocephalus. All patients with an intraventricular hemorrhage should receive external ventricular drainage of CSF.

Systolic blood pressure should be maintained below 160 mmHg while the aneurysm is unsecured. Agents that are centrally sedating such as methyldopa should be avoided. Nausea and vomiting should be treated with agents that are not sedating as well (i.e., use ondansetron rather than droperidol). Pain control should be addressed with minimal short-acting narcotics, without excessive sedation that may mask neurological (especially mental status) deterioration.

### Neurological Consequences of Subarachnoid Hemorrhage

#### Rebleeding

After initial hemorrhage from a ruptured cerebral aneurysm, the greatest immediate concern is rehemorrhage of the unsecured aneurysm. In fact, the risk of rebleeding is greatest in the first 24 hours following SAH (1,3). Of untreated aneurysms, 20% rehemorrhage within two weeks, 50% rehemorrhage within one month, and by six months the risk stabilizes to approximately 2% to 3% per year (27,28). The consequences of rehemorrhage are devastating, with an overall mortality of 70% and accounting for 50% of all deaths occurring within 48 hours of the initial SAH (29,30). It is for these reasons that ruptured aneurysms should be treated early whenever feasible.

#### Vasospasm

Vasospasm is the constriction of arteries in the intracranial circulation in response to subarachnoid blood. A major complication that creates significant morbidity and mortality, vasospasm is noted angiographically in 70% of patients and leads to ischemic symptoms in 20% to 30% of patients (31). It may occur as early as the third day after the original SAH, with the incidence peaking between days 5 to 10 and remains a possible occurrence up to three weeks after the original hemorrhage (3). Ultimately, vasospasm leads to stroke or death in up to 15% of patients surviving the initial SAH (32).

**Presentation and Diagnosis.** During the pathological evaluation of vessels in vasospasm, intimal proliferation and medial necrosis is found. The amount of blood in the subarachnoid space and its location correlates directly with the likelihood of vasospasm and the vessels that are likely to be affected. The pathogenesis of vasospasm is unknown, but thought to result from the products of local erythrocyte degradation, and may be in part related to the sequestration of endothelial nitric oxide by the heme moiety of stroma-free hemoglobin.

The clinical presentation of vasospasm is variable and often progressive over a few hours, but can also occur suddenly. Symptoms may fluctuate ranging from a mild decrease in consciousness to focal neurological deficit from ischemic or infarcted brain, and even profound coma. The diagnosis is made when a delayed neurological deficit or deterioration occurs in a patient with SAH. Rehemorrhage and hydrocephalus must be excluded by urgent CT scan before attributing a delayed neurological deficit or deterioration to vasospasm. For definitive diagnosis of vasospasm, cerebral angiography should be performed. However, angiographic vasospasm is not always symptomatic. Since angiography carries a stroke risk of 1% to 2%, its utility as a screening or monitoring tool must be carefully considered (3,33).

The most commonly used bedside noninvasive monitoring technique to detect cerebral vasospasm is transcranial Doppler (TCD) ultrasonography (34). An inverse relationship between vessel caliber and flow velocity is predicted by the Bernoulli effect. Clinically, elevated TCD values and upward trends in TCD values are correlated with vasospasm, and guide the timing of noninvasive vasospasm treatment (35). This technique is also commonly used for monitoring poor-grade SAH patients in whom clinical signs of worsening neurological deterioration may be difficult to ascertain. Currently, xenon-133, single-photon emission computed tomography (SPECT), and positron emission tomography (PET) are being studied for their utility in directly measuring cerebral blood flow in

vasospasm. Due to its noninvasive nature, TCD should be performed daily or every other day after aneurysmal SAH, reserving angiography for the diagnostic confirmation and therapeutic intervention of clinical vasospasm.

**Management of Vasospasm.** The goal of management is to minimize ischemic brain injury, especially from vasospasm.

☞ **The mainstay of therapy in the United States, once clinical vasospasm is suspected or confirmed, is nimodipine (to minimize vasospasm) and “triple-H” therapy; the three H’s being hypervolemia, hypertension, and hemodilution.** ☞

A calcium channel antagonist such as nimodipine should be started upon admission to the ICU, since several studies with an oral nimodipine have demonstrated improved outcomes in SAH, particularly with poor-grade patients (36,37). Fewer infarcts were noted, although there was no difference in the incidence or extent of angiographic vasospasm. Beneficial effects are most likely related to the calcium-blocking properties of these agents, which interfere with the ischemic cascade in marginally ischemic neurons (37). Calcium-channel blockers may also dilate leptomeningeal vessels, thereby improving collateral circulation to ischemic areas (38). Patients should be started on nimodipine 60 mg every four hours for 21 days, and if hypotension is encountered the dosage can be changed to 30 mg every two hours.

The other measure used to counteract the effects of vasospasm is triple-H therapy. The aim of triple-H therapy is to improve cerebral perfusion by raising systolic blood pressure and intravascular volume so as to optimize cardiac output. In the setting of SAH, circulating red blood cell volume is decreased, which predisposes patients to a higher incidence of delayed neurological deficit or deterioration from cerebral ischemia (39,40). Volume expansion, independent of effects on cerebral perfusion pressure, improves cerebral blood flow in patients with vasospasm (41). The critical factor in preventing or reducing cerebral ischemia may be the prevention of hypovolemia, rather than the creation of a hypervolemic state (42). Expanding the intravascular volume in patients with SAH also creates hemodilution. Hemodilution alone can improve both cerebral blood flow and oxygen delivery by decreasing blood flow viscosity (43). The use of hypertension in the treatment of vasospasm is based on the observation that cerebral autoregulation is lost with SAH. A direct correlation between mean arterial pressure and cerebral blood flow has also been demonstrated, and several studies have shown that such induced hypertension can reduce delayed neurological deficits from vasospasm in aneurysmal SAH (44,45). The combination of hypervolemia, hemodilution, and hypertension is now well accepted therapy for clinical vasospasm. The goal of intravascular volume expansion with isotonic crystalloid is to maintain a central venous pressure of 7–10 mmHg, and a hematocrit of 30% to 32%. Hypertension is induced in a stepwise fashion with volume and pressures, primarily beta agonists, to a systolic pressure of 160–200 mmHg until the neurological deficit or elevated TCD values improve (46). The use of triple-H therapy is not without risk, and should be instituted in the intensive care setting with a pulmonary artery catheter in place for continual cardiopulmonary assessment. This therapy has been associated with heart failure, pulmonary edema, and electrolyte disorders. Furthermore, induction of hypertension can lead to myocardial ischemia and infarction, intracranial hemorrhage, and rupture of unsecured aneurysms.

With the evolution of neuroendovascular techniques, another weapon in the armamentarium against vasospasm has been developed. Transluminal balloon angioplasty can be used to selectively dilate severely narrowed arteries. The ability to reverse clinical symptoms of vasospasm with this technique is related to how quickly after symptoms arise that angioplasty is performed. More significant improvement of symptoms is achieved when angioplasty is performed within 24 hours of neurological deterioration (47). In select patients, vasospasm refractory to medical therapy may be reversed in up to 98% of cases (48). Lastly, intra-arterial perfusion of vasoactive agents (e.g., papaverine) has also been used in treating vasospasm with varying degrees of success.

### Hydrocephalus

Hydrocephalus may develop at different times after SAH. A large volume of blood in the subarachnoid space or in the ventricles can cause acute hydrocephalus due to obstruction of cerebrospinal drainage pathways. This may occur in up to 20% of patients and is more common in poor-grade patients since the degree of hemorrhage tends to be large in these patients (49). External ventricular drainage of CSF would be necessary to reduce ICP and to facilitate the removal of blood clots.

Hydrocephalus occurring in the subacute or late period after SAH is usually of the communicating type. The problem arises from decreased absorption of CSF by the arachnoid villi, caused by the products of blood degradation. These patients should be treated based on their clinical scenario. If there is ventriculomegaly and the patient is neurologically intact, then a period of observation and repeat CT scanning is warranted. However, if the patient has a neurological deficit or persistent headache, temporary CSF drainage and permanent CSF diversion with a ventriculoperitoneal or lumboperitoneal shunt may be needed. As many as 20% of patients with SAH will need permanent CSF diversion (50).

### Seizures

Seizures occur in up to 25% of patients with aneurysmal SAH (51). Rebleeding or vasospasm can be exacerbated during the seizure episode. For this reason, anticonvulsants are used on a prophylactic basis for SAH patients in most American centers. Phenytoin is used for a two-week period and its use is extended to three months for witnessed seizure or postoperative intracranial hemorrhage. If fever, rash, or hepatotoxicity develops, phenytoin should be discontinued and a different anticonvulsant should be used (52).

## Medical Consequences of Subarachnoid Hemorrhage

### Cardiac Complications

Intracranial hemorrhage, particularly SAH, is associated with hypothalamic dysfunction and catecholamine release with unique cardiac complications. This adrenergic release causes prolonged myocardial contraction, decreased cardiac compliance, and is directly cardiotoxic. Sustained catecholamine release can eventually cause myofibrillar degeneration and necrosis (53). ⚡ **Electrocardiogram (ECG) changes are common in patients with SAH, even in patients without prior history of cardiac disease.** ⚡ Prominent U waves, inverted T waves, and minor elevation or depression of the ST segment can occur. Large upright T waves and prolonged QT intervals may also be encountered, and arrhythmias can occur in up to 30% of patients (54). Despite the aforementioned ECG changes in the setting of

SAH, permanent myocardial ischemia is relatively rare. The finding of pathologic Q waves warrants a diligent workup for myocardial infarction (55). Cardiac complications with SAH can be life threatening, and every patient should receive close cardiac monitoring, particularly during the first 48 hours after SAH when catecholamine release is greatest and during the institution of triple-H therapy.

### Pulmonary Complications

⚡ **After rebleeding, vasospasm, and hydrocephalus, morbidity following SAH can be attributable to pulmonary complications including pulmonary edema, pneumonia and/or pulmonary embolism.** ⚡ Pulmonary edema may be either neurogenic or cardiogenic in origin. The neurogenic pulmonary edema associated with SAH arises from induced alterations in pulmonary vascular permeability and results in edematous fluid with high protein content. Cardiogenic pulmonary edema is secondary to vascular congestion and results in edematous fluid with low protein content. This may be caused by primary cardiac failure or exuberant volume expansion in triple-H therapy, and underscores the need for using pulmonary artery catheters (56). Pneumonia occurs in 20% of SAH patients, usually from aspiration or prolonged mechanical ventilation. Timely intubation during neurological deterioration, vigilant pulmonary therapy, appropriate antibiotic management, and employment of tracheostomy are the basic principles guiding the management of pneumonia (57).

### Thromboembolism

Thromboembolism poses a major concern in SAH patients who are frequently immobilized for long periods. These patients should receive intermittent pressure stockings. Anticoagulation is withheld until the aneurysm is secured. An established DVT in the setting of an unsecured aneurysm should be managed with an inferior vena caval filter. If anticoagulation is required, it is generally considered safe 48 hours after surgery.

## ARTERIOVENOUS MALFORMATION

### Pathogenesis

AVMs of the brain are congenital lesions of the vascular system. They begin to evolve between the fourth and eighth weeks of embryonic life, most likely from a defect in the development of the capillary system between the arteries and veins (58,59).

In a normally developed vascular system, cerebrovascular resistance, determined by the capillary system, prevents arterial blood from directly entering the veins. The capillary bed functions normally, allowing the developing brain access to nutrients from the blood. In the area of an AVM, however, this resistance bed does not exist and blood is shunted directly from the arterial into the venous system (Figs. 9 and 10). Since these anomalies arise during brain development, the part of the brain normally supplied by the absent capillary bed does not develop. Its function is subserved by surrounding cerebral components. For this reason, the patient may function normally and the AVM remains undetected. At the site where the AVM develops, a gliotic plane forms between the AVM and the surrounding brain. Lastly, the absence of the capillary bed also creates pathways which offer the least resistance to blood flow. These abnormal, low-resistance pathways

**Figure 9** Cerebral angiogram, lateral projection, with occipital arterial venous malformation seen during the arterial phase.

gradually “capture” blood from the surrounding circulation and enlarge. The AVM eventually becomes a lesion comprised of abnormal channels of variable sizes. Aneurysms may also develop in this malformed vascular tree. AVMs may be extremely small and cryptic or so extensive as to involve an entire hemisphere. Because these vessels are malformed, under abnormal flow and pressure forces, they have a predilection to hemorrhage.

### Presentation

✂️ **AVMs are the leading cause of SAH in young people although they account for only 5% of SAH in adults (58,60).** ✂️ AVMs may become symptomatic at any age. The most common presentation is an intracranial hemorrhage that occurs in up to 40% of the patients. This is more commonly seen in smaller AVMs. Seizure is also a presen-

**Figure 10** Cerebral angiogram, lateral projection, with occipital arterial venous malformation (AVM) seen during the venous phase; note the large dilated draining veins characteristic of an AVM.

tation of AVMs. This is presumed to arise from the gliotic plane between the AVM and the brain. Headache is the third symptom associated with an AVM. This is usually of a vascular pulsatile nature. In patients with large AVMs, progressive neurological deficits may develop, and this is thought to occur as blood is diverted from other areas of the brain to the malformation, causing progressive ischemia in those areas immediately surrounding the AVM. This diversion of blood is often referred to as steal.

The most threatening symptom of an AVM is hemorrhage. In those patients who did not present with a hemorrhage, the chance of a hemorrhage is 1% to 3% per year. On the other hand, AVMs which present with a hemorrhage, possess a hemorrhage risk of 3% to 5% per year. Since an AVM occurs mainly in younger individuals and the natural history in regard to hemorrhage for these patients is unfavorable, treatment is essential. In contrast to a mortality rate of 20% to 23% following rupture of an intracranial aneurysm, the initial mortality rate for a ruptured AVM is approximately 10% (58,60). The likelihood of surviving such a hemorrhage is, therefore, substantially higher than in a patient who suffers SAH from an aneurysm.

### Diagnostic Evaluation

On CT scanning, a ruptured AVM assumes the appearance of an intracerebral hemorrhage. Blood can be intracerebral, intraventricular, subarachnoid, or some combination of the aforementioned. Calcifications may also be seen. Magnetic resonance (MR) imaging often shows signal voids as a result of traversing vessels and is more accurate at diagnosing AVM, particularly in the unruptured cases. The definitive diagnosis of an AVM is made using conventional cerebral angiography, which shows abnormal blood vessels and the classic early draining veins. In recent years CT angiography and MR angiography have been used increasingly in the diagnosis and evaluation of AVMs; however, therapy is offered only after establishing the diagnosis through a conventional cerebral angiogram (61).

### Therapy

Therapy for AVMs has traditionally been operative. However, treatment of AVMs in critical areas (i.e., speech and motor centers) has been associated with marked morbidity and mortality. Therefore, alternative therapy is sought. Various forms of radiation have been tried and shown to be effective in selective situations (62–64). The limitation has been the size of the lesion. Focused radiation has particularly been effective in smaller AVMs. Gamma knife radiotherapy is now commonly used and can treat lesions up to 3.5 cm in diameter. The results, however, may not be evident for two years.

Concurrent developments of sophisticated flow-directed intravascular catheters and a variety of balloon occlusive devices, both stable and leaking, which allow the placement of glue into AVMs, have also contributed greatly to both the nonsurgical and surgical treatment of these lesions (65). Endovascular occlusion of AVMs can significantly reduce the size of the lesion facilitating operative resection, however, it is not used as the only treatment because of the risk of recanalization of the glued vessels.

Operative excision of small malformations, particularly those on the cortical surface, is usually straightforward (Table 3). Recent major improvements in surgical technique, as well as in nonsurgical methods such as radiographically guided embolization of such malformations,

Source: From Ref. 65.

have made the large lesion somewhat less formidable than before. Nevertheless, large, deep-seated, or precariously located AVMs require a substantial amount of surgical expertise found only in a few centers with significant experience (60,66,67).

The intraoperative management of patients undergoing surgery for large AVMs is critical. Depending on the size and complexity of the AVM, surgery for removal may be done in either single or multiple stages. Staged excision is intended to allow for the gradual redistribution of blood from the AVM to the surrounding brain. Regardless of the staging, great care must be taken to successfully occlude all the vessels. Even small bleeders must be thoroughly coagulated because they may give rise to hemorrhage as the blood flow shifts from the malformation to other portions of the brain.

In the operative treatment of large, high-flow AVMs, catastrophic intraoperative as well as postoperative brain engorgement/hemorrhage can occur. The pathophysiology of such engorgement/hemorrhages lies in the redistribution of blood into vessels in the peri-AVM brain tissues that cannot accommodate the increased blood flow. Vasomotor paralysis ensues with resultant engorgement and hemorrhage. This bleeding, which has been called perfusion pressure breakthrough bleeding, is a major problem during operations on large and deep AVMs (68). Hemorrhage or malignant brain swelling can occur at a distance from the malformation in an area where the vasculature is normal, indicating that tremendous shifts in brain blood flow can occur in such patients. In such occurrences, reduction of cerebral blood flow through hypotension or the induction of barbiturate coma has been the most effective therapy.

### Medical Intensive Care Unit Management

The combination of a large bed of recently divided and cauterized vascular elements and the risk of perfusion pressure breakthrough bleeding makes optimal postoperative management of patients undergoing resection of large AVMs very important. It is crucial that rapid increases in blood pressure during emergence from anesthesia be avoided. ⚡ **Some large and deep AVMs are therefore rejected under deep barbiturate anesthesia. In such cases the goal of a smooth awakening is aided by the slow metabolism of pentobarbital.** ⚡ If this is not the case, sedation must be maintained, often with propofol, to the extent of relaxing

the patient without interfering with extubation. It is important for the anesthesiologist and surgeon to inform the patient thoroughly of the conditions under which he or she will emerge from anesthesia (ICU environment, endotracheal tube, etc.) prior to surgery (58). The blood pressure is frequently kept within very stringent limits (between 110 and 130 mmHg systolic). In the treatment of elevated blood pressure in the postoperative setting, sodium nitroprusside is generally avoided owing to its cerebral vasodilatory effects. Beta blockers such as labetalol are usually used, sometimes in very high dosages. In combination with sedation, these agents are usually sufficient to maintain stable cerebral perfusion dynamics during the critical postoperative period.

## INTRACEREBRAL HEMORRHAGE

### Pathogenesis

Spontaneous intracerebral hemorrhage accounts for as many as 25% of all strokes or up to 100,000 cases a year in the United States (69,70). Sudden intracerebral hemorrhage (ICH) is not always immediately catastrophic, although in many instances death occurs within minutes or hours. ICH is even more likely to result in death and major disability than SAH or ischemic stroke (71). Indeed, 35% to 52% are dead within one month; half of these dying within the first two days, and only 20% are able to live independently at six months (71).

⚡ **Most hypertension-associated hemorrhagic strokes occur in the basal ganglia or the thalamus. An additional 10% occur in the cerebellar hemispheres, and a similar percentage in the brainstem (Table 4) (71).** ⚡ Occasionally, lobar hemorrhages (bleeding in a localized area of the brain near its outer surfaces) result from uncontrolled hypertension. However, amyloid angiopathy is the most common cause of lobar intracerebral hemorrhage in the elderly (Table 5).

### Presentation

Hemorrhagic stroke classically presents as the sudden onset of a focal neurologic deficit that progresses over minutes to hours and is accompanied by severe headache, nausea, and vomiting. If the hemorrhage is large, there is often a rapid decline in the level of consciousness, and there is almost invariably an associated elevation in blood pressure. The clinical presentation is caused by a sudden and progressive expanding lesion that produces both a substantial shift of brain tissue and intracranial hypertension over a relatively short period.

Prognosis for patients suffering hemorrhagic stroke depends on age, location, size, and the rapidity with which the hemorrhage produces brain shift and distortion (72). In a recent Japanese study, 30-day mortality was 0% for cerebellar, 9% for thalamic, 11% for putaminal, 11% for lobar, 14% for caudate, and 53% for brainstem hemorrhage (73).

**Table 4** Location of Intracerebral Hemorrhages

	%

Brainstem	3

Source: From Ref. 70.

**Table 5** Common Causes of Intracerebral Hemorrhage

Hypertension	Most common cause Usually in the basal ganglia, thalamus or pons, but can occur anywhere Possibly secondary to microaneurysms in the lenticulostrates (supply putamen) and basilar pontine branches (supply pons)
Tumor	Tumors are highly vascular and some have a predilection for hemorrhage such as renal cell, choriocarcinoma, and melanoma Lung and breast cancer metastases are the most commonly found tumors, with hemorrhage due to a higher prevalence of these tumors
Amyloid angiopathy	Most common cause of hemorrhage in elderly patients who do not have hypertension Due to abnormal deposition of amyloid in the media of cerebral arteries Tends to be cortical and multifocal
AVM	Intracerebral hemorrhage is the most common presentation for an AVM Hemorrhage may extend to intraventricular space
Aneurysm	Usually cause subarachnoid hemorrhages but if abutting the parenchyma may have intracerebral component to hemorrhage
Stroke	Usually during reperfusion of an ischemic stroke (infarct), the injured area may hemorrhage from damaged vascular endothelium
Coagulopathy	Most commonly from anticoagulation treatment of cardiovascular or ischemic cerebrovascular disease with warfarin Also may be caused by thrombolytics
Infection	Fungal infections may have vascular invasion and consequent intracerebral hemorrhage Herpes virus may cause hemorrhage in the temporal lobes
Miscellaneous	Postoperative after carotid endarterectomy Leukemia Dural sinus thrombosis Substance abuse with cocaine or amphetamines resulting in vasospasm or arteritis

Abbreviation: AVM, arteriovenous malformation.

Source: From Ref. 72.

Outcome is directly related to the level of consciousness at the time the patient is first seen. A patient who has had a severe headache but is awake and stable at the time of hospitalization is likely to survive with optimum therapy, whereas the patient presenting in coma is likely to do poorly despite the most intense surgical and/or medical treatment.

Hemorrhages in the brainstem frequently result in a sudden loss of consciousness and death within a few hours or days. Patients with brainstem hemorrhages characteristically have disconjugate gaze, major disturbances of respiration, and dramatic swings in blood pressure with systemic arterial hypertension. In general, no specific therapy is currently available for such patients. Despite occasional reports of successful evacuation of brainstem hemorrhage, surgery should only be considered in very select cases (Table 6).

**Table 6** Clinical Presentation of Intracerebral Hemorrhages Based on Location

Putamen	Contralateral hemiparesis or hemiplegia Altered level of consciousness if significant mass effect
Thalamus	Contralateral hemisensory loss If internal capsule is involved: hemiparesis If upper brainstem is involved: gaze and pupillary dysfunction
Frontal	Contralateral hemiparesis, usually of arm worse than leg
Parietal	Contralateral hemisensory loss and hemiparesis
Temporal	Dysphasia or aphasia if hemorrhage in dominant hemisphere
Occipital	Contralateral homonymous hemianopsia
Cerebellar	Ataxia If brainstem compression, then also decreased level of consciousness If obstructing fourth ventricle, acute hydrocephalus
Brainstem	Highly variable based on location; including but not limited to cranial nerve deficits, hemiplegia, hemisensory loss

Source: From Ref. 72.

### Diagnostic Evaluation

CT scanning is the imaging test of choice in diagnosing intracerebral hemorrhage. Acute blood is hyperdense to surrounding brain and is readily identified on CT. Magnetic resonance (MR) imaging shows brain anatomy more clearly, but it can be difficult to identify acute hemorrhage on MR. In addition, the time it takes for an MR scan limits its practicality in the acute setting (Figs. 11–14).

**Figure 11** Head computed tomography, noncontrast, demonstrating a left thalamic hyperdensity consistent with acute intracerebral hemorrhage.

**Figure 12** Head computed tomography, noncontrast, with right parietal hyperdensity consistent with acute intracerebral hemorrhage; note hemorrhage extends into right lateral ventricle.

### Therapy

One of the major controversies regarding cerebrovascular disease is the treatment of hemorrhagic stroke. Japanese centers have been extremely aggressive in surgical intervention, in part perhaps because patients present earlier in Japan (74–76). In the United States there appears to be a much higher incidence of delay prior to hospitalization.

Morganstern et al. conducted a small single-center trial of surgical treatment for intracerebral hemorrhage (STICH) comparing standard craniotomy versus medical therapy. Entry criteria were supratentorial location of ICH, with volume  $\geq 10 \text{ cm}^3$ , and GCS between 5 and 15. Of the 34 patients entered, 17 were randomized to surgical therapy. The median time till surgery was 8.3 hours (range, 3.75–26.1 hours). The six-month mortality was 17.6% for the surgi-

**Figure 13** Head computed tomography, noncontrast, with left frontal hyperdensity consistent with intracerebral hemorrhage.

**Figure 14** Head computed tomography, noncontrast, with pontine intracerebral hemorrhage.

cal group and 23.5% for the medical group ( $P = \text{NS}$ ). However, the surgical group had a greater number of hemorrhages located in an unfavorable location; only 1 of 17 patients (6%) had a lobar hemorrhage, whereas 7 of 17 (41%) of the medically treated patients had a lobar hemorrhage ( $P = 0.04$ ).

In further pursuit of an answer to the debate of operative versus nonoperative management, a randomized international surgical trial for intracerebral hemorrhage (ISTICH) is now under way (77). In a recent update, Mendelow, the principal ISTICH investigator, reported on data collected from 985 patients at 107 centers (77). Unfortunately, the operation rates varied between 90% in Lithuania and 2% in Hungary (76). The disparity in operation rates could not be explained by differences in patient characteristics alone. This finding brings questions to the ultimate utility of this study, but also demonstrates the need for further trials given that current treatment for intracerebral hemorrhage appears to be at least partly governed by local custom. Since the treatment of patients with hemorrhagic stroke is still in flux, it is difficult to elaborate a specific set of rules regarding appropriate management.

As noted previously, patients who present awake will generally have a more favorable outcome and are less likely to require surgical intervention. It is the patient who presents with some impairment of consciousness, albeit mild, and then begins to deteriorate who presents the most difficulty (75,78,79). If the hemorrhage is large and located in a portion of the brain not involving the speech or motor systems, aggressive removal is frequently pursued with acceptable results. It appears that many nerve fiber tracts are separated and not destroyed by the intracerebral hemorrhage, particularly in younger patients, and that clot removal, if done through an appropriately placed small cortical incision, will often yield only a modest and relatively remediable neurological deficit. Lesions in the dominant hemisphere are mostly treated nonoperatively in the United States, especially when they are deep seated.

Historically, ICH bleeding was thought to be completed within a few minutes of onset, and the neurological

deterioration resulting mainly from mass effect and cerebral edema. However, recent prospective data show that hematoma growth occurs in at least 38% of patients if scanned within three hours of onset, and that this expansion is highly correlated with neurological deterioration (80). On the basis of these observations, Mayer has hypothesized that ultra-early hemostatic therapy could reduce ultimate ICH volume and improve outcome (80). Mayer further hypothesized that recombinant factor VIIa (rFVIIa) was the most promising agent available as it promotes local hemostasis at sites of vascular injury in both coagulopathic and normal patients.

Mayer et al. presented the results of a recent phase IIb proof-of-concept study at the World Stroke Congress (Vancouver, California, June 26, 2004) (81). In that trial, rFVIIa was shown to reduce the morbidity and mortality of ICH by about one-third of patients (81). Four hundred patients with ICH were randomized to one of four groups (rFVIIa at one of three doses vs. placebo). rFVIIa was administered at 40 mg/Kg, 80 mg/Kg, or 160 mg/Kg versus placebo within one hour of CT-demonstrated intracerebral hemorrhage (performed within three hours of onset of symptoms) in the trial. All three doses reduced the percentage increase in hematoma size (about 5 mL less blood on CT), with an attendant 35% reduction in mortality and morbidity (35). Therefore, treatment with rFVIIa holds promise in the nonoperative treatment of intracerebral hemorrhage. In addition to corroboration of this study with a definitive phase III study, similar trials will also need to be done in operative patients.

### Medical Intensive Care Unit Management

Patients who are operated on for major intracranial hemorrhages require postoperative critical care management similar to that required for head injury. Frequently their decline is precipitous and the recovery period protracted. Respiratory care is particularly important in the early postoperative period.

Significant hypertension is frequent, and a modest attempt should be made to return the patient's blood pressure to pre-morbid levels. Systolic blood pressures under 200 mm Hg are usually tolerated in such individuals, and help prevent hematoma expansion. However, because the majority of these patients are more than 60 years of age and have had long-term hypertension with the attendant arterial changes, vigorous attempts to control the blood pressure may produce symptoms of cerebral ischemia and must be avoided (82–84). It is preferable to tolerate modest hypertension in such situations. After recovery, blood pressures can usually be lowered to a satisfactory range with oral medication.

The patient with hemorrhagic stroke is the stroke patient most often seen in the critical care unit. Owing to the sudden onset of neurological deficits in patients with hemorrhagic stroke, loss of consciousness and inadequate oxygen exchange are often encountered. Careful assessment of the patient's level of consciousness and neurological status provides valuable information about the stability of his or her intracranial compliance. A patient with a known intracerebral hemorrhage who deteriorates from lethargic to unresponsive needs immediate medical evaluation and intervention to control rising ICP (83,85,86).

There are a large number of patients who lie in an area of uncertainty with respect to management. These patients often have relatively large masses with intermediate shift of 3–6 mm and comparatively good clinical states. In these

patients, there is a significant correlation between ICP and clinical status. Therefore, ICP monitoring can be quite useful in guiding management decision (78,79,83,84). If the ICP remains below 20 mmHg, the hemorrhage may be managed nonoperatively in the absence of other surgical indications. Conversely, ICP elevations above 30 mmHg indicate that deterioration is in progress and that surgical intervention should be promptly reconsidered.

### ISCHEMIC CEREBROVASCULAR DISEASE

CVA is a focal neurological deficit of abrupt onset resulting from disturbance of the cerebral circulation and persisting more than 24 hours. Those deficits resolving within 24 hours are referred to as transient ischemic attacks (TIA). The incidence of CVA varies across ethnicities, rises exponentially with age, and is uniformly greater in men than in women. Furthermore, there is a recent increase in the annual incidence of stroke in the United States from 500,000 CVA in 1995 to roughly 750,000 events today (87,88). In total, the overall incidence for stroke has been estimated at 259 per 100,000 (age- and sex-adjusted for the 1995 U.S. population), and approximately 90% of patients undergoing CVA were hospitalized following the onset of symptoms.

The disturbance of the cerebral vasculature that results in focal neurologic deficit generally takes one of two forms. In one, the vasculature is affected by arteriosclerotic changes to produce vessel occlusion and subsequent focal ischemia in a condition referred to as ischemic stroke. In the other, the vasculature is disrupted to such a degree that intracranial bleeding results and a hemorrhagic stroke ensues. This following section will focus on the former form of cerebrovascular disease, ischemic stroke, which has been estimated to constitute roughly 85% of the cerebrovascular disease encountered in the clinical setting.

### Pathophysiology

In order to sustain its normal level of function, the brain must maintain a highly active metabolic milieu. Although accounting for only 2% or so of overall body weight in the average adult, it receives roughly 20% of cardiac output at rest. Moreover, the brain is an obligate aerobe, highly dependent on the oxidative metabolism of glucose to meet its metabolic needs. Estimates of cerebral metabolic demands suggest that the average brain consumes roughly 50 mL of oxygen and 100 mg of glucose every minute. Consequently, the brain is exquisitely dependent on the maintenance of cerebral blood flow (CBF) for its continuing function. Mean CBF in the cortex has been estimated as roughly 50 mL/100 g/min. The cerebral vasculature maintains this value via autoregulation (vasodilation with lower pressures, and vasoconstriction in response to elevations in mean arterial pressure). Once the mean arterial pressure drops below the autoregulatory setpoint of around 50 mmHg, the cerebral blood flow drops down below the normal 50 mL/100 g/min. The brain has additional reserve mechanisms for lower flows, and is able to maintain brain oxygenation during a decrease in CBF to as low as 20 to 25 mL/100 g/min by increasing its oxygen extraction. Below that threshold, however, oxygen extraction fails and ischemic processes ensue that may progress to infarction.

✎ **Two distinct mechanisms by which CBF fails secondary to occlusion of the cerebral vasculature are**

generally recognized, one involving local thrombosis and the other embolism. ⚡

Thrombosis of larger vessels (so-called atherothrombotic stroke) is rare and generally results from clotting initiated by debris originating from intracranial atherosclerotic plaques. This process may be slow in evolution and thus thrombotic stroke may take the form of so-called “stroke in progression,” in which neurologic deficits progress over a few hours or days. Whether the progressive thrombosis occurs in a smaller vessel or a major vessel such as the internal carotid artery, heparin and thrombolytic therapy may arrest progression. Local thrombosis is also seen in small intracranial vessels (~30 to 100  $\mu\text{m}$  in diameter) and results in so-called “lacunar strokes,” in which a small volume of brain tissue supplied by an occluded end artery infarcts. In such cases, the most likely underlying pathology involves either lipohyalinosis or microthromboma and overlying thrombosis within the vascular lumen. Clinically, these insults may be asymptomatic or may produce a wide array of subcortical deficits.

Embolic stroke is classically differentiated from thrombotic stroke by the greater acuity of its onset and the maximal extent of its deficits at that time. The classical presentation is a transient alteration of mono-ocular vision called an amaurosis fugax or transient motor or speech dysfunction. Vessels in the middle cerebral artery distribution are the most commonly affected. A common source of emboli into the cerebral vasculature is an atherosclerotic plaque in a portion of the arterial tree proximal to the embolic destination. Such plaques, whether in the intracranial vasculature itself, along the course of the extracranial carotid artery (Fig. 15), or within the aortic arch, can generate thrombotic lesions that dislodge from the friable plaque and travel down arterial lumina of decreasing diameter until reaching a distal occluding point. Strokes of this sort are referred to as atherothromboembolic strokes. Another source of emboli is the heart itself. Strokes of this type, cardioembolic strokes, can involve a variety of emboli. Although most commonly consisting of red atrial thrombi as are generated in conditions such as atrial fibrillation, cardiogenic emboli may also consist of material such as infective elements from valvular lesions, necrotic endocardial tissue after acute myocardial infarct, and any of a number of entities from the venous system in the case of paradoxical emboli traversing a persistent foramen ovale. Embolic strokes have a higher risk of transforming into hemorrhagic strokes in which petechial or frank hemorrhage into the infarcted tissue follows the initial ischemic insult by hours or days (89).

**Table 7** Differential Diagnosis of New, Sudden-Onset Neurological Deficit

Stroke/TIA
Postictal Todd's paralysis
Tumor
Migraine
Trauma: e.g., epidural hematoma, subdural hematoma
Infectious encephalopathy: e.g., abscess, encephalitis
Metabolic encephalopathy: e.g., hypoglycemia, drug toxicity, hepatic encephalopathy

Abbreviation: TIA, transient ischemic attacks.

### Laboratory and Radiological Evaluation

The history of acute disease presentation in a patient with a new focal neurological deficit is exceedingly important in establishing a diagnosis of cerebrovascular disease. The physical examination identifies the extent of the patient's pathology. In atypical patients, intoxicant and medication history may be particularly relevant (Table 7). Even if the differential has been narrowed to CVA versus TIA, neither history nor physical can distinguish between ischemic and hemorrhagic causes. Accordingly, a noncontrast CT of the brain must be obtained immediately after presentation with a new focal neurological deficit. ⚡ **Should the CVA prove to be of the ischemic variety (Fig. 16), immediate initiation of thrombolytic therapy should be considered (90).** ⚡ If the CVA is of the hemorrhagic variety, thrombolytics and anticoagulants are contraindicated and clinical management should involve neurosurgical consultation. Ultimately, carotid Doppler ultrasound, MRI and MRA, and increasingly CT angiogram are useful in the workup of stroke (Figs. 17 and 18) (91–93).

The patient's vital signs will guide the evaluation of airway and respiratory management as well as the cardiovascular status, e.g., hypotension or hypertension. A

**Figure 16** Head computed tomography, noncontrast, with left frontoparietal hypodensity consistent with left middle cerebral artery ischemic stroke.

**Figure 17** Magnetic resonance angiogram, diffusion weighted, with left cerebellar hyperintensity consistent with acute stroke.

complete blood count can suggest infectious causes of neurological deficit and diagnose polycythemia, thrombocytopenia, or thrombocytosis. A coagulation panel may detect hypo- or hypercoagulable states. Hypoglycemia will be detected by the metabolic panel, which also guides initial fluid resuscitation. A lipid panel may guide evaluation of the proximal arterial tree for atherosclerotic plaques, whereas an electrocardiogram may suggest (e.g., with a reading of atrial fibrillation) a cardiac source. A toxicology screen may suggest a triggering substance, but it will also guide initial management if the patient is prevented from gaining access to substances of chronic abuse when admitted. Finally, a chest radiograph will indicate whether or not the patient has suffered an aspiration incident (Tables 8 and 9).

### Management

Initial management of a patient who presents with a new, abrupt-onset neurological deficit goes hand in hand with assessment. Airway management, respiratory control, and cardiovascular status must be assessed and addressed prior to any further evaluation. Once the patient is sufficiently stable, neuroimaging must be obtained. A noncontrast head CT remains the imaging modality of choice in the setting of acute stroke for its rapidity, relatively low expense, and clarity in identifying new hemorrhage. When imaging indicates a hemorrhagic condition, appropriate measures should be immediately implemented (see above). If, however, CT reveals a normal or hypodense area consistent with acute ischemic stroke, the patient should be admitted to a level of care appropriate to disability and concomitant medical issues, and treatment should be initiated to reverse or reduce the amount of tissue undergoing ischemia and/or infarction. These treatments fall into five broad categories: (i) supportive care, (ii) thrombolytic therapy, (iii) anticoagulation, (iv) antiplatelet medication, and (v) neuroprotective measures.

**Table 9** Uncommon Causes of Stroke

Disorder	Examples
Hypercoagulable states	Protein C deficiency Protein S deficiency Antithrombin III deficiency Antiphospholipid syndrome Factor V Leiden mutation Malignancy Polycythemia vera Systemic lupus erythematosus Nephrotic syndrome Inflammatory bowel disease
Fibromuscular dysplasia	Increased muscle and fibrous tissue in arterial wall of carotid and cerebral arteries Also affects kidneys, coronary arteries, mesenteric arteries, and iliac arteries
Vasculitis	Primary CNS vasculitis Systemic vasculitis (e.g., giant cell)
Cardiogenic syndrome	Atrial myxoma Marantic endocarditis Libman-Sacks endocarditis Mitral valve calcification

### Supportive Care

The immediate goal of supportive care in patients suffering cerebral ischemia is optimization of cerebral perfusion to the at-risk periphery of the ischemic insult, the so-called "ischemic penumbra." Hypertension should be treated in the acute phase unless either cardiac risk factors are too great (in which case, rate reduction with the beta-1 antagonist esmolol is a first step) or malignant hypertension is developing. Hypotension should be addressed with intravenous fluids or vasopressor medications. Measures to facilitate prevention and treatment of common complications in debilitated patients such as pneumonia, urinary tract infections, or deep venous thrombosis formation are instituted. Fever is detrimental to neurons and should be treated aggressively with antipyretics. In the intermediate term, cerebral edema is a common sequela after ischemic insult (89). This effect peaks on roughly the second or third day after injury and persists for up to two weeks. In 5% to 10% of cases, edema is adequate to cause brain shifts leading to obtundation or coma. Care must be taken, therefore, to monitor progression of symptoms. Both medical and surgical management of ICP are instituted where adequate.

### Thrombolytics, Anticoagulants, and Antiplatelet Drugs

Extensive study has been dedicated to the use of thrombolytic agents in acute ischemic cerebral infarct. Particular attention has been paid to recombinant tissue plasminogen activator (rtPA). Because of significant variations in study design, however, the precise effectiveness of intravenous thrombolytic agents for acute ischemic stroke remains unclear. The risk of intracranial hemorrhage is well established and appears to increase with increased size of infarct, increased duration of symptoms, and increased dose of rtPA administered (94). The drug is now approved for use in the United States and Canada within three hours of onset based on certain selection criteria (Table 10). Onset of symptoms is defined by either the moment symptoms

began or the last time the patient was observed at baseline. Consequently, patients "found down" or awakening with symptoms must have their onset of symptoms set at the last witnessed episode during which they were seen to be baseline (Table 11) (95). Studies are currently under way to evaluate the benefit of intra-arterial thrombolytic administration, but FDA approval has not yet been obtained.

The role of anticoagulation in the setting of acute ischemic stroke is unclear. Results from clinical trials do not support the use of heparinization for patients with atherothrombotic stroke of greater than 12 hours' duration. Heparin is widely used in the context of so-called "crescendo TIA," in which TIAs follow rapidly on one another with increasing frequency and severity. However, no definitive clinical evidence supports this practice. Since approximately 20% of patients with acute stroke show a continuing neurological decline over several hours to days, many physicians heparinize all patients with recent mild ischemic stroke to avoid this progression; some advise heparinization until demonstration of patency of all major carotid and intracranial vessels (96,97). In view of the 10% bleeding complication rate per week from heparinization, the value of this approach remains to be clarified.

Aspirin is the only antiplatelet agent demonstrated effective in prospective clinical trials for the treatment of acute ischemic stroke. These trials [international stroke trial (IST) and Chinese acute stroke trial (CAST)] show that the use of aspirin (150–300 mg) within 48 hours of the onset of symptoms is safe and produces a small, but definite net benefit in reducing both recurrence risk and mortality (98). For every 1000 patients given aspirin for acute ischemic stroke, roughly 9 patients will avoid death or nonfatal stroke recurrence in the early poststroke weeks and approximately 13 fewer will have died or been debilitated (98–101).

**Table 10** Criteria for Recombinant Tissue Plasminogen Activator Eligibility in Setting of Acute Ischemic Cerebrovascular Accident

Indications	Contraindications
Clinical diagnosis of stroke	Sustained BP >185/110
Onset of symptoms less than three hours prior to rtPA administration	Platelets <100,000 Hematocrit <25% Glucose <50 or >400
CT scan showing no hemorrhage or significant edema	Use of heparin within 48 hours and prolonged PTT, or elevated INR
Patient age at least 18 years	Rapidly improving symptoms
Consent by patient or surrogate	Prior stroke or head injury within 3 mo Prior intracranial hemorrhage Major surgery in preceding 14 days Minor stroke symptoms Gastrointestinal bleeding in last 21 days Recent myocardial infarction Coma or stupor

Abbreviations: BP, blood pressure; CT, computed tomography.

**Table 11** Interventions Required for the Administration of Recombinant Tissue Plasminogen Activator for Acute Ischemic Cerebrovascular Accident

Intervention	Comments
Intravenous access	Two peripheral intravenous lines (arterial and central venous lines are to be avoided)
Bolus dose	Administer 0.9 mg/kg (to a maximum of 90 mg) intravenously as 10% total dose by bolus, followed by remainder of total dose over 1 hr
BP monitor	Continuous cuff manometer blood pressure monitoring, or arterial line (if patient debilitated)
Additional anticoagulants	No other antithrombotic treatment for 24 hr, no other anticoagulants
Reasons to halt therapy	Decline in neurologic status Uncontrolled blood pressure
Additional treatment for neurological decline or uncontrolled BP requiring cessation of Rx	Administer cryoprecipitate Reimage brain emergently Avoid urethral catheterization or other elective invasive procedures for 2 or more hours

## MISCELLANEOUS CEREBROVASCULAR LESIONS

### Traumatic Aneurysms

Traumatic aneurysms comprise <1% of all intracranial aneurysms and are by definition false aneurysms (102). The aneurysm dome is formed by the surrounding cerebral structures and blood clot, subsequent to perforation of all layers of the vessel wall. This usually results from either penetrating head trauma or closed head injury. Penetrating trauma with gunshot wounds or actual penetration with a sharp object directly lacerates the vessel wall (103). The mechanisms behind the creation of traumatic aneurysms after closed head injury are less well understood, with the most widely accepted theories being either traction injury to the vessel wall or entrapment within a fracture. Traumatic aneurysms in closed head injury are usually accompanied by basal skull fractures (104).

☞ **Any patient with significant SAH or intraventricular hemorrhage after penetrating head injury should be evaluated for a traumatic aneurysm. Also, dense subarachnoid blood after head trauma or delayed intracranial hemorrhage after head trauma should raise suspicion for traumatic aneurysm, and cerebral vessel evaluation with MRA or CT angiogram is essential.** ☞ Traumatic aneurysms have a high rate of rupture and direct treatment is recommended. Internal carotid aneurysms at the skull base should undergo balloon trapping or embolization, and peripheral aneurysms should undergo endovascular coiling or clipping (105).

### Cerebral Venous Thrombosis

Intracranial venous thrombosis can develop rapidly with grave consequences. The thrombosis reduces venous outflow from the brain. The resultant venous engorgement causes white matter edema, which may cause cerebral venous infarction and intraparenchymal hemorrhage (106,107). This ultimately leads to elevated ICP, the severity of which will dictate neurological deterioration and clinical presentation. The patients usually have headache and nausea/vomiting, papilledema, blurred vision, seizures, and altered level of consciousness (108). The etiologies behind the development of cerebral venous thrombosis are many, but most include some element of hypercoagulable state, dehydration and/or trauma (Table 12).

The diagnosis is made with either a CT scan or MR study. Often the CT scan is performed first. The finding of hyperdense sinuses and veins and/or petechial intracerebral hemorrhages occurring bilaterally is highly suggestive of venous thrombosis (109). MRI with MR venogram is the mainstay of diagnosis. It is superior to CT in demonstrating both vascular and parenchymal changes and can differentiate an occluded sinus from its congenital absence (109,110).

**Table 12** Etiologies of Cerebral Venous Thrombosis

Infection
Pregnancy
Dehydration
Ulcerative colitis
Diabetic ketoacidosis
Trauma
Iatrogenic
Hypercoagulable state

Source: From Ref. 99.

☞ The treatment of cerebral venous thrombosis should be aggressive, yet with the caution that interventions that counteract thrombosis tend to increase the risk of hemorrhage. ☞ The ICP should be monitored in the obtunded (GCS  $\leq 8$ ) patient. Hypertension should be controlled and any underlying abnormality that may have precipitated the event should be corrected. Also, the patient should be hydrated and treated with anticonvulsants. The mainstay of therapy is systemic heparin and conversion to Coumadin beyond the intensive care period. However, there is no consensus on the duration of these therapies (111,112). Even in the setting of intracranial hemorrhage, heparin remains the best treatment (113). If the patient continues to deteriorate, tPA systemically or locally injected into the clotted sinus can be attempted. Surgical or endovascular thrombectomy and surgical sinus reconstruction is rarely indicated due to the excessively high rates of rethrombosis (114).

### Carotid Cavernous Sinus Fistulae

Carotid-cavernous sinus (CC) fistulae are rare vascular anomalies. They can arise spontaneously or result from maxillofacial and head trauma (60–80%) (115). The carotid artery courses through the cavernous sinus en route to its intradural distribution; subsequently perforations during this segment can lead to CC fistulae. The clinical features may include proptosis, chemosis (arteriolization of conjunctiva), bruit, ophthalmoplegia, visual deterioration, orbital pain and/or headache. Occasionally CC fistulae may present with SAH (115).

A bruit over the eye may be palpable or heard with a stethoscope, raising suspicion for a CC fistula, while the diagnostic procedure of choice is a cerebral angiogram. Because traumatic CC fistulae are high-flow vascular abnormalities and spontaneous closure is uncommon, intervention is indicated. The untreated patient may not deteriorate rapidly; the usual course is one of progressive visual loss from decreased retinal blood flow (116). Intolerable bruit and/or disfiguring proptosis may also progress.

Various approaches have been used to treat CC fistulae. The current treatment is occlusion of the fistula using a detachable balloon and/or coils with preservation of blood flow in the carotid artery. If this is technically unfeasible, two balloons may be placed on either side of the fistula to trap it, resulting in the deliberate sacrifice of the carotid artery. Test occlusion must be performed to establish patency of the circle of Willis, and the ability of the patient to tolerate loss of internal carotid artery flow to the distribution distal to the CC fistula (116,117).

## EYE TO THE FUTURE

Expanding the horizon for improvement of therapeutic interventions in the arena of cerebrovascular disease is imperative given the morbidity and mortality associated with these disease entities. Future directions in the treatment of cerebrovascular diseases aim to correct the underlying pathologies and the deleterious ischemic effects they produce on the brain.

Tremendous improvements in endovascular occlusion of aneurysm and AVMs have recently occurred. Current investigations are exploring the use of even smaller microcatheters for the delivery of devices farther into the cerebrovasculature. Porous stents are being developed to provide

a scaffold onto which wide-based aneurysms may be coil occluded without the risk of coil embolization (118–120).

Intracerebral hemorrhage management continues to be investigated. Thrombin is being studied as a major mediator of perihematoma edema. Accordingly, the use of antithrombin therapy for ICH management is being explored (121). Additionally, many patients requiring urgent neurosurgical intervention have coagulopathies. Standard use of blood products, including fresh-frozen plasma or cryoprecipitate to correct the coagulopathy, often leads to significant delays in treatment. Recombinant activated factor VII (rFVIIa) has recently been shown to reverse the coagulopathy in neurosurgical patients with intracerebral hemorrhage (ICH), intraventricular hemorrhage (IVH), hydrocephalus, diffuse cerebral edema, and epidural hematoma as early as 20 minutes after infusion (122). There were no procedural or operative complications, no postoperative hemorrhagic complications, and no thromboembolic complications observed with the use of rFVIIa in this group of patients (122). These experiences combined with the demonstrated 35% reduction in mortality and morbidity in hemophiliac patients with ICH treated with rFVIIa is likely to promote rFVIIa toward a mainstream treatment following ICH in the near future (80,81). More studies are currently required to provide dosing studies, and to review thrombotic complications in greater degree (122). Surgical approaches using early CT-guided clot aspiration and tPA for clot lysis remain possibilities as minimally invasive surgical approaches to intracerebral hematoma evacuation are developed (123,124).

Future directions in the management of acute cerebral ischemia focus on reperfusion and neuronal protection. Although intra-arterial thrombolysis was demonstrated to be effective in the prolyse in acute cerebral thromboembolism II (PROACT II) study, its use has been limited. Current investigations are exploring the use of both intravenous and intra-arterial thrombolysis as a sort of “bridging therapy” that may offer benefit over either alone in reestablishing blood flow.

A new, more potent form of tissue plasminogen activator t-PA, called TNKase™ (Tenecteplase), has recently been produced by Genetech (South San Francisco, California). TNKase™ is produced using recombinant DNA technology, and holds promise for accomplishing clot dissolution with fewer bleeding complications than t-PA. This new drug can be delivered faster as a single intravenous treatment rather than the prolonged infusion ordinarily needed to give t-PA. In the presence of fibrin, *in vitro* studies demonstrate that Tenecteplase conversion of plasminogen to plasmin is increased relative to its conversion in the absence of fibrin. This fibrin specificity (10 times more than normal t-PA) decreases systemic activation of plasminogen and the resulting degradation of circulating fibrinogen, and unwanted bleeding. A multicenter clinical trial is currently under way, with regional coordination occurring at two major university stroke centers, University of California, San Diego (UCSD) Medical Center, and the University of Virginia Health System in Charlottesville, VA. TNK is administered to patients who arrive at hospital emergency rooms with significant stroke three hours or less from symptom onset (personal communication from Patrick Lyden, M.D., UCSD Stroke Center director). The first phase of the study was completed in April 2004, and the results are in press; phase 2 (dosing regimen review) will begin in December 2004.

In the realm of neuronal protection, clinical administration of current pharmacological agents such as NMDA antagonists, calcium channel blockers, anti-inflammatory antibodies, and free-radical scavengers, have yet to demon-

strate conclusive benefit in a large, prospective, randomized efficacy study (125,126). Nevertheless, animal models have demonstrated a beneficial effect using antioxidants to limit lipid peroxidation, an essential step in the pathogenesis of cerebral ischemia. Future research will continue to explore the molecular basis of cerebral ischemia and develop opportunities for the management of cerebral ischemia. This may include the use of neuronotrophic factors.

## SUMMARY

Intracerebral vascular catastrophes have diverse etiologies but their effects on the brain share many common features. Management of ischemic insults is guided by many of the same basic principles of emergent neurosurgical intensive care. The patients receive basic cardiopulmonary support to protect the airway and maximize cerebral perfusion. Often this requires intubation and ICP management. Ultimately, ensuring adequate cerebral blood flow and neuronal preservation are the key goals of therapy.

Nontraumatic SAH is almost always secondary to aneurysmal hemorrhage and necessitates immediate intervention. Diagnostic evaluation for the possible aneurysm should be performed urgently with MRA or CT angiogram. Ultimately a cerebral four-vessel angiogram is necessary to plan exclusion of the aneurysm from the cerebral circulation with endovascular coils or surgical clipping. The clinician should maintain high suspicion for the complications that may arise, such as hydrocephalus and vasospasm.

Intracerebral hemorrhage, when in eloquent areas of the brain or large enough to cause significant mass effect, is a devastating event. Controversy exists regarding the timing and indications for operative evacuation, and is generally reserved for patients with acute mass effect and the possibility of a functional postoperative recovery. Ultra-early administration of rVIIa may soon become the standard of care for ICH management and viewed as the counterpart to thrombolytic treatment of acute ischemic stroke.

AVM hemorrhage may also present as an intracerebral hemorrhage, often with ventricular extension of the blood. Cerebral angiography is necessary for definition diagnosis and formulation of a treatment plan. In the nonemergent setting, most AVMs are treated with endovascular occlusion, stereotactic radiation and/or surgical resection. In large and deep AVMs, intraoperative challenges of hemostasis and potential cerebral edema/brain engorgement persist, and appropriate measures such as barbiturates may need to be instituted.

Ischemic cerebrovascular disease is associated with certain risk factors and may lead to fixed neurological deficit. Its management in the acute setting begins with a noncontrast CT of the head to exclude a hemorrhagic stroke, which would be a contraindication for rtPA. If certain inclusion criteria are met, rtPA is indicated. Subsequently, a workup for the particular etiology of the stroke is pursued to guide long-term management.

Future challenges include the selective elimination/correction of the underlying vascular pathologies, reestablishment/maintenance of adequate cerebral blood flow, and promotion of neuronal viability and function.

## KEY POINTS

- ✦ The mortality associated with the initial hemorrhage is around 20%.

- 9 Saccular aneurysms must be differentiated from traumatic, dissecting, mycotic and/or tumor-associated aneurysms because the classification dictates management.
- 9 Immediately following documentation of SAH, attention is directed toward the identification of the responsible vascular abnormality, most commonly a ruptured aneurysm.
- 9 Patients with a lower Hunt and Hess grade (Hunt and Hess grade I–III) should undergo an urgent craniotomy and surgical clipping of anatomically accessible (anterior circulation) aneurysms.
- 9 The goal of treatment is to secure the neck of the aneurysm by clipping, so that the common complications of SAH, such as rebleeding, vasospasm, and hydrocephalus can be eliminated or maximally treated.
- 9 Coil occlusion is indicated for the treatment of aneurysms which are: (i) difficult to clip surgically, (ii) occur in patients who are unsuitable for early surgery due to a poor SAH grade, and (iii) occur in patients who are medically unstable.
- 9 Due to its noninvasive nature, TCD should be performed daily or every other day after aneurysmal SAH, reserving angiography for the diagnostic confirmation and therapeutic intervention of clinical vasospasm.
- 9 The mainstay of therapy in the United States, once clinical vasospasm is suspected or confirmed, is nimodipine (to minimize vasospasm) and “triple-H” therapy; the three H’s being hypervolemia, hypertension, and hemodilution.
- 9 Electrocardiogram (ECG) changes are common in patients with SAH, even in patients without prior history of cardiac disease.
- 9 After rebleeding, vasospasm, and hydrocephalus, morbidity following SAH can be attributable to pulmonary complications including pulmonary edema, pneumonia and/or pulmonary embolism.
- 9 AVMs are the leading cause of SAH in young people although they account for only 5% of SAH in adults.
- 9 Some large and deep AVMs are resected under deep barbiturate anesthesia. In such cases the goal of a smooth awakening is aided by the slow metabolism of pentobarbital.
- 9 Most hypertension-associated hemorrhagic strokes occur in the basal ganglia or the thalamus. An additional 10 percent occur in the cerebellar hemispheres and a similar percentage in the brainstem (Table 4).
- 9 Two distinct mechanisms by which CBF fails secondary to occlusion of the cerebral vasculature are generally recognized. One involves local thrombosis and the other embolism.
- 9 Should the CVA prove to be of the ischemic variety (Fig. 16), immediate initiation of thrombolytic therapy should be considered.
- 9 Any patient with significant SAH or intraventricular hemorrhage after penetrating head injury should be evaluated for a traumatic aneurysm. Also, dense subarachnoid blood after head trauma or delayed intracranial hemorrhage after head trauma should raise suspicion for traumatic aneurysm, and cerebral vessel evaluation with MRA or CT angiogram is essential.
- 9 The treatment of cerebral venous thrombosis should be aggressive, yet with the caution that interventions that counteract thrombosis tend to increase the risk of hemorrhage.

### INTRODUCTION

Optimum management of pediatric neurosurgical emergencies requires the collaborative involvement by numerous specialties within a trauma center. This chapter describes the major pediatric neurosurgical conditions encountered, with an emphasis on the information that would aid trauma surgeons or critical care physicians in the management of such children. Other consulting specialties should also find this information germane when assisting in the management of pediatric neurosurgical patients.

Traumatic brain injury (TBI) is a significant cause of morbidity and mortality in children. This chapter emphasizes the injuries and pediatric management considerations that are dissimilar from those of adult trauma. Children engage in activities that can be associated with penetrating injuries; these lesions will also be explored. Traumatic birth injuries can lead to devastating effects that persist throughout life; accordingly, these are briefly reviewed. Trauma-related cerebral vascular lesions in children share significant overlap with those occurring in adults; hence, only the key points and the few pediatric-specific points will be discussed here. However, vascular lesions unique to children, such as vein of Galen aneurysms, which have classic clinical presentations, are reviewed in greater detail. Hydrocephalus, congenital or acquired, can present acutely and require emergent care as well. Pediatric tumors and infections are briefly discussed with an emphasis on the emergent issues. The chapter concludes with a discussion of pediatric intensive care unit (ICU) complications, and the "Eye to the Future" section reviews neuroprotective strategies and drugs that are currently under investigation.

### PEDIATRIC-SPECIFIC INTRACRANIAL PRESSURE CONSIDERATIONS

Most neurosurgical catastrophes result from acute increases in intracranial pressure (ICP). The physiologic mechanisms that maintain the balance between pressure and volume inside the skull and dural sac were reviewed in Volume 2, Chapters 1 and 7, and are largely similar in adults and children (1,2). However, following trauma and other pathologic conditions, the manifestations of elevated ICP can be quite different in neonates and in children. This chapter provides an abbreviated review of ICP physiology, with a focus upon considerations that are specific to pediatric neurosurgical emergencies.

The contents of the intradural space are brain, brain stem, spinal cord, blood, and cerebral spinal fluid (CSF). **☞ In an infant, with an open fontanel and open cranial sutures, small increases in the volume of intradural contents can be accommodated by separation of the sutures and distention of the fontanel.** **☞** This accommodation is generally achieved with a gradual increase in intradural volume. However, a sudden large increase in the intradural contents will only be minimally accommodated by distention of the dural sac and an open fontanel; under these circumstances, ICP will increase dramatically, as in adults.

The intradural space is divided into a series of compartments by the foramen magnum and the folds of the dura, the falx, and the tentorium. The compartments are important because increases in pressure in one compartment can result in distortion and displacement of brain into another compartment, with consequent tissue and vascular compression, ultimately resulting in brain dysfunction and

herniation. The most frequent location for cerebral herniation is at the tentorial hiatus. Supratentorial pressure causes distortion and displacement of the mesial temporal lobe or lobes, forcing the parahippocampal gyrus through the tentorial notch (transtentorial herniation), thereby compressing the brain stem—perforating vessels, the posterior cerebral arteries, and the perforating vessels to the thalamus.

☞ **In children, hemiparesis occurs on the side ipsilateral to the herniation 50% of the time, whereas in adults hemiparesis is ipsilateral to the herniation 75% of the time.**

☞ Hemiparesis occurring on the same side as the intracranial lesion is due to the effect of brain stem itself shifting away from the mass and impinging upon Kernohan's notch of the tentorium, and is referred to as Kernohan's phenomenon. Why this occurs more often in children is unknown. But this finding can cause clinical confusion in pediatric neurosurgery, and must be quickly resolved with a neuroimaging study. Impending foramen magnum herniation can be heralded by complaints of headache and neck pain. The pain may initially be relieved by extension of the neck. As herniation progresses, the medulla oblongata is compressed with resulting elevation in ICP, systemic hypertension, and bradycardia (Cushing's triad), along with bradypnea, and finally apnea. In some cases, the onset of apnea may be preceded only by severe headache or neck pain with no other clinical signs.

A mass in the posterior fossa (common site for pediatric brain tumors) can occasionally cause herniation of the cerebellar vermis upward through the tentorial notch, with compression of the brain stem and posterior cerebral and thalamic perforating vessels. In children, this "upward herniation" is frequently precipitated by abrupt drainage of the lateral ventricles in the presence of a posterior fossa mass.

In addition to causing distortion and herniation of neural tissue and focal vascular compression, elevated ICP can affect general cerebral blood flow (CBF). As occurs in adults, the cerebral blood vessels of children exhibit autoregulation in response to changes in cerebral perfusion pressure (CPP). However, the range of autoregulation is different in children compared to that in adults. The CPP formula is provided below (where MAP is mean arterial pressure and ICP is intracranial pressure):

$$CPP = MAP - ICP$$

The cerebral vessels respond to a decrease in CPP by vasodilatation, decreasing resistance to flow and thus maintaining the same CBF despite either a decline in MAP or an increase in ICP. The exact limits of autoregulation are not known through the period of infancy and childhood but probably range between 35 and 40 mmHg at the lower end and is greater than 100 mmHg at the upper end. Below the limits of autoregulation, the CBF decreases as the CPP is lowered. Cerebral metabolism is preserved to a CBF of about 50% of normal, after which some degree of cerebral ischemia begins. As CBF decreases below 25% of normal, irreversible brain damage begins. Thus, autoregulation is a further brain-protective mechanism against increased ICP. Trauma in children often leaves autoregulation intact, whereas ischemia seems more likely to abolish autoregulation, making the CBF more sensitive to small changes in the CPP. ☞ **Unfortunately, the status of autoregulation is not known in the clinical setting, and thus therapy is directed at maintaining normal or nearly normal ICP and MAP in the hope that this will preserve CBF.** ☞ When the ICP is too high, or the MAP is too low, the CPP will be

inadequate to maintain CBF, and cerebral ischemia will result. The ultimate manifestation of this deficit is the cessation of CBF that results in brain death (2).

Before any surgical intervention, resuscitation of a child with a neurosurgical catastrophe addresses the usual concerns of airway patency, bleeding, and circulation. Specific therapy to lower the ICP (e.g., mannitol) depends on the severity and rapidity of the ICP elevation along with an evaluation of the degree of neurologic deterioration. The history is often the deciding factor, because absolute signs of intracranial hypertension are difficult in pediatrics, depending on the rate of increase in ICP. Papilledema is a sure sign of intracranial hypertension but is often absent because of the rapidity of the onset of symptoms or because the anatomy of the subarachnoid space in the optic nerve is such that papilledema does not occur. ☞ **Acute loss of consciousness after pediatric head trauma is less commonly the result of increased ICP unlike in adults. Accordingly, osmotic diuretics should not be routinely administered to children in coma after head trauma.** ☞

The most important initial issues to address in the child with TBI are the airway, breathing, and circulation (ABCs). When intracranial hypertension is suspected in a comatose child, endotracheal intubation is performed. Next, the immediate clinical presentation is addressed. Is the patient unconscious, seizing, posturing, exhibiting abnormal respiratory patterns, protecting his/her airway, displaying any focal neurologic deficits, or exhibiting any signs of high ICP? This information is quickly processed as a head computed tomography (CT) scan is being arranged. As the patient is being transported to CT, one can attain further details surrounding the injury. Indeed, from compiling the history and physical, one should have a pretty accurate prediction of what the head CT will reveal.

If a patient has a significantly large acute mass-occupying lesion, the child must be immediately rushed to the operating room for evacuation. If, on the other hand, there is no space-occupying lesion (just diffuse swelling), or a relatively small lesion, the patient may be initially managed nonoperatively in the ICU.

In the ICU, the head is maintained midline and (if the MAP is adequate and concomitant spinal trauma is ruled out), the head is elevated 30 degrees. The most important information in the brain-injured patient is the neurologic examination. ☞ **A reliable and reproducible neurologic examination is much more important than any number or value from an ICP monitor or ventriculostomy catheter.** ☞ If the child is at least able to localize the pain, the clinical neurologic examination is the best method of monitoring neurologic status. Close, hourly neurologic examinations should be able to detect any deterioration under these conditions. If the patient does not have a reliable examination either due to injury, intubation, or medications, ICP monitoring is required. However, an ICP monitor should only be placed after early resuscitation and verification that coagulation factors and platelets are adequate.

The preferred method of choice for ICP monitoring in children is with a ventriculostomy catheter (in infants the fontanel can be safely drained with a butterfly needle as needed). The ventriculostomy provides not only a reliable method of ICP monitoring, but also allows for efficacious treatment of high ICP pressures by drainage of CSF. There are certainly other means for treating high ICP, including hyperventilation, head elevation, sedation, mannitol, hypertonic saline, and so on. However, particularly in the setting of an acute closed head injury, the primary means of treating high ICP should always be CSF drainage. For this reason,

ventriculostomy placement is the first method of choice for ICP monitoring (see Volume 2, Chapter 12, Fig. 10). If a ventriculostomy cannot be placed, then other means of ICP monitoring must be employed. The first 24 to 72 hours following a head injury are the most critical. If a ventriculostomy is present, one should be liberal in CSF drainage if the patient is exhibiting high ICP. In most instances, leaving the ventriculostomy open to drain at 15 cm of water pressure represents the optimum management. After allowing a few days for resolution of edema and secondary changes, the ventriculostomy should be weaned by slowly raising the drain reservoir height, then eventually clamping it. Some pediatric TBI patients will not be able to be weaned from ventricular drainage and will require placement of a ventriculoperitoneal (V-P) shunt (1–4).

## CLOSED HEAD TRAUMA

Traumatic lesions that require surgical therapy in children are less common. They occur in 20% to 30% of children with a Glasgow Coma Scale (GCS) score  $\leq 8$ . Traumatic unconsciousness is a neurologic emergency, and although it may be associated with elevated ICP, it most often requires rapid resuscitation rather than surgical intervention. **Lesions that may require immediate surgery are intracranial hematomas, compound depressed skull fractures, and penetrating trauma.** Post-traumatic subarachnoid hemorrhage (SAH), brain swelling, brain edema, arterial spasm, and focal strokes are all lesions not improved by surgery. Traumatic lesions that evolve over time and ultimately do require acute surgery include post-traumatic hydrocephalus, delayed intracranial hemorrhage, and ruptured traumatic aneurysm. Post-traumatic hydrocephalus can occur anytime up to one year after the injury, but most commonly requires a shunt in the first three months following the trauma. Delayed intracranial hemorrhage and ruptured traumatic aneurysm generally occur 7 to 14 days after injury.

### Epidemiology

Injuries remain a leading cause of death for children over the age of one year in the United States. Pediatric trauma also results in an increased cost to society due to long-term disability (5,6). Nearly five million children sustain traumatic head injury in the United States each year, and about 200,000 of these children require hospitalization (7).

The mean age of pediatric trauma victims is between six and seven years with two-thirds of these being boys. Head injury is involved in as many as 80% of the children with multiple trauma. In 60% of these cases, head trauma is the most severe injury within the injury pattern and is the predominant factor that determines outcome. The most frequent combination of injuries is head trauma and an extremity fracture (8). The mortality of children related to trauma and head injury is second only to congenital diseases in the developing countries (9). Head injuries are responsible for 75% of all pediatric trauma hospital admissions and result in 70% of all trauma deaths in children (10). Children suffer TBI more frequently than any other age group (11,12). Head injuries account for up to 80% of fatal child abuse injuries at the youngest ages (13).

### Mechanisms of Injury

#### *Injuries from Falls*

Falls represent the most common mechanism of injury in all pediatric age groups except for those less than one year of age. Child abuse is the most common cause of injury for

those  $\leq 1$  year of age (14,15). Deaths in childhood can result from falls of less than 10 feet (16). Skull fracture is much less commonly associated with fatal head injury in children than in adults (16–18).

The mechanism of falling also differs according to age group. Younger children most often fall down stairs or out of windows. Prepubescent children tend to fall from a wide variety of places, with the majority occurring outside the home during play, whereas adolescents are reported to fall from much greater heights and sustain more severe injuries (19). The severity of the injuries resulting from falls varies according to the age of the child, the type of fall, and the height of the fall (16–21).

Although the incidence of possible complications is higher with increasing height of the fall, skull fractures and intracranial injuries can be sustained by children with falls of less than or equal to three feet (22–26).

### *Injuries Resulting from Vehicular Crash*

#### *Bicycle Collisions*

Approximately 200,000 children and adolescents are injured and more than 600 die annually from bicycle-related trauma (5,27,28). Taken together, motor vehicle and bicycle collisions are the most common causes of head injury and death in children (29). It is the head injuries that cause most bicycle-related morbidity and mortality. More than half the deaths occur in children from 5 to 19 years of age (30,31). The use of bicycle helmets can prevent an estimated 85% of head injuries and 88% of brain injuries but many parents are unaware of the need for helmets, and children may be reluctant to use them (32,33). Helmet laws have resulted in a decreased number of head injuries in cyclists (34). A reduction in the risk of bicycle-related head injury among helmet wearers was demonstrated in cyclists of all ages in crashes, including crashes with automobiles (35). The principal injuries related to bicycle accidents include head trauma from road collisions, including compressive neuropathic injury (36–40).

#### *Motor Vehicle Collisions*

Motor vehicle–related trauma accounts for nearly half of all pediatric injuries and deaths (5,24). Proper use of seat restraints and lap-shoulder harnesses can prevent an estimated 65% to 75% of serious injuries and fatalities in passengers under four years of age, and 45% to 55% of all pediatric motor vehicle passenger injuries and deaths (41). Children and adolescents must be well secured in the car via a shoulder restraint and a lap belt. Although a 16-year-old boy sustained a common carotid artery and tracheal injury from a shoulder strap following a high-speed motor vehicle collision (MVC), most of these injuries occur with automated shoulder straps without a secured lap belt (42). Approximately 50% of adolescent motor vehicle fatalities involve alcohol (41), and a large proportion of all pediatric motor vehicle occupant deaths occur in vehicles operated by inebriated drivers (41).

### *Shaken Baby Syndrome and Other Forms of Child Abuse*

Intentional injury is the most common cause of severe TBI in infants (43) and children less than one year of age (44,45). Additionally more child abuse deaths occur from head injuries than from any other form of trauma (46,47). Infants and toddlers who survive abusive head trauma often have serious neurologic sequelae (48–49). Intentional injuries, however, are more difficult to diagnose due to lack of accurate history and delay in presentation (50).

Utilizing the resources of the departments of health, social services, coroner, district attorney, and law enforcement, Wang et al. (49) documented that in Los Angeles County 54% of child abuse victims were under one year of age, and one-third of cases had a previous record of intervention by child-protective services. The cause of death in homicides was head trauma in 27% of the cases.

The most frequently inflicted form of infantile head injury results from the "shaken baby syndrome" (48). The classic description of abuse was documented by Kempe et al. (50) in 1962, as the "battered child syndrome" and later by Caffey (51), who coined the term "whiplash shaken baby syndrome." Briefly, the constellation of findings with "shaken baby syndrome" include subdural and subarachnoid hemorrhage, retinal hemorrhages, and traction-type metaphyseal fractures. This was based on evidence that angular (rotational) deceleration is associated with cerebral concussion and subdural hematoma (52). Furthermore, fewer than 2% of children with significant accidental head injuries have retinal hemorrhages. Blunt-force impact as well as vigorous shaking may play a role in the pathogenesis of these injuries (53,54).

### Imaging Following Mild Alterations in Consciousness

Considerable controversy surrounds the appropriate evaluation of children with mild alterations in consciousness after closed head trauma (GCS score of 13–14). In a population-based, multicenter prospective study of all patients to whom Emergency Medical Services (EMS) responded over a 12-month period, 8488 patients in the pediatric age group (<15 years old) were transported by EMS for injuries. Of these, 209 had a documented field GCS score of 13 or 14. One hundred fifty-seven patients were taken to trauma centers and 135 (86%) received CT scans. Forty-three (27.4%) had an abnormal head CT scan, 30 (19.1%) had an intracranial hemorrhage, and five required a neurosurgical operative procedure for hematoma evacuation (55). Positive and negative predictive values of deteriorating mental status (0.500/0.844), loss of consciousness (0.173/0.809), skull fracture (0.483/0.875), and extracranial injuries (0.205/0.814) were poor predictors of intracranial hemorrhage. The incidence of intracranial injury in pediatric patients with mild alterations in consciousness in the field is significant. The great majority of these patients do not require operative intervention, but the implications of missing these hemorrhages can be significant for this subgroup of head-injured patients (55). **It is recommended that, because clinical criteria and skull X rays are poor predictors of intracranial hemorrhage, all children with a GCS score of 13 or 14 routinely have a screening noncontrast-enhanced CT scan.**

### Specific Pathologic Lesions

#### Intracerebral Hematoma

Most intracerebral hematomas occur with severe head trauma and often in association with diffuse axonal injury. They are encountered in 3% to 5% of postinjury CT scans in children who usually have a GCS score of <8. Many hematomas are in the deep white matter or basal ganglia, and it is rare that surgical evacuation is necessary or advisable. These children are at risk for elevated ICP and may require intense medical treatment to control brain swelling and edema. Large, more superficial hematomas are occasionally identified, and they may require surgical evacuation to control herniation and severely elevated ICP. Surgery, if necessary, should focus on evacuation of the

hematoma, preserving as much brain tissue as possible. Acute cerebral contusions are relatively rare after pediatric head injury, and in general do not require surgical resection, primarily because of the need to remove brain that often can recover. In follow-up studies of children with moderate or severe head injuries, a high incidence of contusions has been identified (50%); the majority is in the frontal area, followed by the anterior temporal tip (55). Although some of these lesions were visible on the original CT scan, the majority was not. The latter are also clearly not surgical lesions and require no specific early intervention.

#### Epidural Hematoma

Epidural hematomas are usually of arterial origin, resulting from rupture of branches of the middle meningeal or posterior meningeal arteries. They are found in 6% to 8% of children who undergo CT scanning after head injury (see Volume 2, Chapter 12, Fig. 2). The children are almost equally divided into three groups, one-third never being unconscious, one-third being unconscious from the time of injury, and one-third demonstrating a lucid interval followed by unconsciousness. Early CT scanning to identify the lesion is important because the patient's outcome is closely correlated with the level of consciousness at the time of surgical evacuation and with the constellation of brain injuries present. In children younger than eight years of age, the epidural hematoma is more frequently situated in the parietal and temporal-parietal region rather than in the anterior temporal location typically observed in adults. Thus, blindly placing burr holes in children is rarely advisable. A CT scan should be obtained whenever possible to pinpoint the precise location of the lesion and to identify other intracranial lesions. However, if a child with a skull fracture is showing signs of rapid progression toward herniation, and if time does not permit a CT scan, surgery must be done emergently, with the center of the craniotomy located over the center of the fracture. Most epidural hematomas require surgical removal, but small lesions (especially frontal ones) in the presence of normal consciousness can often be treated nonoperatively.

#### Subdural Hematoma

Subdural hematomas are usually the result of tearing of the bridging cortical veins due to acceleration–deceleration injury or tearing of the cerebral cortex and cortical arteries following blunt trauma. The incidence varies from 5% to 30% in children hospitalized for head injury (see Volume 2, Chapter 12, Fig. 3). The highest frequency is in children younger than one year, and the cause is usually child abuse. In infants and toddlers, the lesions are usually small and bilateral and do not require surgery. Children with an open fontanel, and in extremis, can have their ICP lowered by withdrawing bloody fluid through the fontanel. The major problem with subdural hematoma is the underlying brain swelling. Thus treatment with ICP monitoring and medical management of the elevated ICP is essential.

Many of these lesions do not require surgery; rather, the emphasis is placed upon control of the brain swelling and ICP. In general, if the brain distortion is considerably more than the width of the subdural hematoma and the subdural hematoma is less than 1 cm, surgery is not performed; however, the indications for surgery vary with the condition of the individual child and the neurosurgeon's individual criteria for surgery in this setting.

### Complex Depressed Skull Fractures

Compound depressed skull fractures are open wounds of the brain and require urgent surgical debridement as soon as the patient is stabilized and the associated cerebral edema minimized. These fractures are the most common reason for surgery after trauma in children. The aim of the surgery is to debride the brain of contamination including bone fragments, remove any associated hematomas, repair the dura to prevent cerebral herniation and CSF leakage, and reconstruct the skull either with the fragments present or with split cranial bone. It is usually possible to replace the fragments and avoid the need for a second reconstructive operation.

### Cranial Burst Fractures in Infants

Cranial burst fracture is a unique type of head injury that occurs in infants (56). This lesion is characterized as a widely diastatic skull fracture associated with dural laceration and extrusion of cerebral tissue through the dural defect and outside the calvarium (but beneath the unbroken scalp). Prompt diagnosis and reduction of the cerebral hernia and repair of the dural tear prevents the sequelae of a “growing skull fracture.” The diagnosis can be initially missed on skull X rays and even CT scans (Fig. 1) (56).

**Figure 1** Cranial burst fracture. (A) Skull radiograph four hours after injury shows a widely diastatic right frontal skull fracture; (B) computed tomograph scan of acute cranial fracture four hours after injury shows hemorrhagic contusion beneath the fracture, overlying scalp swelling, and moderate eversion of fracture edges; (C) axial T2-weighted magnetic resonance (MR) image; and (D) sagittal T1-weighted MR image. Both (C) and (D) were taken 15 hours after injury and show acute transcalvarial brain herniation. Brain parenchyma is clearly differentiated from scalp soft tissue and hematoma. Note associated convexity and interhemispheric subdural hematoma and cortical contusions. *Source:* From Ref. 56.

Scalp swelling associated with cranial burst fracture can be misdiagnosed as a simple skull fracture with underlying subgaleal hematoma. Often the diagnosis is not made until weeks to years after the acute trauma, as this condition converts to a “growing skull fracture” (56).

Prompt treatment will likely increase neurologic outcomes, but acute neurologic imaging is the key to early delineation of the injury. Figure 1 elucidates one of the important pitfalls of using skull radiographs and CT alone, and also demonstrates the imaging characteristics seen on magnetic resonance imaging (MRI, the diagnostic modality of choice for cranial burst fractures).

### PENETRATING TRAUMA

✎ Most forms of penetrating cranial injury (PCI) require surgical exploration ✎ (e.g., dog bites or dart injuries). Gunshot wounds of the head and other forms of PCI are increasingly common in children. The actual incidence is difficult to determine due to gaps in reporting, absence of a centralized database, and the presumption that—as in the adult population—a substantial number of victims die prior to arrival at emergency departments (57,58). The causes of PCI can be broadly categorized as follows: (i) accidental injury with sharp or semisharp objects, (ii) warfare, (iii) accidentally discharged firearms, (iv) suicide, and (v) homicides. Most PCIs require surgery to debride superficial bone fragments from the brain, remove intracranial hematomas, and repair the dura and cranium. The indications for surgery also depend upon an estimate of whether or not a child is likely to survive the injury.

By their very nature, children are prone to accidental injuries with common household and environmental objects. The literature has afforded scattered case reports of PCIs involving impalements with items such as pencils and chopsticks (59–62), broom handles, metal strips, plant branches, kitchen knives, dinner forks, wires, nails, spikes, scissors, and screwdrivers. Flying objects during automobile accidents have also been described as a cause of PCI (63–65). Low-velocity missiles such as arrows, and pellets accidentally discharged from pneumatic “toy” weapons would be included in this category as well (66,67). Lawn darts have been banned from retail sale in the United States due to the significant number of severe and fatal PCIs that occurred in young children; nonetheless, an estimated 10 to 15 million sets still remain in American households and will likely remain a significant mechanism of injury for years to come (68). A special consideration in the management of impalements is the frequent entrance through thin calvarial regions (such as the squamous temporal bone) or foramina or canals (such as the optic canal) with a high risk of vascular or cranial nerve damage, despite initial impressions that the injuries may be trivial. Accordingly, all these patients should receive prompt neurosurgical evaluation and brain CT scanning.

### Prognostic Factors for Penetrating Head Injury

A discussion on outcomes in pediatric PCI is problematic, because most of the literature involves the adult population. The immediate and early mortality rates are high and the overall numbers are low enough that the generation of useful analyses and predictive models is difficult. As discussed above, it is reasonable to withhold aggressive care from the patient presenting with a GCS score of 3 and

fixed pupils after initial resuscitative efforts. Furthermore, one recent series (69) found that no pediatric TBI patient with concomitant anoxic insult regained useful consciousness, implying that limited management is probably appropriate for this group. Conversely, patients with minimal initial neurologic impairments (i.e., GCS scores of 12–15) and limited parenchymal injuries generally make excellent functional recoveries, indicating that aggressive neurosurgical management is appropriate for all these patients.

The dilemma in neurosurgical management involves decision making in patients with moderate to severe injuries, and those with concomitant hypotensive and/or hypoxemic events. Most studies focus on closed head injuries; therefore, application to the PCI group must be done cautiously. Children with prolonged unconsciousness and vegetative states are more likely than adults to have protracted survivals; however, severe residual cognitive and motor deficits may occur (69–70). Children with milder injuries can be left with residual cognitive deficits, limitations in physical health, and behavioral problems. Although children generally fare better than adults with similar degrees of blunt TBI, Kaufman's analysis of PCI patients found similar incidences of functional disabilities, special educational needs, and extreme emotional lability (71). Other investigators have determined that cognitive recovery in moderately and severely injured children generally plateaus around the first postinjury year (72,73). For some patients with less severe injuries, the deleterious consequences on cognition, behavior, and psychosocial adjustment may not be fully realized until adulthood (74). One study found that only 23% of adults who sustained TBI in the preschool years were able to work, and only 36% lived independently at home (75). This correlated with the delayed development of cerebral atrophy and porencephalic cysts.

### **Surgical Approach to Penetrating Head Injury**

A number of studies have concluded that it is unnecessary to reoperate for retained bone fragments and that it is often possible to temper the initial debridement in an effort to preserve additional cerebral tissue (60,61,76–78). Long-term follow-up in one series failed to document a significant difference between survivors with retained bone fragments (48%) and survivors without retained fragments with regard to epilepsy or central nervous system (CNS) infection (77). In a prospective series of 32 military patients with intracranial bone fragments who underwent debridement of the entry wound and dural closure, only one patient developed a subsequent CSF leak, seizure, and a CNS infection. No CSF leaks or infections were reported in the remaining 31 patients (76).

In summary, the current literature supports a conservative surgical approach. Surgical management begins with evacuation of mass lesions and debridement of necrotic tissue and bony fragments at entrance and exit sites. Only superficial or local bone fragments need be debrided. Deep parenchymal fragments and those not readily accessible should not be removed unless obviously grossly contaminated.

### **TRAUMATIC BIRTH INJURIES**

The overall incidence of traumatic birth injuries has dramatically declined; however 2% to 5% of all neonates sustaining craniocerebral trauma die (79). Infants at an increased risk

for birth injury include those born to primiparous women, those whose birth weight is greater than 3500 gm, and those who are born with forceps-assisted delivery. Furthermore, breech presentation and forceps or precipitous deliveries are significantly correlated with intracranial hemorrhage (80,81). Shoulder dystocia is associated with injury to the brachial plexus, as is prolonged pregnancy and macrosomia (82).

Although high-forceps deliveries have been abandoned in modern obstetrical care, mid-forceps deliveries have clear indications, such as fetal distress. A mid-forceps delivery involves the application of the instrument to a fetus whose biparietal diameter is somewhere between the pelvic inlet and the maternal labia in a vertex presentation. Mid-forceps deliveries have been associated with brachial plexus injury. When shoulder dystocia complicates a mid-pelvic delivery, the incidence of birth injury has been reported to be as high as 47%. Indeed, one recent review demonstrated that one-half of all brachial plexus injuries during delivery was attributed to mid-forceps extraction (83).

Vacuum cup extraction was introduced in an effort to reduce injury associated with forceps-assisted delivery. A pliable, soft cup is favored over the metal cup, which has been associated with a high incidence of scalp injuries and lacerations (84). Extraction by vacuum cup is associated with cephalohematoma (84) and has been associated with growing skull fractures (85); the overall incidence of complications from vacuum cup delivery is similar to that from forceps (86).

In addition, retinal hemorrhage appears to be higher with the vacuum cup method. This finding is assumed to represent exposure to sudden changes in ICP inherent in the vacuum extraction technique independent of the type of cup used (84). The significance of retinal hemorrhage in these neonates is unknown. Retinal hemorrhages have been reported with bloody CSF (82), but have not correlated with intracranial hemorrhage in other studies. Excluding an isolated report of SAH, intracranial hemorrhage has not been reported with vacuum cup extraction. Retinal hemorrhages associated with vacuum extraction have been of the peripheral type, and are thought to have no influence on the subsequent function of the eye (85–87).

It has been generally recognized that basic differences exist between the nature of tissue damage of craniocerebral trauma occurring in infants and that in children and adults (88). The scalp is subject to a considerable amount of stress and is frequently injured in the birth process. Exsanguination from a rapidly expanding subgaleal hemorrhage can occur and, as an isolated lesion, represents the most serious of superficial birth injuries. Extracranial cerebral compression may jeopardize the infant's life. Management consists of measures to correct hypovolemic shock and disseminated intravascular coagulation, as well as surgical intervention to control elevated ICP. Skull fractures are common but in general are not associated with underlying intracranial hemorrhage or pathology and require no treatment. The growing skull fracture and occipital osteodystasia are exceptions.

Intracranial hemorrhage has many potential sources in the neonate with varying prognosis. Mass lesions require surgical management. All forms of intracranial hematomas are encountered in the neonatal period, but all are rare. Epidural hematomas occur in the supratentorial and infratentorial spaces and, if producing cerebral compression, require evacuation. Before any surgery is performed on a

neonate, clotting studies must be performed and abnormalities corrected, if necessary. Subdural hematomas are a difficult problem to handle surgically, and if they are not large, efforts to control the ICP medically should usually be attempted before resorting to surgery. Most intracerebral hematomas in neonates are hemorrhagic infarctions or venous hemorrhages, and surgery is rarely indicated. The brain is 90% water, and hemostasis can be very difficult; the pia mater and cerebral vessels can be peeled off the brain by the operative suction devices, resulting in increased damage.

With the exception of scalp injury, trauma to the craniocerebrum and spine necessitates neurosurgical consultation and frequently surgical intervention. The brain of the newborn is not yet myelinated and is subject to shearing forces at junctional levels in a manner different from adult brain. In particular, cortical, subcortical, parenchymal-ventricular, interhemispheric–corpus callosum, and cerebral hemisphere–brain stem levels are at particular risk (14). Blunt head trauma in the newborn and infant produces tears in the cerebral white matter, parallel to the surface, and similar (microscopic) tears in the superficial cortical layers. When craniocerebral injury is of such a nature and severity as to produce the shearing forces, which result in intracranial mass lesions in the form of hematomas, the underlying brain damage is likely severe. In such a scenario, surgical evacuation of the clot may not alter the clinical outcome (88).

## TRAUMATIC VASCULAR LESIONS

Cerebrovascular trauma includes a broad array of injuries both direct and indirect. Epidural hematoma and carotid-cavernous sinus fistula are two examples of the better-recognized sequelae of intracranial vascular disruption. Unfortunately, neither all vascular injuries associated with head trauma are as readily identifiable nor are they associated with definite treatment guidelines. Their management remains in evolution as medical, surgical, and endovascular options develop. Furthermore, many of the management strategies have arisen from the care of adults and will also be discussed in other chapters (Volume 1, Chapter 15 for initial evaluation of blunt cervical spine injuries and Volume 1, Chapter 24 for penetrating neck trauma).

### Cervical Carotid Injury

Injury to the extracranial carotid and vertebral arteries is uncommon in pediatrics, but in adults represents one of the most common vascular injuries following neck trauma. Well over 90% of the major arterial trauma in the neck is caused by penetrating wounds (see Volume 1, Chapter 24) (89). Nonpenetrating traumatic lesions of the extracranial cerebral vasculature provide the most difficult diagnostic and management problems. The most important symptoms of carotid arterial injury are those of cerebral ischemia, including hemiparesis or hemisensory deficit with or without associated homonymous hemianopsia suggesting ischemia in the internal carotid territory. Symptoms may be fleeting as in transient ischemic attack (TIA), or more prolonged in their presentation. The neurologic deficit worsens and eventually becomes permanent. Also, the level of consciousness may be affected, but frequently the neurologic deficit is out of proportion to any reduction in the level of consciousness, in contradistinction to what would be expected solely as a result of the head injury.

Traumatically induced dissection of the internal carotid artery in the neck also occurs in association with head injury. As in thrombosis, the critical element is disruption of the intima. Aneurysms may also result from injury of the carotid artery in association with head trauma. The arterial wall is thinned and weakened, and the pulsatile column of blood produces an aneurysm in association with an area of dissection that is extensive enough to disrupt both the intima and adventitia. Turbulence may cause the aneurysm to enlarge and also provide for thrombus formation, which can subsequently embolize distally. Patients may complain of a pulsatile neck mass, dysphagia, or noise in the neck that may radiate into the head. Also, lower cranial nerve palsies including hoarseness or weakness of the tongue may occur in association with large aneurysms of the carotid artery (90).

Patients exhibiting signs or symptoms consistent with blunt cerebral vascular injury must undergo emergent diagnostic evaluation. Because a negative noninvasive study should not be accepted in this instance, the gold standard (four-vessel cervical arteriography) is the study of choice, but this is rapidly changing toward CT angiogram (CTA) and magnetic resonance angiogram (MRA) (Fig. 2).

♣ The typical angiographic picture of trauma-induced occlusion of the cervical internal carotid artery is abrupt blockage of contrast flow approximately 1–3 cm above the bifurcation of the common carotid artery in the neck. ♣ Although traumatic dissection can occur anywhere along the course of the internal carotid artery, it most frequently begins in the section of the artery adjacent to the C1 and C2 vertebra. Dissecting aneurysms may present as irregular enlargements of the contrast column in association with segmental narrowing of the cervical internal carotid artery. These aneurysms tend to become more localized and saccular in nature. Duplex scanning has well-documented limitations, which must be acknowledged if this test is used. Before exclusively embracing CTA or MRA, their limitations must also be acknowledged.

The treatment of patients with carotid thrombosis depends upon the stage at which it is diagnosed. Those with a completed stroke of more than 12 hours' duration or who present in a coma will most likely prove refractory to any type of treatment. ♣ Patients with fluctuating neurologic symptoms in the face of an acutely occluded internal carotid artery may benefit from urgent exploration and thromboendarterectomy. ♣ Prior to any thoughts

**Figure 2** Magnetic resonance (MR) angiography. MR arteriogram (left) and MR venogram (right) revealing normal cervical and cerebral vasculature.

of surgical therapy, the patient who presents with an occluded carotid artery with or without ischemic neurologic deficits should be managed with attempts to increase cerebral perfusion. Hypotension resulting from associated injuries should be rapidly reversed with fluid therapy or pressor agents. In those few patients who are found to have a carotid occlusion in the absence of neurologic symptoms, a high circulating intravascular volume should be maintained in order to obviate any potential hypotensive episodes in the first few days following the injury. Those patients who have a mild to moderate neurologic deficit and who may or may not be candidates for surgical therapy, can benefit by trial of induced hypervolemia (91).

Therapeutic embolization of head and neck vascular injuries may be considered as an alternative to surgery particularly in lesions whose anatomic location makes them unsuitable for surgical treatment. Complications from therapeutic embolization, if carefully performed, are usually less than with surgery, and embolization can be performed in conjunction with the initial angiographic workup. Therapeutic embolization is preferably performed with preservation of parent arteries. When this is not possible, the involved carotid or vertebral arteries are occluded proximally by placing detachable balloons or coils. The safety of permanent arterial occlusion must be verified first by temporary test balloon occlusion, which provides information regarding the collateral blood flow.

### Vertebral Artery Injuries

Injuries to the cervical portion of the vertebral artery occur infrequently. The relatively deep position of the vertebral artery in the neck associated with its protection by the foramina transversaria tends to reduce its vulnerability to both blunt and penetrating injuries. Further, the relative redundancy of the vertebral system makes injuries to one vertebral artery less likely to cause ischemic cerebrovascular symptoms. The majority of patients with vertebral artery injuries associated with head and neck trauma will present with the delayed onset of symptoms and signs of brain stem or cerebellar ischemia. Vertigo, blurred vision, ataxia, and dysarthria are common. In the setting of cervical vertebral artery trauma, neck ache, suboccipital pain, and headache are also frequent concomitants.

The classical Wallenberg syndrome as a result of trauma to the vertebral artery is also known to occur following minor head and neck injury (92). This consists of Horner's syndrome with decreased sensation to pain and temperature on the ipsilateral face and contralateral arm and leg in association with ataxia on the ipsilateral side. These symptoms may follow any traumatic incident that causes acute hyperextension or rotation of the cervical spine. Neurologic symptoms usually occur within 24 hours but may be delayed as long as a month after the trauma.

In some cases, associated neck movements serve to exacerbate the symptoms of ischemia. This clinical scenario should also alert the treating physician to a potential vertebral artery injury. Injuries to the cervical vertebral arteries most commonly result in thrombosis. However, intimal disruption, dissection, aneurysm formation, and fistula formation are also known to occur. Ischemia usually results from distal embolization but also may result from flow-restrictive lesions in dominant vertebral arteries.

As with carotid arterial injuries, treatment depends on the location and nature of the lesion as well as on any existing neurologic deficit. Total occlusion of the vertebral artery

may not lead to ischemic symptoms because of a patent vertebral artery on the other side. In this instance, no further therapy is warranted. In those cases where vertebral thrombosis results in significant neurologic symptoms, attempts at thrombus removal or thromboendarterectomy of the vertebral artery have usually been unsuccessful (93). Supportive therapy with a trial of increased intravascular volume or mild hypertension may obviate some of the ischemic manifestations. Other injuries including traumatic narrowing, dissection, and mural hemorrhage with pseudoaneurysm formation are potential sources for distal embolization. In documented cases of embolization with mild or transient neurologic deficits, anticoagulation with heparin is recommended with consideration given to repair of the vessel. If angiography documents that the injured vessel is the dominant vertebra, reconstruction or repair using suitable graft material or possibly ligation or balloon occlusion with concomitant extracranial to intracranial bypass grafting can also be contemplated. In a situation where the nondominant vertebral artery is injured and is considered to be beyond repair, a successful trial of balloon occlusion under local anesthesia can be followed by permanent occlusion.

### Intracranial Vascular Injury

Disruption of the intracranial vasculature is the rule rather than the exception with severe head injury. SAH due to loss of integrity of small pial vessels can be documented in the majority of fatal brain injuries. However, documentation of traumatic lesions in major branches of the circle of Willis or in dural venous sinuses is relatively uncommon in blunt head trauma.

♣ **The most common intracranial arterial structure to be occluded in blunt head injury is the internal carotid artery.** ♣ Although the majority of injuries to the internal carotid artery occur in its cervical portion, injury at the base of the skull, within the carotid canal, or at its cavernous segment have all been reported with some regularity (94). The patient is typically admitted comatose following an automobile accident. Within 24 hours the neurologic condition deteriorates further, and evidence of a hemiparesis tends to emerge, subsequent to infarction from internal carotid artery occlusion.

Occlusion of other major intracranial vessels has also been documented subsequent to head trauma. Evidence of injury to cerebral cortical branches may be seen, especially in relation to skull fractures. Findings may include branch occlusion, segmental narrowing, traumatic aneurysm formation, or slow flow in the cortical surface veins. A sharp angulation of a damaged cortical branch (Z deformity) is suggestive of entrapment of the vessel within the fracture line.

The mechanisms of middle cerebral artery thrombosis secondary to trauma are incompletely explained. The middle cerebral artery may become occluded indirectly secondary to injury to the internal carotid artery. Alternatively, the middle cerebral artery may be compressed by extracerebral or intracerebral hematomas. The management of traumatically induced middle cerebral artery occlusion remains empirical and relegated to supportive care. In the majority of those patients who survive and have follow-up angiography, the middle cerebral artery is again patent (95). In those cases where the artery does not recanalize or remain patent, the patient will progress to complete infarction of that vascular territory (Fig. 3).

**Figure 3** Computed tomography (CT) of the brain showing a left parietal hypodense area in the distribution of the left middle cerebral artery (MCA). This CT scan is consistent with infarct due to occlusion of the left MCA.

Basilar artery occlusion has also been noted secondary to head trauma (96). These patients invariably present with ischemic brain stem symptoms, and the majority of them do not survive. Basilar artery occlusion or stenosis can often be inferred from a carotid arteriogram that shows filling of the distal basilar artery through a posterior communicating artery. This observation should prompt complete examination of the vertebrobasilar circulation. Not infrequently, the basilar artery may be occluded due to associated injury to one or both vertebral arteries, which then act as a source of emboli. The majority of cases of basilar artery occlusion are documented at the time of autopsy; thus, no satisfactory treatment regimen has yet evolved.

### Traumatic Aneurysms

Traumatically induced intracranial artery aneurysms are rare lesions. None of the intracranial aneurysms cataloged in the Cooperative Aneurysm Study was of traumatic origin. ⚡ **The most common mode of presentation in symptomatic patients is that of delayed SAH following a head injury.** ⚡ Typically, a decrease in the level of consciousness to the point of coma heralds the SAH. Further evaluation may reveal nuchal rigidity or complaints of a severe headache. Unless a high index of suspicion is maintained, the symptoms may be ascribed to an intracranial expanding process such as a hematoma or edema or possibly post-traumatic hydrocephalus. Other presenting symptoms include progressive deterioration following head trauma, most likely due to vasospasm following rupture of the aneurysm. Epistaxis or a delayed cranial nerve palsy following trauma may also give evidence of the presence of an internal carotid aneurysm near the skull base. Extracerebral hematomas following trivial head trauma and unexplained arterial bleeding during hematoma removal have all been reported as evidence of traumatically induced cerebral aneurysms (97).

Blunt head trauma is responsible for the majority of these lesions; however, penetrating lesions including bone fragments and missiles of various types including radio antennas, umbrella tips, bullets, knives, and surgical instruments are responsible for some of these cases.

The majority of traumatic cerebral aneurysms are located on branches of the middle cerebral artery. The next most common site is the internal carotid artery as it enters the skull. The pericallosal artery, most likely because of its proximity to the falx, is another important site for the occurrence of traumatically induced aneurysms. Angiographic hallmarks including delayed filling and emptying of the aneurysm, an irregular contour, the absence of a neck, and a peripheral location other than at a branching point tend to distinguish the traumatically induced aneurysm from that of the congenital or atherosclerotic forms. As with other types of intracranial aneurysm, management is directed toward avoiding recurrent hemorrhage, which is higher in traumatic aneurysms than in berry aneurysms. Aneurysm coiling or clipping should be pursued.

## CONGENITAL VASCULAR ANOMALIES

### Vein of Galen Aneurysm

⚡ **Early high-output cardiac failure in neonates can occur with vascular shunting lesions in the cranium.** ⚡ The most frequent cerebral vascular shunting lesion is the vein of Galen aneurysm, a misleading term. The vein of Galen aneurysm is actually an arteriovenous malformation (AVM) of the vessels that supply the choroid plexus of the third ventricle (98). It is different from most AVMs, which contain tangled webs of abnormal vessels. The vein of Galen aneurysm is a direct left-to-right shunting of branches of any or all of the following arteries into the vein of Galen: anterior cerebral, posterior lateral and medial choroidal, thalamic and hypothalamic perforators, posterior cerebral, anterior choroidal, and least likely the middle cerebral. The term aneurysm is also misleading: The aneurysm is of the internal cerebral veins or the vein of Galen itself and the straight sinus and is not arterial.

The vein of Galen aneurysm rarely bleeds in the first few months of life. Rather, the major clinical problem involves controlling secondary heart failure. This can often be accomplished by medical means. However, if medical management is insufficient, then selective embolization of particular arterial feeders with coils or balloons may help decrease the flow and attenuate the cardiac failure. Another option is embolization of the venous aneurysm via a transvenous route or directly through the torcula. Rarely is operative control of the feeder vessels successful in the first few days of life. If the heart failure can be initially controlled, and if after six weeks of age the failure should recur, then surgery to occlude the direct shunting arteries can usually be successfully accomplished. Interventional embolization of venous or arterial components represents a less dangerous option, although the risks of hemorrhage, pulmonary embolization by the coils, and myocardial ischemia remain concerns.

Other arteriovenous shunts that occur in neonates usually affect the dura mater, with or without cerebral involvement. Early treatment focuses on control of the heart failure with embolization if necessary. Early open surgery is rarely advisable because of the high risk of excessive blood loss.

### Arteriovenous Malformations

AVMs are congenital anomalies of the vascular system and can occur anywhere in the cerebrum, brain stem, cerebellum, and spinal cord. Lesions in the spinal cord are rare in children. AVMs result in neurosurgical emergencies, as a result of rupture of usually venous components of the AVM and ensuing acute hemorrhage of blood at arterial pressure into the cerebral substance or the ventricular system (Fig. 4). In children, AVMs are four times more likely than aneurysms to be the cause of intracranial hemorrhage (99). The result is a sudden increase in ICP manifested clinically by the sudden onset of severe headache or sudden loss of consciousness. The signs and symptoms depend on the location of the hemorrhage and can include hemiparesis, aphasia, hemisensory loss, hemianopsia if the hemorrhage occurs in the supratentorial brain, or focal brain stem symptoms if the hemorrhage is in the posterior fossa. The only manifestation may be the acute onset of coma. The mortality from the first bleed has been reported to be as high as 24% in children (100). Standard resuscitation is followed by a CT scan to confirm the diagnosis of intraventricular or intraparenchymal hemorrhage. Treatment varies depending upon the clinical state of the patient. With signs of progressive herniation and impending death, acute evacuation of the hematoma may be necessary. Although obtaining an angiogram to identify the anatomy of the AVM is ideal, this is not always possible because of the rate of neurologic deterioration. The aim of surgery is to evacuate the clot, to decrease ICP, and to reverse any herniation. If an obvious AVM is encountered and is small, it may be possible to remove it. However, the safer course is to stop after evacuation of the clot. Arteriography can then be performed, followed subsequently by a second operation to resect the lesion.

Acute rebleeding from an AVM is rare, and urgent surgery therefore is not necessary to prevent a rebleed. If the blood is predominantly in the ventricle, an intraventricular catheter is required to monitor the ICP and provide for CSF drainage. Acutely, as little CSF as possible is drained to prevent the catheter becoming clogged by blood clot.

**Figure 4** Computed tomograph of the brain showing a large right and small left cerebellar hemorrhage. Local mass effect on the fourth ventricle and absence of the perimesencephalic space is also noted; both findings are consistent with poor outcome.

**Figure 5** Vertebral arteriogram with an arteriovenous malformation nidus (circled).

The ICP is controlled by a combination of therapy. When a patient is stable and has recovered consciousness, arteriography (Fig. 5) and definitive therapy can be undertaken. When the clot is parenchymal, and the ICP and herniation can be controlled by medical means, it is advisable to postpone surgery until the clot has liquefied and the brain swelling and edema have subsided. This hiatus makes the surgery much safer and allows adequate investigation and therapeutic planning. Treatment is either surgery, embolization followed by surgery, or, for smaller deep lesions, focused radiation therapy. In a small percentage of cases, no obvious site of hemorrhage is identified. A repeat arteriogram some months later is required to be certain that a small lesion was not present but compressed by the acute hemorrhage. The rate of rebleeding from AVMs is 2% per year. In children in whom no lesion is identified, the rebleed rate is close to zero (101).

### Aneurysms

As noted earlier, intracranial hemorrhage in children is less frequently a result of rupture of an aneurysm than that of an AVM (102). Aneurysms may be congenital or mycotic and may be found on the feeding arteries of an AVM. Aneurysms occur in the subarachnoid space, and thus SAH rather than intraparenchymal hemorrhage is the usual result of rupture. The signs and symptoms are typically sudden onset of unendurable headache followed by a stiff neck and photophobia and in about 50% of cases by coma. Diagnosis is made by the history and by a CT scan. The CT findings may appear normal or may show SAH. If the CT scan is normal while clinical suspicion for SAH remains high, the diagnosis can be made by lumbar puncture (seeking xanthochromic CSF).

Because aneurysms tend to rebleed in 24 to 48 hours, the next step in diagnosis is cerebral arteriography. MRI angiography is not adequate to visualize a small aneurysm (<5 mm). Although the most common location is at the bifurcation of the carotid, many aneurysms occur distally in children, and they are often gigantic (>2.5 cm). Mycotic aneurysms in particular occur on the distal branches of the cerebral vessels, and the rare post-traumatic aneurysm can occur on any vessel but is most frequently encountered on the anterior cerebral artery (102). Ruptured aneurysms are usually treated by angiographic coiling or by acute surgery to clip or trap the aneurysm. After rebleeding, the next major complication is cerebral ischemia, which usually results from cerebrovascular spasm (103). This is treated by

volume expansion, calcium-channel blockers, and induced arterial hypertension as in adults (103,104). Because of the need for elevating the blood pressure to treat spasm, it is currently believed that early control (clipping or coiling) of the aneurysm makes this therapy to reverse or prevent ischemia safer. The use of free-radical scavengers is theoretically beneficial, but has not yet been shown to improve the outcome in patients with SAH. The grading of SAH in children is similar to the Hunt–Hess Classification used in adults (see Volume 2, Chapter 14, Table 1) (105).

### Cavernous Angiomas and Venous Angiomas

Although both cavernous and venous angiomas can present with the acute onset of a new neurologic deficit and headache, it is rare that they require emergency surgery. Venous angiomas are most likely when the hematoma is in the posterior fossa, where brain stem compression can be sufficiently severe to require treatment by clot removal. In venous angiomas, the large draining vein should not be occluded because it is often the only venous drainage from a large area of the cerebellum (106,107).

The diagnosis is usually established on a noncontrast CT scan, which shows acute hemorrhage, and a contrast scan, which in the case of a cavernoma may demonstrate enhancement and in the case of a venous angioma shows the large vein and often its tributaries. Both cavernous and venous angiomas are well demonstrated on an MRI scan, which shows evidence of old hemorrhage and the surrounding edema. Cerebral arteriography usually shows no lesion in the case of the cavernous malformation and the caput of draining veins and the single large vein of the venous angioma. Acute hydrocephalus can occur as a result of posterior fossa hematoma and may require treatment with a ventriculostomy. The ventricle should be drained slowly, and the supratentorial pressure should be kept above 15 mm Hg in order to prevent upward herniation of the cerebellar vermis. This is true whenever a ventricular drain is required for relief of acute hydrocephalus secondary to a posterior fossa mass. Anticonvulsants are necessary if a patient presents with seizures, and corticosteroids are helpful to treat the cerebral edema that is often present. It is rare that severe intracranial hypertension is present. In most cases, definitive resection of the cavernous angioma is the treatment of choice once the hematoma and brain edema have subsided. The best treatment for venous angiomas often is to leave them alone unless repeated bleeding occurs, in which case a small AVM is often present and may be resected.

### HYDROCEPHALUS

It is unusual for a newborn with hydrocephalus to present as a neurosurgical emergency. Because congenital hydrocephalus is a prenatal (i.e., chronic) condition, the brain accommodates and the sutures may be widely separated and the cranium may be significantly enlarged, accommodating the increased CSF volume without compression of neural structures (108). This also affords time to make an accurate diagnosis of the etiology of the hydrocephalus and to shunt the lesion electively. If signs such as apnea or bradycardia are present (representing increased ICP), the ventricle can be acutely tapped through the fontanel and the pressure relieved until an elective shunt is placed.

**Figure 6** Computed tomograph of the brain showing massive bilateral ventriculomegaly subsequent to prolonged hydrocephalus.

Acute hydrocephalus due to congenital and acquired causes can present later in life, in a child with closed sutures (Fig. 6). In this case, rapid diagnosis and therapy may be required to prevent serious brain damage or death because the cranium cannot expand, and by the time a child presents for medical care, the compensatory mechanisms are usually exhausted. This also is true in children who have a CSF shunt in place and in whom a shunt malfunction has occurred. The difficulty with diagnosis in this group of patients is the lack of definitive signs that confirm the diagnosis. ✎ **The diagnosis of shunt malfunction or acute intracranial hypertension due to hydrocephalus is essentially based on the history and often confirmed by a neuroimaging study (CT or MRI), that shows ventricular dilatation.** ✎ In a small group of children with slit ventricle syndrome, the ventricles do not enlarge, or enlarge only minimally, in the presence of high ICPs and shunt dysfunction (109,110). In these children, it is important to compare their current scan with a previous scan; if none is available, act on the history and assume a shunt malfunction.

Because autoregulation of CBF is typically intact in a child presenting with acute hydrocephalus, the ICP waves that occur are often unassociated with any signs. The symptoms are of severe, episodic headache that may be associated with vomiting or visual disturbances. The pain may be located behind the eyes or in the back of the neck as a result of tonsillar herniation. The headache may be relieved by vomiting, because this triggers hyperventilation and thus a decrease in ICP that can abort the pressure wave. If a child is not having a wave of pressure at the time of the examination, he or she may appear perfectly normal, and even with a wave of high pressure there may be nothing to identify other than the pain of the headache, which is of course subjective to the patient.

The examination may reveal papilledema, but as mentioned earlier, the absence of papilledema does not rule out intracranial hypertension of a life-threatening degree. Decreased level of consciousness either accompanying the headache or continuously may occur as may a stiff neck due to tonsillar herniation, cranial nerve VI palsy due to diffuse ICP, or more rarely a cranial nerve III palsy. Visual acuity may be decreased as a result of chronic

papilledema or optic atrophy. Changes in vital signs, such as bradycardia and hypertension, may occur but are often late manifestations, occurring at the time of brain stem decompensation, and cannot be relied upon as early indicators of increased ICP. Ventricular enlargement, as evidenced by CT imaging, can confirm the diagnosis of hydrocephalus.

When ICP elevation is suspected, it is preferable to avoid sedation in spontaneously breathing patients. If sedation is needed, it is best to give the minimum amount required and to recognize that sedation often leads to decreased ventilation, increased arterial partial pressure of carbon dioxide (PaCO<sub>2</sub>), and further increased ICP. A plan to treat both hypoventilation (i.e., intubation or mask ventilation) and ICP should be in place before administering sedation. When hydrocephalus is present, urgent therapy is sometimes required to treat the increased ICP. Therapy ranges from acute administration of corticosteroids in those patients with a tumor and vasogenic edema, to ventriculostomy or an emergency shunt procedure in those with pathology unlikely to respond to steroids. In patients without a tumor or preexisting shunt, and in whom an acute or chronic CNS infectious process is not suspected, the ideal treatment is insertion of a shunt as an emergency procedure.

In children with a preexisting shunt, a radiographic shunt survey to evaluate the intactness and position of the shunt system is necessary in addition to the scan. If there is question about a shunt block, the shunt system can be tapped and the site of block identified as proximal or distal to the shunt reservoir. In children with the slit ventricle syndrome, when very little fluid is present in the ventricle and the ability to remove fluid is therefore limited, it is often better to test the proximal catheter by back-injecting contrast medium into the ventricle to establish the patency of the proximal shunt catheter. The distal end of the shunt can be checked by measuring the runoff pressure with a manometer. When the shunt is blocked proximal to the valve system such that CSF cannot be withdrawn, it is safer to revise the shunt immediately rather than to wait until the next day. If the shunt is blocked distal to the valve, adequate ventricular decompression can be attained by tapping the reservoir and removing CSF. In this setting, the shunt revision may be postponed until the next convenient opening in the operating schedule, and diamox and dexamethasone may be used to slow CSF production during the waiting period. Severe headaches need to be treated by further fluid withdrawal from the shunt and not treated with narcotics; if headaches persist, shunt revision is urgently required (109–111).

## INFECTION

☞ **The most frequent setting in which an infectious process requires emergency neurosurgery is that of a brain abscess (111,112). The presentation is either with focal neurologic deficit or the signs of intracranial hypertension.** ☞ The aims of therapy are: (i) to obtain a specimen for culture and (ii) to evacuate any intracranial mass. CT scan usually identifies the lesion, and the therapy is increasingly often stereotactic drainage with or without leaving a catheter in situ for further drainage. It is rare that an attempt at abscess removal is performed as the primary procedure, unless the abscess is very large and superficially located in the brain. Even then, because of the surrounding edema, it

is generally preferable simply to drain the lesion, treat with antibiotics, and monitor with serial neuroimaging. Indeed, in many cases, craniotomy is never necessary and the abscess can be treated simply by antibiotics with or without repeated needle drainage.

The antibiotic selection depends upon the likely organisms (Volume 2, Chapter 53). For staphylococcus coverage, oxacillin is the first drug of choice unless the organism is methicillin-resistant, in which case vancomycin is used. Daptomycin or linazolid is used for vancomycin-resistant organisms. Ceftriaxone has excellent CSF penetration and is effective against most methicillin-sensitive gram-positive organisms. It also has activity against all gram-negative bacteria except for pseudomonas. If pseudomonas is present or suspected, ceftriaxone should be replaced by ceftazidime along with an aminoglycoside (e.g., amikacin). Metronidazole has excellent brain tissue penetration and is the drug of choice for anaerobic brain abscess. For fungal infections, seek infectious disease consultation and review Volume 2, Chapter 53.

## Subdural and Epidural Empyema

Epidural empyema usually occurs with either severe air sinus infections or osteomyelitis of the skull (113). The mass effect is usually small, and acute drainage is only rarely necessary. In the frontal area, drainage of the frontal sinus often results in drainage of the epidural abscess.

Subdural empyema is a more catastrophic situation, with underlying pial and often cerebral inflammation, septic thrombophlebitis, and brain edema. In the past, this was always treated by urgent craniotomy and aspiration of the pus (114). Currently, with earlier diagnosis as a result of CT scan, burr hole aspiration for culture and immediate relief of mass effect is often all that is required, followed by antibiotics and corticosteroids. In children, the subdural empyema commonly recurs at different locations and may require repeated surgery, which may require extensive craniotomy if resolution is not achieved by medical management. Small lesions may require no surgery.

## Meningitis

Bacterial meningitis is a medical emergency requiring antibiotic treatment. Because of vaccination programs, *Haemophilus influenzae* is less commonly seen in children. Currently, most common bacterial organisms carrying meningitis in children are *Meningococcus* and *Pneumococcus*, which can be treated with high-dose penicillin (115,116). Bacterial meningitis rarely requires acute neurosurgical management. However, acute hydrocephalus can occur with bacterial meningitis, and emergent placement of a ventricular drainage device may be necessary. This is most often the case in tuberculous meningitis but does also occur with the more common infectious organisms.

## Shunt Infection

Most shunt infections do not require emergent shunt removal; rather they are treated by shunt culture and appropriate antibiotics. In children with an acute abdomen as a result of the shunt infection, emergency exteriorization of the abdominal end of the shunt may be required. Most commonly, the infecting organism is *Staphylococcus*, in which case the shunt will require elective removal and replacement. With other organisms, the shunt can often be saved (117).

## NEOPLASMS

In only a few cases do pediatric brain tumors become neurosurgical catastrophes, but these must be rapidly identified and treated. These children are usually admitted with a history of headache, nausea, and vomiting, and are at risk of herniation while awaiting workup for a suspected gastrointestinal lesion. Others are admitted after a lesion is identified on CT or MRI scan, but the symptoms of increased ICP may be subtle, or initially ignored, resulting in clinical herniation and death. The problem is exactly as described in children with hydrocephalus, in whom autoregulation of CBF is intact and very high pressures can be tolerated without apparent clinical signs. Posterior fossa tumors often present this way when associated with hydrocephalus.

In 5% to 10% of cases of pediatric brain tumor, hemorrhage occurs into the tumor, producing acute deterioration that is no different from that related to other types of intracranial hemorrhage (118). Tumors in the supratentorial compartment are usually easier to diagnose because of accompanying local signs (e.g., hemiparesis, visual field defect) (Fig. 7). Rarely is an emergency operation necessary, but in the presence of progressive herniation, repeated ICP spikes and/or unconsciousness, rapid surgical debulking may be required. As noted previously, ventricular drainage in the presence of a large posterior fossa tumor can result in upward herniation; thus, resection of the tumor may be required at the time of insertion of the ventricular drain. In patients with less acute symptoms, corticosteroids usually bring about rapid clinical improvement, permitting surgery to be performed electively.

✎ **Another presentation of tumor that requires emergency surgery is the rapid progression of visual loss.** ✎ This may be due to local compression of the optic

**Figure 7** Magnetic resonance image with contrast revealing right parieto-occipital cystic mass/tumor with heterogeneous enhancing areas. Note significant mass effect and right-to-left midline shift.

nerves, chiasm, or tracts by tumor, and can occur as a result of hemorrhage into such tumors as optic gliomas or pituitary tumors or can result simply from a tumor mass expansion, as in craniopharyngioma or meningioma. Such rapid visual loss that is the result of local compression is an indication for emergency surgical decompression. The other setting in which rapid visual loss can occur is the result of papilledema. In this setting, ventricular drainage or shunting plus steroids is usually chosen over emergency tumor resection in an effort to lower the ICP gradually and prevent the acute blindness that can occasionally occur after posterior fossa decompression. Rarely in children do tumors erode into adjacent structures, but epistaxis or bleeding from the ear occasionally is the first manifestation of a large skull base tumor. Although these rarely require acute neurosurgical intervention, if bleeding is severe or hard to control, CT or MRI scan may be necessary to make the diagnosis and acute embolization or vein ligation may be necessary to attain hemostasis.

## SPINE

### Spina Bifida

Spina bifida is derived from Latin, meaning “split spine.” Spina bifida is a type of neural tube defect (NTD), which results in incomplete closure of one or more vertebral arches of the spine, and is often associated with malformation and/or malfunction of the spinal cord in the region of the lesion. Neuroulation is the process whereby the neural plate is formed, and then closed dorsally to become the neural tube. Failure of this process results in an open NTD (119).

In the majority of cases, spina bifida is an isolated birth defect and can be minimized by the administration of folic acid 0.4 mg/day before conception and during the first three months of pregnancy. Alpha-fetoprotein (AFP) screening during the first 15 to 20 weeks of pregnancy can help identify mothers at risk for spina bifida, anencephaly, trisomy 21, and other anomalies.

Spina bifida occurs most commonly in the lumbar and sacral regions, and presents in the three major subtypes: occulta, cystica (myelomeningocele), and meningocele. Spina bifida occulta is the mildest form and does not require early surgical treatment. The skin completely covers the defect, and the spine can appear normal or have a tuft of hairs growing from it. There may or may not be a dimple over the defect. The posterior split in the vertebral arch is usually so small that the spinal cord does not protrude. However, mild sacral symptoms such as incontinence and some gait abnormalities are common.

Spina bifida cystica (myelomeningocele) is the most serious form. Failure of closure of the skin, muscle, bone, and spinal cord constitutes a myelomeningocele. These can occur at any level of the spinal canal but are most frequent in the lumbar area. These lesions frequently have disruption of the thin covering of arachnoid over the placode and leak CSF. There is no real emergency about closing these lesions, but in most pediatric neurosurgical centers they are closed within 24 to 48 hours after birth, assuming the neonate is otherwise stable (120). If closure is to be delayed more than a few hours, the lesions are covered with sterile saline-soaked sponges, and broad-spectrum antibiotics are begun.

✎ **Closure of the open spinal NTD is undertaken within the first few days of life, in order to cease the leakage of CSF and cover the spinal cord with an intact epithelial barrier.** ✎ If a marked kyphotic deformity is present,

this can be corrected at the time of closure with resection of one or more of the normal vertebral bodies. A CSF-diverting shunt may be placed concomitantly if hydrocephalus is already obvious. CNS deformities with the closed NTD are limited to the spinal cord and not associated with the Chiari II malformation and hydrocephalus. The prognosis for an infant at birth with a closed form of NTD is vastly better than one with an open NTD (121).

Meningoceles appear in 5% or less of open NTDs. Because meningoceles do not have exposed neural tissue and do not leak CSF, they can be closed electively. As the child grows, the neurologic deficit often progresses in an asymmetric fashion in lipomatous malformations, and operative intervention is advocated early in infancy to ameliorate further loss of neurologic function.

Congenital dermal sinuses are squamous epithelial lined tracts that occur in or very near the midline. These frequently go unnoticed until the patient presents with meningitis or an extra- or intradural abscess. *Staphylococcus aureus* is the most common infecting organism, although gram-negative bacteria are more frequently found in abscesses located at the low spinal region. Urgent operative intervention is required to drain these abscesses. If meningitis is present, surgical intervention should be briefly delayed until the patient receives a course of appropriate antibiotic therapy. It is often advisable to limit the procedure to drainage of purulent material, delaying the removal of the remaining tract or cyst capsule until the inflammation has subsided.

Diastematomyelia is a term used to describe the malformation in which the spinal cord is split into two hemispheres. Neurologic abnormalities are similar to those found with lipomatous malformations. Treatment consists of an elective laminectomy at least one level above and below the area of deformity. Neuroenteric cysts may or may not be associated with other forms of closed NTD such as split cord malformations. The cysts slowly enlarge by the secretion of mucinous material, which leads to compression of the adjacent neural structures. The surgical approach is individualized, depending upon the extent of the associated malformations.

Arachnoid cysts may have either an intra- or extradural location, and the pathophysiology, clinical findings, and management are similar. The dominant symptom noted with arachnoid cysts of the thoracic region is progressive lower extremity weakness, often symmetrical, which can occasionally result in paralysis if not treated. MR is the initial imaging modality of choice. Treatment of symptomatic arachnoid cysts is surgical, because aspiration would provide only temporary relief. The prognosis for patients with these cysts is excellent and recovery dramatic if surgical treatment occurs before irreversible spinal cord damage has occurred.

### Vascular Malformations

Vascular malformations of the spine are aneurysmal, arterial, arteriovenous, or venous, with the arteriovenous form being the most common (122). Spinal AVMs in children are difficult to treat surgically without causing additional damage to the spinal cord. The incidence of hemorrhage is over 50% in children, as opposed to only 10% in adults. Emergent decompression is indicated following hemorrhagic rupture.

### Spine Neoplasms

It is exceedingly rare for intramedullary neoplasms of the spinal cord to be symptomatic at birth. In Von

Hippel-Lindau disease (autosomal dominant neurocutaneous syndrome with variable penetrance), hemangioblastomas are found in the cerebellum, spinal cord, and medulla in decreasing order of frequency. Neurofibromatosis is associated with increased incidence of tumors of the entire nervous system and its coverings, including intramedullary spinal cord neoplasms (123). Intramedullary spinal cord metastases have also been found.

Intramedullary lipomas of the spinal cord are very rare congenital lesions that may first become manifest during rapid growth or excessive weight gain. If symptomatic, they can be surgically debulked; total removal is unnecessary and possibly hazardous (124).

In children, the most common extramedullary tumor is the result of seeding of the subarachnoid space from an intracranial neoplasm (such as primitive neuroectodermal tumor), which on occasion can be present at birth. Sometimes the spinal cord compression from subarachnoid seeding is the first manifestation of an intracranial tumor. Nerve sheath tumors and meningiomas are infrequently found in childhood. In children, the intra- and extradural (dumbbell) extension of a tumor is pathognomonic of a neurofibroma (125). Deformity of the spine may be the first manifestation of a neurofibroma but abnormal curvature in the spine in the absence of tumor is also common in neurofibromatosis. The diagnostic imaging modality of choice for spine tumors is MR, supplemented by CT and CT myelography if necessary. If an extramedullary tumor of the thoracic spinal cord is present, imaging of the entire CNS is advisable as multiple tumors are frequently found. Treatment is surgical removal of the tumor.

Neuroblastoma is the most common intra-abdominal malignancy of childhood. It may be manifest at birth with thoracic spinal cord compression secondary to extension of the tumor through neural foramina into the epidural space (126). Treatment is laminectomy for spinal cord decompression.

Failure of formation and segmentation of the vertebrae early in development can lead to clinical deformities that have neurologic sequelae. Spinal cord compression is most often seen in structural defects that produce kyphosis, as dorsal angulation of the spine is most likely to compromise the spinal canal (127).

Embryologic segmental maldevelopment can lead to hypoplastic or absent thoracic or lumbar vertebrae (128). The nerve roots adjacent to the bony deformity are either dysplastic or lacking in a condition referred to as segmental spinal dysgenesis. The neurologic deficit distal to the segmental dysgenesis can be partial or complete. The lower extremities are often deformed. The loss of neurologic function, if present, can occur secondary to rapidly increasing kyphosis from an unstable spine. Decompressive laminectomy in this situation would add to the lack of spinal stability. Thus, an anterior approach is advisable if necessary to decompress the spinal cord and stabilize the spinal column.

In achondroplasia, spinal cord compression can occur with development and growth. With aging, the stenosis can be further exacerbated by osteoarthritic spurs, disk degeneration, and kyphosis (129).

A severe form of kyphoscoliosis in the cervical and thoracic region is commonly seen in neurofibromatosis, regardless of the presence or absence of a neurofibroma. Such marked deformities, unless aggressively treated, can lead to paralysis secondary to spinal cord compression (130).

## MISCELLANEOUS

### Craniofacial Anomalies

Anomalies of the craniofacial skeleton can result in gruesome facial appearances including those involving amniotic band syndromes, facial clefts, cloverleaf skull appearance, and congenital absence of the nose or eyes. Children with severe Crouzon's, Apert's, or Pfeiffer's syndromes also appear dramatically abnormal, and a correct initial diagnosis often is not made. Despite their appearance, few of these children require emergency neurosurgery. The most common acute problem involves the airway, because choanal atresia or marked hypoplasia of the midface may interfere with ventilation (131). Endotracheal intubation can be very difficult, and a tracheostomy may occasionally be required to save a child's life. The globes of the eyes occasionally are completely dislocated out of the orbit, with closure of the lids posterior to the globe. This results in exposure and ischemia and requires treatment, first with lubricant and plastic wrap to keep the conjunctiva moist. Rarely is tarsorrhaphy adequate because of the degree of exorbitism, and early surgery with supraorbital rim advancement and tarsorrhaphy is occasionally the only way to obtain some coverage for the eyes. In general, craniofacial surgery for children with severe anomalies is delayed until after four months of age unless they show evidence of intracranial hypertension. It is almost impossible to correct any aspect of the facial anomaly before four months, even in the upper orbital area.

### Encephaloceles

Encephaloceles occur at a rate of 1:10,000 live births in North America, and about 70% occur in the posterior region of the cranium and are either supratentorial or infratentorial (132). Despite presenting with a dramatic external appearance, most encephaloceles are not surgical emergencies. However, those with incomplete skin coverage, leaking CSF, or displaying visible brain tissue do require urgent closure (i.e., within 24 hours), provided the general condition of the neonate is otherwise stable. The exposed lesion is covered with sterile saline-soaked sponges, and broad-spectrum antibiotics are begun. CT or MRI scan or both are required to define the anatomy of the encephalocele and the intracranial brain.

Prognosis is best correlated with the size and anatomic appearance of the residual intracranial brain rather than with the size of the encephalocele. The herniated cerebral tissue is not normal and no effort is made to replace it within the cranial cavity; the abnormal tissue is removed, sparing the intracranial vasculature, and the dura closed. Hydrocephalus is common but usually does not need therapy in the first few days. With severe hydrocephalus, it is preferable to insert a shunt and decompress the brain before performing a definitive operation on the encephalocele. Anterior encephaloceles (in the nose or mouth), often in association with a cleft palate, can produce acute airway obstruction and feeding problems that require tracheostomy for emergency management of the airway. In such cases, it is advisable to postpone definitive surgery for as long as several months if possible to make the surgery safer.

### Aplasia Cutis Congenita

Aplasia cutis congenita is an area of the skull where bone and skin fail to form, leaving exposed and occasionally slightly herniating dura, most commonly in the midline, associated with a suture or venous sinus. This is not an encephalocele

and, because the dura is intact, often can be treated conservatively until a child is older, at which time surgery to rotate skin over the lesion is usually undertaken. Smaller lesions can be treated by immediate surgical closure of the skin.

### Teratomas and Choristomas

Teratomas and choristomas are rare lesions, but they can present at birth as an emergency because of airway obstruction or feeding problems. The most common location is in the tongue or facies. These lesions are usually small at birth and grow rapidly in the first few days of life, yet they are rarely malignant. Tracheostomy and a feeding tube are often required during the early life-threatening phase. Those that come to neurosurgical attention usually involve the intracranial space and exit from the cranium through the cranial nerve foramina, most frequently the trigeminal or superior or inferior orbital fissures, and present in the mouth and neck. These lesions can usually be completely removed in a single operation in the first few months of life, with cure of the lesions. It is unclear whether these should be categorized as congenital or neoplastic lesions, and in some cases true tumors are found.

## PEDIATRIC INTENSIVE CARE UNIT COMPLICATIONS FOLLOWING CENTRAL NERVOUS SYSTEM TRAUMA

### Hypotension

Marked worsening in outcome after TBI is associated with hypotension (133). The adverse effect of hypotension in head-injured children is as great as in head-injured adults. Children, in whom hypotension is present upon admission to the emergency department, suffer significantly higher mortality rates compared to those in children who are normotensive at the time of admission. The mechanism of the adverse effect of hypotension on outcome is thought to be decreased CPP (134,135).

### Acute Lung Injury

Bratton and Davis used the Traumatic Coma Data Bank to study the incidence and negative prognostic sign of acute lung injury after isolated head trauma (136). Of the 100 patients in the study, the 20 who developed acute lung injury, most commonly in the form of neurogenic pulmonary edema, had more severe global brain injury: lower GCS scores, more frequent episodes of intracranial hypertension, and more ominous findings on the initial CT scan, and were almost three times more likely to die or survive in a persistent vegetative state.

### Neuroinflammation

☞ There exists a neuroinflammatory response to TBI (137). This phenomenon contributes to the secondary injury that, along with the primary or biomechanical injury, is a major determinant of outcome. ☞ Whalen (138) noted elevated levels of interleukin-8 (IL-8) in the CSF of children in the first four to five days after head injury, which correlated directly with mortality. IL-8 might thus be a useful prognostic indicator of outcome in head-injured children.

### Hypopituitarism

Hypopituitarism as a sequela of head trauma was first described by Escamilla and Lisser more than 50 years ago (139). Benvenga (140) reviewed a total of 367 cases of

post head trauma hypopituitarism (PHTH) and pointed out that: (i) the head trauma could have been minor; (ii) the head trauma could have occurred several years before the onset of the hypopituitarism; and (iii) the patient could have forgotten about the head injury.

The epidemiology of PHTH indicates that the male-to-female ratio is five to one. In about 60% of cases, the head trauma had occurred when the patient was between the ages of 11 and 29. Although the majority of patients developed PHTH within one year after the trauma, 15% of patients were diagnosed five years or more after the accident.

## EYE TO THE FUTURE

The horizon for pediatric neurosurgery is intertwined with the continual evolution of molecular biology, critical care medicine, and neuroimaging. Advances have been implemented such as neuroendoscopy and hyperosmolar therapy, and the future for molecular therapies remains promising.

### Molecular Therapies

Historically, neoplasms such as medulloblastomas and other embryonal tumors have been classified by location, histology, and extent of surgical resection. More recently, molecular biologic studies have led to a new understanding of cell signaling pathways that promote tumor growth. Research continues to develop brain tumor therapies based on molecules that target growth factor receptors or downstream effectors. Also, molecular markers are being studied to validate outcome predictors and to stratify patients in standard and high-risk groups for clinical trials (141).

Whereas some cell damage occurs at the time of the traumatic event, much of the damage occurs between minutes and days after injury. This delayed injury process, known as secondary injury, is mediated by injury factors that, if identified, could be treated with "antifactors" that could prevent or at least attenuate the secondary injury process.

Four key mechanistic causes are associated with secondary damage from TBI. These include: (i) ischemic excitotoxicity, (ii) neuronal death cascades, (iii) cerebral swelling, and (iv) inflammation. Therapies have been aimed at all of these mechanisms.

### Hypothermia

The therapeutic use of hypothermia in a patient with TBI was first described by Fay in 1943 (142). Because of the dearth of comparative studies during subsequent years, its therapeutic efficacy remained unestablished (143–145) despite the associated neuroprotection. Hypothermia can be utilized for neuroprotection. For every degree celsius ( $^{\circ}\text{C}$ ) decrease in body temperature, there is a 7% decrease in cerebral metabolic rate for oxygen ( $\text{CMRO}_2$ ) (146). Moderate hypothermia to  $32^{\circ}\text{C}$  or  $33^{\circ}\text{C}$  for 24 hours, initiated soon after severe traumatic brain injury, significantly improved the outcome and decreased tissue injury in rats (147,148). However, moderate hypothermia for 24 hours following TBI in humans did not improve outcomes (149).

The specific putative beneficial effects of hypothermia include the reduction of cerebral ischemia, edema, and tissue injury, and the preservation of the blood-brain barrier (150). Hypothermia may mitigate secondary brain injury by

suppressing the post-traumatic inflammatory response and by reducing the extracellular concentrations of excitatory neurotransmitters, particularly glutamate. Thus far, there are no studies documenting the routine use of hypothermia in the management of pediatric patients with head injury; however, a recent paper suggests that it is likely a safe therapeutic intervention for children after severe TBI up to 24 hours after injury. Although laboratory experimental research has shown beneficial effects of hypothermia in TBI, studies in humans (meta-analysis) have yielded conflicting results with respect to the risk of death and poor neurologic outcome (151–156). Part of the conflict arises from the fact that most studies have different speeds of induction of hypothermia. Neuroprotective measures may have limited time to be effective. The duration of hypothermia and the rate of rewarming, with the potential deleterious effects on ICP, were all different (149,151–159). Further studies are necessary and warranted to determine its effect on functional outcome and intracranial hypertension (160).

### Hypertonic Saline

In pediatric patients, clinical experience with the use of hypertonic saline is still limited compared to use in adults. Hypertonic saline has been found to be helpful in the management of severe TBI in infants and children (161). Hypertonic saline decreases ICP by mechanisms similar to other hyperosmotic agents. Sodium has a low penetration of the blood-brain barrier. Saline restores normal cellular resting potential, cell volume, may inhibit inflammation, and lowers ICP. Hypertonic saline may have beneficial effects on excitatory neurotransmitters and the immune system (162,163). The major disadvantages of hypertonic saline include hypernatremia with consequent cellular dehydration and the development of central pontine myelinolysis and intracranial hemorrhage (164–170). Currently studies evaluating long-term neurologic outcome and the possible role of even more aggressive hyperosmolar therapy are needed (171). These studies should consider initiation of hypertonic saline as soon as feasibly possible, including the prehospital period (172).

### New Intracranial Pressure Monitoring and Cerebrospinal Fluid Draining Techniques

Hydrocephalus treatment received great advancement with the application of endoscopic third ventriculostomy. Used in hydrocephalus where the point of obstruction is below the third ventricle (aqueduct and/or fourth ventricle), third ventriculostomy has obviated the need for ventricular shunting for certain etiologies and decreased the drainage dependence on shunts for other etiologies of hydrocephalus. Studies evaluating its efficacy in hydrocephalus from infection, hemorrhage, and other causes are currently under way. Given the many complications with shunting children, the role of third ventriculostomy will surely expand (173).

### Magnesium Therapy

Work by McIntosh (1993) (174) revealed that a large number of intracellular metabolic processes implicated in TBI are regulated by magnesium ( $\text{Mg}^{2+}$ ). These include energy metabolism, membrane stability, calcium-channel function, as well as protein and DNA synthesis (175,176). At the extracellular level, the ability of  $\text{Mg}^{2+}$  to block the *N*-methyl-D-aspartate channel is recognized as neuroprotective (177).

Several researchers have documented that TBI causes a reduction in the brain intracellular free  $Mg^{++}$  levels and that this is correlated with functional outcome (178). The possible beneficial role of  $Mg^{++}$  has been documented in a recent study that demonstrated a reduction in post-traumatic lesion size after treatment with  $Mg^{++}$  (179).

Magnesium therapy has been shown to reduce infarct size and volume, inhibit neuronal death, and attenuate motor impairment. Deficiencies in  $Mg^{++}$  can increase substance P release and induce a proinflammatory response. The proinflammatory responses accompanying TBI are also associated with a decrease in intracellular brain  $Mg^{++}$ . In animal studies, acute treatment with  $MgSO_4$  attenuated the long-term hippocampal tissue loss after TBI, but did not affect the animal's learning (180–183). Although  $Mg^{++}$  has a tremendous beneficial potential in the treatment of TBI, it has not yet been studied in large randomized control trials in children.

## SUMMARY

Severe head injuries are generally classified as a GCS score  $<8$ . By definition, a serious head injury is one in which the patient has a GCS score of 10 or less. A decrease in the GCS score by 3 following the initial examination, pupillary inequality greater than 1 mm, lateralized extremity weakness, a markedly depressed skull fracture, or an open fracture with evident brain or CSF leakage will require head CT scan. Approximately 50% of these patients will have an expanding intracranial clot and there is an overall 41% mortality, 26% good recovery, 16% moderate disability, and severe disability/vegetative state in 17%.

The usefulness of skull X rays was evaluated in a prospective study of 7035 patients with closed head injury. Patients with high risk for intracranial injury included those with a progressive decline or depression in level of consciousness, focal neurologic deficit, progressive headache and/or identified penetrating or depressed fracture. All were admitted for close in-house observation and underwent a CT of the head. Skull films were only helpful if penetrating injury was present.

The level of consciousness and arousability of the child is a key variable in assessing potential increases in ICP. The immediate examination includes the GCS score, pupillary, and motor function. All examinations should be performed promptly and sequentially with a final examination prior to discharge or admission. The contribution of intoxicants and hypotension must also be addressed. Clinical evidence of a basilar skull fracture includes CSF rhinorrhea or otorrhea, hemotympanum, blood in the external auditory meatus, subconjunctival hemorrhage, raccoon eyes, or a Battle's sign.

Pitfalls in the evaluation of patients following head injury include alternative causes for a blown pupil including direct ocular injury, vitreous hemorrhage, vitreal-retinal injury, and injury to the optic nerve. Monoparesis can result from brachial plexus injury and/or fracture. In addition, subgaleal hematomas can frequently mimic skull fractures on palpation. On examining children, evidence of a subhyaloid hemorrhage or full fontanel is usually assessed. The presence of a ventriculoperitoneal shunt and the potential for abuse are additional considerations that can modify the management of these children. As rules of thumb, all unconscious patients, all temporal skull fractures, all depressed and basilar fractures, and all serious head injuries

undergo CT scanning. In multisystem trauma, low systemic blood pressure signifies depletion of blood volume until proven otherwise.

Once an injury has occurred, survival and good recovery mandate adequate initial assessment of the pediatric patient in the field with cardiovascular and mechanical stabilization, airway control, and either intravenous or intraosseous access for fluid resuscitation.

Innovative research efforts, aggressive injury prevention schemes focusing on the design of appropriately sized automotive and sports safety equipment (e.g., seatbelts, helmets), and intensified education of parents and caretakers in schools and playgrounds on the prevention of accidents and child abuse will all contribute to the reduction of head injuries in children.

## KEY POINTS

- ✎ In an infant with an open fontanel and open cranial sutures, small increases in the volume of intradural contents can be accommodated by separation of the sutures and distention of the fontanel.
- ✎ In children, hemiparesis occurs on the side ipsilateral to the herniation 50% of the time, whereas in adults hemiparesis occurs ipsilateral to the herniation 75% of the time.
- ✎ Unfortunately, the status of autoregulation is not known in the clinical setting, and thus therapy is directed at maintaining normal or nearly normal ICP and MAP in the hope that this will preserve CBF.
- ✎ After pediatric head trauma, acute loss of consciousness is less commonly the result of increased ICP unlike in adults. Accordingly, there is no indication for routinely administering an osmotic diuretic to children in coma after head trauma.
- ✎ A reliable and reproducible neurologic examination is much more important than any number or value from an ICP monitor or ventriculostomy catheter.
- ✎ Lesions that may require immediate surgery are the intracranial hematomas, compound depressed skull fractures, and penetrating trauma.
- ✎ It is recommended that, because clinical criteria and skull X rays are poor predictors of intracranial hemorrhage, all children with a GCS score of 13 or 14 routinely have a screening noncontrast-enhanced CT scan.
- ✎ Most forms of penetrating cranial injury (PCI) require surgical exploration.
- ✎ The typical angiographic picture of trauma-induced occlusion of the cervical internal carotid artery is abrupt blockage of contrast flow approximately 1–3 cm above the bifurcation of the common carotid artery in the neck.
- ✎ Patients with fluctuating neurologic symptoms in the face of an acutely occluded internal carotid artery may benefit from urgent exploration and thromboendarterectomy.
- ✎ The most common intracranial arterial structure to be occluded in blunt head injury is the internal carotid artery.
- ✎ The most common mode of presentation of traumatic aneurysm in symptomatic patients is that of delayed SAH following a head injury.
- ✎ Early high-output cardiac failure in neonates can occur with vascular shunting lesions in the cranium.

- ✂ The diagnosis of shunt malfunction or acute intracranial hypertension due to hydrocephalus is essentially based on the history and often confirmed by a neuroimaging study (CT or MRI), that shows ventricular dilatation.
- ✂ The most frequent setting in which an infectious process requires emergency neurosurgery is that of a brain abscess (111,112). The presentation is either with focal neurologic deficit or the signs of intracranial hypertension.
- ✂ Another presentation of tumor that requires emergency surgery is the rapid progression of visual loss.
- ✂ Closure of the open spinal NTD is undertaken within the first few days of life, in order to cease the leakage of CSF and cover the spinal cord with an intact epithelial barrier.
- ✂ There exists a neuroinflammatory response to TBI (137). This phenomenon contributes to the secondary injury that, along with the primary or biomechanical injury, is a major determinant of outcome.

### INTRODUCTION

Brain death is often perceived as the tragic end to the life of a loved one, and sometimes as a medical failure. However, the prospect of organ donation can refocus the grief emanating from an otherwise devastating event toward the greater good of extending the life of another patient who would otherwise also die. Indeed, the gift of organs provides tremendous benefits to the recipient, but also honors the departed patients, and assuages some of the grief experienced by the family and friends of the donor.

The concept of brain death is a relatively recent idea that began to emerge following advances in life support technology which occurred during the second half of the twentieth century (1,2). Classically, death had been defined as the cessation of respiration and heart beat. However, respiration can now be supported with mechanical ventilation, and cardiac function can be assisted both pharmacologically and mechanically well after the patient's brain has ceased viability. Despite science fiction stories, such as Robin Cook's *Coma* (3), the patient whose brain has died is incapable of recovery, and without special intervention typically succumbs to cardiac arrest within a week (2). Because several elements of the cardiovascular and endocrine system often become unstable following brain death, decisions regarding organ donation need to be made very soon after brain death is declared.

This chapter begins with a brief, partly historical survey of the medical advances, religious and philosophical principles involved in the conceptual evolution in the definition of brain death. Some religious and cultural objections to the definition of brain death remain, and these are discussed in greater detail in Volume 2, Chapter 68. After the historical review, the chapter focuses upon the main emphasis, which is diagnosis of brain death and the management of the brain dead organ donor. The diagnosis of brain death has clinical criteria (sufficient in the majority of cases) and confirmatory tests (occasionally required to expedite diagnoses) both of which are completely reviewed in this chapter. The management of the brain dead patient is divided between critical care considerations while awaiting organ procurement (section "ICU Management of the Brain Dead Organ Donor"), and operative management, which reviews both the anesthetic and surgical considerations for organ procurement (section "Operative Management During Organ Procurement"). Finally, this chapter provides a glimpse into the future with a sampling of ideas regarding

a worldwide unification of brain death criteria, and search for earlier markers of brain death.

### EVOLVING CONCEPT OF BRAIN DEATH

#### Advances in Organ Preservation and Transplantation

The concept that brain death is philosophically and ethically equivalent to the death of the person as a whole, developed very recently in response to prolonged futile maintenance of unrecoverable patients in intensive care units (ICUs) during the 1950s and 1960s. The nascent idea of brain death emerged as physicians and families grappled with the reality that medical technology had advanced beyond our philosophical constructs (see the section on philosophical evolution). Indeed, one half century ago medical science progressed to the degree that viable hearts, lungs (and other organs) could be maintained in patients long after blood flow to the brain had ceased and/or brain and brainstem neurons had become necrotic. One of the first clinical-pathological (and conceptual) descriptions of brain death was provided in France, when Mollaret and Goulon introduced the term *coma dépassé* (irreversible coma) in 1959 (4). In this report, 23 comatose patients are described, all with absent brainstem reflexes, documented apnea, and flat electroencephalograms (EEGs). The subsequent autopsy findings revealed necrotic brain and brainstem (4).

The concept of brain death also coincided with important advances in organ transplantation and an increased demand for organ donors. Pioneering trauma anesthesiologist, Henry K. Beecher, at Massachusetts General Hospital, chaired the Harvard University committee that defined the diagnosis and validity of brain death. ⚡ **Beecher's white paper, published in JAMA in 1968, concentrated on limiting the use of ICUs to maintain futile life support for patients who had no chance of recovery secondary to death and necrosis of their entire brain (5).** ⚡

Harvard University set out clinical and laboratory criteria required to declare a patient brain dead. These criteria (Table 1), which included lack of brainstem reflexes, unresponsiveness to noxious stimuli, and lack of spontaneous respiratory activity despite an elevated PaCO<sub>2</sub>, were developed as safeguards to prevent withdrawal of life support from an otherwise viable patient in deep coma. Initially, these clinical criteria for brain death received rather slow acceptance among the medical community. Indeed, it took a decade before the uniform brain death act

**Table 1** Original Harvard Criteria for Diagnosing Brain Death

Criteria	Clinical examination, testing results
Unreceptivity and unresponsivity	No response to intensely painful stimuli
No movements, and no breathing	No spontaneous movement observed by physicians during period of at least one hour, no effort to breathe when normocarbic and ventilator discontinued for three minutes
No reflexes	Fixed dilated pupils, no oculovestibular or oculocephalic reflex, no blinking, no postural activity (decerebrate), no swallowing, yawning, or vocalization, no corneal or pharyngeal reflexes
Flat EEG	Isoelectric at standard gains 50 $\mu$ V/5 mm for 10–20 min, also isoelectric at 25 $\mu$ V/5 mm

Source: From Ref. 53.

legislation began to be prepared in 1979 by representatives of the medical community, the legal community, and state governments. The President's Commission for the Study of Ethical Problems in Medicine and Biomedical and Behavioral Research published the Uniform Determination of Death Act in 1981 (6). This act defined death as the irreversible cessation of circulatory and respiratory functions or irreversible cessation of brain and brainstem activities (1). The Uniform Determination of Death Act in the United States became a model for the 50 states to write legislation defining brain death. **Currently, the U.S. standard to declare brain death is to document the absence of brain and brainstem activity (7).**

In 1995, the American Academy of Neurology (AAN) established practice parameters for the diagnosis of brain death (8). These guidelines represent a formalization of clinical practice incorporating the Harvard criteria. Follow-up studies have not identified any patient recovery subsequent to the strict application of these guidelines. In 2000, the Canadian Neurocritical Care Group published Guidelines for the Diagnosis of Brain Death, that closely mirror the AAN guidelines.

In 1971, brainstem death was shown to be the critical CNS lesion that when present was incompatible with unresponsive survival (9). Subsequently, the Medical Royal Colleges and their faculties published a statement in the United Kingdom that defined brain death as complete, irreversible loss of brainstem function (10). **The current U.K. standard for the diagnosis of brain death is complete and irreversible loss of brainstem function.**

Although the medical community in both Europe and America has been proactive in developing the concept of brain death, the lay public continues to reveal confusion about the terminology and whether brain death means the person is irreversibly dead (11). A 1992 survey of over 6000 adults in the United States found that 21% believed it was possible for a brain dead person to recover and 16% were unsure (11). A similar survey of families of brain dead organ donors and nondonors performed in 1994

found similar levels of misunderstanding concerning brain death (12).

**A patient who meets the clinical definition of brain death by either the U.S. or U.K. criteria is in essence dead as a person, as he/she will never recover sentient function.** Because cessation of cardiac activity usually proceeds relatively soon following the death of the brainstem, successful organ transplantation requires a reasonably brief duration between the declaration of brain death and the initiation of plans for organ procurement (12,13). Originally, the declaration of brain death required that two clinical examinations (both consistent with brain death) be conducted 24-hour apart. Two independent physicians are still required, but the 24 hours interval is no longer required in the United States. Experience has demonstrated that a rigorous clinical examination when properly performed clearly identifies patients with irreversible brain death. The purpose of the second examination is to confirm that the first examination was accurately performed. It is now considered ethical that the two examinations be performed within the same hour, because of the unstable homeostasis that develops soon after brain (and brainstem) death. However, because these patients are almost always receiving mechanical ventilation and have a spontaneously beating heart, the skin may be warm to the touch and the body could appear to be merely sleeping by family and others. The imperative that a patient meets the full criteria for brain death before organ procurement commences goes without saying (Table 2) (13–15).

Because experience demonstrates that a carefully performed clinical examination is fully sufficient to diagnose brain death, confirmatory laboratory tests are seldom needed (except for an arterial blood gas to document respiratory unresponsiveness to profound respiratory acidosis) (7,8). While EEG, angiography, transcranial Doppler, and radionuclide perfusion scans of the brain and brainstem are confirmatory of brain and brainstem death, they don't add any information to a properly performed clinical examination (8,13–15). However, these confirmatory studies can be useful when the etiology of a patient's profound coma is uncertain or when some elements of the clinical criteria cannot be determined (i.e., the patient denatures or becomes hemodynamically unstable during apnea testing).

### International Variability in Definition

As mentioned above, in the United Kingdom, brain death is defined as "complete and irreversible loss of brainstem function" (7). In the United Kingdom, brain death is called "brain stem death" because a functioning brainstem is required to maintain life. Furthermore, a patient can suffer significant loss of cerebral cortex and maintain life through a functioning brainstem. Legally, the British physician only needs to document loss of brain stem function unlike the U.S. physician who must document brain (cerebral) and brainstem death.

As in America, the British public and medical community was initially relatively slow to accept the notion that brainstem death is equivalent to death of the patient. The U.K. criteria are observed by many of the previously colonized countries (including Australia and New Zealand), whereas Central and South American countries follow the U.S. criteria. Non-U.K. European countries, and those of the Middle East, Africa, Asia, and South Pacific have variable definitions (7). In Mainland China a specific legal definition of brain death does not yet exist, whereas Hong Kong follows the U.K. criteria. The brain death criteria in Japan have many unique features, and acceptance of

**Table 2** American Academy of Neurology Practice Parameters for Determining Brain Death in Adults

Category	Criteria	Subcategory, explanation, comments
A	Prerequisite: document absence of exclusion criteria	Known reversible causes of coma or depressed brain function Complicating medical conditions Drug intoxication or poisoning Core temperature $\leq 32^{\circ}\text{C}$
B <sub>1</sub>	Coma or unresponsiveness	Lack of cerebral motor response (in any extremity) to pain by supraorbital pressure
B <sub>2</sub>	Absence of brainstem reflexes	Pupils—midposition (5–7 mm) no response to bright light Ocular movement No oculocephalic reflex (contraindicated with unstable c-spine) No oculovestibular reflex (cold caloric) Facial sensation and facial motor response No corneal reflex, no grimacing to deep pain No jaw reflex Pharyngeal and tracheal reflexes (no gag or cough)
B <sub>3</sub>	Apnea	Start with PaCO <sub>2</sub> = 40 and PaO <sub>2</sub> $\geq$ 200 Disconnect patient from ventilator Administer O <sub>2</sub> 8–10 L/min via suction catheter with tip placed at level of carina (optional) Observe closely for respiratory motion Measure PaO <sub>2</sub> /PaCO <sub>2</sub> /pH at end of apnea trial (8–10 min) Reconnect the ventilator if respirations seen or hemodynamic instability occurs Positive result requires PaCO <sub>2</sub> to increase to $\geq$ 60 mmHg or by 20 mmHg over baseline
C	Confirmatory tests (seldom required)	<sup>99m</sup> TcHM-PAO brain scan. “Hollow skull phenomenon” Angiography—no intracerebral filling at level of carotid bifurcation or circle of Willis EEG—no activity for 30 min <sup>a</sup> using minimal technical criteria for brain death TCD small systolic peaks and diastolic flow or reverberating flow

To use table: (i) ensure all exclusion criteria in Category A are absent, (ii) ensure that each criteria in B (first 3 points) are present, (iii) confirmatory tests only needed if unclear.

<sup>a</sup>Per minimal technical criteria for brain death.

organ transplantation has been very slow because of religious and cultural difficulties with the concept of brain death (7). The variable worldwide definitions of brain death, and the associated cultural and religious considerations are discussed in greater detail in Volume 2, Chapter 68. Additionally, Wijdicks’ review of international norms of brain death provides the best currently available survey of world wide practices for declaring brain death (Table 3) (7).

**Religious and Legal Viewpoints**

The various religious traditions have differing viewpoints on the concept of brain death. Most faith traditions consider the

**Table 3** Worldwide Brain Death Laws

time of death a medical diagnosis and accept a physician’s diagnosis of death. Therefore, if the medical diagnosis is that brain death means the death of the patient, then the patient is dead and the soul has departed the body. However, a few religious groups still consider the cessation of breathing and heartbeat as a requirement for diagnosing death. State laws in the United States vary to accommodate such differences in religious views (7).

The legal community has been reluctant to define the precise nature of death (i.e., brain death was equivalent to the death of the whole person). Accordingly, most legal jurisdictions in the United States acknowledge that the diagnosis of death is a medical, not a legal issue (12). The Uniform Determination of Death Act serves as a template for most state legislation, and emphasizes that the person is dead when his brain and brainstem irreversibly cease function. However, it is left to the physician to declare when brain and brainstem death has occurred. Furthermore, the development of coma before the person meets the criteria of brain death is not synonymous with the time of death. The person is considered alive until all brain and brainstem activity cease.

**Philosophical Evolution Continues**

It is not surprising that philosophical disagreement about the concept of brain death continues, given the continuing debate about when life starts, and that the ancient quest

for the source of the “mind” (sentient awareness) has only recently been resolved. The current philosophical understanding of brain death as equivalent to death of the sentient portion of the person, is the result of a journey several millennia in duration.

Hippocrates (460–377 BC) was convinced that consciousness derived from the brain, as evidenced in his writings: “men ought to know that from nothing else but the brain comes joys, delights, laughter and sports, and sorrows, grieves, despondency and lamentations” (16). Some contemporary Greek philosophers, for example, Plato (427–347 BC) published writings that placed the seat of thought in the brain [e.g., the *Timaes* (360 BC)] (17). However, other writings from Plato imply an extracorporeal source for the mind. Aristotle (384–322 BC.), the father of comparative biology, believed that the mind resided in the heart, and the function of the brain was to cool the heart. It is likely that Aristotle performed experiments on the brains of animals, and found it lacking sensation (17). The later Christian philosophers St. Augustine (354–430) and St. Thomas Aquinas (1225–1274) believed that the mind (or “soul”) was separate from the body (18).

The early Greeks also theorized that all diseases shared a single cause: imbalance of the fluid portions of the body, specifically the four humors, yellow bile, black bile, blood and phlegm. This incorrect thinking paralyzed the advancement of philosophy, science and medicine, and is a major reason why physicians did not know the cause of a single important human disease until a little more than 150 years ago (19).

Galen (130–200) believed that the anatomical seat of the soul was the pineal gland. Unfortunately, Galen’s dogma hopelessly hindered the advance of medical science and natural philosophy for 1300 years (17). Andreas Vesalius (1514–1564) believed the ventricles of the brain served as the seat of perception and cognition (17).

The pervasive belief at that time was that a “vital force” was responsible for life (an archaic philosophy now referred to as vitalism). Indeed, William Harvey (1578–1657) began his research in an effort to determine the precise location of where the vital spirits were brewed. He held the popular view that the blood was made in the liver, and that the heart and lungs made the vital spirits. He discovered the heart to be a muscular pump, and that the blood circulated (17).

Rene Descartes (1595–1650) believed that intellectual thought and reasoning is what makes humans unique among animal species; his famous “*cognito ergo sum*,” literally, “I think, therefore I am,” actually means I think, therefore I have a mind. However, this otherwise brilliant natural philosopher confused later scientific and philosophical thinking, with his dual substance view. Dualism contends that the mind’s function of consciousness occurred via a process independently from the physical brain. The Cartesian model held that the mind and body were separate (18).

John Locke (1632–1704), founder of empiricism attacked the mind-body dichotomy of Descartes (18). The Scottish empiricist, David Hume (1711–1776), a central influence on Charles Darwin, discounted both mysticism and dualism. Although Hume was considered by contemporaries to be a skeptic and atheist, he became a leader of philosophical naturalism, a branch of philosophy which has evolved into neurophilosophy (18). Neurophilosophers believe that the brain is the seat of the mind, and that sound philosophy requires a strong understanding of neuroscience.

Joseph Priestley (1733–1804), naturalist, scientist, and philosopher, discovered oxygen, and that animals need it to survive. Priestley argued against spiritualism, in favor of materiality of the soul. The French philosopher and physician Cabanis (1757–1808) built upon Priestley’s philosophy of materialism to forcefully state, for the first time since Hippocrates, that “the mind and the brain are one.”

Giovanni Batista Morgagni (1682–1771) worked for 50 years to develop a compendium of clinical pathological correlations, in a book entitled “On the seats and causes of disease.” Yet, the concept of living cells was still undiscovered. After Morgagni, Frenchman Xavier Bichat (1800) focused the origin of disease to the tissue level, and finally, Rudolph Virchow (1858) further refined it down to the cellular level. This set the stage for understanding neurological function on a cellular level.

The following scientists and philosophers discovered that the organized function of neurons within the brain are responsible for what we call the mind. Neurons were visualized for the first time by Purkinje (1837), and Santiago Ramon Y Cajal of Madrid (1852–1934), along with Camillo Golgi of Pavia (1843–1926) later won the Nobel Prize for describing the histologic anatomy of the brain and spinal cord.

Charles Bell (1774–1842), a Scottish surgeon, discovered that the ventral roots of the spinal cord contain only motor and the dorsal roots only sensory fibers. In so doing, he developed the foundation for neural organization within the CNS. Later, Johannes Muëller (1801–1858) of Berlin presented a unified theory of neurophysiology involving two cardinal principles (*i*) that the nervous system serves as an intermediary between the world and the mind, and (*ii*) the sensory nerve for vision is insensible to sound, as the nerve of audition is to light.

Paul Broca (1824–1880), the French physician, discovered that a lesion in the left frontal lobe was responsible for the pathology of a speechless, right hemiplegic patient. Finally, John Hughlings Jackson (1835–1911), an English Physician, provided the first general description of the functional organization of the nervous system. Discrete lesions of specific areas of the CNS have since been demonstrated to abolish the function attributed to it. However, death of the entire brain had never been observed in a patient with a pulse and warm skin until the modern development of ventilators.

Consciousness has reemerged as a topic in philosophical inquiry once again over the past three decades. Modern neurophilosophers such as Paul Churchland (20) are exploring the use of neural networks to help unlock the neurobiologic explanation of consciousness. Francis Crick and Christof Koch are studying the visual system in an effort to find a universal clue to the mechanism of consciousness (21). All agree consciousness occurs in the brain, but there are likely discrete areas that are responsible for certain elements of consciousness and higher thought (including attention, reasoning, memory, etc.). For example, the area of the brain that governs free will may be located in Brodman’s area 24 according to Crick (16). The future definition of brain death may relate to destruction or death of one of these vital structures.

## DIAGNOSIS OF BRAIN DEATH

### Clinical Determination of Brain Death

♣ Brain death is diagnosed clinically with the establishment of three major criteria. First, the neurological injury

**Table 4** Confounding Agents/Conditions that Need to Be Excluded in Brain Death Testing

Agent/condition	Example
Pharmacologic	Anesthetics, paralytics, methaqualone, barbiturates, diazepam, bretylium, mecloqualone, amitriptyline, meprobamate, trichloroethylene, alcohols, etc.
Metabolic	Hepatic encephalopathy Uremic encephalopathy Hyperosmolar coma Hypophosphatemia
Temperature	Hypothermia $<32^{\circ}$ Celsius
Vascular	Shock or hypotension
Infectious	Brain stem encephalitis Guillain–Barre syndrome

Source: From Refs. 8, 13, 15, and 47.

**should be irreversible (1,13,15,22). Second, there is a loss of cerebral function. Third, there is a loss of brainstem function (13,15).** ⚡ Prior to establishing the clinical criteria for brain death, several potentially confounding factors must be eliminated (Table 4). For example, deep coma secondary to metabolic encephalopathy would not be compatible with the diagnosis of brain death, nor would lack of respiration solely due to a high spinal cord injury (23).

After brain death the pupils become fixed in mid-position due to loss of parasympathetic and sympathetic input. Loss of cerebral or brainstem function due to cell death in this region of the CNS results in painful stimuli in absence of response. Any movement or other response that requires function of these structures is thus incompatible with brain death. For example, decerebrate and/or decorticate posturing usually correlates with severe TBI, but their presence demonstrates that the brain is not yet dead.

⚡ **Spinal reflexes, such as deep tendon reflexes and triple flexion responses, can be preserved following brain death. Release phenomena of the spinal cord are occasionally seen in the setting of brain death and do not exclude brain death; these include shivering, goose bumps, forced exhalation and some arm movements (13,14).** ⚡

### Irreversible Etiology of Coma

Irreversibility is established when a structural disease or an irreversible metabolic cause (e.g., hypoxia, carbon monoxide poisoning) is known to have occurred to the patient resulting in brain cell death. At the same time, agents or conditions that confound the testing of brain death need to be excluded (Table 4). The patient must be documented as normothermic, free of reversible metabolic disturbances (e.g., renal failure, hepatic failure), CNS depressant drugs, or neuromuscular blocking agents. Therefore, it is imperative for the physician approaching a possibly brain dead patient to be fully aware of the patient's history of present illness, and the patient must also be screened for the presence of any drugs or conditions that mimic brain death (13). If any doubt exists, the observation period should be extended to 12 to 24 hours (two brain death examinations separated in time by 12 to 24 hours) (13,14). The role of confirmatory tests is discussed later in this section.

### Loss of Cerebral Function

The loss of cerebral function can be found in some vegetative states; only when it occurs along with loss of brainstem function can a person be considered brain dead. In the setting of brain death, there should be no spontaneous movement, eye opening, breathing, or response to any auditory, visual, or painful stimuli. The painful stimuli should be applied to the face (preferably the supraorbital ridge) to rule out any spinal cord injury or spinal-mediated reflexive motor responses.

### Loss of Brainstem Function

The brainstem houses the centers for arousal, respiratory drive, and the cranial nerve nuclei. Accordingly, its viability can be assessed with relevant clinical examinations (Table 2). Clinically, loss of brainstem function is verified by lack of: (i) pupillary reflex, (ii) corneal reflex, (iii) gag and cough, (iv) oculocephalic reflex (doll's eyes), (v) oculovestibular reflex (cold caloric), (vi) respiratory effort (apnea testing), and (vii) motor response. In practice, absence of cranial nerve reflexes is documented first and then apnea testing is performed. Confirmatory tests are not required when all of the above signs of brainstem function are clearly absent.

### Absence of Brainstem Reflexes (Apart from Breathing)

Absence of pupillary reflex is demonstrated in the brain dead patient by pupils that are fixed (usually in mid position), and nonreactive to light (i.e., no change of pupil size, in either eye, after shining a strong light in each eye sequentially in a dark room). The pupillary reflex is mediated by cranial nerves II and III.

The lack of corneal reflex is documented in the brain dead patient when there is lack of eyelid movement after touching the cornea (not conjunctiva) with a cotton swab or tissue; the corneal reflex is mediated by cranial nerves V (afferent) and VII (efferent).

The absence of the gag reflex and cough reflex is documented in brain dead patients when there is a lack of retching or uvula movement after touching the back of the pharynx with a tongue depressor or after moving the endotracheal tube; the gag reflex is mediated by cranial nerves IX (afferent) and X (efferent). Additionally, there should be no coughing with deep tracheal irritation and suctioning; the cough reflex is mediated by cranial nerves IX and X.

The oculocephalic reflex ("doll's eyes" reflex) should be absent in brain dead patients. There should be no eye movement with brisk turning of the head from side to side. During this examination, the patient's head should be elevated  $30^{\circ}$  from the supine position in order to place the semicircular canals in the optimum orientation. This reflex is mediated by cranial nerves III, IV, and VI as well as the medial longitudinal fasciculus (MLF). Trauma patients with known or suspected cervical spine injuries should not have the "doll's eyes" reflex tested because the neck twisting might exacerbate neurologic injury. Instead, cervical spine injured patients should undergo the "cold caloric" test (below).

Brain dead patients should not exhibit any oculovestibular reflex ("cold caloric" reflex). There should be no eye movement with irrigation of each tympanic membrane sequentially with 50cc of ice water with the head of the patient  $30^{\circ}$  elevated from the supine position. Prior to performing this test the patient's external auditory meatus should be free of wax, and the tympanic membrane should

be intact. This reflex is mediated by the cranial nerves III, IV, VI, and VIII as well as the MLF.

Brain dead patients also lack any motor response to pain or any other stimulatory input. There is no localization or withdrawal after painful stimuli, nor do they exhibit extensor or flexor posturing.

#### **Apnea Testing (Documenting Absence of Respiratory Effort)**

Prior to performing apnea testing, the following prerequisites are required: the core temperature needs to be  $\geq 36.5^{\circ}\text{C}$ , the systolic pressure should be  $>90$  mmHg, the patient should be euolemic, the  $\text{PaCO}_2$  should be normal or slightly above normal (i.e.,  $\geq 40$  mmHg), and the  $\text{PaO}_2$  should be supranormal (i.e.,  $\geq 200$ ) to guard against desaturation during apnea. The arterial blood gas needs to be checked to establish baseline values prior to commencing apnea testing (24). The patient is preoxygenated with an  $\text{F}_i\text{O}_2$  of 100%, preferably with an arterial line in place for rapid blood gas measurements, while adjusting ventilatory rate and volume to achieve a  $\text{PaCO}_2$  of 40–45 mmHg. Next the patient is disconnected from the ventilator and humidified  $\text{O}_2$  at 8–12 L/min is delivered via a cannula advanced 1–2 cm beyond the end of the endotracheal tube but still above the carina to facilitate apnea oxygenation (25). Pulse oximetry is used to detect oxygen desaturation, which usually does not occur when the above detailed oxygen supplementation maneuvers are employed. Usually after 8 to 10 minutes has elapsed the patient's  $\text{PaCO}_2$  has typically increased above 60 mmHg, and an arterial bloodgas (ABG) is measured at this time for confirmation (26). The exact carbon dioxide level needed to ensure lack of respiratory drive is unknown, but a  $\text{PaCO}_2$  of 60 mmHg is well accepted because higher partial pressures of  $\text{CO}_2$  may begin to impart anesthetic effects and depress the respiratory centers in a positive feedback loop (13,15). The ventilator is reconnected after the 8–10 minute apnea event, if the patient is a candidate for organ donation. If there is no evidence of spontaneous respirations before reinstatement of mechanical ventilation in the presence of a  $\text{PaCO}_2$  greater than 60 mmHg or an increase of greater than 20 mmHg from the normal baseline value, the criteria for a positive apnea test are met. If the patient desaturates or becomes hemodynamically unstable during the apnea test, an ABG is immediately drawn and the patient is reconnected to the ventilator (27). Confirmatory tests are necessary for patients who do not achieve adequate levels of hypercarbia prior to becoming unstable.

#### **Confirmatory Studies**

☞ **Confirmatory tests are not necessary for the declaration of brain death in the vast majority of cases. They may be used in cases where the observation period needs to be shortened (unstable patient intended for organ donation), children younger than one, and when clinical brain death testing is confounded by certain agents and/or conditions (Table 5).** ☞

Confirmatory tests evaluate the loss of neuronal function or evaluate the cessation of intracranial blood flow (13,14). Neuronal function is best assessed with an electroencephalogram. The dead brain is no longer capable of maintaining cellular membrane potentials or electrical signals among cells, therefore, the EEG recorded from a dead brain is flat line with total electrical silence. The machine is set for minimal technical requirements for brain death and run for at least 30 minutes to document electrical

**Table 5** Confirmatory Tests for Establishing Brain Death

Category or test	Specific test technique
Electrical neuronal activity	EEG Evoked potentials
Evaluation of intracranial blood flow	Nuclear medicine blood flow studies Four-vessel cerebral angiography Digital subtraction angiography Xenon-enhanced computed tomography Magnetic resonance angiography Transcranial Doppler study

silence. Measurements of evoked potentials have also been used but they are less widely used than EEG due to decreased specificity.

For the detection of intracranial blood flow, the four-vessel cerebral angiogram is the most sensitive and specific study. All other tests are less sensitive (digital subtraction angiography/venography, transcranial Doppler study), or indirect (CT, EEG). ☞ **Nuclear medicine cerebral blood flow studies are increasingly used as the confirmatory test, because the equipment can be brought to the ICU providing images with the presence or lack of radioactive tracer within the cranial vault (Fig. 1).** ☞ Recent advances in positron emission tomography (PET) scanning using F-fluorodeoxyglucose to assess brain metabolism have introduced an alternative method for confirmation of brain death. However this test is not yet universally accepted (13). Other brain flow imaging techniques discussed in Volume 2, Chapter 7 may also be helpful.

#### **Brain Death Determinations in Children**

The assessment of brain death in children is performed using different guidelines than those for adults. For the purposes

**Figure 1** Nuclear cerebral blood flow study depicting lack of tracer in the intracranial circulation (supplied by the internal carotids and vertebral arteries) with preservation of tracer in the distribution of the external carotid arteries (face and scalp). The lack of tracer within the cranial vault is consistent with absence of intracranial blood flow.

**Table 6** Brain Death Evaluation in Children

Evaluation element	Comments/specific details
History	Exclusion of reversible causes of coma (Table 4)
Clinical examination	Loss of consciousness, vocalization, and volitional activity Failed standard apnea test Absent brainstem function: Midposition or fully fixed and dilated pupils Absent spontaneous eye movements, oculocephalic, and oculovestibular reflexes Absent movement of lower cranial nerve musculature (pharynx, larynx, uvula, including gag or cough) Absent corneal, sucking, and rooting reflexes Flaccid tone and absent spontaneous or induced movements (excluding spinal cord reflexes) Findings should be consistent throughout entire examination observation period
Age-specific observation and retesting	7 days of age to 2 mo: two examinations and EEGs separated by 48 hr 2 mo to 1 yr of age: two examinations and EEGs separated by at least 24 hrs or initial examination plus isoelectric EEG followed by nuclear medicine study confirming no cerebral blood flow >1 yr of age: two examinations at least 12 hrs apart, with EEG and cerebral nuclear medicine blood flow studies optional but recommended

Source: From Ref. 29.

of brain death documentation, the term child is applied to patients less than 7 to 12 years of age. After seven years of age most children can use abstract reasoning and communication skills. By 12 years of age, the differences with young adults are minimized. In younger children language, coping skills, and reasoning are less developed, and special clinical exam criteria are needed (29). Accordingly, a few changes in the clinical exam and retesting frequency are recommended (Table 6). These pediatric-specific principles are most useful for children less than seven years of age. **The criteria for assessing brain death in children incorporates the routine use of confirmatory tests as well as longer observation periods between examinations, as underscored by the variability of EEG and nuclear studies in newborns in comparison to the clinical exam (Table 6).**

**ORGAN DONATION**

**Balancing Sensitivity for the Grieving Family with the Need for Organ Donors**

Most families have a better understanding of the organ donation process if the ICU staff entirely separates the declaration of brain death from discussions about organ donation. Thus, the determination of brain death is performed first

and presented to the family who are given time to digest the information (11,13,30). Before support is withdrawn, a request for organ donation is made by a representative of the Organ Procurement Organization (OPO). **Decoupling of the process of brain death declaration from the request for organ donation has resulted in an increase in next of kin authorizing organ donations (11,30,31).**

Visceral organ transplantation is a relatively recent achievement with the first successful kidney transplant having occurred in 1954, from a twin living related donor, and the first successful cardiac transplantation in 1967 (1,2,6,33). Dramatic improvements in transplanted organ survival have occurred recent years due to advances in modern surgical techniques and immunosuppressive medications. Thus, a large backlog of patients with failing internal organs exists, all of whom are awaiting the donation of healthy organs. Advancements in immunosuppressive care and surgical techniques has improved both survival, following transplantation, and life style (34). Due to the expanding world population the number of patients awaiting transplantation has increased exponentially while available organs for donation has increased only linearly. On January 1, 2000, there were 71,380 patients in the United States on waiting lists for organ transplantation. For perspective on the availability of organs for transplantation, there were 64,579 transplant-eligible patients in 1998, and 21,197 received organ transplantation (personal communication—Gift of Life Organ Procurement Organization).

**Several strategies have been developed to procure more organs for donation (27). These strategies include expanding the pool of acceptable donors, the use of living related donors, education of the public to the benevolence of organ donation, and use of non-heart-beating donors (33,35–38).**

The trauma population provides a large pool of potential donors because serious head injury and subsequent brain death can frequently occur in an otherwise minimally injured patient. Experience with organ donation has demonstrated that donors who at one time were thought to be unsuitable can provide quality solid organs for transplantation (33,39). Table 7 lists the general requirements for live organ donations. Currently, organs are accepted from donors as old as 80, especially since many of the recipients are also elderly. The only two absolute contraindications for organ donation are systemic cancer and a disseminated viral infection such as rabies, HIV, or West Nile virus. Bacterial infections that are antibiotic sensitive are only relative contraindications.

Another technique to expand the pool of organ donors is the use of living related donors such as a sibling

**Table 7** Requirements for Live Organ Donors

Competent—able to give consent
Willing to donate
Free of coercion
Medically suitable
Psychosocially suitable
Fully informed of risks and benefits as donor
Fully informed of risks and benefits to recipient
Benefits to both donor and recipient must outweigh risks of donation and transplantation

Source: From Ref. 35.

donating a kidney or lobar lung to a brother or sister or a parent donating part of his/her liver or lung to a child (33,36,37). Improved surgical techniques for obtaining organs from living related donors, such as laparoscopic nephrectomies should, increase the popularity of this technique by decreasing donors' morbidity. Improved recipient immunosuppression has allowed the potential donor pool to expand to those unrelated to the recipient, but with an emotional relationship such as a spouse (34). It is even possible for living donors to donate kidneys to strangers.

Public education of the desirability of postmortem organ donations has led to laws that present people with the opportunity to designate their wish to be an organ donor on their driver's license before they become critically ill. Permission must still be obtained from the next of kin in cases where the patients have expressed on their driver's license their desire to donate their organs.

### Role of the Organ Procurement Organization

Public education about organ procurement has derived from studies conducted to determine what makes a family decide to donate or not donate their relatives' organs. These studies have revealed that decoupling the request for organ donation from the discussion of death (or brain death) with a relative increases the likelihood that families will agree to organ donation (11,30). Therefore, the medical staff discusses with the family the facts that the patient has suffered a devastating brain injury and will be tested for brain death. Later the ICU staff informs the family of the results of the brain death test. If the patient is declared brain dead, the relatives are provided time to grieve and accept their loss. After a brief period of mourning, a representative from the OPO approaches the family about the issue of organ donation. General principles of cadaveric organ donation are listed in Table 8. This process has been better accepted by families than a combined discussion of organ donation and possible brain death. Similarly, if a patient has irrecoverable brain damage, but is not brain dead and the family wishes to withdraw life support, the issue of non-heart-beating organ donation (NHBOD) should be introduced only after the decision to withdraw support is finalized (see below) (32).

### Non-Heart-Beating Organ Donation (Special Case)

The NHBOD organ procurement protocol was designed to expand the pool of available organs for donation (35). In this (still controversial) scenario, a person with devastating, irrecoverable brain damage, but possessing a few residual brainstem reflexes (thus not brain dead), and whose family has decided to withdraw life support becomes an organ donor after support is withdrawn and the patient is declared

dead. Most commonly the patient is withdrawn from mechanical ventilatory support, and sedatives and analgesia are administered while the patient is allowed to die from respiratory and cardiac arrest. The sedatives and analgesics are administered to ensure that the patient does not suffer any more under the ethical principle of "double effect" (see Volume 2, Chapter 67). Double effect states that although sedatives and analgesics may hasten death as a secondary effect, their primary intent is to allow death to occur without pain, fear, anxiety; thus their administration is ethically moral.

The withdrawal of life support for NHBOD patients often takes place in the operating room (OR), but can occur in the ICU, or a room adjacent to the OR. After the cardiac death occurs the patient is transferred to the operating room for organ procurement. After the patient's heart stops, a suitable time period is allowed to pass (1–2 minutes of cardiac asystole) to ensure that the patient is indeed dead before transporting to the OR, and before the kidneys and/or liver are perfused with cold preservation fluid and removed (38).

Close monitoring of the actual support withdrawal and organ donation process at the University of Pittsburgh, in 15 NHBOD cases, demonstrated that no one's heart spontaneously restarted following more than one minute of circulatory cessation. Therefore, DeVita et al. recommend a two-minute wait following cessation of the circulation as documented by loss of the heart beat and pulse (40). This two-minute delay would ensure the patient's cardiopulmonary death, yet also minimize the warm ischemia time for donated kidneys and liver. This is an obviously important consideration, made even more salient when it is revealed that 45 minutes of warm ischemia time is the maximum tolerated by most solid organs, and at least one patient in the De Vita study took 33 minutes following extubation to become asystolic (i.e., likely had marginal organ perfusion for many of these 33 minutes prior to cardiac asystole).

Although initial organ transplantation was performed after the donors suffered cardiac arrest, this technique, which puts transplanted organs at risk for warm ischemic damage, has sparked medical and ethical debate about its propriety. Indeed, some in the medical community view NHBOD to be akin to euthanasia (38). Furthermore, the NHBOD technique is suitable only for donation of kidneys, livers, pancreas, and (occasionally) lungs.

Non-heart-beating organ donation is not euthanasia. Mechanical ventilation and intravenous hemodynamic support are withdrawn in NHBOD just as they would be in the ICU—while the patient receives sedatives and analgesics (but no neuromuscular blockade drugs), and no drugs with the specific intent of hastening death (i.e., no KCl solution) are administered, rather, patients are allowed to naturally expire. That the withdrawal often occurs in the operating room is the only difference. To avoid potential conflicts of interest, the anesthesiologist is usually tasked with declaring the patient dead before the transplant team begins organ procurement. If the patient's heart beat and respiration remain strong and he/she doesn't die within an hour, the organ procurement is canceled and the patient is returned to the ICU or to the floor for hospice-type care. Whether or not the patient is extubated after the termination of ventilator support is up to local hospital custom. Likewise, the use of intravenous opioids and sedatives as a comfort measure are also up to local hospital custom of withdrawing support for terminally ill patients (35,38). However, the

**Table 8** General Principles of Cadaveric Organ Donation

---

Society benefits from promoting organ donation
Cadaveric donors of internal organs must be brain dead when organs are removed
Active euthanasia is absolutely prohibited
Policies and procedural protocols are completely open to the general public
Informed consent is required
Wishes of donors and their families are respected and honored

administration of sedatives and analgesics at withdrawal of life support from hopelessly ill patients at end of life is a well-established practice, and endorsed by medical ethicists as well as the authors (41). Heparin must be given in time to circulate through the solid organs to prevent post mortem coagulation from obstructing organ circulation. Many institutions also administer phentolamine to block vasoconstriction in the vital organs. Although phentolamine has the potential to cause systemic vasodilation, its use will result in better preservation of organs by preventing sympathetic nervous system vasoconstriction. Because the systemic vasodilation effect of phentolamine may hasten death, phentolamine use is controversial (42). The survival of kidneys from non-heart-beating donors is comparable to kidneys from brain dead donors (43).

**INTENSIVE CARE UNIT MANAGEMENT OF THE BRAIN DEAD ORGAN DONOR**

Once an ICU patient has been identified as a potential organ donor and declared brain dead, management decisions are aimed at ensuring optimum survival of potential transplantable organs. **Optimal care of organ donors requires maintenance of organ perfusion, oxygen delivery, body temperature, and euolemia with normal serum sodium values.** Boyd et al. suggest classifying organ donors according to their stability allowing clinicians to prioritize management (44). Stable patients can tolerate further ICU management while awaiting operating room time and the arrival of the transplant team (organ sharing, multiple procurements) without jeopardizing their organ function. Moderately stable patients that respond to vasopressors can be maintained in the ICU while the organ-tissue typing and recipient compatibility process occurs. However, moderately unstable patients with a poor response to therapy, and unstable patients who don't respond to corrective therapy need to proceed to the operating room with urgency, and in some case their organs offered for organ sharing during or after procurement. The only solid organs suitable for this emergent "crash" organ procurement process are for liver, kidney, and pancreas. The heart and lungs are much less tolerant of ischemia (maximum cold ischemia time 4–6 hours). Thus, crash organ procurement is not a viable procedure for heart or lung transplantation because the potential recipients must already be in the hospital and ready for the operating room at time of procurement, otherwise these organs will not be viable.

Recently declared "brain dead" donors occasionally undergo a brief period of medical optimization prior to organ procurement. **In these patients, simple volume resuscitation is adequate to achieve Phillips' Rule of Hundreds—systolic pressure >100 mmHg, PaO<sub>2</sub> >100 mmHg, and urine output >100 mL/hr (44).** Moderately stable patients are divided into two categories: those with a good response to volume loading and pressors to achieve Phillips' Rule of Hundreds and those with a transient response to volume loading and pressors. This second group often requires escalating pressor therapy to maintain systolic blood pressure. Finally, the grossly unstable patient never achieves Phillips' Rule of Hundreds and requires the greatest urgency to salvage transplantable organs (Table 9).

**Table 9** Perioperative Management of the Multiorgan Donation

Step 1	Ensure that patient meets criteria for brain death or support withdrawal
Phillips' Rule of 100s	Systolic BP > 100 mmHg PaO <sub>2</sub> > 100 mmHg urinary output > 100 mL/hr
Cardiovascular	Maintain perfusion pressure through adequate hydration and inotropic/pressure support of treat dysrhythmias
Pulmonary	Maintain normal blood gases: PaO <sub>2</sub> 100–150 mmHg PaCO <sub>2</sub> 35–40 mmHg, pH 7.35–7.45 F <sub>I</sub> O <sub>2</sub> ≤ 0.40 for heart-lungs donation
Endocrine	Treat diabetes insipidus—replace urine output and DDAVP or vasopressin titrate to urine output 2–3 mL/kg/hr
Hematology	Prevent anemia—maintain hematocrit near 30% Minimize coagulopathy

*Abbreviations:* BP, blood pressure; PaO<sub>2</sub>, partial pressure of oxygen in the arterial blood; P<sub>a</sub>CO<sub>2</sub>, partial pressure of carbon dioxide in arterial blood; F<sub>I</sub>O<sub>2</sub>, fraction of inhaled oxygen; DDAVP, D-des-arginine-vasopressin (Desmopressin®)

**Hemodynamic Management**

Hypotension usually accompanies brain death when the vasomotor centers in the brainstem become impaired. Furthermore the hypotension is exacerbated by both the decreased cardiac output from diminished brainstem mediated inotropy, as well as the intra-vascular depletion resulting from diabetes insipidus (DI) (44,45). Patients should be monitored with an intra-arterial catheter and central venous pressure (CVP) catheter.

The first step toward improving blood pressure in the brain dead organ donor is to provide adequate volume resuscitation. Although transplantable kidneys perform very well when the donor is managed in the hypervolemic state causing a brisk diuresis, other transplantable organs (particularly heart and lungs) do not perform as well when obtained from a hypervolemic, edematous donor. Therefore, maintenance of a CVP in the 5–10 mmHg range and use of pressors/inotropics if the systolic pressure remains less than 100 mm Hg is recommended in heart and lung donor patients.

Volume loading should also lead to a urine output >100 mL/hr. If urine output is much greater than 100 mL/hr, intravenous fluid management must include replacement for urine output to keep CVP in the 5–10 mmHg range.

The decision to place a pulmonary artery catheter is usually based on the possibility of donation of a heart or lung for transplantation. The pulmonary artery catheter is optional for the management of a donor who is not going to donate heart or lungs. Additionally, the management of the stable and moderately stable patient is often facilitated by the information from a pulmonary artery catheter. End points of volume resuscitation are often more clearly achieved by following cardiac output and pulmonary artery pressure as well as CVP. The unstable donor who needs pressor and inotropic support as well as volume loading will be managed more optimally with a pulmonary artery catheter.

### Ventilation Management and Infection Control

The brain dead organ donor has an obligatory dependence on mechanical ventilators for ventilation and gas exchange. The respiratory centers in the lower brainstem that normally integrate demand signals from blood pH, PaCO<sub>2</sub>, and PaO<sub>2</sub> and match these signals with appropriate ventilatory response are dead and unresponsive. Therefore, the patient will not activate the respiratory muscles for ventilation in response to hypercarbia and hypoxia. Thus, the medical team caring for the organ donor must review the arterial blood gases and adjust the ventilator to optimize them.

Because the organs for potential donation require adequate oxygen delivery to maintain function, it is recommended to aim for a PaO<sub>2</sub> of 100 mmHg or greater. Controlled ventilation modes, either pressure control or volume control, are used on the ventilator because the donor is incapable of spontaneous ventilation. The F<sub>I</sub>O<sub>2</sub> is adjusted to provide a PaO<sub>2</sub> >100 mmHg while ventilation is set to normalize PaCO<sub>2</sub>. The brain dead donor has a lower metabolic rate and a reduced CO<sub>2</sub> production that needs to be cleared by ventilation to maintain PaCO<sub>2</sub>.

Care must be exercised to prevent ventilator-induced lung injury for the potential lung donor. Thus, tidal volume should be kept in the 6–7 mL/kg range if lung compliance is low, whereas 10–15 mL/kg is acceptable if the compliance is normal. Additionally, the positive and expiratory pressure (PEEP) is kept at the minimum required to maintain the PaO<sub>2</sub> >100 mmHg or an F<sub>I</sub>O<sub>2</sub> ≤ 0.4 or less. These patients must continue to be turned and suctioned every two to four hours. Albuterol metered dose inhalers (MDI) are administered 2 to 4 puffs every four hours to minimize closure of small airways.

### Endocrine Changes

Diabetes insipidus (DI) occurs very frequently in the brain dead donor secondary to infarction of the hypothalamus and pituitary. Loss of antidiuretic hormone (ADH) from the pituitary leads to inability of the kidney to concentrate the urine, thus the patient excretes copious dilute urine. The hallmarks of DI are urine output >4 mL/kg/hr, urine osmolality <300 mOsm/kg, with serum osmolality >310 mOsm/kg, serum sodium [Na] >145/meg/L, and a urine specific gravity <1.005. Treatment is with intravenous vasopressin for both blood pressure and urinary concentration or DDAVP to concentrate urinary solutes and conserve free water losses. Either drug is titrated to maintain urinary output at 2–3 mL/kg/hr (44,45).

Serum sodium also needs to be controlled because livers from donors with Na >155 have reduced graft survival. Extreme hyponatremia, which usually precedes the occurrence of brain death, must also be corrected before the patient is transferred to the operating room. Brain dead donors are also prone to develop profound hypokalemia, hypomagnesemia, and hypophosphatemia because of the high urinary output. These electrolyte abnormalities must be corrected prior to organ explantation in the operating room.

Other metabolic and endocrine abnormalities that must be corrected include hyperglycemia, thyroid insufficiency, and adrenal suppression. Hyperglycemia secondary to reduced insulin secretion or catecholamines and glucocorticoid administration is treated with intravenous insulin.

Brain dead donors often have depressed thyroid function similar to the “sick euthyroid” syndrome; it is controversial whether thyroid replacement is needed. Because

T<sub>3</sub> levels are reduced by the “sick euthyroid” syndrome, the administration of thyroid replacement as a single dose of T<sub>3</sub> or T<sub>4</sub> is occasionally recommended.

The brain dead donor will have an impaired immune response; therefore, they must be managed with careful techniques to avoid seeding an infection in donor organs. Hyperthermia and fever is seldom a problem with the brain dead donor because hypothalamic temperature control centers are destroyed when the brainstem infarcts (i.e., these patients become poikilothermic) (44,45). These donors should be kept at 36°C to 37°C to optimize organ function before transplantation. If heated fluids and a warm room do not adequately maintain a normal body temperature, forced hot air warming (e.g., Bair Hugger®) may be required, but these are only recommended for temperature <36°C.

If the organ donor received enough dexamethasone to suppress adrenal function prior to brain death, he will need replacement therapy with hydrocortisone.

### OPERATIVE MANAGEMENT DURING ORGAN PROCUREMENT

☞ **Management of the organ donor in the operating room (OR) is a continuation of the hemodynamic, temperature, and endocrine (diabetes insipidus) management of the organ donor in the ICU.** ☞ The goal of the donor procurement process is to recover viable organs with minimal warm ischemia time, hypotension, hypoxia, or surgical trauma. The procedure described below pertains to procurement from the brain dead organ donor only. Readers interested in a review of organ procurement considerations for the NHBOD are referred to the discussion by Von Norman (42).

### General Considerations

Prior to transporting the brain dead donor to the OR, the anesthesiologist ensures that the patient meets appropriate criteria for brain death, has permission to be an organ donor, and that the consent stipulates which organs are to be procured. The stable patient can be managed on a more elective basis than the moderately unstable and unstable patient. Unstable patients must have priority of operating room space in order to procure viable organs for transplantation.

The operating room needs to be warm to prevent hypothermia, as the brain dead patient is poikilothermic, and regional cooling and perfusion of certain organs in situ, prior to perfusion of the heart and lungs, may cause premature hypothermia-induced dysrhythmias or arrest.

Phillips' Rule of 100s is the goal of cardiopulmonary management during the organ exposure phase of surgery prior to aortic cross clamping. Fluid management and pressors should be continued into the operating room to maintain blood pressure and urine output. The ventilator is adjusted to maintain PaO<sub>2</sub> greater than 100 mmHg. Frequently, anesthesiologists administer inhalational anesthesia and muscle relaxants to prevent Lazarus reflexes and occasional hypertension with surgical organ exposure (46–48).

### Rationale for Organ Excision Sequence

The precise operative sequence depends upon the organs to be procured, and to some degree on the routine of the teams involved. However, certain general concepts are universally

**Table 10** Donor Organ Excision Order and Cold Perfusion Solution Type, Amount, and Cannula Location

Standard excision order	Organ	Perfusion solution type (amount)	Cold perfusion cannula site
1	Heart	Cardioplegia (1–2 L)	Ascending aorta
2	Lungs	Pulmoplegia (3–6 L)	Pulmonary aorta
3	Liver	Viaspan <sup>TM</sup> <sup>a</sup> (5–6 L)	Abdominal aorta and mesenteric vein
4	Pancreas	Viaspan <sup>TM</sup> <sup>a</sup> (5–6 L)	Abdominal aorta
5	Kidneys	Viaspan <sup>TM</sup> <sup>a</sup> (5–6 L)—if all abdominal organs procured (2 L)—if only kidneys procured	Abdominal aorta

<sup>a</sup>Belzer's UW Solution.

followed (Table 10). The thoracic organs (heart and lungs) are less ischemia tolerant than the abdominal viscera (liver, pancreas, kidneys, small bowel), and are removed first when procured. Despite this, abdominal team will often start their part of the pre-excision visceral exposure and vessel cannulation prior to the thoracic team because the abdominal dissection takes longer. Both teams communicate with each other, and cold preservation fluids are never administered until after aortic cross clamp, which only occurs at a mutually agreed upon time in a special choreographed way (described below). This approach avoids premature or inadvertent cardiac arrest, which could damage the donor organs.

### Technical Overview of Organ Procurement

The sequence provided below occurs when both the thoracic and abdominal teams begin operative exposure together. The donor patient is positioned on the OR table in the supine position, and the anesthesiologist assures all appropriate monitoring is applied and functioning optimally. Surgical skin preparation and draping commences with exposure of the entire anterior chest, abdomen, and both groins. The thoracic team makes a standard median sternotomy, then carries the incision down the midline to join the full-length midline abdominal incision created by the abdominal team (which carries down to the pubic symphysis).

Hemostasis is obtained while exposing the pericardium and great vessels. After pericardiotomy, the heart size and function is assessed, and the epicardial coronary arteries are grossly palpated for atherosclerotic plaques. Additionally, the heart is systematically inspected for any other abnormalities. Next, the lungs are inspected grossly for size and examined for any previously undiagnosed lesions or abnormalities. Once both the heart and lungs have passed the gross inspection, the ascending aorta is dissected and circumferentially freed of attachments, to the level of the left subclavian (in preparation for later placement of the thoracic aortic cross clamp). The superior vena cava (SVC) and inferior vena cava (IVC) have loosely placed circumferential vascular tapes with rubbershods for

later vascular control. The thoracic team may scrub out of the case for a brief respite while the abdominal team completes their, more time consuming, dissection.

The liver is exposed and freed from its ligamentous attachments to the diaphragm. The abdominal aorta above the celiac artery is encircled with loose ligature placed circumferentially, and rubbershods are placed for later. Next, the hepatic artery is identified, and the inferior mesenteric vein is cannulated with a tube and infused with normal saline to keep the vein open (Pre-Cool); later this line will be used to infuse cold perfusion fluid as part of the systemic cooling. The donor's kidneys are then dissected and renal arteries and veins are identified and vascular control is obtained (loose vascular tapes—with rubbershods as above). Similarly, other visceral organs to be transplanted are dissected out. Once this is done, the thoracic team returns, and the patient is systemically anticoagulated (typically 40,000 units heparin). Perfusion catheters are then inserted into the ascending aorta (which will soon be used to infuse 1–2 L of cold cardioplegia solution), and pulmonary artery (soon to be used to perfuse 3–6 L of cold pulmoplegia solution). Cannulas are also placed in the abdominal vessels (which will soon receive 5–6 L) of cold Viaspan<sup>TM</sup> (Belzer's UW Solution) (Table 10). The typical placements for the two abdominal cannulas are the descending aorta (just below the previously placed loose ligature at the crus of the diaphragm) and the inferior mesenteric vein (which flows to the portal vein—this catheter was placed previously). Once all cold infusion catheters are properly placed, and all teams are ready, two aortic cross clamps are applied simultaneously. The first one is applied on the thoracic aorta; just proximal to the subclavian vein; and the other cross clamp is applied to the abdominal aorta, at the crus of the diaphragm. Immediately after aortic cross clamp, the cold preservation fluids are perfused through the previously situated cannulas, and the IVC is transected to vent the warm blood (some prefer to vent the IVC into the abdomen; some prefer to vent into a large, caliber drainage tube directly into the suction canister, diverting heat away from donor organs).

After all of the cardioplegia solution is infused in the heart (ascending aorta), and the pulmoplegia has perfused the lungs (via pulmonary artery), and the Viaspan<sup>TM</sup> (Belzer's UW Soln.) has perfused the visceral organs (via abdominal aorta and mesenteric vein), the organs are resected working from the top down (hearts, lungs, liver, pancreas, kidneys). After excision, some surgeons will administer additional cold flush to the excised organs on the back table (1–2 L of the appropriate fluid) prior to bagging for transport.

The heart is rinsed and examined for any valvular lesions or a patent foramen ovale (PFO); if present, the PFO is noted (for later repair at the recipient institution), and the heart is placed in a sterile plastic bag full of cold cardioplegia solution. This bag is placed within two other bags, and sealed, and then placed inside a bag of cold cardioplegia slush, placed in an ice chest and shipped to the recipient hospital (only 4–6 hours of ischemia time starting with x-clamp is allowed). Similarly, the perfused lungs are inspected again and placed inside a sterile plastic bag of cold pulmoplegia fluid, (triple bagged) and then placed inside a bag of cold pulmoplegia slush, and placed inside bags, and the organs are then placed in insulated labeled coolers for transport.

After the thoracic team has removed the heart and lungs, the abdominal team removes the organs located below the diaphragm. The common bile duct and hepatic

artery are divided, and the freed liver is removed. Next, the ureters are dissected and divided, the aorta and vena cava on either side of the renal pedicles are transected, followed by enbloc nephrectomy. These organs are triple bagged in cold Viaspan™ (Belzer's UW Soln.) analogous to that described for the heart and lungs.

After the aorta is cross-clamped and organs perfused with their corresponding solutions, the ventilator is switched off and the anesthesiologist's role has concluded. During the entire procedure, the donor cadaver should be treated with dignity and respect, to honor ethical, religious, and cultural norms.

## EYE TO THE FUTURE

Despite more than 30 years' experience with brain death as one criteria for determining death, some clinicians are still skeptical of the concepts (49,50). Thus, we are likely to see continued reevaluation of brain death criteria and refinement of the diagnosis. Additionally work needs to be done to educate the public that brain death is synonymous with death of the sentient portion of the individual, and that a declaration of brain death is synonymous with death of the patient even though some tissues (heart, lungs, liver, kidney, pancreas, bowel, skin) can be kept alive by artificial means. The medical profession also needs to emphasize to the public the difference between brain death and persistent vegetative state (51).

Alternatively, Truog and Robinson propose that society scrap the whole concept of brain death (47). They further propose that organ donation occur from patients who give informed consent to receive euthanasia under anesthesia while their vital organs are procured for recipients in organ failure. Society is unlikely to be persuaded by the arguments of Truog and Robinson, and it is unlikely that many anesthesiologists would agree to participate in the administration of such terminal anesthetics. Their arguments against brain death also fail to address the original need to acknowledge brain death: reduce the prolonged futile ICU management of patients who were already dead from permanent loss of brain function and infarction of most or all of their brain. A movement toward the simpler, yet equally valid, U.K. criteria of brainstem death would be a far more pragmatic remedy for the numerous confounding brain death definitions.

The search for chemical markers of brain death is probably at least a decade away. However, Dimopoulou et al. have recently identified a serum protein (S-100b), which is elevated in brain dead patients (52). These investigators found that the median S-100b level was higher in clinically brain dead patients than those patients who did not become brain dead ( $p < 0.0001$ ). The S-100b protein has a high specificity for CNS lesions, is released in a time locked sequenced with injury, has a short half life, and does not have any significant age or gender variability. The presence of elevated S-100b in the serum indicates that both brain cell damage has occurred, and that there is increased permeability of the blood-brain barrier. Although far more additional work is required to determine the extents to which this protein can be used clinically, experimental results indicate that S-100b might be used in a fashion analogous to myocardial infarction markers (e.g., troponin), and when elevated, indicate the degree of brain injury (cell death) that has occurred. While the S-100b protein studies

are intriguing, they cannot be construed as a serological surrogate for the clinical determination of brain death.

Care of critically ill patients has revealed that death of various tissues or organs within the body occur as a complex temporal process, rather than as an instantaneous event for the entire body. This scientific fact has facilitated the philosophical and scientific concept of brain death. Skin cells, with their lower metabolic requirements, remain viable much longer than most other cells in the body, whereas neurons within the central nervous system are the least tolerant to ischemia, and some of these (i.e., hippocampal neurons) may be the least tolerant of all. In the critically ill TBI patient, supported by mechanical ventilation, death of the brain and brain stem may represent the first organs to die in a long succession of dying organs. With this current understanding and the ongoing research in neurophysiology and neurophilosophy, we may one day in the future evolve to a new definition of brain death; one where death of certain critical structures in the brain that are absolutely required for reasoning and understanding would be tantamount to brain death (16,18,20,21).

## SUMMARY

Advances in life support techniques following World War II led to the appearance in intensive care units of patients who were unresponsive and totally dependent on ventilator support. When these patients succumbed to cardiac arrest, autopsy would reveal a liquefied brain, which was named "respirator brain." A Harvard University committee published a paper in JAMA that outlined the procedure to recognize that a critically ill patient's brain had died, thus rendering further care futile (5). This concept of brain death was used to effectively allow cessation of futile intensive care and coincided with the rapidly developing field of organ transplantation. Because it was recognized that death of the brain and brainstem was equivalent to death of the entire patient, it became permissible to procure solid organs from brain dead patients and minimize warm ischemic organ damage.

State laws have been updated to be consistent with guidelines of the Uniform Determination of Death Act, allowing physicians to declare a patient's death based on permanent cessation of brain and brain stem activity or permanent cessation of respiration and cardiac activity. The medical diagnosis of brain death requires: (i) brain damage consistent with permanent loss of brain function and lack of confounding metabolic or pharmacologic factors (not hypothermic, normal electrolytes, metabolism, metabolites, and no sedatives or neuromuscular blocking drugs), and (ii) total loss of responsiveness (spinal cord reflexes are allowed).

There continues to be an ever-increasing demand for organ donation from brain dead patients because of the advances in organ transplantation medicine has made it the treatment of choice for many types of organ failure. Strategies to increase the supply of donated organs include societal educational efforts to increase the percentage of brain dead patients who donate organs, expanding the pool of acceptable organs by accepting a wider age range of donors and less than perfect organs, increasing the use of live donors, and the use of non-heart-beating donors.

Although non-heart-beating donors or patients who died from cardiopulmonary arrest were the original

cadaveric organ donors, this technique has fallen out of favor because the transplanted organs suffer longer warm ischemic times. Organs from brain dead donors that are procured while the heart is still beating have much shorter ischemic times. However, survival of kidney grafts from either procedure is comparable. Non-heart-beating donors are patients with extremely poor prognosis from brain injury who maintain some level of brainstem activity. Withdrawal of life support typically occurs in the operating room, and organ removal is delayed until the patient is declared dead (typically after 1–2 minutes of asystole).

The diagnosis and management of brain dead trauma patients is an important aspect of post-traumatic critical care to optimize the potential pool of organ donors and to prevent futile care of otherwise dead patients.

## KEY POINTS

- ✍ Dr. Beecher's white paper, published in JAMA in 1968, concentrated on limiting the use of ICUs to maintain futile life support for patients who had no chance of recovery secondary to death and necrosis of their entire brain.
- ✍ Currently, the U.S. standard to declare brain death is to document the absence of brain and brain stem activity.
- ✍ The current U.K. standard for the diagnosis of brain death is complete and irreversible loss of brainstem function.
- ✍ A patient who meets the clinical definition of brain death by either the U.S. or U.K. criteria is in essence dead as a person, as he/she will never recover sentient function.
- ✍ Brain death is diagnosed clinically with the establishment of three major criteria. First, the neurological injury should be irreversible. Second, there is a loss of cerebral function. Third, there is a loss of brainstem function.
- ✍ Spinal reflexes, such as deep tendon reflexes and triple flexion responses, can be preserved and do not exclude brain death. Release phenomena of the spinal cord are occasionally seen in the setting of brain death and do not exclude brain death; these include shivering, goose bumps, forced exhalation, and some arm movements.
- ✍ Confirmatory tests are not necessary for the declaration of brain death in the vast majority of cases. They may be used in cases where the observation period needs to be shortened (unstable patient intended for organ donation), children younger than one, and when clinical brain death testing is confounded by certain agents and/or conditions.
- ✍ Nuclear medicine cerebral blood flow studies are increasingly used as the confirmatory test, because the equipment can be brought to the ICU providing images with the presence or lack of radioactive tracer within the cranial vault.
- ✍ The criteria for assessing brain death in children incorporates the routine use of confirmatory tests as well as a longer observation period between examinations, as underscored by the variability of EEG and nuclear studies in newborns in comparison to the clinical exam.
- ✍ Decoupling of the process of brain death declaration from the request for organ donation has resulted in an increase in next of kin authorizing organ donations.
- ✍ Several strategies have been developed to procure more organs for donation. These strategies include expanding the pool of acceptable donors, the use of living related donors, education of the public to the benevolence of organ donation, and, use of non-heart-beating donors.
- ✍ Optimal care of organ donors requires maintenance of organ perfusion, oxygen delivery, body temperature, and euolemia with normal serum sodium values.
- ✍ In these patients, simple volume resuscitation is adequate to achieve Phillips' Rule of Hundreds—systolic pressure >100 mmHg, PaO<sub>2</sub> >100 mmHg, and urine output >100 mL/hr.
- ✍ Management of the organ donor in the OR is a continuation of the hemodynamic, temperature, and endocrine (diabetes insipidus) management of the organ donor in the ICU.

### INTRODUCTION

Optimum cardiovascular management of critically ill trauma patients often requires accepting hemodynamic indices that are reasonable rather than normal. When clinicians insist upon pushing the patient's hemodynamic system toward normal or even supranormal targets, iatrogenic complications can occur (1).

This chapter provides the trauma intensivist with a review of reasonable hemodynamic goals in hypertensive patients by surveying the normal cardiovascular indices during health, and explaining how these parameters are altered by trauma and critical illness (1–4). This chapter also reviews the vasoactive drugs commonly used in trauma and critical care. A complete review of cardiovascular physiology is presented in Volume 2, Chapter 3 and cardiovascular monitoring in Chapter 9. Accordingly, these topics are only briefly reviewed here. The optimum management for both hypotension and significant hypertension is summarized for the most common etiologies. **Optimum hemodynamic management is based upon (i) the immediate cause of hypotension or hypertension, (ii) the presence of concomitant injuries, and (iii) the baseline medical conditions affecting the patient.**

In the "Eye to the Future" section, we introduce some of the newer cardiovascular drugs as well as some diagnostic and monitoring tools that are on the horizon but not yet used in clinical practice.

### NORMAL AND RATIONAL HEMODYNAMIC INDICES

Normal age-specific hemodynamic indices have been established for healthy patients. Following trauma and critical illness, the normal physiologic response is typified by abnormal hemodynamic indices. For example, massive hemorrhage leads to an increase in heart rate (HR), systemic vascular resistance (SVR), and contractility in compensation for the decreased intravascular volume (preload), blood pressure (BP), and cardiac output ( $\dot{Q}$ ) (5–7). For a brief period, these compensatory responses will help maintain  $\dot{Q}$  and BP to the central circulation at the expense of an underperfused periphery. Sepsis results in an increased HR and decreased preload, but with an associated decrease in SVR and myocardial contractility. This results in a decreased BP despite an increased  $\dot{Q}$ .

Treatment of hemorrhage begins with control of bleeding and repletion of intravascular volume. Further decreases in BP in this setting can be potentially disastrous, as oxygen delivery ( $\dot{D}O_2$ ) is already low. Likewise, the septic patient will likely require some additional intravascular volume, but the primary defect is sepsis-mediated vasodilation and myocardial depression. Accordingly, drainage of infected, necrotic tissue (as in necrotizing fasciitis) and immediate administration of appropriate antibiotics (Volume 2, Chapter 53) are equally important. Only after volume repletion, infection debridement, and appropriate antibiotics are instituted, should the inotropic support be initiated (8,9). A summary of the normal hemodynamic parameters and the typical disease-related alterations in these variables is provided in Table 1.

### Heart Rate

**The HR should be maintained within a reasonable range in order to sustain adequate  $\dot{Q}$  for tissue perfusion (10,11).** The normal resting adult HR ranges between 60 and 100 beats/min. Numerous physiologic perturbations (e.g., exercise, body temperature) and pathophysiologic insults (e.g., trauma, burns, and critical illness) result in variances in this "normal" range.

Although the relationship " $\dot{Q} = HR \times \text{stroke volume (SV)}$ " holds within the normal HR range, when HRs become excessively high, there begins to be an associated decrease in SV (i.e., decreased preload due to inadequate filling time). Accordingly, HRs above 120 should be discouraged in normal patients and rates above 90 should be prevented in patients with coronary artery disease (CAD).

Tachycardia is defined as a HR greater than 100 beats/min and is caused by mechanisms that increase the firing rate of the sinoatrial (SA) node (sinus tachycardia) and by atrial and ventricular dysrhythmias (Volume 2, Chapter 20). The most common causes of sinus tachycardia in the critical care setting result from conditions that increase sympathetic tone (e.g., hypovolemia, hypercarbia, hypoxemia, pain, fear, anxiety, etc.) and conditions that increase the metabolic rate (e.g., fever, thyroid storm, etc.).

Trauma patients have several reasons why they may develop tachycardia, including hypovolemia from hemorrhage, pain, anxiety, and third spacing. Third spacing in the traumatized patient is a result of circulating cytokines causing leaky capillaries, as well as a result of decreased albumin from

**Table 1** Normal Hemodynamic Parameters and the Direction of Alteration with Various Forms of Shock

	HR	MAP	PP	PACWP	Q̇	SVR	SVO <sub>2</sub>	a-vdO <sub>2</sub>	LAC
Normal	80	85	40	4–10	5	1200	75%	3–4	2–3
Hemorrhage	↑↑	↓	↓	↓↓	↓	↑↑	↓↓	↑	↑↑↑
Sepsis	↑	↓	↑↓	↓	↑	↓↓	↑	↓	↑
Cardiogenic	↑	↓	↓	↑	↓	↑	↓	↑	↑↑
Neurogenic	↓	↓	↑↓	↓	↓	↓	↑↓	↑↓	↑↓

*Abbreviations:* HR, heart rate; LAC, lactate; MAP, mean arterial pressure; PP, pulse pressure; PACWP, pulmonary artery capillary wedge pressure; Q̇, cardiac output; SVR, systemic vascular resistance; SVO<sub>2</sub>, mixed venous hemoglobin O<sub>2</sub> saturation; a-vdO<sub>2</sub>, arterial–venous difference in O<sub>2</sub> saturation or content.

blood loss and crystalloid resuscitation. Additionally, hypoxemia from pulmonary contusion, pneumothorax or hemothorax, atelectasis, cardiac tamponade, myocardial contusion, sepsis, and pulmonary embolism may cause tachycardia (12). Trauma results in fever through numerous mechanisms including tissue injury, hematoma, subarachnoid blood, burns, and infection. ⚡ **In a febrile patient, the basal metabolic rate increases approximately 8% per degree centigrade, which correlates with an increase in HR of approximately 18 beats/min (i.e., 10 beats/min for each degree Fahrenheit) (13,14).** ⚡ Trauma patients may also develop tachycardia due to underlying medical conditions, such as thyrotoxicosis and withdrawal from alcohol or other psychotropic drugs.

Bradycardia is defined as a HR less than 60 beats/min and results from mechanisms that decrease the SA node firing rate (sinus bradycardia) as well as by pathology at the SA or atrial-ventricular (AV), node, leading to junctional or ventricular

bradycardias (Volume 2, Chapter 20). Following trauma, bradycardia can result from spinal cord injury that causes a decrease in the relative sympathetic tone (15). Brainstem ischemia, hypoxia, brainstem herniation (Cushing response), sick sinus syndrome, and myocardial ischemia (Volume 2, Chapter 19) are additional causes of bradycardia. Moderate to severe hypothermia (Volume 1, Chapter 40) is another important cause of bradycardia, as is opioid intoxication.

⚡ **Some patients can manifest a form of bradycardia that is unresponsive to the elevated catecholamine state, associated with trauma or critical illness.** ⚡ For example, patients taking beta-blockers, or occasionally young athletic patients with an exaggerated vagal tone, may not have the expected response to the elevated catecholamines during early shock following blunt or penetrating trauma (16). Some common causes and therapeutic options for the bradycardic patient are listed in Table 2.

**Table 2** Bradycardia: Causes and Drug Options

Causes	Diagnosis	Treatment/comments
Increased vagal tone	Common in athletes and elderly/spinal cord injury	Only if symptomatic; atropine 0.5–1 mg
ETT at carina	Chest X ray	Reposition ETT
Large mucus plugs	Chest X ray	Suction or bronchoscopy
Gastric distention	Abdominal flat plate/chest X ray; hiccoughs	Nasogastric decompression
Overdistension of the bladder	Suprapubic pain/distended bladder	Bladder decompression via Foley catheter
Increased ICP	Cushing's reflex—bradycardia and hypertension with increased ICP	Decrease ICP
Hypothermia	Temperature ECG	Warm patient; treat underlying cause
Drug-induced (digitalis, beta blockers, calcium-channel blockers)	Electrolytes ECG digoxin level	Replace electrolytes; may need digibind, calcium chloride
Hypothyroidism	Thyroid function studies; electrolytes	Treat thyroid disorder
Sick sinus syndrome "tachy-brady syndrome"	ECG—intermittent sinus pauses	Pacemaker
Ischemic or hypertensive cardiomyopathy	ECG 2-D echo	If HR too low, may need nitroglycerin
First-degree AV block	ECG—pr interval >0.2 seconds	If symptomatic (e.g., hypotensive, syncope), treat with atropine 0.5–1 mg or glycopyrrolate 0.2 mg (longer acting)
Second-degree Mobitz Type I—Wenckebach	ECG—progressive prolongation of pr interval until beat is dropped	Treat if symptomatic with medications
Second-degree Mobitz Type II	ECG—regular dropping of ventricular beats	Treat with atropine or glycopyrrolate; if no response, infusion of dopamine, epinephrine, or isoproterenol until pacemaker can be inserted
Third-degree AV block	ECG—complete AV dissociation	Above medications; temporary pacemaker—transthoracic or transvenous, Permanent pacemaker
Inferior wall MI	ECG—cardiac enzymes	Fluid; treat MI

*Abbreviations:* AV, atrial-ventricular; ETT, endotracheal tube; ECG, electrocardiogram; ICP, intracranial pressure; MI, myocardial infarction.

## Rhythm

Normal sinus rhythm is the ideal condition for both recently traumatized victims and those who are critically ill, because the atrial contraction preceding the ventricular contraction augments the left ventricular (LV) preload and coordination of myocardial mechanics. Several conditions following trauma (myocardial contusion, concomitant drug intoxication) and critical illness (ischemia, thyrotoxicosis, etc.) are associated with dysrhythmias and an impaired hemodynamic performance. Patients who have sustained a myocardial contusion after blunt trauma may present with sinus tachycardia or atrial and ventricular dysrhythmias, all of which can result in decreased myocardial performance.

☞ **Elderly patients suffering from trauma or critical illness are prone to develop atrial fibrillation or supraventricular tachycardia, secondary to elevated catecholamines, baseline myocardial irritability, direct myocardial injury, or ischemia, all of which can impair pump function (17,18).** ☞ These aberrations can eventually lead to inadequate perfusion of end organs and contribute to multiple organ failure. In order to maintain tissue perfusion, the astute physician maintains vigilance for, and is prepared to treat, these aberrations in the intensive care unit (ICU) setting.

## Preload

Hemorrhage is the most common cause of decreased preload following acute trauma. When patients first present to the trauma bay, clinical signs are surveyed to assess preload. When the patient entering the trauma bay is pale, tachycardic, and hypotensive, the patient is assumed to be in hemorrhagic shock and in need of intravascular volume. However, in less obvious situations, evaluation of the intravascular volume requires all the diagnostic tools and experience of a master clinician. ☞ **Parameters measured by noninvasive means, such as HR, BP, urine output, skin color, turgor, and temperature, along with capillary refill, can be obtained quickly and reflect the patient's intravascular volume status prior to the placement of invasive monitors (19,20).** ☞

The focused abdominal sonography for trauma (FAST) examination is designed to identify extra anatomic fluid within the peritoneal cavity. FAST can also be used to evaluate the intravascular volume status by estimating the size and function of the cardiac chambers. Although not as specific as transesophageal echocardiography (TEE), using FAST to perform a transthoracic echo (TTE) can yield gross measures of left ventricular (LV) volume and the presence or absence of cardiac tamponade. Later, central lines and pulmonary artery (PA) catheters can be inserted to assess intravascularly by measuring surrogates for pressure, including central venous pressure (CVP) or PA catheter wedge pressure. These invasive measures help to gauge the physiologic adequacy of the volume status, by determining the SV under similar conditions of contractility and afterload (i.e., construct a Starling curve, because  $SV = \text{preload} \times \text{contractility}$ ) (21–23). Additional specific monitoring techniques for the evaluation of intravascular volume are reviewed in Volume 2, Chapters 3, 9, and 21. Drugs (both endogenous and those discussed in this chapter) mainly affect the afterload and contractility and, to a somewhat lesser extent, the preload of the cardiovascular system.

## Afterload

Afterload can be determined using Ohm's law ( $E = IR$ ) as represented in the following estimates:  $PVR = [PA - \text{left atrial pressure (LAP)}]/Q$  and  $SVR = (MAP - CVP)/Q$ . However, the clinician is warned that these measures are

not perfect. Indeed, Ohm's law refers to electricity or rigid pipes, and the blood vessels are not rigid structures. Additionally, one must account for the volume of blood that is pumped and pushed out of the way with each ejection of the heart. The true afterload is the sum of forces against which the LV must act to eject blood into the aorta.

☞ **The measured SVR can be two to three times higher than normal following massive hemorrhage, due to catecholamine-mediated arteriolar constriction in compensation for the decreased intravascular volume.** ☞ In this setting, the blood flow is shunted away from skin, muscle, splanchnic and renal circulation, with the majority of the dramatically diminished  $\dot{Q}$  directed centrally to the heart and brain via the large arteries. In this setting, increased alveolar dead space may cause  $\dot{V}/\dot{Q}$  related hypoxemia (Volume 2, Chapter 2). Several abnormal patient conditions can complicate trauma resuscitation and SVR interpretation.

For example, patients with aortic stenosis (AS) or coronary artery disease (CAD) with left ventricular hypertrophy (LVH) typically have a higher than normal baseline SVR as a compensatory mechanism, to augment perfusion through the coronary arteries during diastole. Any reduction in afterload in these patients (as can occur with the administration of sedatives or analgesics), without first restoring the missing blood volume, will result in decreased coronary perfusion and likely cause myocardial ischemia. Conversely, cirrhotic patients will demonstrate a low baseline SVR because of arterio-venous (A-V) shunting. Patients suffering from septic conditions will also have a low SVR secondary to the systemic levels of circulating cytokines. Consequently, sepsis in a patient with coincident acute blood loss or baseline AS can unfavorably stress the myocardial supply/demand ratio and potentially cause myocardial ischemia.

## Contractility

Myocardial contractility can be estimated by observing LV function with a TEE or by constructing Starling curves (via serial  $\dot{Q}$  measurements and a plot of SV vs. left ventricular end diastolic volume (LVEDV) or left ventricular end diastolic pressure (LVEDP)). Only when LVEDV and SVR are perfectly controlled can accurate determinations of contractility be made. Accordingly, clinical measures are never perfect.

In addition, drugs that increase both SV and afterload (e.g., norepinephrine) may not result in a measured increase in  $\dot{Q}$ , partly because of the baroreceptor-mediated decrease in the HR and partly due to the elevated SVR. Drugs that increase contractility while decreasing afterload (e.g., dobutamine or milrinone) will likely demonstrate an increase in  $\dot{Q}$  (due to an increase in both SV and HR), but with a decrease in SVR and pulmonary vascular resistance (PVR).

When the myocardial perfusion is dependent upon the SVR for coronary artery perfusion (i.e., severe AS or CAD with significant LVH), ischemia can be precipitated when the afterload is reduced and result in decreased contractility and myocardial failure. However, a patient with a dilated cardiomyopathy and normal coronaries will likely benefit from a decreased SVR. A trauma patient who has been bleeding and requires intravascular volume may suffer profound hypotension following the administration of drugs with direct or indirect vasodilating effects, such as sedatives and analgesics. Drugs that increase afterload also tend to increase preload, and thus have countervailing effects on SV. Accordingly, monitoring multiple measures of these various parameters is the best way to keep track of the progress being made.

## Adequacy of Perfusion (Oxygen Delivery = $\dot{D}O_2$ )

✎ **Adequacy of perfusion to tissues is the most important endpoint of resuscitation.** ✎ Unfortunately, only global measures of oxygen delivery ( $\dot{D}O_2$ ) are in wide clinical use (see Volume 1, Chapters 12 and 18, and Volume 2, Chapter 18). Global measures of  $\dot{D}O_2$  tell only a part of the picture,  $\dot{D}O_2 = O_2 \text{ content} \times \dot{Q}$ . Normal  $\dot{Q} = 5 \text{ L/min}$  at rest in a 70-kg patient. The normal arterial  $O_2$  content is 200 cc  $O_2$ /L, thus  $\dot{D}O_2 = 1000 \text{ cc } O_2/\text{min}$ . Because a normal 70-kg patient will consume 250 cc  $O_2/\text{min}$  at rest, the mixed venous saturation at rest is normally approximately 75% in a healthy adult patient. Although the  $\dot{D}O_2$  may be globally adequate, certain tissues may remain ischemic (24–26). Accordingly, specific measures of perfusion are required for each tissue bed of interest (this is an area of continued research).

When titrating therapy, the clinician has to anticipate variation in the patients' tissues needs. Exercising and febrile patients need higher  $\dot{Q}$ s, and certain disease states will be associated with supranormal  $\dot{Q}$ s [e.g., the systemic inflammatory response syndrome (SIRS)]. Conversely, other disease states are associated with low  $\dot{Q}$ s (e.g., hypothyroidism and hypothermia). Other conditions [e.g., congestive heart failure (CHF)] are associated with high preload, high SVR, and impaired pump function.

Clinically, the global adequacy of  $\dot{D}O_2$  is determined by reviewing patient mentation, skin perfusion, BP, urinary output, base deficit, lactate, mixed venous saturation, and thermal dilution derived  $\dot{Q}$  measurements.

## OPTIMUM MANAGEMENT OF HYPOTENSION

### Definitions and Causes of Hypotension in the Trauma ICU

Hypotension is the most common hemodynamic perturbation requiring immediate physician attention following trauma and critical illness. ✎ **When the mean arterial pressure (MAP) falls below 60 mmHg, organ perfusion to renal and splanchnic organs begins to fall. As the MAP dips below 50 mmHg, perfusion to brain and myocardium can become diminished.** ✎ In the setting of atherosclerotic disease, chronic hypertension, as well as in traumatic brain injury (TBI), cerebral ischemia may begin at higher MAPs, especially when the intracranial pressure (ICP) is elevated (27). Similarly, myocardial ischemia will occur at normally adequate MAPs when associated with severe tachycardia, anemia, or increased metabolic rate.

A normal MAP in a 70-kg adult varies with age and the degree of associated atherosclerotic disease, but typically ranges between 85 and 105 mmHg in healthy patients who are at rest. Patients who sustain trauma or critical illness often have tachycardia, and thus, those with coronary artery disease are at increased risk.

Although staying cognizant of the important concerns mentioned, it is sometimes necessary to accept lower MAPs in various conditions. For example, the patient with sepsis or SIRS may suffer from such a profound degree of vasodilation that administering drugs in high enough quantities to normalize MAP would potentially lead to additional complications, including renal insufficiency or decreased gut perfusion; thus compromises occasionally need to be accepted.

The most common cause of hypotension following trauma is hemorrhage. In the ICU, the most common causes are hypovolemia (due to numerous causes), vasodilation, and impaired cardiac output. Less commonly, bradycardia can be the culprit (Table 2).

Hypovolemia can result from hemorrhage, third spacing, increased intrathoracic pressure (tension pneumothorax, excessive PEEP, or high tidal volumes), excessive diuresis (e.g., iatrogenic, Lasix, mannitol), diabetes insipidus, hyperglycemia, alcohol or caffeine intoxication, excessive dialysis, evaporative losses following burns (Volume 1, Chapter 34), toxic epidermal necrolysis (TENS), and heat stroke. Anaphylaxis (Volume 1, Chapter 33) causes hypovolemia by two mechanisms, vasodilation and increased capillary permeability. Dysrhythmias (Volume 2, Chapter 20) can have an effect analogous to hypovolemia, by either not allowing enough LV filling time or due to loss of the atrial contraction, as occurs with a junctional rhythm. Pericardial tamponade is an important cause, which typically presents early following penetrating thoracic trauma, but can have a delayed and insidious presentation following blunt trauma and when resulting from numerous medical needs etiologies.

Decreased SVR, which leads to hypotension, occurs in various conditions such as sepsis (Volume 2, Chapter 47), spinal cord injury (Volume 2, Chapter 13), neuroaxial block (spinal or epidural anesthesia) with local anesthetics, after administration of systemic vasodilators (e.g., propofol for sedation, nimodipine to treat cerebral vasospasm, nitroglycerin to treat coronary artery spasm), and during SIRS (Volume 2, Chapter 63). SIRS is a common cause of hypotension in trauma and critical care, resulting from circulating inflammatory cytokines released following tissue injury from trauma, burns, infection, and pancreatitis (Volume 2, Chapter 39). Anaphylaxis (Volume 1, Chapter 33), also decreases SVR, as does cirrhosis and other etiologies of A–V shunting.

Another cause of hypotension in the critically ill patient is that of relative adrenal insufficiency (Volume 2, Chapter 62). ✎ **Any patient who is adequately fluid resuscitated and requiring vasopressor support, but remains unresponsive to these measures, may have adrenal insufficiency and may need steroid administration for improvement in vasomotor tone (28–33).** ✎ Relative adrenal insufficiency is common in patients with refractory septic shock, and moderate doses of steroids may restore cell sensitivity to vasopressors. A randomized, controlled trial performed in France demonstrated a significant survival benefit among patients receiving moderate-dose corticosteroid therapy in critically ill patients (34). A cosyntropin (synthetic ACTH) stimulation test might help to diagnose this problem (Volume 2, Chapter 62). However, if adrenal insufficiency is suspected, and this test is not readily available, patients may benefit from empiric initiation of steroids without waiting for the results of this test.

## Evaluation Principles

Beside examination is initially employed in the evaluation of the hypotensive patient. Prior to a global exam of the patient (including evaluation of the skin, neck, cardiovascular system, pulmonary system, abdomen, extremities, and neurological systems), a careful survey of the patient's vital signs may offer some clues regarding the etiology of the hypotension. In addition to HR, BP, and respiratory rate, it is important to obtain information regarding the temperature, cardiac rhythm, skin color and temperature, oxygen saturation, and urine output.

TEE is the current gold standard for evaluating intravascular volume and can quickly diagnose most causes of hypotension because LV function and size are readily visualized, as is the presence or absence of tamponade (Volume 2, Chapter 21). However, TEE is not always immediately available in the ICU and may be contraindicated in patients with esophageal injury.

Accordingly, in addition to clinical examination parameters, an ECG, chest X ray, central lines (CVP, PA catheters), and TTE can assist in determining the cause of the hypotension (also see Volume 2, Chapter 9).

**Management Goals Based upon Etiology and Other Conditions Present**

☞ **The overall goal is to ensure adequate tissue perfusion by repletion of intravascular volume first. Vasoconstrictor or inotropic support drugs are generally best administered after intravascular repletion is assured. However, occasionally, both drug support and volume repletion must be employed concomitantly to maintain an adequate BP, until sufficient fluid repletion can be achieved.** ☞

**Intravascular Volume Repletion**

TEE is an excellent monitor for evaluating the efficacy of volume repletion. In the absence of TEE, intravascular pressure measurements (CVP, PACWP) are used as surrogates of intravascular volume status.

The choice of fluid for intravascular repletion depends upon several factors discussed at length in Volume 1, Chapter 11. In general, crystalloids are employed first. Colloids and blood products are added depending on the extent of hemorrhage and whether bleeding has been controlled or remains ongoing.

**Vasopressor and Inotropic Drug Therapy**

After ensuring adequate intravascular volume repletion, vasopressor therapy may be appropriate (e.g., when SVR is very low). Table 3 shows the dose range, receptor activity, predominant hemodynamic effects, and the complications for the most commonly employed vasopressor drugs. Note that some drugs, like norepinephrine and calcium chloride, have both inotropic and vasoconstrictor effects. Norepinephrine has recently been found to be less renal toxic than dopamine in euvolemic patients with sepsis (35–39).

**Review of Vasopressors for Hypotension**

**Phenylephrine (Neo-Synephrine®)**

Phenylephrine (Neo-Synephrine®) is commonly used in the treatment of hypotension due to hypovolemia, anaphylaxis,

or drug-induced vasodilation (40). This  $\alpha_1$ -agonist causes arterial and venous vasoconstriction. It may cause a reflex decrease in HR. A loading dose is not required, and the drug is usually given as an infusion at 20–200 mcg/min titrating to effect in a 70-kg adult. It must be used with caution in patients with aortic insufficiency or mitral regurgitation. The drug usually decreases cardiac output as well as renal and splanchnic blood flow.

Phenylephrine is best infused via a central line, but can be initially administered using a peripheral IV. When a peripheral IV is used, it should be in concert with a carrier solution so as to prevent an unintentional bolus of a line containing pure phenylephrine. An arterial line should be used to monitor therapy and to titrate the infusion. The patient may also need a PA catheter to help guide therapy.

**Norepinephrine (Levophed®)**

☞ **Norepinephrine (Levophed®) can be used to increase BP in hypotensive patients who fail to respond to adequate volume resuscitation and other, less potent, vasopressors.** ☞ It is commonly employed in septic patients because it increases the BP and SVR without altering Q (38,39,41–44). Norepinephrine is an  $\alpha$ - and  $\beta_1$ -agonist that causes arterial and venous vasoconstriction. It has minimal chronotropic effects and is typically infused at a rate of 0.05–40 mcg/kg/min. Norepinephrine causes vasoconstriction of the systemic, renal, and splanchnic beds. Complications include decreased renal perfusion in hypovolemic patients, peripheral vasoconstriction, and dysrhythmias. Norepinephrine can cause tissue necrosis following extravasation. The drug must be given through a central vein with careful monitoring of arterial pressure, perfusion, and renal function to prevent organ ischemia and excessive increases in ventricular afterload.

**Arginine Vasopressin**

Arginine vasopressin has been used for decades to treat esophageal variceal bleeding and diabetes insipidus. Recently, vasopressin has been shown to be useful in the treatment of refractory septic shock and during resuscitation from cardiac arrest (45–51).

The dose of vasopressin for treatment of diabetes insipidus is 2.5–10 U subcutaneously or intramuscularly three

**Table 3** Vasopressors

Drug	Dose range	Receptor activity	Hemodynamic effects	Complications
Phenylephrine	20–200 mcg/min	$\alpha_1$ -agonist	↑ SVR ↑ MAP	Hypertension, bradycardia, myocardial ischemia, ↓ renal perfusion
Norepinephrine	0.05–1.5 mcg/kg/min	Strong $\alpha_1$ -agonist; moderate $\beta$ -agonist	↑ Contractility ↑ SVR ↑ MAP	Peripheral vasoconstriction, arrhythmias, ↓ renal perfusion, tissue necrosis with extravasation, hyperglycemia
Vasopressin	0.01–0.04 units/min	Neurohypophyseal peptide Vasoconstriction of vascular smooth muscle	Potent vasoconstrictor ↓ CO ↓ Renal perfusion	Mesenteric ischemia, ↓ CBF, CNS disturbances, hyponatremia, metabolic acidosis, hypertension
Calcium chloride 10% <sup>a</sup>	Loading dose—90 mg 0.5–2 mg/hr adjusted to ionized calcium level	Stimulates the intracellular release of calcium from the sarcoplasmic reticulum	↑ SVR ↑ MAP ↑ Ionized concentration of calcium	Hypercalcemia, hypophosphatemia, ↓ sensorium, arrhythmias, chemical burn if extravasates

<sup>a</sup>1 ampule of 10% calcium chloride = 13.6 mEQ of calcium, 1 ampule of calcium gluconate = 4.65 mEQ calcium.

Abbreviations: CBF, cerebral blood flow, CNS, central nervous system; MAP, mean arterial pressure; SVR, systemic vascular resistance.

to four times a day. In the treatment of esophageal and gastric variceal bleeding, the dose is 20 U in 100 mL of normal saline given over 15 to 30 minutes or an infusion of 0.4 U/min intravenously. The recommended dose during Advanced Cardiac Life Support® (ACLS®) for refractory ventricular fibrillation is 40 U intravenously (52). Some investigators believe that vasopressin is superior to epinephrine in arrest situations (48). Although it is a weak vasopressor in normal subjects, the addition of vasopressin, infused at a fixed rate of 0.04 U/min, to norepinephrine is more effective in reversing late vasodilatory shock than norepinephrine infusion alone (41,53). ⚡ **The use of vasopressin has also been shown to decrease the requirement for other vasopressors and is associated with a higher urine output and improved creatinine clearance (54,55).** ⚡ Vasopressin is used with caution in patients with coronary artery disease. Complications include coronary and mesenteric ischemia, hyponatremia, pulmonary vasoconstriction, and skin necrosis from peripheral infusion. When using this agent as a vasopressor, it is preferably infused through a central line, and titrated based on invasive pressure monitoring (56).

### Calcium Chloride

Calcium chloride is required for a wide variety of cellular functions. Ionized calcium is essential to the process of excitation-contraction coupling. When it is given exogenously, it stimulates the intracellular release of calcium from the sarcoplasmic reticulum. Indications for administration include ionized hypocalcemia, especially following rapid administration of citrate, containing blood products, or in continuous renal replacement therapy (CRRT). Calcium chloride is also recommended for the treatment of acute hyperkalemia, hypermagnesemia, and calcium-channel blocker overdose. Calcium administration can increase peripheral vascular tone and myocardial contractility, both serving to increase BP. Ionized calcium can also potentiate the peripheral vascular and inotropic effects of catecholamines.

The utility of calcium for the treatment of citrate intoxication is based upon the function of citrate. The citrate is used in blood products and with CRRT to bind calcium and inhibit clotting because  $\text{Ca}^{++}$  is needed in both the intrinsic and final common coagulation pathways. Exogenously administered citrate is rapidly cleared by the liver in normal healthy patients. However, when massive transfusion occurs, a concomitant massive quantity of citrate is coadministered and this can temporarily overwhelm the liver's ability to metabolize it, resulting in transient ionized hypocalcemia.

In severe liver disease, citrate is not metabolized and the citrate level in the blood will increase. When large quantities of citrate build up in the blood, free ionized  $\text{Ca}^{++}$  is diminished below the levels required to maintain vascular tone or myocardial contractility.

Calcium is given as a loading dose of 100 mg and then 1–5 mg/kg/hr, adjusted to the ionized calcium level. In the setting of massive blood product administration, or during the anhepatic stage of liver transplantation patients (where citrate is not being metabolized), much larger quantities of calcium are required. Calcium chloride has approximately three times the calcium bioavailability of the gluconate form. There are 13.6 mEQ of calcium in one 10-mL ampule of calcium chloride, whereas there are only 4.65 mEQ of calcium in one 10-mL ampule of calcium gluconate (57,58). Excessive calcium can precipitate or exacerbate digitalis toxicity, leading to dysrhythmias, and therefore

should be cautiously administered in patients taking digoxin. Calcium forms an insoluble precipitate if mixed with bicarbonate (calcium carbonate). Calcium chloride may sclerose peripheral veins and can produce a severe chemical burn if it infiltrates into the subcutaneous tissues. It is preferably infused through a central line to decrease the risk of peripheral vein injury.

### Inotropes for Decreased Contractility Conditions

Perhaps the most commonly employed inotropic drug is dopamine. Though less potent than epinephrine, dopamine has a wide therapeutic range. Dopaminergic receptors are stimulated in the 2–3 mcg/kg/min range, whereas 5–10 mcg/kg/min stimulates beta-receptors, and >10 mcg/kg/min stimulates alpha-receptors. The dose ranges, receptor activities, predominant hemodynamic effects, as well as complications for the most commonly employed inotropic drugs are reviewed in Table 4.

### Epinephrine

Epinephrine is an endogenous catecholamine with nonselective  $\alpha$ - and  $\beta$ -adrenergic agonist effects. It is often used to treat hypotension and low  $\dot{Q}$  following cardiopulmonary bypass (CPB), acute asthma, cardiac arrest, and anaphylaxis. Epinephrine is a third-line agent in the treatment of septic shock (after dopamine and norepinephrine) (59–62). Epinephrine at low dose (0.01–0.02 mcg/kg/min) stimulates predominantly  $\beta$ -receptors, and above 0.2–0.4 mcg/kg/min begins to have significant  $\alpha$ -receptor agonist effects as well.

Low doses of epinephrine cause primarily  $\beta_1$ -adrenergic receptor agonist effects increasing inotropy and chronotropy, as well as  $\beta_2$ -adrenergic effects causing mild vasodilation; and the combined  $\beta_1$  and  $\beta_2$  effects increase  $\dot{Q}$  and mildly increase MAP. High-dose epinephrine stimulates  $\alpha_1$  receptors causing vasoconstriction, and  $\beta_1$  receptors increasing chronotropy and inotropy, producing a large increase in MAP. At high doses, the  $\alpha_1$  effects overwhelm the  $\beta_2$  effects, causing an increased SVR. This, along with an increase in  $\dot{Q}$  due to the concomitant  $\beta_1$ -adrenergic agonist effects—markedly elevate the MAP.

For the treatment of acute asthma, epinephrine is given as 0.3–0.5 mg of 1:100 dilution subcutaneously, repeated at 20-minute to four-hour intervals or one inhalation (metered dose) repeated in one to two minutes until symptoms abate. For emergency cardiac care, epinephrine is given at 0.5–1 mg (1:10,000) intravenously every three to five minutes to response. When used in the surgical intensive care unit (SICU) for inotropic support, it is infused at 0.01–0.4 mcg/kg/min. Complications include increased myocardial oxygen consumption with ischemia, dysrhythmias, hypertension, hyperglycemia, and decreased renal perfusion, especially in hypovolemic patients. Epinephrine should be administered through a central vein and monitored with an intra-arterial catheter.

### Norepinephrine (Levophed®)

Norepinephrine is an endogenous catecholamine with potent  $\alpha$ -adrenergic receptor agonist and moderate  $\beta_1$ -adrenergic agonist effects. It produces potent vasoconstriction with a less pronounced increase in cardiac output. A reflex bradycardia can occur in response to the increased SVR and MAP, so that the mild chronotropic effect is negated and the HR remains unchanged or even decreases slightly.

**Table 4** Inotropes

Drug	Dose range	Receptor activity	Hemodynamic effects	Complications
Epinephrine	0.01–0.4 mcg/kg/min 0.5–1 mg (1:10,000) 0.3–0.5 mg SQ (1:1000)	Potent $\alpha_1$ -agonist Nonselective $\beta$ -agonist	$\uparrow\uparrow \dot{Q}$ $\uparrow\uparrow$ Contractility $\uparrow$ HR $\uparrow\uparrow\uparrow$ Vasoconstriction (high dose) $\uparrow\uparrow$ Vasodilation (low dose) $\uparrow$ MAP Bronchodilation	$\uparrow$ Myocardial consumption with ischemia; arrhythmia, hypertension, hyperglycemia, poor renal perfusion, local ulceration if infiltrated
Norepinephrine	0.05–1.5 mcg/kg/min	Potent $\alpha_1$ -agonist Moderate $\beta_1$ -agonist	$\uparrow$ Contractility $\uparrow$ SVR $\uparrow$ MAP	Arrhythmias; peripheral vasoconstriction, tissue necrosis, hyperglycemia
Dopamine	1–3 mcg/kg/min 2–10 mcg/kg/min >10 mcg/kg/min	DA receptor $\beta$ and DA $\alpha_1$ , $\beta$ and DA	$\uparrow\uparrow$ Contractility $\uparrow$ HR Vasoconstriction $\uparrow$ SVR $\uparrow\uparrow\uparrow$ Renal blood flow $\uparrow\uparrow\uparrow \dot{Q}$	Arrhythmias; tachycardia, necrosis at injection site with extravasation
Dobutamine	2.5–20 mcg/kg/min	Potent $\beta_1$ -agonist	$\uparrow\uparrow\uparrow$ Contractility $\uparrow$ HR $\uparrow\uparrow\uparrow \dot{Q}$ Peripheral vasodilator $\downarrow\downarrow$ SVR	Tachycardia, hypotension
Isoproterenol	0.01–0.1 mcg/kg/min	Potent $\beta_1$ - and $\beta_2$ -agonist	$\uparrow\uparrow\uparrow$ Contractility $\uparrow\uparrow\uparrow$ HR $\uparrow\uparrow\uparrow$ Vasodilation $\uparrow\uparrow\uparrow \dot{Q}$ Bronchodilator	Tachycardia, tachyarrhythmias, myocardial ischemia, flushing of the skin
Amrinone/ milrinone	Load 0.75 mg/kg over 3 minutes 2–15 mcg/kg/min Load 50 mcg/kg over 10 minutes 0.375–0.75 mcg/ kg/min	Inhibits phosphodiesterase $\uparrow$ cAMP	$\uparrow\uparrow\uparrow$ Contractility; systemic and pulmonary vasodilation	Dose-related thrombocytopenia with amrinone, synergy with dobutamine, arrhythmia

*Abbreviations:*  $\dot{Q}$ , dopaminergic; cAMP, cyclic adenosine monophosphate; HR, heart rate; MAP, mean arterial pressure; SVR, systemic vascular resistance; DA, cardiac output.

Norepinephrine is most commonly used in acute hypotensive states, especially to treat septic shock. Its major indication is to increase BP in hypotensive patients who fail to respond to adequate volume resuscitation and other, less potent, vasoconstrictors and inotropes. It causes systemic vasoconstriction and coronary artery vasodilation. Norepinephrine is inactivated by the pulmonary circulation, and thus does not cause an increase in PVR. Thus, it can be used in patients with PA hypertension (63,64).

Complications include dysrhythmias, hyperglycemia, and splanchnic vasoconstriction. When given to patients taking tricyclic antidepressants, norepinephrine can lead to a severe hypertension. As an inotrope, norepinephrine is infused at a rate of 0.05–1.5 mcg/kg/min, and titrated based on the arterial pressure. It is best given through a central vein to avoid tissue necrosis from extravasation. Careful monitoring of arterial pressure, perfusion, and renal function is necessary during infusions to prevent organ ischemia.

### Dopamine

Dopamine has a variety of actions depending upon the dose administered. At doses of 1–3 mcg/kg/min, dopamine acts predominantly on  $D_1$ -receptors in the renal, mesenteric, cerebral, and coronary beds, resulting in selective vasodilation. It has been shown that this low-dose dopamine can increase urine output and renal blood flow (65–69).  
 $\heartsuit$  **Although low-dose dopamine increases renal blood**

**flow, it does not ameliorate renal failure, and has not improved outcomes in nonliguric patients recovering from acute tubular necrosis (ATN) (70,71).**  $\heartsuit$  At 5–10 mcg/kg/min, the  $\beta_1$ -adrenergic effects of dopamine predominate. Dopamine at these doses will increase cardiac output by increasing SV and HR. The effect of dopamine on HR is variable at all dose ranges. At doses greater than 10 mcg/kg/min, the predominant effect of dopamine is to stimulate  $\alpha_1$ -receptors. This dose will produce vasoconstriction and consequent increase in SVR. The vasoconstrictor effect of dopamine is weaker than that produced by norepinephrine. In some patients, doses greater than 3 mcg/kg/min result in dose-limiting dysrhythmias due to  $\beta_1$ -adrenergic receptor stimulation. Dopamine is most often used in hypotension due to sepsis, impaired cardiac function, and other combined vasodilated states. Once started, dopamine is titrated to a desired effect rather than a pharmacologic range. It is preferably administered through a central line and monitored with an intra-arterial catheter. Monitoring HR and rhythm, systemic and renal perfusion is also recommended. Dopamine has a mild increased effect on hypoxic pulmonary vasoconstriction but does not increase PVR and can be safely used in patients with pulmonary hypertension. Nausea, emesis, and tachyarrhythmias are the most common complications associated with dopamine infusion. Of note, patients on monoamine oxidase inhibitors (MAOI) can have exaggerated hypertensive effects following dopamine administration. Patients on MAOIs should only receive direct-acting drugs to increase BP (e.g., phenylephrine) and contractility (e.g., epinephrine).

If extravasation of the dopamine infusion occurs, tissue necrosis can develop if not treated by local injection of phentolamine (72–74).

### Dobutamine

Dobutamine is a synthetic inotropic drug derived from isoproterenol, in an attempt to decrease the dysrhythmogenic and vasodilatory effects. Dobutamine has  $\beta_1$ -adrenergic receptor effects that increase  $\dot{Q}$  and HR. It typically decreases both systemic and pulmonary vascular resistance because of minimal  $\alpha_1$ - and moderate  $\beta_2$ -adrenergic receptor effects. Dobutamine is most frequently used in severe, medically refractory heart failure and cardiogenic shock. It is not routinely used in patients with sepsis or hypovolemic shock because it may exacerbate hypotension (72–80). Dobutamine is infused at a rate of 2.5–20 mcg/kg/min and is monitored by effect or cardiac parameters. Dysrhythmias and decreases in BP are the most frequent side effects.

### Isoproterenol

Isoproterenol is a potent, nonselective  $\beta_1$ - and  $\beta_2$ -adrenergic receptor agonist with prominent chronotropic and vasodilator effects. The  $\beta_2$  effects cause vasodilation and a decrease in MAP, and therefore isoproterenol has virtually no role in either the acute trauma or critical care setting. Isoproterenol can be used to treat pulmonary hypertension and right ventricular (RV) failure following heart transplantation, and in young patients without CAD. It can be used cautiously to treat hemodynamically significant bradycardia, but other choices are usually preferred (i.e., pacemakers, atropine, epinephrine, etc.).

Isoproterenol is avoided in patients with CAD because it can induce myocardial ischemia. Other complications are tachydysrhythmias and flushing of the skin. Isoproterenol is infused at a rate of 0.01–0.1 mcg/kg/min and is adjusted to produce the desired hemodynamic effect. Isoproterenol should never be used in patients without intra-arterial catheters, or in those with aortic stenosis, mitral stenosis, hypertrophic left ventricles, CAD, or other disease states that will not tolerate combined hypotension and tachycardia.

### Phosphodiesterase Inhibitors

Amrinone and milrinone inhibit phosphodiesterase, resulting in an increase in intracellular cyclic adenosine monophosphate cAMP. These are nonadrenergic drugs with inotropic and vasodilatory actions. These agents are most

commonly used to treat patients with impaired cardiac function and heart failure refractory to  $\beta_2$ -agonists (81–83). Because these phosphodiesterase inhibitors cause systemic and pulmonary vasodilation, their role is limited in the trauma patient (84,85). Both drugs can cause dysrhythmias, and amrinone can also result in a dose-related thrombocytopenia (86,87).

### Dopexamine

Dopexamine is a dopamine analog used intravenously in the treatment of heart failure and low  $\dot{Q}$  states. It produces systemic vasodilation by stimulating  $\beta_2$ -adrenoceptors and peripheral dopamine receptors. It is a weak inotrope and has no  $\alpha$ -adrenergic receptor activity. Dopexamine is given as an infusion ranging from 1  $\mu$ g/kg/min to a maximum dose of 6  $\mu$ g/kg/min. Although primarily used in heart failure, some studies have proposed its use in high-risk surgical and critically ill patients, because it preserves hepatosplanchnic and renal perfusion (88–92). This preservation of flow is thought to aid in the prevention of multiple organ dysfunction in critically ill patients. Dopexamine may also ameliorate the vasopressin-associated decrease in tissue oxygen in sepsis, thereby increasing the  $\dot{Q}$  and  $\text{DO}_2$  in these patients (89). The most common complication associated with its use is tachyarrhythmias, which may be undesirable in the patient population subjected to its use.

## OPTIMUM MANAGEMENT OF SIGNIFICANT HYPERTENSION

### Definitions and Causes of Hypertension in the Trauma ICU

Most patients who present with hypertension in the ICU are baseline hypertensives who have stopped taking medications or who have a new medical problem that causes exacerbation of their normal conditions, for example, intracranial hemorrhage (ICH), aortic dissection, and cocaine or amphetamine intoxication.

In 2003, the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure published their latest set of recommendations (JNC 7) on the diagnosis and treatment of hypertension (93–95) (Table 5). Hypertension is defined as a BP greater than 140/90. In contrast to JNC 6 (published in 1997), the new guidelines have only two stages of nonurgent or emergent hypertension. Unless there are compelling indications, stage 1 (140 to 159/90 to 99 mmHg) patients are recommended to receive

**Table 5** Blood Pressure Classifications per Joint National Committee (JNC) 7 (2003)

BP classification	SBP (mmHg)	DBP (mmHg)	Comments (examples)
Normal	<120	and <80	In JNC 6 this was called optimal
Pre-HTN	120–139	or 80–89	In JNC 6 this was called normal or borderline
Stage 1 HTN	140–159	or 90–99	Thiazide diuretics first-line therapy
Stage 2 HTN	$\geq 160$	$\geq 100$	Thiazide + ACEI, or ARB, or BB, or CCB
HTN urgency	$\geq 160$	$\geq 100$	May have symptoms, but no evidence of end-organ failure (e.g., may have headache, but no ICH, encephalopathy, or seizure; e.g., may have shortness of breath, but not acute pulmonary edema)
HTN crisis	$\geq 180$	$\geq 120$	Evidence of impending or progressive target organ dysfunction (e.g., HTN encephalopathy, ICH, acute MI, acute LV failure with pulmonary edema, aortic dissection, eclampsia)

*Abbreviations:* ACEI, angiotensin-converting enzyme inhibitor; ARB, angiotensin receptor blocker; BB,  $\beta$  blocker; BP, blood pressure; CCB, calcium-channel blocker; DBP, diastolic blood pressure; HTN, hypertension; ICH, intracranial hemorrhage; JNC, Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure; LV, left ventricle; MI, myocardial infarction; SBP, systolic blood pressure.

thiazide diuretic therapy only, and stage 2 ( $>160/ >100$  mmHg) patients are treated with thiazide diuretics and a second drug such as an angiotensin-converting enzyme inhibitor, an angiotensin receptor blocker, a beta blocker, or a calcium-channel blocker.

The traumatologist and intensivist need to be aware of the pharmacology and side effects of these common drugs, because of their prevalence in the critically ill population and because they are used in the treatment of hypertensive crises. Hypertensive urgency is defined in JNC 7 as stage 2 hypertension plus symptoms, but no overt evidence of end-organ damage. Hypertensive crisis is defined by JNC 7 as BP greater than 180/120 mmHg and evidence of current or impending end-organ damage [(e.g., ICH, acute myocardial infarction (MI), acute LV failure with pulmonary edema, aortic dissection, pre-eclampsia)] (96,97).

Malignant hypertension (MHTN) is defined by the World Health Organization as severe hypertension with bilateral retinal hemorrhages and exudates. There is no defined level of systolic BP; however, the diastolic BP is usually greater than 120 to 130 mmHg (98–100).

Although the trauma intensivist must be cognizant of these definitions, common causes of hypertension may be present. Pain, fear, and anxiety are commonplace in the trauma ICU and need to be treated first. While evaluating and treating these common problems leading to hypertension, the intensivist must also search for the other life-threatening conditions. **In all scenarios, the goal of MHTN treatment is to prevent end-organ damage.**

### Evaluation Principles

Because the causes of hypertension in the ICU are numerous, bedside evaluation of the patient is imperative. It is most practical to obtain an assessment of pain, fear, and anxiety by examining the patient. By evaluating the patient at the bedside, the physician obtains a global assessment of the patient's condition and can begin treating the common problems of pain, fear, or anxiety. In examining the patient, the clinician can also rule in (or out) life-threatening conditions while surveying the patient for evidence of end-organ damage. Antihypertensive therapy can be started if there is no response to the other measures. However, it is important to avoid overcorrection because autoregulation is typically impaired, and hypotension can trigger hypoperfusion and organ ischemia.

During the bedside evaluation, a history of hypertension and medical treatment is sought. Hypertensive patients should be restarted on their antihypertensive medications as soon as it is safe to do so.

The physical exam provides clues to the cause and potential complications of hypertension. The head-to-toe examination focusses upon any obvious injuries that may cause pain and also evaluates the neurological status, checking for papilledema, assessing the HR and rhythm, and ruling out any occult injuries or causes.

Laboratory data should include a toxicology screen for cocaine, amphetamine, alcohol, and so on. Some withdrawal syndromes result in hypertension, including alcohol (e.g., delirium tremens) and abrupt cessation of clonidine. Serum chemistries and thyroid function studies help exclude renal vascular hypertension, thyroid storm, or hyperadrenalism. If the laboratory results and clinical evaluation does not return a clear etiology of the new-onset hypertension, it is important to rule out a pheochromocytoma (particularly when episodes of severe hypertension persistently recur) (101,102).

Imaging studies can define the cause of hypertension, such as in the setting of altered mental status. A CT scan of the head will help determine whether TBI or ICH is the culprit, while a CT scan of the abdomen and pelvis may lead to medical renal disease or an adrenal mass as the inciting factor.

### Hypertension Management Goals Based upon Etiology

After ruling out pain, fear, or anxiety as the cause, it is important to treat the acutely hypertensive patient in order to prevent end-organ damage. Acutely, nitroprusside therapy is easily titrated, but beware of cyanide toxicity and exacerbation of tachycardia. If the patient is tachycardic, beta blockers are sometimes appropriate.

### Peripheral Vasodilators

#### Nitroprusside

Nitroprusside is a direct vasodilator with rapid onset and elimination. Its use is indicated in the setting of hypertensive crisis, aortic dissection, or when rapid titration of vasodilatory effects is needed. The dose is 0.5–10 mcg/kg/min and the duration upon termination is three to five minutes. The dose is titrated to effect and to specific BP parameters. Monitoring with an indwelling arterial pressure line is a more accurate method of BP assessment when titrating the drug (Table 6).

Nitroprusside is contraindicated in the setting of acute TBI because of the cerebral vasodilatory effects that result in increased cerebral blood flow (CBF) and ICP (103).

Cyanide toxicity is the major concern with high dose ( $>8-10$  mcg/kg/min) or prolonged therapy (e.g.,  $>24$  hours of dosages  $>2$  mcg/kg/min) (104). Cyanide toxicity is particularly problematic in patients with thiosulfate deficiency (104). Other complications include metabolic acidosis, nausea, and coronary steal (103). Nitroprusside use is avoided in pregnant patients.

#### Nitroglycerin

Nitroglycerin is a venous and arterial dilator with a fast onset of action and a short duration. It is indicated in myocardial ischemia and postcoronary bypass. Its dose ranges from 0.1 to 10 mcg/kg/min and is titrated to symptomatic relief or desired effect. Because it increases CBF, it is relatively contraindicated in patients with TBI and elevated ICP. Complications of nitroglycerin infusion include headache, tachycardia, tolerance, and methemoglobinemia. Therapy is monitored based on desired effect. It is helpful to have an arterial line for more accurate BP control.

#### Hydralazine

Hydralazine is a direct arteriolar dilator. Its peak onset of action is 15 to 30 minutes, and its duration is two to four hours. Indications for hydralazine include pre-eclampsia and postoperative hypertension. Hydralazine can be given intravenously or intramuscularly. The intravenous dose is 10–20 mg, every 20 to 30 minutes as needed, and the intramuscular dose is 10–50 mg, every one to two hours as need. It is most commonly given in bolus doses without regularly scheduled times. Relative contraindications to use include patients with preexisting CAD, angina, or arrhythmias. Side effects include hypotension (especially when given more frequently than every 20–30 minutes IV). Tachycardia is common due to the vasodilator effects. Complications also include flushing, angina, and supraventricular tachycardia.

**Table 6** Vasodilators

Drug	Dose	Action	Indications	Complications
Nitroprusside	0.25–10 mcg/kg/min	Direct vasodilation; rapid onset; rapid offset; onset: seconds. Duration: 3–5 minutes	Hypertensive crisis; aortic dissection, need for rapid titration of vasodilatory effects	Coronary steal; cyanide toxicity; metabolic acidosis; ↑ ICP in TBI; nausea; avoid in pregnancy
Nitroglycerin	0.1–10 mcg/kg/min	Venous and arterial dilator Onset: 1–2 minutes. Duration: 5–10 min	Myocardial ischemia; post-coronary bypass	Headache; tachycardia tolerance; methemoglobinemia; ↑ CBF
Nicardipine	5–15 mg/hr IV 10–50 mg IM	Ca <sup>2+</sup> channel blocker onset: 3–5 minutes. Duration: 1–4 hours	CA vasodilator; prevents vasospasm	Tachycardia; hypotension
Hydralazine	10–20 mg IV 10–50 mg IM	Direct arteriolar dilation Onset: 15–30 minutes Duration: 2–4 hours	Eclampsia; postoperative hypertension	Tachycardia; SVT; flushing; angina; Lupus-like syndrome
Phentolamine	5–10 mg IV bolus every 15 minutes	α <sub>1</sub> blockade onset: 1–2 minutes. Duration: 3–10 minutes	Pheochromocytoma; recreational drugs; tyramine and MAOI ingestion; spinal cord dysreflexia	Tolerance; tachycardia vomiting; angina nausea
Diazoxide	Mini bolus 50–100 mg every 5 minutes up to 600 mg 7.5–30 mg/min	Direct arteriolar dilation Related to thiazides. Onset: 2–5 minutes. Duration: 4–12 hours	Causes ↑ CO, ↓ CBF, fluid retention; caution with Coumadin	Tachycardia; angina hyperglycemia; hyperuricemia; extrapyramidal symptoms
Fenoldopam	0.1 mcg/kg/min	Peripheral dopamine-1 agonist. Duration: 10 minutes.	Maintains or increases renal perfusion while it lowers BP	Contraindicated in patients with glaucoma

*Abbreviations:* BP, blood pressure; CBF, cerebral blood flow; CA, coronary artery; ICP, intracranial pressure; IM, intramuscular; MAOI, monoamine oxidase inhibitors; Q, cardiac output; SVT, supraventricular tachycardia; TBI, traumatic brain injury.

There is also a lupus-like syndrome that develops in as many as 10% of patients chronically using this drug. Therapy is monitored by desired effect.

## Beta Blockers

### Esmolol

Esmolol is a β<sub>1</sub>-selective (i.e., cardioselective) adrenergic receptor blocking agent (Table 7). Its onset is immediate and has a clinical duration of 10 to 15 minutes after cessation of infusion. Esmolol is usually given as a loading dose of 500 mcg/kg/min over one minute, followed by an infusion rate of 50–100 mcg/kg/min. Indications for use include aortic

dissection and abdominal aortic aneurysm. Complications of esmolol included excessive bradycardia and rarely bronchospasm. It may prolong the effects of succinicholine and should be used with caution in patients with systolic cardiac dysfunction. It is easily titrated and is an appropriate drug to use when both a decrease in HR and BP are needed. Titration is based on BP measurements, preferably from an arterial line.

### Metoprolol

Metoprolol is a selective β<sub>1</sub>-adrenergic receptor blocking agent with a clinical duration of four to six hours. It is dosed intravenously in 5 mg increments, usually every six hours. The dose can be increased to a maximum of 10 mg

**Table 7** β-Blockers

Drug	Dose	Action	Indications	Complications
Esmolol	Load 500 mcg/kg/min over 1 minute 10–300 mcg/kg/min	Selective β <sub>1</sub> -blocker Onset: immediate Duration: 10–15 minutes	Aortic dissection; abdominal aortic aneurysm	Bradycardia; bronchospasm, may prolong effects of succinicholine; caution with systolic cardiac dysfunction
Metoprolol	5-mg increments	Selective β <sub>1</sub> -blocker Duration: 3–4 hours	Myocardial infarction; hypertension; angina	Bradycardia
Labetolol	20-mg test dose 20–80 mg Q 10 minutes to total of 300 mg 0.5–2 mg/min	α <sub>1</sub> and nonselective β-blocker. Onset: 5–15 minutes. Duration: 2–12 hours	Eclampsia; spinal cord dysreflexia, intracranial process when nitroprusside not available	Bronchospasm; bradycardia

every six hours, or the frequency can be adjusted to every four hours or more frequently; with the physician at the bedside, 5 mg can be administered every 15 minutes for four doses. Once a stable IV dose is determined, metoprolol can be administered orally in doses of 25–200 mg twice daily. The maximum oral daily dose is approximately 450 mg in a 70-kg patient. The higher the dose, the less the cardioselective metoprolol becomes. It is indicated in myocardial infarction, hypertension, and angina. It is easily converted to an oral form once a regular dosing and effect has been established. Bradycardia is the main complication. Therapy is typically monitored based on increasing dosage, until the desired effect (control of BP and HR) is achieved or until important side effects occur.

### Labetolol

Labetolol is a combined  $\alpha_1$ -blocker and a nonselective  $\beta$ -adrenergic receptor blocker. Its peak onset of action is five minutes, with clinical duration of approximately six to eight hours. Indications include eclampsia, spinal cord dysreflexia, intracranial processes when nitroprusside is not available, and all situations where both a decrease in HR and a decrease in SVR are sought. Labetolol is administered intravenously in five-minute intervals starting with 5 mg aliquots, and increasing dose by 5–10 mg with each administration, until the desired effect is achieved or a complication occurs, up to a total of 300 mg in a 70-kg patient. Once the desired effect is achieved, the aggregate milligram dose required can be administered orally every eight hours to provide continued BP control. Additional IV doses can be administered as needed to supplement the baseline oral dose. It can also be given as an infusion of 0.5–2 mg/min; however, labetolol is not as easily titrated as esmolol, nitroprusside, or nitroglycerin because of the long duration of action.

### Calcium-Channel Blockers

Calcium-channel blockers comprise two subclasses, dihydropyridines and nondihydropyridines, which are different with respect to vascular selectivity, negative inotropy, effect on cardiac impulse formation, and conduction. Both subclasses have efficacy as antihypertensive agents. However, several of these drugs have found certain niches. Diltiazem is commonly used for A–V nodal blockade and rate control of supraventricular tachycardias (Volume 2, Chapter 20), nimodipine is used for control of cerebral vasospasm following subarachnoid hemorrhage (SAH) (Volume 2, Chapter 14), and nifedipine is used for brief periods as an infusion in situations that were previously relegated to nitroprusside (discussed subsequently) (105).

### Verapamil

Verapamil is calcium-channel blocker with an elimination half-life of four to five hours (Table 8). A loading dose of 5 to 10 mg over two to three minutes is given, and then it is infused at a rate of 5 mg/hour or 0.075–0.15 mg/kg/hr, and titrated to effect. Indications include angina, hypertension, hypertrophic cardiomyopathy, and supraventricular tachyarrhythmias (106). Hypotension, bradycardia, constipation, and AV block with beta blockers are some of the complications. Therapy is monitored based on desired effect, whether it is HR control, BP control, or chest pain control.

### Nifedipine

Nifedipine is a calcium-channel blocker with an elimination half-life of three hours. Its use may be limited in the ICU setting because there is no intravenous dosing. It is given as a 10–20 mg orally or sublingually, with a maximum dose of 180 mg/day. Its indications include hypertension

**Table 8** Calcium-Channel Blockers

Drug	Dose	Duration	Indications	Complications
Verapamil N	Load 5–10 mg over 2 to 3 minutes, 5 mg/hr (0.075 to 0.15 mg/kg/hr)	Elimination half-life: 4–5 hrs	Angina; hypertension, hypertrophic cardiomyopathy SVT	Hypotension, bradycardia, AV block with $\beta$ -blockers <sup>a</sup> constipation
Nifedipine D	No IV dose 10–20 mg PO or SL Max 180 mg/day	Elimination half-life: 3 hrs	Angina, hypertension	Headache, hypotension reflex tachycardia
Diltiazem <sup>b</sup> N	Load 0.25 mg/kg over 2 minutes 5 to 15 mg/hr, max 360 mg/day	Elimination half-life: 2–5 hrs	Prevention of reinfarction angina, hypertension, rate control in atrial flutter/fibrillation	Hypotension, AV block with beta-blockers <sup>a</sup>
Nicardipine D	5–15 mg/hr	Onset: 3–5 minutes Duration: 1–4 hrs	Postoperative hypertension, prevention of vasospasm from SAH, angina, least potential cardiac contractility suppression	Long half-life, reflex tachycardia hypotension
Nimodipine N	60 mg PO every 4 hours		Prevention of vasospasms following SAH	

<sup>a</sup>Verapamil and diltiazem have significant A–V node blockade effect, thus useful in controlling the ventricular response to SVTs.

<sup>b</sup>Diltiazem has the least amount of vasodilation compared to A–V node blockade effect, thus is the best choice for infusion in critically ill patients with atrial fibrillation or flutter and hypotension.

Abbreviations: AV, atrial-ventricular D, dihydropyridine type; N, nondihydropyridine type; SVT, supraventricular tachycardia; PO, per oral; SAH, subarachnoid hemorrhage.

and angina. Complications are limited to headache, hypotension, and reflex tachycardia.

### Diltiazem

Diltiazem is a calcium-channel blocker with an elimination half-life of two to five hours. It is given as a loading dose of 0.25 mg/kg over two minutes and then infused at 5 to 15 mg/hr. The maximum dose is 360 mg/day. Indications include prevention of reinfarction, angina, hypertension and, most commonly, rate control in atrial fibrillation or flutter. Hypotension is the main complication of this drug. Therapy is monitored based on desired effect.

### Nicardipine

Nicardipine is a calcium-channel blocker with an onset of one to three minutes and duration of 15–40 minutes. Because of its relatively selective inhibition of vascular smooth muscle contraction along with its short half-life, some practitioners now use nicardipine in place of nitroprusside, especially in patients with evidence of cyanide toxicity or low endogenous thiosulfate levels (i.e., higher risk of cyanide toxicity).

Intravenous nicardipine was compared with nitroprusside in a randomized, multicenter trial, in 74 patients with hypertension (MAP  $\geq$  100 mmHg) following coronary artery bypass surgery (107). Nicardipine was administered as a 2.5- to 12.5-mg bolus followed by a 2- to 4-mg/hr infusion, and nitroprusside as a 0.5- to 6.0-mg/kg/min infusion. The aim was to reduce MAP to less than 90 mmHg within 50 minutes and maintain it stable at  $85 \pm 5$  mmHg. Nicardipine was effective in 35 of 38 patients (92%), and nitroprusside in 29 of 36 (81%) (108). The decrease in MAP was not statistically different, but time until reaching the therapeutic endpoint was shorter with nicardipine ( $P < 0.01$ ).

Nitroprusside was associated with greater increase in HR and decreases in mean PA, right atrial, and PACWP were more marked with  $P < 0.01$  and  $P < 0.05$ , respectively, whereas nicardipine administration resulted in a greater elevation of  $\dot{Q}$  and depression of SVR ( $P < 0.01$  and  $P < 0.05$ , respectively). Patients on nicardipine had slightly more stable postreduction MAP and less need for drug titration with nicardipine. Interestingly, transfused blood volume was also lower with nicardipine ( $924 \pm 644$  mL) than nitroprusside ( $1306 \pm 901$  mL) ( $P = 0.08$ ), despite similar postoperative blood losses.

Nicardipine is usually infused at 5–15 mg/hr. It is used in postoperative hypertension, the prevention of vasospasm from SAH, and angina. Nicardipine has the least potential cardiac contractility suppression of all calcium-channel blockers, but a long half-life. Complications

include reflex tachycardia and hypotension. Therapy is titrated based on the drug's desired affect.

### Nimodipine

Nimodipine is a calcium-channel blocker that only comes in oral form. It is usually given at 60 mg orally every four hours. The main indication for use is prevention of vasospasm following SAH. Nimodipine is a calcium-channel blocker that can alleviate vasospasm after SAH (see Volume 2, Chapter 14) (109). Intravenous nimodipine was recently used in two patients with primary thunderclap headache (TCH) after ischemia stroke had developed (110,111), with suggestive improvement. In addition, a small clinical series of nimodipine treatment in 11 consecutive patients with primary TCH showed some benefit in relieving vasospasm and headache. Similarly, intra-arterial nimodipine has been recently shown to reverse symptomatic vasospasm after SAH (112).

For the usual treatment of vasospasm following SAH, nimodipine is usually delivered in the oral form (the only available form until recently).

### Angiotensin-Converting Enzyme Inhibitors

Enalaprilat is the only parenterally available ACE inhibitor, and thus the only drug of use for acute trauma or critical care related hypertensive crisis (113,114). The response to enalaprilat is variable and not predictable. The usual initial dose is 1.25 mg and is given every six hours. The maximum dose is 5 mg every six hours. The onset of action begins is 15 minutes but the peak effect may not be seen for four hours. The duration of action ranges from 12 to 24 hours. There are compelling indications for its use in heart failure, postmyocardial infarction, patients with high coronary disease risk, diabetes, chronic kidney disease, and for recurrent stroke prevention (Table 9). It is not used as a first-line agent for hypertension in the ICU setting. Typically, it is added as another agent to help control the hypertensive patient who needs a longer-acting drug, or in patients that are on oral forms of ACEIs at home. The main complication is hypotension. It is contraindicated in pregnancy.

## SPECIAL CONSIDERATIONS

### Coronary Artery Syndromes in the Trauma Patient

Suspicion of acute CAD in the critically ill trauma patient requires immediate attention and further diagnostic work-up. This should include a 12-lead ECG to document progression of disease, an echocardiogram to evaluate function, and a consultation with the cardiology service. If the patient goes to Catheterization lab, the information contained in Table 10 will be obtained in order to assist in management.

**Table 9** Compelling Indications for Antihypertensive Drugs Based upon Clinical Trials Reviewed in Joint National Committee 7

Compelling indication	Thiazide diuretic	BB	ACEI	ARB	CCB	Aldosterone antagonist
Heart failure	X	X	X	X		X
Post MI		X	X			X
High coronary disease risk	X	X	X		X	
Diabetes	X	X	X	X	X	
Chronic kidney disease			X	X		
Recurrent stroke prevention	X		X			

*Abbreviations:* ACEI, angiotensin-converting enzyme inhibitor; ARB, angiotensin receptor blocker; BB,  $\beta$ -blocker; CCB, calcium-channel blocker; MI, myocardial infarction.

**Table 10** Ventricular Function Data Expected from the Catheterization Lab

Parameters evaluated on cath	Good	Impaired
RA, RV, PA, PACWP, LA, LV, AO contractility: EF, RVEDP, LVEDP wall motion abnormalities CA anatomy and description of lesions (>70% stenosis is significant)	EF > 0.55 LVEDP < 12 RVEDP < 6 CI > 2.5	EF < 0.4 LVEDP > 18 RVEDP > 12 CI < 2.0

*Abbreviations:* AO, aorta; CA, coronary artery; CI, cardiac index; EF, ejection fraction; LA, left atrium; LV, left ventricle; LVEDP, left ventricular diastolic pressure; PA, pulmonary artery; PACWP, pulmonary capillary wedge pressure; RA, right atrium; RV, right ventricle; RVEDP, right ventricular and diastolic pressure.

Cardiac enzymes, including serial troponin, should be sent in addition to the other diagnostic studies. Therapy, such as aspirin, heparin, or platelet inhibitors, is essential in the management of acute cardiac ischemia. However, these therapies are contraindicated in the acutely traumatized patient with active CAD. Nitroglycerin may be considered in the trauma patient with acute CAD, but is harmful and essentially contraindicated in acute TBI with elevated ICP. Although the management is usually beta blockade if tolerated, following serial cardiac enzymes, supportive therapy, and watchful waiting, it is imperative to get the cardiology team involved early in these patients.

Once the information from the echocardiogram is obtained, there are certain hemodynamic goals to reach in the patient with cardiac ischemia. The echocardiogram will determine pump function, valve function, intravascular volume, and rule out tamponade. The hemodynamic goals for the patient with myocardial ischemia may be at odds with the resuscitation requirement for hemorrhage. For instance, in the patient with myocardial ischemia, the goal is to decrease preload and increase the SVR. However, if the patient is traumatized and has ongoing hemorrhage, the goal is to increase the intravascular volume, which will start to normalize the SVR after fluid repletion (Table 11). As stated previously, some specific therapies for the CAD patient (e.g., heparin, aspirin, Plavix, etc.) are contraindicated in the trauma patient with active bleeding.

**Valvular Heart Disease and Trauma/Critical Illness**

The critically ill trauma patients with valvular heart disease may also create some management dilemmas. These patients may have specific hemodynamic requirements that may be contrary to the goals of resuscitation in hemorrhagic shock. Suspicion warrants immediate evaluation by the cardiology service, a 12-lead ECG, and an echocardiogram. Resuscitation considerations for patients with valvular heart disease are reviewed in Table 12. Managing these patients takes continuous communication with the

**Table 11** Effects of Hemodynamic Parameters on Oxygen Supply and Demand of the Myocardium and Target Values for Patients with Coronary Artery Disease

Hemodynamic parameter	Effect on O <sub>2</sub> supply	Effect on M <sub>v</sub> O <sub>2</sub>	Target value
HR	↓	↑↑	↓↓↓
Dysrhythmia	↓ - ↓↓↓↓	↑ - ↑↑	NSR
Preload	↑	↑↑	↓↓
Afterload	↑↑	↑	↑↑↓
Contractility	↑↑	↑↑	↑↓

*Abbreviations:* HR, heart rate; NSR, normal sinus rhythm.

cardiology team, as well as constant reassessment of the hemodynamic goals.

**EYE TO THE FUTURE**

Developments in the cardiovascular management of critically ill patients continue to be made in diagnosis, monitoring, and support (mechanical and pharmacologic). Recent research indicates that early recognition and goal-directed therapy in septic patients improve outcomes (115,116). This concept of recognizing patients with sepsis syndromes early, so that aggressive therapy is instituted when patients arrive in the emergency department (ED), has led to a decrease in mortality from sepsis (117). Early goal-directed therapy in critically ill surgical patients has also led to better outcomes and a successful decrease in hospital stay (118,119).

Innovations in monitoring have also improved the care of the critically ill patient. Although invasive measures monitoring devices are still commonly employed, numerous noninvasive hemodynamic monitoring devices have become available that can provide accurate data in trauma and critically ill patients (120,121). These noninvasive devices can assess the adequacy of tissue perfusion and give hemodynamic parameters, such as cardiac index, without placing a Swan-Ganz catheter (122–124). A new form of inotropic drug is now being evaluated that may shorten the relaxation phase of the cardiac cycle and reduce filling pressures. These so-called “calcium sensitizers” provide better inotropic support in acute heart failure syndromes than the commonly employed inotropes (125,126).

Because the average age of the general population is increasing there are more elderly trauma and critically ill patients in our ICUs. The resuscitative efforts required to treat these elderly injured patients must now be more attuned to fluid overload, myocardial ischemia, or dysrhythmias, because the geriatric trauma patient is more prone to develop heart failure and inadequate tissue perfusion. The trauma intensivist needs to employ a wide array of strategies to ensure adequate tissue perfusion.

**SUMMARY**

The overriding management principles for the treatment of both the hypotensive and hypertensive conditions are firstly patient survival and secondly the prevention of end-organ damage. Although supranormal hemodynamic indices were at one time the goals of resuscitation, we now recognize that the side effects of attempting to achieve these supranormal values can cause ischemia, dysrhythmias, or be otherwise harmful.

The trauma intensivist now has a large armamentarium of diagnostic tools and therapeutic interventions to assist in

**Table 12** Resuscitation Considerations for Patients with Valvular Heart Disease

	Aortic stenosis	Aortic insufficiency	Mitral stenosis	Mitral regurgitation
Pathophysiology	Concentric hypertrophy	Dilated LV volume overloaded	Dilated LA, ↑ PAP Empty and protected LV	Dilated LA and LV, volume overloaded
Hemodynamic goals	Hypertrophic LV requires high CA perfusion pressure (best assured by maintaining high SVR)	Stroke volume and ejection fraction maintained with preload reserve	May present with dyspnea, may be 2° to increased cardiac output (pregnancy or sepsis)	May underdiagnose LV failure because of regurgitant flow to LA despite severely decreased forward stroke volume
HR	↓ ↓	↑	↓ ↓	↑
Rhythm	SR <sup>a</sup>	–	Frequently in AS but NSR → AF = ↓	–
LV preload	↑	↑	↑	↑
SVR	↑	↓	↔	↓
PVR	↔	↔	↓ (These patients may have severe PA HTN)	↓
Contractility	↔ ↑	↔ ↑	↔	↔ ↑
RESUSC. pearls	Avoid myocardial depression, maintain CA perfusion pressure (↑ SVR, ↑ BP)  Be prepared to cardiovert if an arrhythmia occurs (CPR is futile)  Treat hypotension with neosynephrine (etomidate = good induction choice)	Minimize myocardial depression and keep the patient fast, full, and vasodilated  A PAC is useful for measuring filling pressures and cardiac output  Dobutamine is a reasonable supportive drug at induction	Avoid tachycardia (No Pavulon, inc. conduction through the AV node may dramatically inc. ventricular HR)  Don't decrease contractility. Inadequate sedation can precipitate extreme anxiety and tachycardia  Consider esmolol to Rx tachycardia and hypotension	Isolated MR rare. Usually two papillary muscle dysfunction or RHD  MVP = most common cause of trivial isolated MR  Maintain elevated HR, intervascular repletion and vasodilation (Have several ways to increase HR)

*Note:* Management of the patient with ischemic CAD is identical to that used for AS, except, the goal for the coronary artery patient should be to decrease the preload as hemodynamic improvement allows. Also note, for both AS and MS, CPR will be entirely ineffective, thus early cardioversion is required for the onset of V-fib, and very soon after the onset of atrial fib if medication does not quickly restore normal sinus rhythm.

<sup>a</sup>Maintaining SR is particularly critical in aortic stenosis.

*Abbreviations:* AV, atrial-ventricular; AI, aortic insufficiency; A-Fib, atrial fibrillation; BP, blood pressure; CA, coronary artery; CPR, cardiopulmonary resuscitation; CHF, congestive heart failure; Cong, congenital; HR, heart rate; HTN, hypertension; LA, left atrium; LV, left ventricle; MVP, mitral valve prolapse; mm, muscle; MR, mitral regurgitation; PA, pulmonary artery; PAC, pulmonary artery catheter; PAP, pulmonary artery pressure; PVR, pulmonary vascular resistance; RF, rheumatic fever; RHD, rheumatic heart disease; SBE, sub acute bacterial endocarditis; SVR, systemic vascular resistance.

resuscitative efforts. Therapy should be targeted to specific end points that provide adequate perfusion pressures and flows to critical organ beds. In order to monitor the success of therapy, the end points discussed in Volume 1, Chapters 12 and 18, and Volume 2, Chapter 18 should be reviewed.

In addition to understanding the hemodynamic goals of therapy, the clinician must be cognizant of side effects of the various drugs employed so that therapeutic goals can be obtained. As the patient population ages, more treatments are required on increasingly frail patients. Optimal management of these and other critically ill patients will likely be improved by early implementation of goal-directed therapy, where "reasonable" rather than "supranormal" resuscitation goals are targeted.

## KEY POINTS

- 🦄 Optimum hemodynamic management is based upon (i) the immediate cause of hypotension or hypertension, (ii) the presence of concomitant injuries, and (iii) the baseline medical conditions affecting the patient.
- 🦄 The HR should be maintained within a reasonable range in order to sustain adequate Q for tissue perfusion (10,11).
- 🦄 In a febrile patient, the basal metabolic rate increases approximately 8% per degree centigrade, which correlates with an increase in HR of approximately 18 beats/min (i.e., 10 beats/min for each degree Fahrenheit) (13,14).

- Some patients can manifest bradycardia that is unresponsive to the elevated catecholamine state, associated with trauma or critical illness.
- Elderly patients suffering from trauma or critical illness are prone to develop atrial fibrillation or supraventricular tachycardia, secondary to elevated catecholamines, baseline myocardial irritability, direct myocardial injury, or ischemia, all of which can impair pump function (17,18).
- Parameters measured by noninvasive means, such as HR, BP, urine output, skin color, turgor and temperature, along with capillary refill, can be obtained quickly and reflect the patient's intravascular volume status prior to the placement of invasive monitors (19,20).
- The measured SVR can be two to three times higher than normal following massive hemorrhage, due to catecholamine-mediated arteriolar constriction in compensation for the decreased intravascular volume.
- Adequacy of perfusion to tissues is the most important end point of resuscitation.
- When the MAP falls below 60 mmHg, organ perfusion to renal and splanchnic organs begins to fall. As the MAP dips below 50 mmHg, perfusion to brain and myocardium can become diminished.
- Any patient who is adequately fluid resuscitated and requiring vasopressor support, but remains unresponsive to these measures, may have adrenal insufficiency and may need steroid administration for improvement in vasomotor tone (28–33).
- The overall goal is to ensure adequate tissue perfusion by repletion of intravascular volume first. Vasoconstrictor or inotropic support drugs are generally best administered after intravascular repletion is assured. However, occasionally, both drug support and volume repletion must be employed concomitantly to maintain an adequate blood pressure until sufficient fluid repletion can be achieved.
- Norepinephrine (Levophed®) can be used to increase BP in hypotensive patients who fail to respond to adequate volume resuscitation and other, less potent, vasopressors.
- The use of vasopressin has also been shown to decrease the requirement for other vasopressors and is associated with a higher urine output and improved creatinine clearance (54,55).
- Although low-dose dopamine increases renal blood flow, it does not ameliorate renal failure, and has not improved outcomes in nonoliguric patients recovering from ATN (70,71).
- The traumatologist and intensivist need to be aware of the pharmacology and side effects of these common drugs, because of their prevalence in the critically ill population and, more importantly, because they are used in the treatment of hypertensive crises.
- In all scenarios, the goal of MHTN treatment is to prevent end-organ damage.

## INTRODUCTION

Shock was recognized by Hippocrates and his contemporaries as a “post-traumatic syndrome” occurring in those who had sustained major injuries. The origins of the word “shock” traces back to the French word *choc* meaning violent attack, and was first used by Le Dran in 1737 in his text, “A treatise on reflections drawn from practice on gunshot wounds” (1). The term “shock” entered into more common usage after Edwin Morris published his book “A practical treatise on shock after operations and injuries” in 1867 (2).

Prior to World War I, Cannon postulated a “toxic” theory, whereby shock was attributed to the effects of circulating toxins causing vasomotor pooling and loss of blood and fluids into the injured tissues (3). An alternative theory was presented by Dr. Alfred Blalock with his research on dogs, where he suggested that blood loss alone was responsible for the hypotension seen in traumatized animals. Blalock revolutionized the management of patients in hemorrhagic shock, and his enthusiasm for the transfusion of blood and blood products certainly saved numerous lives during World War II (4). It has become increasingly clear that both the volume loss and toxin production hypotheses are involved in various aspects of the current shock paradigm, and treatment today attempts to address both considerations.

In 1972, Hinshaw and Cox proposed a classification system for shock, which is among several currently utilized today. Their description is based largely on the cardiovascular characteristics seen with each type and includes hypovolemic, cardiogenic, obstructive, and distributive. The category of distributive shock is sometimes eschewed in favor of its constituent categories (septic, anaphylactic, neurogenic, and adrenal crisis) being listed separately. In addition, many investigators believe a fifth category should be added, which includes a “cellular” designation (Table 1) (5).

☞ **Shock is defined as inadequate perfusion of the tissue. This inadequacy can result from deficient oxygen delivery ( $\text{DO}_2$ ), excessive utilization, or a combination of the two. In “cytotoxic” shock tissue, mitochondria are unable to utilize the  $\text{O}_2$  delivered.** ☞

Hemorrhage and sepsis are common etiologies of shock, following central nervous system injury as the most common etiologies of death in trauma patients (6–9). Trauma patients are subject to a variety of shock etiologies, often progressing from one form to another. Neurohumoral mechanisms initially compensate for cardiovascular derangements and maintain vital organ perfusion, but compensatory mechanisms can ultimately become overwhelmed. When the perfusion of tissues with oxygenated blood falls below the basal state required to maintain cell viability, cellular injury, organ ischemia, multiple organ dysfunction, and death may ensue. Diagnosis and treatment of the underlying etiology is the foundation of shock treatment, and prompt initiation of therapy is vital to forestall adverse consequences.

☞ **Hypovolemic shock is caused by acute blood loss of greater than 30% of the circulating blood volume (class III/IV hemorrhage).** ☞ The severity of the hypovolemic shock is correlated with the degree of volume loss (Table 2) as well by the rapidity with which it occurs. Prolonged hypovolemic shock can proceed to irreversible shock with diffuse organ injury resulting in irreversible circulatory failure. Aggressive fluid resuscitation remains the mainstay of care. Cardiogenic shock is caused by primary myocardial dysfunction and inability to generate effective cardiac output (Q). Distributive shock is characterized by arterial and venous dilation with venous pooling. Its causes are numerous, including: bacterial sepsis and its byproducts, mediators of systemic inflammatory response syndrome (SIRS), anaphylactic and anaphylactoid reactions, neurogenic shock, and adrenal crisis. Obstructive shock results from mechanical impediment to blood flow; that is, obstruction of venous return and/or arterial outflow from the heart. Causes include tension pneumothorax, pericardial tamponade, pulmonary embolism (PE), excessive positive end expiratory pressure (PEEP), and abdominal compartment syndrome (ACS) (Volume 2, Chapter 34).

This chapter provides an overview of the pathophysiology, diagnosis, and management of various shock states, emphasizing those most commonly seen in trauma and critical care. Cellular shock etiologies are mentioned for completion,

**Table 1** Classification of Shock and Common Etiologies

Categories	Common etiologies
Hypovolemic	External and occult hemorrhages, skin losses (severe burns), third spacing (pancreatitis, bowel obstruction, and prolonged abdominal surgery), gastrointestinal tract losses (vomiting, diarrhea), urinary tract losses
Cardiogenic	Acute myocardial infarction and its complications (e.g., acute mitral regurgitation, rupture of the interventricular septum, rupture of the free wall), myocarditis, end-stage cardiomyopathy, myocardial contusion, myocardial dysfunction after prolonged cardiopulmonary bypass, valvular heart disease, and hypertrophic obstructive cardiomyopathy
Obstructive	Cardiac tamponade, massive pulmonary embolism, tension pneumothorax, cor pulmonale, atrial myxoma, coarctation of aorta
Distributive	Septic shock, anaphylactic shock, neurogenic shock, adrenal crisis
Cellular <sup>a</sup>	Cyanide intoxication, carbon monoxide intoxication, iron intoxication

<sup>a</sup>Cellular shock results from processes that render the cell incapable of utilizing the O<sub>2</sub> which is delivered.

but not reviewed here. These conditions are thoroughly covered elsewhere (e.g., CN Toxicity in Volume 1, Chapter 34 and CO Toxicity in Volume 1, Chapters 31 and 34).

## PATHOPHYSIOLOGY

The oxygen delivery ( $\dot{D}O_2$ ) to tissues is related to the  $\dot{Q}$  and arterial O<sub>2</sub> content (CaO<sub>2</sub>) as seen in Equation 1. The  $\dot{Q}$  component can be augmented by increasing either the stroke volume (SV) or the heart rate (HR) (Equation 2). The CaO<sub>2</sub> is

derived from the hemoglobin concentration [Hgb] in g/dL, the amount of O<sub>2</sub> bound to the Hgb (generally, 1.34 mL O<sub>2</sub>/g Hgb) multiplied by the SaO<sub>2</sub>; and the amount of O<sub>2</sub> dissolved in the plasma (0.003 × PaO<sub>2</sub>) as per Equation 3.

$$\dot{D}O_2 = \dot{Q} \times CaO_2 \quad (1)$$

$$\dot{Q} = SV \times HR \quad (2)$$

$$CaO_2 = [Hgb] \times 1.34 \times SaO_2 + 0.003 \times PaO_2 \quad (3)$$

Stressful events affecting the body, for example, trauma, burns, sepsis, and so on, will increase O<sub>2</sub> demand (10). O<sub>2</sub> consumption ( $\dot{V}O_2$ ) will usually increase to meet that demand so long as an adequate  $\dot{D}O_2$  is being provided (11). If  $\dot{D}O_2$  fails to increase adequately to meet the demands of the tissues, tissue ischemia develops and cell death and organ dysfunction may ensue (12). With studies supporting these relationships, it is easy to see why shock research initially became focused on maximizing  $\dot{D}O_2$ , either by increasing  $\dot{Q}$  or CaO<sub>2</sub>.

The targets for improving  $\dot{D}O_2$  have been largely aimed at maximizing the  $\dot{Q}$  after ensuring that hemoglobin concentration [Hgb] and saturation is adequate. Often the focus for increasing  $\dot{Q}$  has been increasing the SV. Studies which demonstrate maximized  $\dot{D}O_2$  have not, however, consistently shown improved survival (13,14).

In both hemorrhagic and septic shock, maximal  $\dot{D}O_2$  has not consistently increased  $\dot{V}O_2$ . Therefore, two hypotheses emerged: (i) systemically adequate  $\dot{D}O_2$  is not necessarily sufficient when measured at the tissue level (i.e., macrocirculation ≠ microcirculation); and (ii) cells in shock may be unable to utilize the O<sub>2</sub> being delivered.

## Systemic $\dot{D}O_2$ Adequacy Does Not Ensure Sufficient Tissue Perfusion

✎ Blood flow to organs is regulated by mechanisms that control systemic, regional, and local perfusion. Dysfunction can occur at any of these points. ✎

Historically, clinicians have targeted the “macro” circulation, mainly because it was the only tissue bed that could be monitored. It is certainly easier to implement goal-directed therapy toward arterial blood flow than toward microcirculatory blood flow. Technological advances are

**Table 2** Estimated Fluid and Blood Losses Based on Patient's Initial Presentation<sup>a</sup>

	Class I	Class II	Class III	Class IV
Blood loss (mL)	Up to 750	750–1500	1500–2000	>2000
Blood loss (% blood volume)	Up to 15%	15–30%	30–40%	>40%
Pulse rate	<100	>100	>120	>140
Blood pressure	Normal	Normal	Decreased	Decreased
Pulse pressure (mmHg)	Normal or increased	Decreased	Decreased	Decreased
Respiratory rate	14–20	20–30	30–40	>35
Urine output (mL/hr)	>30	20–30	5–15	Negligible
CNS/mental status	Slightly anxious	Mildly anxious	Anxious, confused	Confused, lethargic
Fluid replacement (3:1 rule)	Crystalloid	Crystalloid	Crystalloid and blood	Crystalloid and blood

<sup>a</sup>For a 70-kg man. The guidelines in this table are based on the 3:1 rule. This rule derives from the empiric observation that most patients in hemorrhagic shock require as much as 300 mL of electrolyte solution for each 100 mL of blood loss. Applied blindly, these guidelines can result in excessive or inadequate fluid administration. For example, a patient with a crush injury to the extremity may have hypotension out of proportion to their blood loss and require fluids in excess of the 3:1 guidelines. In contrast, a patient whose ongoing blood loss is being replaced by blood transfusion requires less than 3:1. The use of bolus therapy with careful monitoring of the patient's response can moderate these extremes.

Abbreviation: CNS, central nervous system.

Source: From Ref. 192.

increasingly allowing cellular perfusion to be evaluated, but these are still largely in the experimental phase and not yet validated in patient populations.

The microcirculation consists of vessels  $<300\ \mu\text{m}$  in diameter. In excess of 10 billion capillaries supply nutrients and remove waste from cells in a normal 70-kg individual (15). Capillary  $\text{PO}_2$  and Hgb saturation values are markedly decreased from arterial values at this level (15,16). In addition, the hematocrit in the microvasculature is decreased from arterial values and heterogeneously distributed leading to uneven  $\dot{\text{D}}\text{O}_2$  at the tissue level (17).

The microcirculation is particularly vulnerable to dysfunction in diseased states (17). Hypovolemic shock is associated with decreased perfusion of muscle, skin, and the splanchnic circulation. Septic models have shown that a large number of capillaries are either not perfused or intermittently perfused in the shock state. Among the capillaries that are perfused, there exists a heterogeneity in blood flow (18,19). Failure of the microcirculation to function normally in the shock state has been attributed to a host of causes including acidosis (20), impaired nitric oxide (NO) (21), leukocyte activation and plugging, coagulation factor activation (22), and the elaboration of other inflammatory mediators (23,24).

### Inability to Utilize Oxygen Hypothesis

☞ If  $\dot{\text{V}}\text{O}_2$  cannot be increased after injury, even if adequate  $\dot{\text{D}}\text{O}_2$  is assured, multiple organ dysfunction syndrome (MODS) may ensue and mortality is increased (12). ☞ Failure to accomplish effective oxidative metabolism, as measured by elevated lactate levels after injury, also predicts MODS (25).

The cytochrome *c* oxidase redox state has been used to reflect  $\dot{\text{D}}\text{O}_2$  to the cells. When  $\dot{\text{D}}\text{O}_2$  falls, the redox state moves toward reduction and when the  $\dot{\text{D}}\text{O}_2$  is increased, the redox state is more oxidized (26). This relationship occurs in healthy cells, and hence the mitochondrial electron transport redox state is said to be “coupled” to  $\dot{\text{D}}\text{O}_2$ . If, for any reason, electron transport is inhibited proximal to the cytochrome *c* oxidase, the redox state will become relatively oxidized in the absence of increased  $\text{O}_2$  availability. In this case, the mitochondrial electron transport redox state is said to be “decoupled” from  $\dot{\text{D}}\text{O}_2$  (27), resulting in anomalous electron transport, the production of reactive oxygen species (ROS), and the potential for free radical-mediated damage (28). Trauma patients who subsequently develop MODS demonstrate decoupling in the setting of both normal or supranormal  $\dot{\text{D}}\text{O}_2$  (28,29).

Evidence of decoupling has been seen in the brain (30), liver (28), and heart (28). Cardiac decoupling is particularly worrisome, as the heart is responsible for supplying itself and the rest of the body with the substrates for oxidative metabolism. Ischemia and reperfusion can produce organ injury by several mechanisms, including direct oxidative injury and the activation of NF- $\kappa\text{B}$  (31). It has been demonstrated that prolonged ischemia followed by reperfusion results in inhibition of mitochondrial oxidative metabolism enzyme systems (31). Free radical-mediated damage, resulting from ischemia and reperfusion, has been observed in every major organ predominantly from activated leukocytes (polymorphonuclear cells) in the vasculature, but also from intracellular processes such as mitochondrial dysfunction (32). These data infer that mitochondrial integrity or injury directly relates to cellular, and ultimately organ function in shock states.

### Oxygen Extraction Ratio

☞ The normal 70-kg patient consumes approximately 250 mL  $\text{O}_2/\text{min}$  and has a  $\dot{\text{D}}\text{O}_2 = 1000\ \text{mL}\ \text{O}_2/\text{min}$ . The  $\dot{\text{V}}\text{O}_2/\dot{\text{D}}\text{O}_2$  is known as the extraction ratio (ER), which is normally about 25% (Fig. 1). ☞

As  $\dot{\text{V}}\text{O}_2$  increases or  $\dot{\text{D}}\text{O}_2$  falls, the ER will increase until a critical ER is achieved, generally thought to be approximately 60% to 70%. At this point anaerobic metabolism begins to predominate, and shock may become profound as tissues become ischemic. There is a family of  $\dot{\text{V}}\text{O}_2/\dot{\text{D}}\text{O}_2$  curves, with each tissue/organ having its unique  $\dot{\text{V}}\text{O}_2/\dot{\text{D}}\text{O}_2$  relationship, and values for maximum ER vary for each tissue, which will vary with stress and the disease state.

Current technology does not allow for determination of these organ-specific relationships in the critically ill patient, and inferences drawn from systemic oxygenation parameters may not be valid in different regional milieus.

One marker for hypoperfusion is compensatory increased oxygen extraction, demonstrated by decreased mixed venous oxygen saturation ( $\text{S}\bar{\text{v}}\text{O}_2$ ) and increased difference between arterial oxygen saturation ( $\text{S}\text{a}\text{O}_2$ ) and the  $\text{S}\bar{\text{v}}\text{O}_2$  ( $\text{S}\text{a}-\text{v}\text{O}_2$ ). Generally, a  $\text{S}\bar{\text{v}}\text{O}_2 < 50\%$  is indicative of the shock state, as is a  $\text{S}\text{a}-\text{v}\text{O}_2 > 50\%$ . Another marker for relative hypoperfusion is an increased  $\text{O}_2$  ER, as can be seen in low delivery states, or high consumption conditions. However, certain disease processes (e.g., sepsis) may actually have an elevated  $\text{S}\bar{\text{v}}\text{O}_2$  and a decreased  $\text{O}_2$  ER due to

**Figure 1** The normal relationship between  $\dot{\text{V}}\text{O}_2$  and  $\dot{\text{D}}\text{O}_2$  is illustrated by line ABC. The  $\dot{\text{V}}\text{O}_2/\dot{\text{D}}\text{O}_2$  is known as the ER. As metabolic demand ( $\dot{\text{V}}\text{O}_2$ ) increases or  $\dot{\text{D}}\text{O}_2$  diminishes (C–B), the ER rises to maintain aerobic metabolism and consumption remains independent of  $\dot{\text{D}}\text{O}_2$ . However, at point B—called critical  $\dot{\text{D}}\text{O}_2$  the maximum ER is reached. This is believed to be 60% to 70% and beyond this point any further increase in  $\dot{\text{V}}\text{O}_2$  or decline in  $\dot{\text{D}}\text{O}_2$  must lead to tissue hypoxia. In critical illness, particularly in sepsis, an altered global relationship is believed to exist (broken line DEF). The slope of maximum ER falls (DE vs. AB), reflecting the reduced ability of tissues to extract oxygen, and the relationship does not plateau as in the normal relationship. Hence consumption continues to increase (E–F) to “supranormal” levels of  $\dot{\text{D}}\text{O}_2$ , demonstrating so called “supply dependency” and the presence of a covert oxygen debt that would be relieved by further increasing  $\dot{\text{D}}\text{O}_2$ . *Abbreviation:* ER, extraction ratio. *Source:* From Ref. 191.

inability of the tissues to utilize the O<sub>2</sub> delivered. This probably reflects a mitochondrial O<sub>2</sub> utilization problem.

## Stages of Shock

### Compensated Shock

☞ The shock state has been described as evolving through stages. The first stage is typically called compensated shock. ☞ During this phase, compensatory mechanisms are successful at counteracting the hemodynamic perturbations of the shock state. The heart rate increases, the systemic vasculature constricts through autonomic involvement, and the renin–angiotensin–aldosterone (RAA) system shifts into a fluid retention mode (see Volume 2, Chapter 44). The decreased urine output in the early stages of the hypovolemic state represents renal compensation; later, renal failure (Volume 2, Chapter 40) can occur, as protective mechanisms are exhausted and cell injury begins to occur.

Local factors initially may compensate with rapid early changes mediated through endothelial stretch receptors, precipitating local bed vascular resistance changes. Additional mechanisms such as the release of CO<sub>2</sub>, H<sup>+</sup>, and NO cause further vascular dilatation, initially helping to preserve perfusion. These mechanisms are unable to fully compensate for extended periods of poor perfusion, and indeed, may exacerbate the perfusion deficit with vascular pooling.

In some patients, this compensated phase is short-lived. Either the total volume lost is too extensive (e.g., hemorrhagic shock), or the toxin load is too great (e.g., septic shock), and so on, or the patient is unable to fully compensate secondary to underlying medical conditions or advanced age. ☞ When compensation begins to fail, worsening circulatory changes and metabolic imbalances become manifest, and shock enters the second phase (uncompensated shock). ☞

### Uncompensated Shock

The shock process progresses to the uncompensated stage when systemic blood pressure (BP) falls, and  $\dot{D}O_2$  at the macrovascular level begins to suffer. At the same time, microvascular changes worsen as tissues become hypoxic. Ongoing uncompensated shock frequently precipitates a transition from aerobic to anaerobic metabolism in those vascular beds where  $\dot{D}O_2$  becomes inadequate for tissue perfusion. Anaerobic metabolism (which occurs in the cytoplasm) is 19 times more energy-costly than aerobic metabolism (which occurs in the mitochondria). Intracellular adenosine triphosphate (ATP) is rapidly depleted and cellular repair systems become disrupted. Endoplasmic membranes swell, mitochondria distend (lack of ATP decreases ability to maintain membrane electrochemical gradients), and lysosomes are released. If shock continues to progress, the diminished end-organ perfusion is said to enter the “irreversible” stage of shock.

### Irreversible Shock

☞ Irreversible shock is said to occur when cellular damage is so extensive that even if hemodynamics are restored, the degree of cell injury/death that has occurred (or will occur due to apoptotic mechanisms) cannot be sufficiently repaired to sustain life. ☞ Permanent cellular damage may ensue with lysosomal release and autolysis. Tissues with high metabolic demands and minimal energy reserves such as the brain, heart, and kidneys are particularly vulnerable to ischemia with hypotension.

The resulting cellular injury and death are responsible for the functional abnormalities affecting individual organs. Should cellular perfusion be restored, further injury may occur early in the reperfusion period due to generation of oxygen free radicals and other cytotoxic products. This cellular injury that occurs following the reestablishment of perfusion is referred to as reperfusion injury.

☞ The state of “irreversible” shock can result from numerous causes, but is particularly devastating following hypovolemia and hypotension due to hemorrhage.

☞ Patients suffering from hemorrhagic shock have usually lost at least 30% to 40% of their blood volume, and if replacement is not adequate, or too long of a duration occurs before the bleeding is controlled, hemodynamic instability can persist even after adequate volume resuscitation has occurred. As many as one-third of patients with massive hemorrhage (i.e., those who have lost greater than or equal to one blood volume within 24 hours) will die from this “irreversible” shock state (33). The study of these patients has been limited because the number of patients is small, and because of injury severity, these patients rarely have time for enrollment and randomization protocols (34).

The irreversible shock state is characterized by vasodilation, representing a failure of vascular smooth muscle regulation, endothelial dysfunction, and activation of white blood cells (WBCs) as well as other circulating cells (35). Initially, lactate was thought to be a prominent vasodilator; however, more recently, other vasodilating agents such as NO have been implicated (36). These vasodilating mechanisms overwhelm the normal compensatory vasoconstriction properties (that operate through elevated adrenergic tone) by at least three mechanisms: (i) K<sub>ATP</sub> channel activation, (ii) NO/cGMP overproduction, and (iii) vasopressin deficiency (37). An increase in exhaled NO concentration has been advocated as an early marker of a hypovolemic state (38). Currently, no analogous (noninvasive) assay exists to detect increased K<sub>ATP</sub> or decreased vasopressin levels.

## Neurohumoral Responses in Shock States

Neurohumoral responses to hypotension stimulate sympathetic discharge via carotid and aortic baroreceptors. The subsequent increase in adrenal release of epinephrine and norepinephrine enhances myocardial inotropy and chronotropy. In addition, the sympathetic-mediated increase in vascular tone temporarily increases BP during the compensated shock phase. Catecholamines, as well as stress hormones such as glucagon, aldosterone, adrenocorticotropic hormone (ACTH), and antidiuretic hormone (ADH) are secreted to maintain homeostasis during shock. Distal tubular sodium and water resorption are optimized to conserve intravascular volume. All of these factors combine to initially preserve hemodynamics.

The metabolic responses can be affected at both the neurohumoral and the local cellular level. Glucagon, epinephrine, and glucocorticoids are part of the “fight or flight” response system leading to increased lipolysis and circulating glucose. Elevated levels of stress hormones promote muscle wasting, poor wound healing, loss of gastrointestinal (GI) mucosal integrity, and hypoalbuminemia. Inflammatory mediators, especially in conjunction with hypoxia, exacerbate proteolysis. Because all of these mediators are catabolic, it is not unusual for patients with chronic inflammatory (SIRS/sepsis) states to have difficulty in maintaining caloric balance, manifest inadequate wound

healing, and suffer variable degrees of hemodynamic instability and difficulty in weaning from mechanical ventilation until the primary disorder is corrected.

## EFFECT OF SHOCK ON ORGAN SYSTEMS

✎ **Hypoperfusion and inadequate  $\text{DO}_2$  to individual organ systems during shock can trigger a cascade of events that disrupt the function of these organs.** ✎ Systemic shock affects all organ systems, with earlier cellular damage and death seen in more rapidly metabolizing organs such as the brain, heart, lungs, kidneys, adrenals, and so on. Many circulating blood and humoral constituents also affect the GI tract, especially, the lining of the gut and the liver.

### Central Nervous System

Central nervous system (CNS) dysfunction is often one of the first clinical signs reflecting from inadequate perfusion during shock states. This can be manifested as confusion or obtundation depending upon the severity of cerebral hypoperfusion, and/or the magnitude of circulating inflammatory mediators with CNS effects.

Although highly susceptible to hypoxemia and hypoperfusion, cerebral blood flow (CBF) is normally maintained at 50 mL/100 g brain tissue/minute as long as the mean arterial pressure (MAP) remains approximately between 50 and 150 mmHg. When MAP acutely moves outside this range, autoregulation of CBF may be compromised. Patients with chronic hypertension are more susceptible to cerebral hypoperfusion with relatively less significant hemodynamic perturbations than normal patients, due in part to a rightward shifted autoregulatory curve with subsequently lower hemodynamic reserve. Delirium and ultimately obtundation from inflammatory cytokines can occur during shock states even in the presence of normal CBF.

Profound hypotension may result in ventilatory and vasomotor collapse due to brainstem ischemia. Increased intracranial pressure (ICP), cerebral metabolic rate of  $\text{O}_2$  consumption ( $\text{CMRO}_2$ ),  $\text{PaCO}_2$ , and  $\text{PaO}_2$  levels, as well as blood viscosity represent additional considerations affecting CBF and perfusion in trauma patients. Posterior pituitary ischemia or trauma can precipitate neurogenic diabetes insipidus (DI) initiated by the inhibition of ADH release by the posterior pituitary. The massive volume losses that accompany DI can dramatically exacerbate shock states occurring from any of the primary categories listed in Table 1.

### Cardiovascular System

The cardiovascular system is greatly affected during shock states, both as a primary effector, and as a target of injury because of its extensive endothelial lining and contact with systemic inflammatory mediators. Sympathetic outflow provides mechanisms to initially maintain perfusion and resultant arteriolar constriction and increased HR are typical initial compensatory mechanisms seen with hypovolemic shock due to hemorrhage in trauma patients. Vascular tone is typically elevated in hypovolemic (early phase), cardiogenic, and obstructive shock whereas decreased in distributive shock states (Table 3).

Hypoperfusion and hypoxia may precipitate myocardial ischemia, decreased contractility, and dysrhythmias. Direct myocardial depression may also occur due to circulating mediators, such as in uncompensated hemorrhagic shock (e.g., following reperfusion and/or large-volume

**Table 3** Shock Hemodynamics

	Hypovolemic	Distributive	Cardiogenic	Obstructive
HR	Increase	Increase	Variable	Increase
BP	Decrease	Decrease	Decrease	Decrease
CVP	Decrease	Decrease	Increase	Increase
$P_{PA}$	Decrease	Decrease	Increase	Increase
$P_{PAO}$	Decrease	Decrease	Increase	Increase/ no change
$\dot{Q}$	Decrease	Increase	Decrease	Decrease
SV	Decrease	Increase	Decrease	Decrease

*Abbreviations:* BP, blood pressure; CVP, central venous pressure; HR, heart rate;  $P_{PA}$ , pulmonary artery pressure;  $P_{PAO}$ , pulmonary artery occlusion pressure;  $\dot{Q}$ , cardiac output; SV, stroke volume.

blood product administration) and septic shock, particularly in the later stages (38). However, similar to the cerebral circulation, cardiac autoregulatory mechanisms normally maintain adequate perfusion to the coronary arteries between a MAP of 50 and 150 mmHg (39).

Patients with the underlying coronary artery disease or left ventricular (LV) hypertrophy (e.g., aortic stenosis), are particularly vulnerable to myocardial ischemia with shock. Myocardial ischemic risk is increased not just by diminished coronary arterial perfusion pressure resulting from hypotension, but also as a result of the compensatory tachycardiac response commonly occurring with hypotension.

### Pulmonary System

Acute respiratory failure is another common finding seen early in the course of shock. Airway protection with intubation and mechanical ventilation support should be considered as an early intervention in the setting of significant shock. In addition to direct traumatic lung injury (e.g., pulmonary contusion), other factors (e.g., aspiration, drug intoxication, spinal cord injury, etc.) play a role in respiratory failure in the trauma patient.

✎ **Lung injury also results from circulating inflammatory mediators following reperfusion, or blood product transfusion in hemorrhagic shock, and from cellular injury following burns or massive blunt trauma, and bacterial toxins in septic shock.** ✎ Smooth muscle regulators such as thromboxane and certain prostaglandins may cause bronchospasm and acute pulmonary hypertension with subsequent ventilation/perfusion ( $\dot{V}/\dot{Q}$ ) mismatch. These initial incidents often evolve into acute lung injury (ALI) and acute respiratory distress syndrome (ARDS). When ALI/ARDS develops following early injury, it often persists, contributing to critical illness and is a leading factor in delayed morbidity and mortality in trauma patients.

The  $P_{aO_2}$  is monitored with arterial blood gas (ABG) measurement and pulse oximetry (see Volume 2, Chapter 2). Capnography is an increasingly appreciated monitor which is of significant value during resuscitation and subsequent management of trauma patients. Low expired end-tidal  $\text{CO}_2$ , in the setting of normal  $\dot{V}_E$ , correlates with low  $\dot{Q}$ , and/or increased alveolar dead space, as can occur in extremely hypovolemic patients (40). Continuous end-tidal  $\text{CO}_2$  ( $P_{ET}\text{-CO}_2$ ) monitoring may aid in the determination of resuscitation of low  $\dot{Q}$  states.

### Renal System

The renal system is particularly vulnerable to the effects of shock. Shock stimulates compensatory mechanisms to

maintain intravascular volume. One of the first clinical signs is oliguria and urinary concentration of solutes. Renal artery constriction and decreased glomerular filtration rate (GFR) occurs early in the shock state. Blood is redistributed from the cortex to the medulla in an attempt to conserve intravascular volume during hypovolemia. These events, mediated by circulating catecholamines, vasoconstrictor prostaglandins, and angiotensin predispose the renal cortex to ischemic injury. Shock patients with associated renal failure have a high mortality (41).

Ischemic injury to the kidney may result in acute tubular necrosis (ATN). Nephrotoxic agents (aminoglycosides or IV radiocontrast) further increase the risk for ATN. During the early phase of shock, patients may become oliguric or anuric. Other than optimizing hemodynamics to ensure adequate renal perfusion, no clear evidence exists that it is possible to alter the course of ATN through the use of such agents as diuretics to prevent tubular sludging or renal dopamine to enhance renal blood flow (RBF).

### Gastrointestinal System

The GI system is particularly susceptible to hypoperfusion, and thus at risk for ischemia during shock states. Sympathetic stimulation during shock diverts blood flow from viscera to more "vital" organs such as the heart and brain. Gut mucosa can be compromised by splanchnic hypoperfusion, and damaged mucosa can then facilitate movement of toxic substances (e.g., proteolytically cleaved peptides, lipids) into the lymph and portal circulation. In addition, GI ulcers, GI hemorrhage, ileus, pancreatitis, and hepatic failure can also occur. Liver failure is an ominous sign given the significance of the liver's synthetic, metabolic, and clearance functions.
